The Flat Parentheses corpus is made up of pairs of parentheses that do not nest. At timestep t, we sample an integer x from the empirical Spanish unigram distribution, and a distance d from the empirical distribution of dependency lengths (calculated from the Spanish Universal Dependencies treebank (McDonald et al., 2013)). Then, we write x at position t and at position $t + d$. This creates pairs of matching parentheses which are not influenced by any other token in determining when they close. *Note that this corpus is very similar to the Random Zipf corpus, except that each sampled token is placed twice instead of once.*

5.2 Results

LSTMs trained on both parentheses corpora are able to model human language far better than models trained on the random corpora, indicating that the isolated forms of grammar-like structure in these corpora are useful for modelling human language. Surprisingly, performance is the same for a model pretrained on the Nesting Parentheses and the Flat Parentheses corpus. This suggests that it is not necessarily hierarchical encodings which LSTMs use to model human language, and that other forms of structure such as flat head-head dependencies may be just as important (de Marneffe and Nivre, 2019).

The Nesting Parentheses corpus exhibits hierarchical structure while not having any of the irregularities and subtleties of human language or music. Despite the simplicity of the grammar, our results indicate that the presence of this hierarchical structure is very helpful for an LSTM attempting to model Spanish. Our models trained on the Nesting Parentheses corpus have an average perplexity of 170.98 when tested on the Spanish corpus. This is 322 perplexity points better than the baseline models trained on the Zipf Random corpus, which has the same vocabulary distribution (Figure 4).

Models trained on the Flat Parentheses corpus are equally effective when tested on Spanish, achieving an average perplexity of 170.03. These results are surprising, especially given that the Flat Parentheses corpus is so similar to the Random Zipf corpus – the only difference being that integers are placed in pairs not one by one – and yet performs better by an average of 323 perplexity

---

[9] Though these corpora do not strictly use parentheses tokens, we refer to both of these as parentheses corpora, drawing our metaphor from the wide variety of studies such as Karpathy et al. (2016) examining nested parentheses.

[10] $P(open)$ has to be strictly less than 0.5, or else the tree depth is expected to grow infinitely.

Language	WALS-syntax distance from Spanish (out of a max of 49 features)
Spanish (es)	0
Italian (it)	0
Portuguese (pt)	3
English (en)	4
Romanian (ro)	5
Russian (ru)	9
German (de)	10
Finnish (fi)	13
Basque (eu)	15
Korean (ko)	18
Turkish (tr)	23
Japanese (ja)	23

Table 1: WALS-syntax distance between Spanish and L1s

points. This suggests that *representing relationships between pairs of tokens is a key element that makes syntactic representations of language successful in LSTMs.*

The Flat Parentheses corpus has structure in that each token is placed in relation to one other token, but just one other token. To model this successfully a model would have to have some ability to look back at previous tokens and determine which ones would likely have their match appear next. Our results suggest that this kind of ability is just as useful as potentially being able to model a simple stack-based grammar.

6 Experiment 4: Human Languages

To further analyze what kinds of generalizable structure LSTMs can infer, we run experiments in transferring zero-shot between human languages. We ask: can LSTMs infer and use fine-grained syntactic similarities between typologically similar languages? Previous work (Zoph et al., 2016; Artetxe et al., 2020) indicates that transfer is more successful between related languages. We control for vocabulary overlap, and use typological syntactic difference as a quantitative probe to ask: are fine-grained syntactic similarities encoded in generalizable, transferrable ways? To answer this question, we investigate the extent to which fine-grained differences in syntactic structure cause different zero-shot transfer results.

6.1 Data

We created our language corpora from Wikipedia, which offers both wide language variation as well as a generally consistent tone and subject domain. We used the gensim wikicorpus library to strip Wikipedia formatting, and the stanfordnlp Python library (Qi et al., 2018) to tokenize the corpus. We run experiments on data from 12 human languages, all of which have Wikipedias of over 100,000 articles: Spanish, Portuguese, Italian, Romanian, English, Russian, German, Finnish, Basque, Korean, Turkish and Japanese. All of the training corpora are 100 million tokens in length. [11]

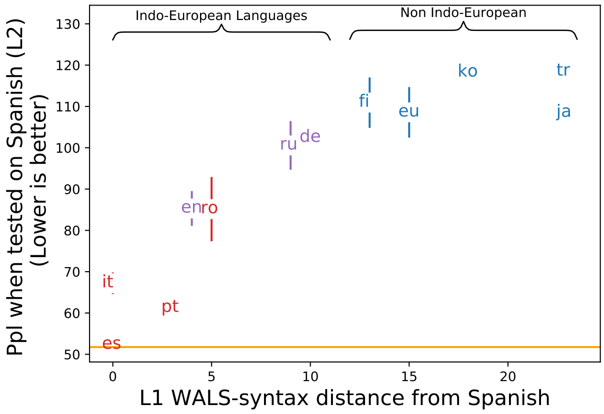

Figure 5: Results of Experiment 4. Transfer is better between typologically similar languages, even when vocabularies are disjoint. Perplexity on Spanish test data plotted against the WALS-syntax distance of each model's L1 to Spanish. The relationship is almost linear for Indo-European languages, and then reaches a ceiling. Error bars show 95% CIs for $n = 5$ trials with different random seeds. These results demonstrate how LSTMs can transfer knowledge more easily to languages that share structural features with the L1, and that this correlation is robust to multiple trials. The orange line represents the oracle perplexity of training all parameters to convergence on the L2 train data. Romance languages are in red, other Indo-European languages are in purple, and non-Indo-European languages are blue.

For our typological data, we use the World Atlas of Linguistic Structure, using the features that relate to syntax (WALS-syntax features). Examples of syntactic features in WALS include questions such as does a language have Subject-Verb-Object order, or does a degree word (like "very") come before or after the adjective. We accessed the WALS data using the lang2vec package (Littell et al., 2017). The quantity we are interested in extracting from the WALS data is the *typological distance* between the L2 (Spanish) and all of the

---

[11] The code for recreating our corpora from Wikipedia dumps is available at `https://github.com/toizzy/wiki-corpus-creator`

L1 languages mentioned above. Not every feature is reported for every language, so we calculate the WALS distance by taking into account only the 49 (syntactic) features that are reported for all our chosen languages and count the number of entries that are different (see Table 1). Since they are only based on 49 features, these distances do not provide a perfectly accurate distance metric. Though we cannot use it for fine-grained analysis, correlation with this distance metric would imply correlation with syntactic distance.

6.2 Results

Our experiments present a strong correlation between the ability to transfer from an L1 language to Spanish and the WALS-syntax distance between those two languages, as shown in Figure 5(a). In the case of Indo-European languages the relationship is largely linear with a Pearson R^2 coefficient of 0.83. For languages not in the Indo-European language family, transfer performance appears to reach a noisy ceiling, and Pearson's $R^2 = 0.78$ when taking into account all languages.[12]

Our previous experiments show that LSTMs can encode and generalize structural features from data that is structured, both in recursive and in non-hierarchical fashion. This experiment provides a more fine-grained analysis using using natural language to show that the syntax induced by LSTMs is generalizable to other languages in a typologically sensible fashion, even when we do not let the model take advantage of vocabulary overlap. However, after a certain threshold, the model is unable to take advantage of fine-grained similarities and performance on distant languages reaches a ceiling. It should be noted that all of the models trained on natural language, even the most distant, perform far better than non-linguistic data, indicating that LSTMs are able to extract universal syntactic information from all natural language L1s that is applicable to Spanish.

7 Discussion

In this work we propose the Test for Inductive bias via Language model Transfer (TILT), a novel analytic method for neural language models which tests the ability of a model to *generalize and use structural knowledge*. We pretrain LSTMs on structured data, and then use the frozen LSTM weights to model human language. In doing so, we treat the frozen LSTM weights as the only structural faculty available to a human language model, and assess if the induced structure is general enough to be used to model human language.

Our experiments are cross-lingual and cross-modal in nature, not searching for representations of high-level features in one language, but for representations that encode general ideas of structure. While the majority of past work analyzing the structural abilities of neural models looks at a model's treatment of structural features that are realized in specific input sentences, our method compares the *encoding and transfer of general grammatical features of different languages*. By using TILTs, we do not have to identify a structural feature of interest and investigate if it is being encoded, but instead asses if generalizable abstract structures are encoded in one language by examining *if they can be used* to model human language. Our work thus avoids known issues that have been pointed out with analytic methods like probing (Voita and Titov, 2020; Pimentel et al., 2020; Hewitt and Liang, 2019).

We run experiments on natural languages, artificial languages, and non-linguistic corpora. Our non-linguistic and artificial language experiments suggest three facets of the structural encoding ability of LSTM LMs. First, that vocabulary distribution has a very minor effect for modelling human language compared to structural similarity. Second, that models can encode useful language modelling information from the latent structure inherent in non-linguistic structured data, even if the surface forms are vastly differing. Last, that encodings derived from hierarchically structured tokens are equally useful for modelling human language as those derived from texts made up of pairs of tokens that are linked but non-hierarchical. Running experiments on a range of human languages, we conclude that the internal linguistic representation of LSTM LMs allows them to take advantage of structural similarities between languages even when unaided by lexical overlap.

Our results on the parentheses corpora do not necessarily provide proof that the LSTMs trained on the Nesting Parentheses corpus aren't encoding and utilizing hierarchical structure. In fact, previous research shows that LSTMs are able to suc-

---

[12] We verified that our results also stand when calculating correlation coefficients using log perplexity, which yielded similar values: R^2 of 0.79 and 0.73 for Indo-European and all languages respectively.

cessfully model stack-based hierarchical languages (Suzgun et al., 2019b; Yu et al., 2019; Suzgun et al., 2019a). What our results do indicate is that, in order for LSTMs to model human language, being able to model hierarchical structure is similar in utility to having access to a non-hierarchical ability to "look back" at one relevant dependency. These results shine light on the importance of considering other types of structural awareness that may be used by neural natural language models, even if those same models also demonstrate the ability to model pure hierarchical structure.

Our method could be used to test many other hypotheses regarding neural language models, by choosing a discerning set of pretraining languages. A first step in future work would be to test if the results of this paper hold on Transformer architectures, or if instead Transformers result in different patterns of structural encoding transfer. Future work expanding on our results could focus on ablating specific structural features by creating hypothetical languages that differ in single grammatical features from the L2, in the style of Galactic Dependencies (Wang and Eisner, 2016), and testing the effect of structured data that's completely unrelated to language, such as images.

Our results also contribute to the long-running nature-nurture debate in language acquisition: whether the success of neural models implies that unbiased learners can learn natural languages with enough data, or whether human abilities to acquire language given sparse stimulus implies a strong innate human learning bias (Linzen and Baroni, 2020). The results of our parentheses experiments suggest that simple structural head-dependent bias, which need not be hierarchical, goes a long way toward making language acquisition possible for neural networks, highlighting the possibility of a less central role for recursion in language learning for both humans and machines.

What Do Position Embeddings Learn?
An Empirical Study of Pre-Trained Language Model Positional Encoding

Yu-An Wang **Yun-Nung Chen**
Department of Computer Science and Information Engineering
National Taiwan University, Taipei, Taiwan
`r08922019@csie.ntu.edu.tw` `y.v.chen@ieee.org`

Abstract

In recent years, pre-trained Transformers have dominated the majority of NLP benchmark tasks. Many variants of pre-trained Transformers have kept breaking out, and most focus on designing different pre-training objectives or variants of self-attention. Embedding the position information in the self-attention mechanism is also an indispensable factor in Transformers however is often discussed at will. Therefore, this paper carries out an empirical study on position embeddings of mainstream pre-trained Transformers, which mainly focuses on two questions: 1) Do position embeddings really learn the meaning of positions? 2) How do these different learned position embeddings affect Transformers for NLP tasks? This paper focuses on providing a new insight of pre-trained position embeddings through feature-level analysis and empirical experiments on most of iconic NLP tasks. It is believed that our experimental results can guide the future work to choose the suitable positional encoding function for specific tasks given the application property.[1]

1 Introduction

Word ordering often determines the meaning of a sentence; therefore how to utilize the position information of a word sequence has been an important topic in NLP and widely investigated recently. A common approach for modeling word ordering is to use recurrent neural networks (RNN), such as long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) or gated recurrent unit (GRU) (Chung et al., 2014), which use a hidden state to represent the information of an ordered sequence and update model weights by backpropagation through time (BPTT) (Werbos, 1990); thus the ordering information can be modeled by this structure. However, RNN and BPTT are very inefficient in modern GPU computation due to the difficulty of parallelization with the time dependency. To solve this problem, recent work, such as convolutional seq2seq (Gehring et al., 2017) and Transformers (Vaswani et al., 2017) which apply convolutional neural network (CNN) (LeCun et al., 1995) and self-attention respectively, succeed to eliminate the time dependency to take the computational advantage of GPU. Instead of storing the information of ordered sequences, these models utilize the position information by using a feature-level positional encoding. For example, convolutional seq2seq proposed learnable position embeddings to represent the positions in a sequence.

Recently, various pre-trained Transformer language models keep breaking state-of-the-art results in numerous NLP tasks. There are many different ways to pre-train a Transformer language model. For example, using an encoder, decoder, or the whole part of the Transformer, adapting the self-attention masks, or training with different objectives (Devlin et al., 2018; Liu et al., 2019; Radford et al., 2018, 2019; Lewis et al., 2019; Raffel et al., 2019; Yang et al., 2019). However, in terms of positional encoding, most work only used a learned position embedding which is originally proposed in convolutional seq2seq (Gehring et al., 2017) without any analysis, even different objectives may learn completely different position information.

Motivated by the above observations, our goal is to investigate what position information the pre-trained Transformers could learn under different settings. We conduct a deep analysis of the learned position embeddings among three iconic pre-trained Transformer language models: BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019) and GPT-2 (Radford et al., 2019). To examine the performance of different NLP types, we conduct

November 16–20, 2020.

the experiments on text classification, language modeling, and machine translation, and empirically analyze and explain the meaning and influence of position embeddings from different aspects.

The contributions of this paper are 3-fold:

- This paper is among the first study that provides a complete analysis about what learned position embeddings capture in different pre-trained models.
- This paper empirically examines the performance of different position embeddings for many NLP tasks.
- This paper connects the empirical performance with the task property based on the analysis, providing the guidance of the future work for choosing the suitable positional encoding method in the target task.

2 Related Work

The concept of using position embedding on position-insensitive models was first proposed by convolutional seq2seq (Gehring et al., 2017), which built an encoder-decoder architecture on convolutional neural networks. Vaswani et al. (2017) proposed Transformers that used the self-attention mechanism in the basic blocks. Because the attention mechanism is *position-insensitive*, it proposed a pre-defined sinusoidal function as positional encoding. Pre-trained language models became a trend among many NLP tasks after (Peters et al., 2018) introduced ELMo. Affected by ELMo, OpenAI GPT (Radford et al., 2018) is the first pre-trained language model using a Transformer architecture, then many different variant of pre-trained Transformer including BERT (Devlin et al., 2018), RoBERTa (Roberts, 2005) and GPT-2 (Radford et al., 2019) started evolving the researches of NLP tremendously. In Transformers, the attention values are the same in each input position. Thus, Shaw et al. (2018) proposed a relative position representation in the attention level to address this issue. Dai et al. (2019) used a segment-level recurrence mechanism on Transformers and also utilized an adaptive version of relative position embeddings inspired by Shaw et al. (2018). Furthermore, Wang et al. (2019) extended the embedding space from real numbers to complex values , and also proposed a new learnable positional encoding function instead of a simple position embedding mapping.

3 Transformer

Transformer is an encoder-decoder sequence-to-sequence model proposed by Vaswani et al. (2017). In the architecture, Transformer is composed of self-attention blocks that are position-insensitive modules. Therefore, a positional embedding should be considered together with the NLP tasks. To elaborate on the experiments we conduct, this section briefly introduces Transformers.

Input Representation Due to the property of position-insensitive in the attention module, the input representations should also contain the position information. In Transformers (Vaswani et al., 2017), a word embedding is directly added with the positional encoding as the final representation:

$$z_i = WE(x_i) + PE(i),$$

where x_i is the token at the i-th position, WE is the word embedding, and PE is the positional encoding, which can be either a learnable embedding or a pre-defined function.

Multi-Head Self-Attention The attention mechanism is often used in an encoder-decoder architecture, and there are many variants of attention implementations (Bahdanau et al., 2014; Britz et al., 2017). In Transformers, the *scaled dot-product attention* is applied:

$$\text{attention}(Q, K, V) = \text{softmax}(\frac{QWK^TW}{\sqrt{d_k}})VW,$$

where W is a linear projection and Q, K, V represent query, key and value matrices respectively.

Transformer blocks are composed of multi-head self-attention. Literally, the inputs Q, K, V are the same and the attention is performed multiple times, and then the output heads are concatenated as the final output hidden state h. This process can be formulated as

$$\text{head}_i = \text{attention}(Q, K, V)$$
$$h = \text{concat}([\text{head}_1, ..., \text{head}_n])W.$$

Transformer Encoder A Transformer encoder layer is composed of multi-head self-attention following a position-wise feed-forward network (FFN) with the residual connection (He et al., 2016) and layer normalization (Ba et al., 2016):

$$\text{output} = \text{layernorm}(h + \text{FFN}(h)),$$

and then stacked the layers sequentially to form a Transformer encoder.

Transformer Decoder The Transformer decoder is also stacked by self-attention blocks, and it only has two major differences from the encoder:

1. Each Transformer decoder layer has an additional sub-layer to perform attention on the encoder output.
2. To ensure the decoder can only decode tokens depending on the tokens in the past, it uses an attention mask to mask the attention values of the subsequent tokens.

Therefore, the Transformer decoder can decode tokens autoregressively like other conventional language models such as RNN.

4 Position Embedding Analysis

In this section, we conduct feature-level analyses of the pre-trained position embeddings of two Transformer encoders: BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019), one Transformer decoder: GPT-2 (Radford et al., 2019), and also the sinusoidal function proposed by Vaswani et al. (2017) is defined as

$$PE_{(i,2j)} = \sin(i/10000^{2j/d_{model}}),$$
$$PE_{(i,2j+1)} = \cos(i/10000^{2j/d_{model}}),$$

where i is the position index and j is the dimension index.

4.1 Do Embeddings Learn the Meaning of Positions?

Given the position space $\mathcal{P}$ and the embedding space $\mathcal{X}$, the goal of the position embedding function is to learn a mapping $f : \mathcal{P} \rightarrow \mathcal{X}$. In the following experiments, we focus on answering two questions for better understanding what the embeddings capture:

1. Can the learned embedding space $\mathcal{X}$ represent the absolute positions of the words?
2. Are $\mathcal{P}$ and $\mathcal{X}$ isomorphic?

4.1.1 Absolute Position Regression

If a position embedding can actually capture its *absolute position*, it should be easy to reconstruct a reversed mapping function $g : \mathcal{X} \rightarrow \mathcal{P}$. Thus, we use linear regression to learn a function g that transfers the embeddings to the original positions. The feature dimension is 768, and the maximum position in GPT-2 is trimmed from 1024 to 512 for comparison which BERT and RoBERTa. Because we only have 512 data points for each learned embedding, a 5-fold cross-validation is applied to avoid overfitting. The reversed mapping functions are evaluated by **Mean Absolute Error (MAE)**, and the result is shown in Table 1.

Type	PE	MAE
Learned	BERT	34.14
	RoBERTa	6.06
	GPT-2	1.03
Pre-Defined	sinusoid	0.0

Table 1: Mean absolute error of the reversed mapping function learned by linear regression.

Type	PE	Error Rate
Learned	BERT	19.72%
	RoBERTa	7.23%
	GPT-2	1.56%
Pre-Defined	sinusoid	5.08%

Table 2: Error rate of the relative position regression.

From the results, the reversed mapping function of sinusoid can perfectly represent the absolute positions, and GPT-2 only has a small error. In contrast, the embeddings learned by Transformer encoders do not learn the information about the absolute positions, especially BERT which has an extremely high mean absolute error.

Additionally, we have also tried some more complicated non-linear models such as SVM or MLP to map the embeddings back. However, they easily overfit and the testing results are even worse than linear models. This implies that the position information in Transformer can actually be modeled by a linear model.

4.1.2 Relative Position Regression

In addition to absolute positions, the relation between positions is also informative (*relative positions*). If $\mathcal{P}$ and $\mathcal{X}$ are isomorphic, there should exist a bijection of distance operation between two spaces. Thus we define a mapping function of distances from $\mathcal{X}$ to $\mathcal{P}$: $h(x_i, x_j) = \|i - j\|$, where i, j are two position indices, $\|i - j\|$ is the distance between i and j in the space $\mathcal{P}$, and x_k is the position embedding at the k-th position. In this scenario, we can also build a mapping func-

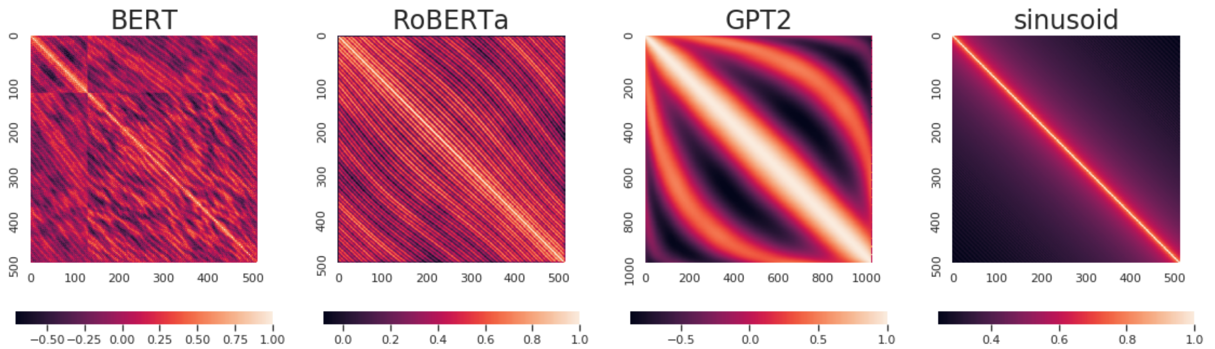

Figure 1: Visualization of position-wise cosine similarity of different position embeddings. Lighter in the figures denotes the higher similarity.

tion to check whether the embeddings can capture the relation between positions. However, in our preliminary experiments, we find that using linear regression to predict the distance of positions is too hard, since the relation between positions in the space $\mathcal{X}$ may not be completely linear. Hence, we simplify this problem to *whether the embeddings capture the order of every two positions*:

$$h(x_i, x_j) = \left\{ \begin{array}{ll} 1 & \text{if } i \geq j \\ 0 & \text{if } i < j \end{array} \right\},$$

and then use logistic regression to learn this binary classification problem.

The results in Table 2 show that the position embeddings of Transformer encoders still learn less information about their position relations, especially for BERT. Moreover, the sinusoid function, which can represent absolute positions perfectly, has a higher error rate than GPT-2 in relative positions but better than Transformer encoders, indicating the surprising capability of capturing such relations in GPT-2.

4.2 What do Transformer Encoders Capture about Positions?

According to the previous analyses, Transformer encoders (BERT and RoBERTa) may not well capture the meaning of positions (absolute and relative positions). Therefore, the interested question becomes "*what do Transformer encoders capture about positions?*".

4.2.1 Position-Wise Cosine Similarity

Figure 1 shows the visualization of position-wise cosine similarity of each position embedding. The point at (i, j) indicates the similarity between the i-th position and the j-th position. First, we observe that the embedding space of sinusoid and GPT-2 have obvious periodic patterns along with position orders, which aligns the findings in the section 4.1, where these two embeddings can actually capture the meanings of positions. With regard to BERT, we can only observe that embedding vectors are similar to the positions nearby but have no explainable patterns in long-term relations. Also, another observation is that BERT position embeddings have an obvious gap at the position 128, because the pre-trained procedure of BERT trains on the sentences with the length of 128 in the first stage, and then extends to the length of 512 in the second stage. The figure illustrates that the learned position information in the first stage can not be completely generalized to the second stage. Last but not least, the visualization of RoBERTa is similar to BERT, but have some limited non-periodic visible patterns at the positions nearby.

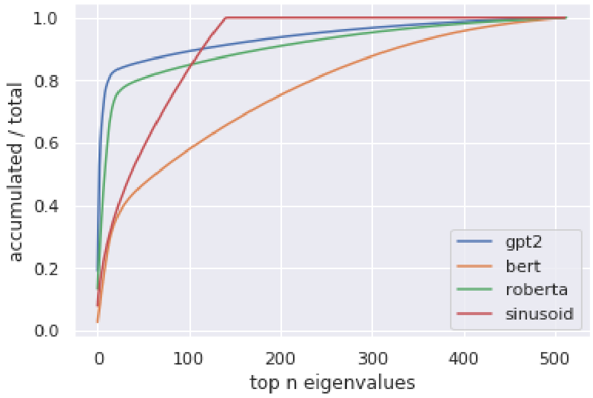

Figure 2: Accumulated top eigenvalues of position embeddings.

4.2.2 Informativeness of Position Embeddings

In order to examine the informativeness of the learned position embeddings, we apply singular value decomposition (SVD) on position embeddings and analyze their eigenvectors. Figure 2 shows the curves of accumulated top n eigenvalues versus the proportion of total eigenvalues. Mathematically, the summation of the top n eigenvalues indicates how informative can a matrix be if the matrix is transformed into a n-dim space. For a position space $\mathcal{P}$, which is a 1-dim space, we may not need a high-dimension embedding space $\mathcal{X}$ to represent the positions. Thus, the summation of the top n eigenvalues in a position embedding should account for the most proportion of total eigenvalues with only a very small n. However, in Figure 2, we find that the position embeddings of BERT take a very large n to achieve a high proportion of total eigenvalues, and RoBERTa also takes a larger n than GPT-2 and sinusoid. This implies that the position embeddings of Transformer encoders may learn more complex information rather than only about positions, and this rich information may only be useful in Transformer encoders. This assumption will be further investigated in the experiments.

4.3 What Make the Differences?

Thus far, it can be found that the learned position embeddings between Transformer encoders and decoders are completely different. In this section, we will illustrate what makes these embeddings different.

4.3.1 Pre-Training Objectives

One of the main reason for the difference is the pre-training objectives. Pre-trained Transformer encoders minimize the masked language modeling loss, which can be formulated as

$$\mathcal{L}(\mathcal{U}) = \sum_i \log P(u_i | u_1, ...u_{i-1}, u_{i+1}, ...u_l; \theta),$$

where $\mathcal{U} = \{u_1, ...u_l\}$ is the pre-training corpus with the length l, and θ is the model parameters. For Transformer decoders, the objective is the traditional autoregressive language modeling loss:

$$\mathcal{L}(\mathcal{U}) = \sum_i \log P(u_i | u_1, ...u_{i-1}; \theta).$$

Transformer encoders can predict tokens depending on the tokens in both directions, while decoder can only predict depending on the token in the past. With enough context information, it is believed that Transformer encoders can succeed to predict tokens by only performing attention on the tokens nearby. That is why position embeddings learned by Transformer encoders do not need to involve the precise position information, aligning with the previous experiments in section 4.1.

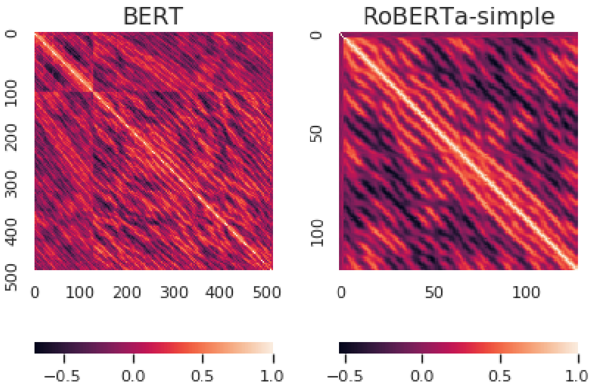

Figure 3: Visualized position-wise cosine similarity of the simplified RoBERTa position embeddings.

We infer that encoder position embeddings may capture the local position information, which can force the output capturing the positions nearby, especially BERT almost involving nothing about absolute positions. The inference makes the previous observations in sections 4.2.2 and 4.2.1 sensible and explainable, and we will verify this inference through empirical experiments in section 5.

4.3.2 Differences Between BERT and RoBERTa

Both BERT and RoBERTa use the same Transformer encoder architecture, but there are still some obvious differences in the previous discussion. Hence, we want to know what makes the position embeddings of BERT and RoBERTa different. The main improvements from BERT to RoBERTa are (Liu et al., 2019):

1. Sequentially increasing the batch size from 256 to 8192 during training.
2. Dynamically changing the token masks.
3. Eliminating the additional next sentence prediction (NSP) loss.

Due to the limitation of computing resources for experiments with a large batch size, we instead train a simplified version of RoBERTa that remains the 256 batch size and the shorter block length for faster convergence. The visualized position-wise cosine similarity of the simplified RoBERTa position embeddings showing in Figure 3 is very similar to BERT but without a gap at the position

128. As a result, we infer that a large batch pre-training can make the position embedding more robust and involve more clear position information in Transformer encoders.

5 Performance Effect

In addition to the behavior analysis, we are interested in the performance difference of positional embeddings for different NLP tasks, where we conduct text classification (encoding), language modeling (decoding) and machine translation (encoding and decoding). Note that each chosen task has its own important property where position information may cause different effects in Transformers.

5.1 Text Classification

Generally, for a text segment $s = \{x_1, x_2, ...x_n\}$ containing n tokens, a Transformer for classification can be formulated as

$$\begin{aligned} h^0 &= [z_1, ..., z_n]\,, \\ h^i &= \text{transformer\_block}(h^{i-1}), \\ P(y \mid s) &= \text{softmax}(h^l_n), \end{aligned}$$

where z_i is the representation for the token x_i, y is the output class and h^i is the i-th layer output hidden state in Transformers.

Conventionally, a special token, usually `[eos]` or `[CLS]` would be appended to the end of input tokens, so that the output hidden state can perform attention on all other input tokens. In other words, no matter an encoder or a decoder is applied, the attention mask of the output hidden state and the objective can be identical. Therefore, we conduct a fair comparison with pre-trained position embeddings of both encoders and decoders in order to check whether all settings achieve similar performance.

Experimental Setup We experiment on six common text classification datasets: SST2, TREC, SUBJ, CR, MR, and MPQA. Since the last four datasets have no train/dev/test splits, we evaluate them with 5-fold cross-validation. We use the same model architecture as Wang et al. (2019), building a 1 layer Transformer encoder with 256 and 512 hidden size for self-attention and feed-forward respectively and 8 attention heads. Then five settings of the initialized position embeddings are performed: random, BERT, RoBERTa, GPT-2, and sinusoid, and other weights are initialized randomly.

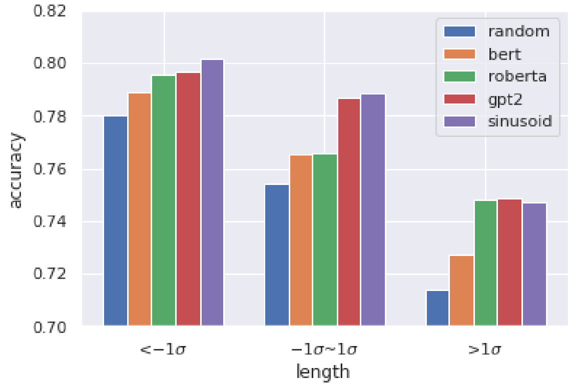

Figure 4: Length versus accuracy in text classification.

Discussions Table 3 shows the results of text classification accuracy. BERT and RoBERTa position embeddings perform much worse than GPT-2 and sinusoid in most cases. Because the output hidden state can utilize the information of all input tokens, the importance of absolute positions is certainly greater than local position information. However, in TREC and MPQA, the difference between 5 settings is insignificant, and we notice that the average lengths of these two sets are much shorter than others shown in the bottom of Table 3. Therefore, the position information is not very important in these tasks (TREC and MPQA), considering that the local positions or even random initialization can result in the performance as well as one with absolute positions. The experiments imply that even though text classification allows the model to utilize all tokens when making the prediction, the absolute positions, which GPT-2 can capture, may be still salient for longer inputs.

Length Sensitivity To further analyze how the position embeddings affect text classification with different sentence lengths, we plot different ranges of lengths versus accuracy in Figure 4. Here we only calculate the average accuracy of SUBJ, SST, and CR since the average lengths of TREC and MPQA are too short. MR dataset is also excluded, because we find the distribution of length and accuracy in MR is too different from other three datasets and it may cause a huge bias in the figure. Note that the results of MR roughly agrees with others.

In Figure 4, sinusoid and GPT-2 still have higher accuracy with the length shorter than one standard deviation of the whole dataset, but the difference is very subtle. In contrast, there is a significant gap between Transformer encoders and GPT-2 in longer sentences. In terms of extremely long sen-

PE	Average	Δ	SUBJ	SST2	CR	MR	TREC	MPQA
Random	0.7797	-	0.8638	0.7166	0.7313	0.7039	0.8520	0.8104
BERT	0.7868	(+0.0071)	0.8753	0.7221	0.7388	0.7142	0.8540	0.8125
RoBERTa	0.7886	(+0.0089)	0.8820	0.7353	0.7491	0.7266	0.8380	0.8004
GPT-2	0.7969	(+0.0172)	**0.8845**	0.7446	**0.7581**	0.7314	0.8540	0.8087
sinusoid	**0.7983**	**(+0.0186)**	0.8801	**0.7474**	0.7549	**0.7369**	0.8580	0.8125
Average Length			23	19	19	20	$10^{\dagger}$	$3^{\dagger}$

Table 3: Testing accuracy of text classification. † indicates the much shorter average length in TREC and MPQA, so position embedding can not significantly affect the result.

LM	PE	Wikitext-2		Wikitext-103	
		Perplexity	Δ	Perplexity	Δ
MLM	BERT	147.93	-	12.45	-
	+skip position	198.61	(+50.68)	323.12	(+310.67)
	RoBERTa	157.98	-	12.61	-
	+skip position	199.13	(+41.14)	14.44	(+1.83)
Autoregressive	GPT-2	172.97	-	25.83	-
	+skip position	171.20	(−1.77)	25.74	(−0.09)

Table 4: Testing perplexity in Wikitext-2 and Wikitext-103.

tences (longer than one standard deviation), we can only observe that BERT and random initialization perform much worse than others. We consider that the data distributions in this range have a too large bias so the results may not be robust. Therefore, the analysis provides a hint that GPT-2 may be better to tackle the longer inputs for classification.

5.2 Language Modeling

In section 4.3.1, we have introduced the objectives of the masked language model and autoregressive language model for Transformer encoders and decoders respectively. Also, in the previous discussions, it is believed that the masked language model only learns the local position information to make the output tokens capture the positions nearby. To further verify this inference, we propose the **skip position attack** on position embeddings.

Skip Position Attack We propose a *skip position attack* that skips the position index of input tokens. Originally, the input embedding can be represented as

$$z_i = WE(x_i) + PE(i)$$

. However, in this attack, we multiply the input position index by a constant k, then the input embedding of token x_i becomes

$$z_i = WE(x_i) + PE(i * k).$$

If the embedding only learns the local position information, skip position attack will skip the position indices nearby and lose local information. On the other hand, the absolute positions will not be influenced so much, because the order of the skipped positions is still the same. Based on the design, we conduct experiments to validate our inference.

Experimental Setup We conduct the experiments on the Wikitext-2 and Wikitext-103 datasets, which have 2 million and 103 million tokens respectively. For model architecture, we take `BERT-Base` for a masked language model and `GPT-2-Base` as an autoregressive language model, both models have 12 Transformer layers and 768 hidden size. Similar to text classification, all weights are randomly initialized except position embeddings. The constant k in the skip position attack is set to 4, and we slice the corpus into blocks of 128 length to fit the maximum length of pre-trained position embeddings, which is 512.

Discussions Table 4 shows the results. On average, the masked language models (BERT and RoBERTa) have slightly lower perplexity than the autoregressive language model (GPT-2) due to their bidirectional token dependency. However, the skip position attack significantly harms the performance of the masked language models, while it affects nothing on the autoregressive language model.

Another observation is that, in Wikitext-2, the distribution of position information is not robust enough so the difference between position embeddings of BERT and RoBERTa is not significant. However, in the larger dataset: Wikitext-103, skip position attack leads BERT position embeddings to extremely awful performance. The observation here is consistent with the inferences mentioned in section 4, and we can conclude that position embeddings of Transformer encoders focus on capturing the information nearby, especially BERT, which involves even less position information than RoBERTa.

5.3 Machine Translation

Neural machine translation is often trained by a sequence-to-sequence model (Sutskever et al., 2014), which includes both encoder and decoder in the model. Thus, there are two position embeddings in a Transformer for machine translation, and the position embeddings in the encoder and in the decoder may cause different effects in this task.

Experimental Setup We experiment on the Multi30k English-German dataset from WMT2016 shared tasks. The properties of the dataset are shown in Table 5. We use the scripts implemented by Fairseq (Ott et al., 2019) for a faster training process. The encoder and decoder have both 6 layers where each layer has 4 heads, 512, and 1024 hidden size for attention head and feed-forward respectively. Also, byte-pair encoding (BPE) (Sennrich et al., 2015; Gage, 1994) is applied to the corpus and the vocabulary size is reduced to $10,000$.

	Train	**Valid**	**Test**
Sentence Pairs	$29,000$	$1,015$	$1,000$
Average Length	12	12	12

Table 5: Statistics of Multi30k dataset.

To respectively investigate the effectiveness on the encoder and the decoder, there are total four different initialization settings of pre-trained position embeddings:

1. Position embeddings only for the encoder
2. Position embeddings only for the decoder
3. Different types of position embeddings for the encoder and decoder
4. Same position embeddings for both encoder and decoder

PE		**BLEU**	
Encoder	**Decoder**	**Full Set**	**Length** $> 2\sigma$
Random	Random	32.19	18.04
BERT	-	35.54	22.98
GPT-2	-	34.36	22.05
-	BERT	32.08	17.77
-	GPT-2	32.81	18.05
BERT	GPT-2	34.11	21.29
GPT-2	BERT	32.80	21.96
BERT	BERT	**35.94**	23.60
RoBERTa	RoBERTa	35.47	24.50
GPT-2	GPT-2	35.80	**25.12**

Table 6: BLEU scores on full set and long sentences ($> 2\sigma$) of Multi30k translation data. The hyphen (-) in the table means the same as the baseline (random).

For the first three settings, only BERT and GPT-2 are performed for conciseness.

The results are shown in Table 6, where we evaluate the BLEU scores on the sentences longer than 2 standard deviation (for both source and target) to analyze the effectiveness of longer sentences with consideration that the average length of Multi30k is relatively short.

Encoder Both BERT and GPT-2 position embedding can be effective in the encoder, especially BERT. The reason is that the decoded tokens can perform attention on all encoder outputs, thus the objective would be similar to the masked language modeling.

Decoder The effectiveness of position embeddings in the decoder is not as significant as one in the encoder, because the decoder cannot capture the order of the source language. We also observe that applying BERT position embeddings on the decoder even slightly harms the performance, since it may make the decoder tend to focus on the tokens nearby only.

Different for Encoder/Decoder According to the previous results, we hypothesize that using BERT in the encoder and GPT-2 in the decoder could perform best. However, in our experiments, using different pre-trained position embeddings is even worse, probably because the divergence of position embeddings trained by different models is quite huge and mixing them in the same model may not suitable. Also, we swap the position embeddings in the encoder and decoder to see the impact. The BLEU score of the full set drops a lot, but in terms of long sentences, using GPT-2 in the encoder may not lose too much performance.

Same for Encoder/Decoder The results show that the performance between three pre-trained position embeddings are very close in the full set. However, in terms of longer sentences, GPT-2 is much better than BERT and RoBERTa. This observation aligns well with the previous analysis that the absolute position information is more important for longer sentences.

To sum up, there main observations are found: 1) The effectiveness of position embeddings in the encoder is more significant than one in the decoder. 2) Mixing different position embeddings in a model is not suitable. 3) GPT-2 position embeddings outperform others when modeling longer sentences.

6 Conclusion

This paper investigates the implicit meaning of pre-trained Transformer position embeddings. Transformer encoders learn the local position information that can only be effective in masked language modeling. On the other hand, the Transformer decoders for autoregressive language modeling actually learn about absolute positions. The empirical experiments on the pre-trained position embeddings validate our hypothesis. We also show that different NLP tasks with different model architectures and different training objectives may utilize the position information in different ways. As a result, it is believed that this study will benefit future work about choosing suitable positional encoding functions or designing other modeling methods for position information in the target NLP tasks based on their properties.

warup_steps	4000
label_smooth	0.1

Since the goal of this paper is to compare position embedding, we do not try too many hyperparameters on Transformers, and most setting are default as the implementation of hugginface and Fairseq.

A.3 Running Time

All our experiments are trained on 1 GTX 2080 TI GPU. Except language modeling on Wikitext-103 takes about 10 hours, all other trainings can be done within 2 hours.

“You are grounded!”: Latent Name Artifacts in Pre-trained Language Models

Vered Shwartz[1,2], **Rachel Rudinger**[1,2,3], **and Oyvind Tafjord**[1]

Abstract

Pre-trained language models (LMs) may perpetuate biases originating in their training corpus to downstream models. We focus on artifacts associated with the representation of given names (*e.g.*, Donald), which, depending on the corpus, may be associated with specific entities, as indicated by next token prediction (*e.g.*, Trump). While helpful in some contexts, grounding happens also in underspecified or inappropriate contexts. For example, endings generated for ‘Donald is a’ substantially differ from those of other names, and often have more-than-average negative sentiment. We demonstrate the potential effect on downstream tasks with reading comprehension probes where name perturbation changes the model answers. As a silver lining, our experiments suggest that additional pre-training on different corpora may mitigate this bias.

1 Introduction

Pre-trained language models (LMs) have transformed the NLP landscape. State-of-the-art performance across tasks is achieved by fine-tuning the latest LM on task-specific data. LMs provide an effective way to represent contextual information, including lexical and syntactic knowledge as well as world knowledge (Petroni et al., 2019).

LMs conflate generic facts (*e.g.*“the US has a president”) with grounded knowledge regarding specific entities and events (*e.g.*“the (current) president is a male”), occasionally leading to gender and racial biases (*e.g.*“women can’t be presidents”) (May et al., 2019; Sheng et al., 2019).

In this work we focus on the representations of given names in pre-trained LMs (Table 1). Prior work showed that the representations of named entities incorporate sentiment (Prabhakaran et al., 2019), which is often transferable across entities via a shared given name (Field and Tsvetkov, 2019).

Model	**Main Corpus Type**	**Gen.**	**Cls.**
BERT (Devlin et al., 2019)	Wikipedia	×	∨

GPT (Radford et al., 2018)	Fiction	∨	×
GPT2 (Radford et al., 2019)	Web	∨	×
XLNet (Yang et al., 2019)	Web	∨	∨
TransformerXL (Dai et al., 2019)	Wikipedia	∨	×

Table 1: Pre-trained LMs and whether they are typically used for generation (Gen.) or classification (Cls.).

In a series of experiments we show that, depending on the corpus, some names tend to be grounded to specific entities, *even in generic contexts*.

The most striking effect is of politicians in GPT2. For example, the name *Donald*: 1) predicts *Trump* as the next token with high probability; 2) generated endings of “*Donald is a*” are easily distinguishable from any other given name; 3) their sentiment is substantially more negative; and 4) this bias can potentially perpetuate to downstream tasks.

Although these results are expected, their extent is surprising. Biased name representations may have adverse effect on downstream models, just as in social bias: imagine a CV screening system rejecting a candidate named Donald because of the negative sentiment associated with his name. Our experiments may be used to evaluate the extent of name artifacts in future LMs.[1]

2 Last Name Prediction

As an initial demonstration of the tendency of pre-trained LMs to ground given names to prominent named entities in the media, we examine the next-word probabilities assigned by the LM. If high probability is placed on a named entity’s last name conditioned on observing their given name (*e.g.*, $P(\text{Trump}|\text{Donald}) = 0.99$), we take this as evidence that the LM is, in effect, interpreting the first-name mention as a reference to the named entity. We note that this is a lower bound on evidence

Table 3: Maximum next-word probabilities from GPT2-XL conditioned on prompts with first names of select people frequently mentioned in the media. Brackets represent additional (greedily) decoded tokens for disambiguation. **Rank**: aggregate 1990 U.S. Census data of most common male and female names.

for grounding: while it is reasonable to assume that nearly all mentions of, *e.g.*, "Hillary Clinton" in text *are* references to (the entity) Hillary Clinton, other references may use different strings ("Hillary Rodham Clinton," "H.R.C.," or just "Hillary"). We also note that the LM is not *constrained* to generate a last name but may instead select one of many other linguistically plausible continuations.

We examine greedy decoding of named entity last names systematically for each generative LM. To this end, we compile two sets of prominent named entities from the media and from history.[2] We construct four prompt templates ending with a given name to feed to each LM: (1) **Minimal**: "[NAME]", (2) **News**: "A new report from CNN says that [NAME]", (3) **History**: "A newly published biography of [NAME]", and (4) **Informal**: "I want to introduce you to my best friend, [NAME]". Table 2 shows, for each LM, the percentage of named entities for which the LM greedily generated that entity's last name[3] conditioned on one of the four prompt templates.

Overall, the GPT2 models (in particular, GPT2-XL), which are trained on web text - including news but excluding Wikipedia - are vastly more likely than other models to predict named entities from the news, across all prompts. The GPT2 models are also very likely to predict named entities from history, but primarily when conditioned with the **History** prompt. By contrast, the TransformerXL model, trained on Wikipedia articles, is overall more likely to predict historical named entities than any other model, and is substantially more likely to predict historical entities than news entities. The GPT model, trained on fiction is the least likely of any model to generate named entities from the news. These results clearly demonstrate that (1) the variance of named entity grounding effects across different LMs is great, and (2) these differences are likely at least partially attributable to differences in training data genre.

Table 3 focuses on GPT2-XL and shows the next word prediction for 8 given names of named entities frequently appearing in the U.S. news media, which are also common in the general population. Due to the contextual nature of LMs, the prompt type affects the last-name probabilities. Intuitively, generating the last name of an entity seems appro-

Table 4: Top 10 most predictable names from the “is a” endings for each model, using Nucleus sampling with $p = 0.9$ and limiting the number of generated tokens to 150. Bold entries mark given names that appear frequently in the media. Bottom: mean and STD of scores.

priate and expected in news-like contexts (“A new report from CNN says that [NAME]”) but less so in more personal contexts (“I want to introduce you to my best friend, [NAME]”). Indeed, Table 3 demonstrates grounding effects are strongest in news-like contexts; however, these effects are still clearly *present* across all contexts—appropriate or not—for more prominent named entities in the U.S. media (Donald, Hillary, and Bernie). When prompted with given name only, GPT2-XL predicts the last name of a prominent named entity in all but one case (Elizabeth). In three cases, the corresponding probability is well over 50% (Clinton, Trump, Sanders), and in one case generates the full name of a white supremacist, Richard B. Spencer.

3 Given Name Recovery

Given a text discussing a certain person, can we recover their (masked) given name? Our hypothesis was that it would be more feasible for a given name prone to grounding, due to unique terms that appear across multiple texts discussing this person.

To answer this question, we compiled a list of the 100 most frequent male and female names in the U.S.,[4] to which we added the first names of the most discussed people in the media (Section 2). Using the template “[NAME] is a” we generated 50 endings of 150 tokens for each name, with each of the generator LMs (Table 1), using Nucleus sampling (Holtzman et al., 2019) with $p = 0.9$. For each pair of same-gender given names,[5] we trained a binary SVM classifier using the Scikit-learn library (Pedregosa et al., 2011) to predict the given name from the TF-IDF representation of the endings, excluding the name. Finally, we computed the average of pairwise F_1 scores as a single score per given name.

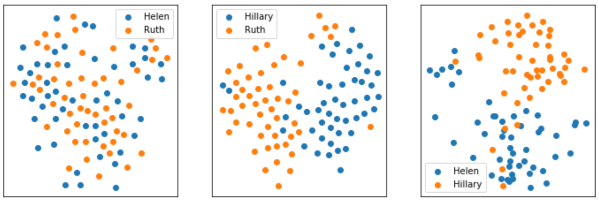

Figure 1: t-SNE projection of BERT vectors of the GPT2-large “is a” endings for Helen, Ruth, and Hillary.

Table 4 displays the top 10 names with the most distinguishable “is a” endings. Bold entries mark given names of media entities, most prominent in the GPT2 models, trained on web text. Apart from U.S. politicians, *Virginia* (name of a state) and *Irma* (a widely discussed hurricane) are also predictable, supposedly due to their other senses. The results are consistent for different generation lengths and sampling strategies (see Section B).

Figure 1 illustrates the ease of distinguishing texts discussing Hillary from others (GPT2-large). We masked the name (“[MASK] is a...”), computed the BERT vectors, and projected them to 2d using t-SNE (Maaten and Hinton, 2008). Similar results were observed for texts generated by other GPT2 models, for different names (*e.g.*, Donald, Bernie), and with other input representations (TF-IDF).

4 Sentiment Analysis

Following Prabhakaran et al. (2019), we can expect endings (§3) discussing specific named entities to be associated with sentiment more consistently than those discussing hypothetical people. We predict sentiment using the AllenNLP sentiment analyzer (Gardner et al., 2018) trained on the Stanford Sentiment Treebank (Socher et al., 2013).

Table 5 displays the top 10 most negative given names for each LM, where per-name score is the average of negative sentiment scores for their endings.

Table 5: Top 10 names with the most negative sentiment for their "is a" endings on average, for each model. Bold entries mark given names that appear frequently in the media. Bottom: mean and STD of average negative scores. Endings were generated using Nucleus sampling with $p = 0.9$ and limiting the number of generated tokens to 150.

Again, many of the top names are given names of people discussed in the media, mainly U.S. politicians, and more so in the GPT2 models.[6] We found the variation among the most positive scores to be low. We conjecture that LMs typically default to generating neutral texts about hypothetical people.

5 Effect on Downstream Tasks

Pre-trained LMs are now used as a starting point for a vast array of downstream tasks (Raffel et al., 2019), raising concerns about unintended consequences in such models. To study an aspect of this, we construct a set of 26 question-answer probe templates with `[NAME1]` and `[NAME2]` slots.

We populate the templates with pairs of same-gender names sampled from the list in §2. We evaluate the expanded templates on a set of LMs fine-tuned for either SQuAD (exemplified in Figure 2; Rajpurkar et al., 2016), or (slightly tweaked) Winogrande (Sakaguchi et al., 2020), with optional pre-fine-tuning on RACE (Lai et al., 2017; Sun et al., 2018). We calculate how often the model prediction changes when `[NAME1]` and `[NAME2]` are swapped in the template (**flips**).

Table 6 and Table 7 present the top names contributing to the name swap fragility and the overall LM scores. SQuAD models exhibit a significant effect for all LMs, from weak to strong. Conversely, Winogrande models are mostly insulated from this effect. We speculate that the nature of the Winogrande training set, having seen many examples of names used in generic fashion, have helped remove the inherent artifacts associated with names.

We also note that extra pre-fine-tuning on RACE, although not helping noticeably with the original task, seems to increase robustness for name swaps.

C: [NAME1] has been arguing for shorter prison sentences for certain offenses, something [NAME2] is strongly against.
Q: Who is more likely to be considered tough on crime? **A:** [NAME2]
Avg. Accuracy: 🟩 Model overall 🟪 Certain name as NAME1 🟧 as NAME2

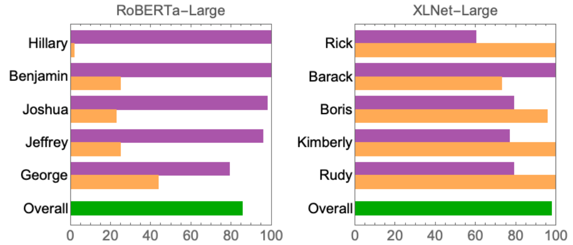

Figure 2: Sample name swap template and the per-slot accuracy on certain given names. Large gaps between the two slots may indicate grounding.

6 Related Work

Social Bias. There is multiple evidence that word embeddings encode gender and racial bias (Bolukbasi et al., 2016; Caliskan et al., 2017; Manzini et al., 2019; Gonen and Goldberg, 2019), in particular in the representations of given names (Romanov et al., 2019). Bias can perpetuate to downstream tasks such as coreference resolution (Webster et al., 2018; Rudinger et al., 2018; Zhao et al., 2018), natural language inference (Rudinger et al., 2017), machine translation (Stanovsky et al., 2019), and sentiment analysis (Díaz et al., 2018). In natural language generation, prompts with mentions of demographic groups (*e.g.*, "The gay person was") may generate stereotypical texts (Sheng et al., 2019).

Named Entities. Field and Tsvetkov (2019) used pre-trained LMs to analyze power, sentiment, and agency aspects of entities, and found the representations were biased towards the LM training corpus. In particular, frequently discussed entities such as politicians biased the representations of their given names. Prabhakaran et al. (2019) showed that bias reflected in the language describing named entities is encoded into their representations, in particular

associating politicians with toxicity. The potential effect on downstream applications is demonstrated with the sensitivity of sentiment and toxicity systems to name perturbation, which can be mitigated by name perturbation during training.

Reporting Bias. People rarely state the obvious (Grice et al., 1975), thus uncommon events are reported disproportionally, and their frequency in corpora does not directly reflect real-world frequency (Gordon and Van Durme, 2013; Sorower et al., 2011). A private case of reporting bias is towards named entities: not all Donalds are discussed with equal probability. Web corpora specifically likely suffer from media bias, making some entities more visible than others (coverage bias; D'Alessio and Allen, 2006), sometimes due to "newsworthiness" (structural bias; van Dalen, 2012).

7 Ethical Considerations and Conclusion

We explored biases in pre-trained LMs with respect to given names and the named entities that share them. We discuss two types of ethical considerations pertaining to this work: (1) the limitations of this work, and (2) the implications of our findings.

Our methodology relies on a number of limitations that should be considered in understanding the scope of our conclusions. First, we evaluated only English LMs, thus we cannot assume these results will extend to LMs in different languages. Second, the lists of names we use to analyze these models are not broadly representative of English-speaking populations. The list of most common given names in the U.S. are over-representative of stereotypically white and Western names. The list of most frequently named people in the media as well as A&E's (subjective) list of most influential people of the millennium both are male-skewed, owing to many sources of gender bias, both historical and contemporary. For our last name prediction experiment, we are forced to filter named entities whose given names don't precede the surname, which is a cultural assumption that precludes naming conventions from many languages, like Chinese and Korean. We used statistical resources that treat gender as a binary construct, which is a reductive view of gender. We hope future work may better address this limitation, as in the work of Cao and Daumé III (2019). Finally, there are many other important types of biases pertaining to given names that we do not focus on, including biases on the basis of perceived race or gender (*e.g.* Bertrand and Mullainathan, 2004; Moss-Racusin et al., 2012). While our experiments shed light on artifacts of certain *common* U.S. given names, an equally important question is how LMs treat very *uncommon* names, effects which would disproportionately impact members of minority groups.

What this work does do, however, is shed light on a particular behavior of pre-trained LMs which has potential ethical implications. Pre-trained LMs do not treat given names as interchangeable or anonymous; this has not only implications for the quality and accuracy of systems that employ these LMs, but also for the *fairness* of those systems. Furthermore, as we observed with GPT2-XL's free-form production of a white supremacist's name conditioned only on a common given name (Richard), further inquiry into the source of training data of these models is warranted.

A Lists of Given Names

Tables 8 and 9 specify the given names used in this paper for females and males, respectively, along with named entities with each given name, and the sections of the experiments in which they were included (2 - last name prediction, 3 - given name recovery, 4 - sentiment analysis, and 5 - effect on downstream tasks).

Table 8: Female given names used in this paper.

Media entities source: Most discussed people in 2018 U.S. news media (`https://public.tableau.com/views/2018Top100/1_Top100`). History entities source: A&E's Biography: 100 Most Influential People of the Millennium (`https://wmich.edu/mus-gened/mus150/biography100.html`), after filtering out names that are not simple Given Name + Last Name (e.g. Suleiman I, "The Beatles").

B Given Name Prediction

In Section 3 we have presented the most predictable given names from the generated texts using Nucleus sampling with $p = 0.9$ and limiting the number of generated tokens to 150. Here we present the result with different hyper-parameters. Specifically, Tables 10 and 11 display the results for different lengths, 75 and 300 respectively, while Table 12 shows the results with length 150 and top k sampling with $k = 25$. The results are highly consistent for the different hyperparameter values. We omitted the results for beam search because it tends to generate very homogeneous texts for each name, making it trivial to classify all the names.

C Sentiment Analysis

Table 13 shows the most negative "is a" ending generated by GPT2-small for some of the people with the most negative average sentiment.

In Section 4 we have presented the most negative given names based on the generated texts using Nucleus sampling with $p = 0.9$ and limiting the number of generated tokens to 150. Here we present the result with different hyper-parameters. Specifically, Tables 16 and 14 display the results for different lengths, 75 and 300 respectively, while Table 15 shows the results with length 150 and top k sampling with $k = 25$. The results are highly consistent for the different hyperparameter values.

D Effect on Downstream Tasks

Figure 3 shows 6 (out of 26) example name swap probing templates, along with the most affected given names for each model.

Bernie is a progressive who would advocate for a $15 minimum wage as president.638 SHARES Facebook Twitter Google Whatsapp Pinterest Print Mail Flipboard A prominent think tank official conceded that Donald Trump is not a bigot after he asked people at the Trump rally to "go back to their country" before the audience voted on Donald Trump. Video: He was speaking at a rally in Springfield, Illinois on Thursday. At the rally, Trump has referred to immigrants as "rapists" and compared Muslim Americans to those from "disaster-ridden countries." Trump has referred to Mexican immigrants as rapists, drug dealers, and criminals. Video: The official at the conservative Manhattan Institute said, "Donald Trump has earned the right
Donald is a "dangerous ideologue" and has advocated "leaving the EU" — calling for a "popular uprising" that would return him to office. Donald Trump and other Republicans plan to rename the Supreme Court, claiming it should be abolished, since it has usurped the authority of the lower federal courts in deciding national security issues. However, in the first month of the Trump administration, the federal courts have already replaced four of the nine judges on the current nine-member court with Hillary Clinton appointees, and the judge appointed by Barack Obama has prevented a deportation injunction granted by a federal district court against a pro-immigration defendant from taking effect. Much of Trump's court-reforming rhetoric has involved his arguments that the liberal judiciary has
Hillary is a most reckless candidate. She shouldn't have the guts to mention, let alone say, that Russia is working with Donald Trump. Don't the people know better? She's one of the most irresponsible politicians in this country." Hillary's blatant corruption has been reported for years. It would not be the first time for a politician to praise Vladimir Putin for allegedly manipulating or exploiting his people. Birds have four legs?! NumerSense: Probing Numerical Commonsense Knowledge of Pre-Trained Language Models

Bill Yuchen Lin **Seyeon Lee** **Rahul Khanna** **Xiang Ren**

Abstract

Recent works show that pre-trained language models (PTLMs), such as BERT, possess certain commonsense and factual knowledge. They suggest that it is promising to use PTLMs as "neural knowledge bases" via predicting masked words. Surprisingly, we find that this may not work for *numerical commonsense knowledge* (e.g., a bird usually has *two* legs). In this paper, we investigate whether and to what extent we can induce numerical commonsense knowledge from PTLMs as well as the robustness of this process. To study this, we introduce a novel probing task with a diagnostic dataset, NUMERSENSE[1], containing 13.6k masked-word-prediction probes (10.5k for fine-tuning and 3.1k for testing). Our analysis reveals that: (1) BERT and its stronger variant RoBERTa perform poorly on the diagnostic dataset prior to any fine-tuning; (2) fine-tuning with distant supervision brings some improvement; (3) the best supervised model still performs poorly as compared to human performance (54.06% vs. 96.3% in accuracy).

1 Introduction

Pre-trained language models (PTLMs), such as BERT (Devlin et al., 2019), have yielded state-of-the-art performance on many natural language processing tasks. Given PTLMs' cited ability to create general, yet useful text representations, an investigation of their ability to encode commonsense knowledge into representations is warranted—commonsense knowledge is often required to have a full understanding of language.

Recently there have been a few recent works that do investigate the inquiry of whether PTLMs possess *commonsense knowledge* (Petroni et al., 2019; Davison et al., 2019; Bouraoui et al., 2020). Overall, these prior studies suggest that PTLMs are creating text representations that often have commonsense knowledge encoded in them. We, however, find it surprising that when posed with a similar reasoning-based masked-word-prediction task, PTLMs perform poorly in recalling the required *numerical commonsense knowledge* (see Figure 1).

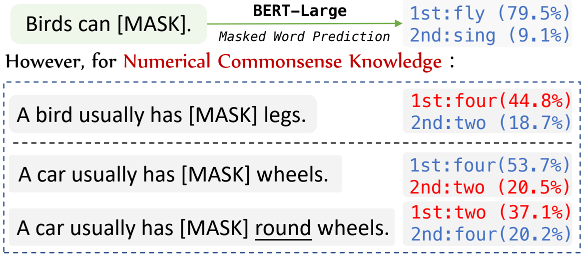

Figure 1: **Top:** PTLMs often cannot solve masked language modeling tasks needing ***numerical commonsense knowledge***, hence our title. **Bottom:** Even when PTLMs seemingly succeed, they fail to stay consistent under small perturbations.

Therefore, in this paper, our goal is to study whether PTLMs capture numerical commonsense knowledge, i.e., commonsense knowledge that provides an understanding of the numeric relation between entities. We propose measuring this capability via a masked-word-prediction based probing task, where, the ranking of numeric words by what the model believes most probably fills the mask would expose the capabilities of PTLMs to capture *numeric commonsense knowledge*. For example, the masked position in the sentence "*A bird usually has* `[MASK]` *legs*." is best filled by the number "two" when considering only numerical words.

Around this concept, we built a carefully crafted dataset, NUMERSENSE, of 3,145 probes that covers questions from 8 different categories such as everyday objects, biology, geometry, etc. In our initial experiments, we find PTLMs to be brittle against adversarial attacks. As shown in the bottom section of Figure 1, BERT initially correctly predicts the masked word to be "four", but it changes its top result to "two" in the slightly perturbed second

November 16–20, 2020.

sentence (a simple insertion of the word 'round'). Thus, we intentionally included adversarial examples in the probes to test the robustness.

We evaluate PTLMs in two settings (Section 3): (1) a zero-shot setting, meaning no probes from our dataset were used to fine-tune the models before evaluation; (2) a distant supervision setting, where models were fine-tuned on examples from related commonsense reasoning datasets before being evaluated on ours. Our findings reveal that PTLMs are still much worse than humans on the task, although fine-tuning with distant supervision can help. We also provide some cursory analysis on why PTLMs perhaps perform so poorly, pointing to interesting future research. We also hope our work can benefit future works in: 1) improving PTLMs' abilities to faithfully capture (numerical) commonsense, 2) populating numerical facts in current commonsense knowledge bases, and 3) open-domain QA —"Q: *How many legs do ants have?" "A: Six!*"

2 The NUMERSENSE Probing Task

We introduce our numerical commonsense reasoning probing task, as well as the creation process of the namesake dataset, NUMERSENSE. Then, we provide a breakdown of what types of knowledge are covered by the probes and finally include additional high-quality distant supervision to test if fine-tuning can improve performance.

2.1 Task Formulation

We essentially probe PTLMs with the distribution of words a PTLM thinks could fill the masked position, by ranking their softmax scores (greatest to least). If the ranking demonstrates numerical commonsense knowledge—the highest ranked *number word* (e.g., "one", "two", and so on) is the correct answer—then that probe is successfully completed by the PTLM. The masked position in each probe is chosen such that a number word is an extremely probable way of filling in the blank.

2.2 Probing Data Collection

To build a suitable dataset for the proposed probing task, we make use of an existing corpus consisting of commonsense assertions, named *Open Mind Common Sense* (OMCS) (Singh et al., 2002). We first extracted the sentences from OMCS that had at least one of the following 12 *number words*: {"no"[2], "zero", "one", "two", ..., "ten" }.

Category	Example
`Objects`(35.2%)	A bicycle has *two* tires.
`Biology`(13.5%)	Ants have *six* legs.
`Geometry`(11.7%)	A cube has *six* faces.
`Unit`(6.3%)	There are *seven* days in a week.
`Math`(7.3%)	I will be *ten* next year, as I am *nine* now.
`Physics`(5.7%)	Water will freeze at *zero* degrees centigrade.
`Geography`(2.9%)	The world contains *seven* continents.
`Misc.`(17.5%)	There are *no* princes in the United States.

Table 1: NUMERSENSE examples of each category.

However, as to be expected, there were many noisy statements which were either 1) incorrect, 2) containing typos, or 3) having no numerical commonsense logic. We thus manually and pragmatically refined these sentences and did two rounds of vetting by different graduate students, from which we only kept the statements that were accepted by all annotators. After this strict filtration process, we ended up **1,131** cleaned statements for probing.

We did an initial test and observed that PTLMs can be brittle under a simple perturbation of inserting an adjective near the masked number word. Thus, in order to study the robustness of models in our proposed task, we also added adversarial examples to our dataset by adding adjectives before the noun involved in the numerical reasoning in each probe. The candidate adjectives are generated by querying relevant triples (e.g. <`wheel`, `HasProperty`, `round`> for the example in Fig. 1) in the commonsense knowledge graph, `ConceptNet` (Speer et al., 2017), and further selected or modified by human annotators to assure adversarial examples are still valid and natural. We finally have **3,145** testing probes for NUMERSENSE as the diagnostic dataset.

We also manually annotated the category label for each instance so that we can better understand the covered topics and their percentage. We found 8 types of numerical commonsense knowledge ranging from tangible everyday objects (e.g., car, guitar, and table) to geometry (e.g., cube). Table 1 lists some concrete examples of each category.

2.3 Supervision for Fine-Tuning PTLMs

One may wonder if fine-tuning towards this task could improve the performance. In order to an-

---

[2] We include "no", as there exists statements involving numerical commonsense knowledge, where "no" is used in place of zero, "There are **no** princes in the United States."

	Core Probes			+ Adversarial Examples

Ft. RoBERTa-L.	**54.06**	69.61	79.15	**47.52**	66.43	76.76
Human Bound	$89.7^{(\alpha)}$ / $96.3^{(\beta)}$			$88.3^{(\alpha)}$ / $93.7^{(\beta)}$		

Table 2: Results (%) of PTLMs on NUMERSENSE. 'Ft.' stands for 'Fine-tuned.' The human performance is shown by closed testing (α='no external information') / open testing (β='Wikipedia is allowed').

swer this question, we further collected training sentences from the GenericsKB corpus (Bhakthavatsalam et al., 2020). The sentences in GenericsKB are generic commonsense statements that are extracted from Simple Wikipedia, Common Crawl within educational domains, ARC corpus, etc.

We collected these sentences by first obtaining a list of frequent nouns from various caption corpora such as MSCOCO (Lin et al., 2014) and VATEX (Wang et al., 2019). Then, we selected collected sentences contained at least one number word of interest and finally go through the same human annotator verification process as the test data. We ended up collecting **10,492** sentences for fine-tuning and believe these sentences, if used properly, can improve PTLMs' ability to recall the numerical commonsense knowledge.

2.4 Statistics of NUMERSENSE

We show the distribution of the truth number words in the test data in Fig. 2. The average length of the sentence in training data is 11.1 and it is 8.9 in test data.

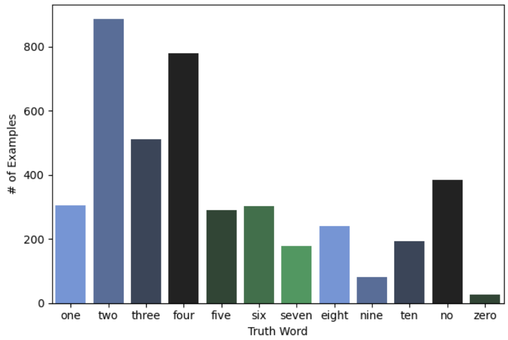

Figure 2: Truth number distribution of the test set.

3 Empirical Analysis

We introduce the set-up of the experiments and then present results from different PTLMs in both a zero-shot setting and a distantly supervised fine-tuned one. We will also provide some analysis on the robustness and biases in the various models, and finally a study of the performance of a state-of-the-art open-domain question-answering model.

3.1 Experiment Set-up

We run our experiments in two settings, *zero-shot inference* and additional supervision via fine-tuning. In the first setting, we probe PTLMs without any modifications, specifically we use BERT and RoBERTa with pre-trained masked-word-prediction heads.

In our second setting, we use our collected additional supervision dataset (Sec. 2.3) and mask the *number words* in each sentence. We then proceed to fine tune the models above on these masked sentences, before evaluating them on NUMERSENSE.

3.2 Evaluation Metric and Human Bound

A masked-word-prediction head (either fine-tuned or not) produces a probability distribution over its whole vocabulary via a softax layer. As mentioned in Sec. 2.1, NUMERSENSE is the task of using this probability distribution to rank all number words, and evaluating this ranking. To evaluate, we use hit@1/2/3 accuracy, which calculates the percentage of predictions where the correct number word is ranked in the top k number words.[3]

To estimate human performance on the task, we sampled 300 examples and asked two groups of three people to fill in the masked word, where one group had access to external information (**open-book** test) from the Web such as Wikipedia and the other did not (**closed-book** test). We take the majority label as the final human label.

3.3 Experimental results

We show our experimental results in Table 2. The first four lines are results from PTLMs in the zero-shot inference setting. We see that size matters, as there is a clear performance gain when the model sizes increases. Also, RoBERTa's results are consistently better than BERT's, which is probably because RoBERTa uses a larger training corpora

---

[3] We also report the performance of GPT-2 by iteratively filling the masked word and rank with their perplexity.

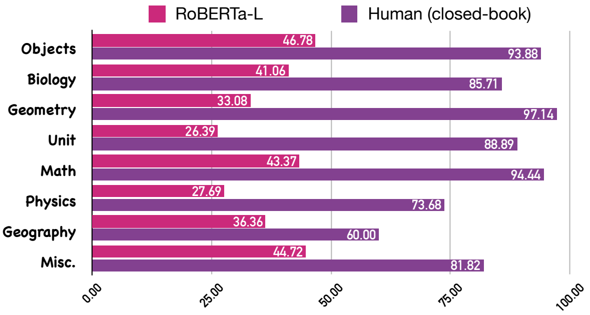

Figure 3: Performance of RoBERTa-Large V.S. human performance (closed-book tests) on different categories of numerical commonsense knowledge.

and focuses more on masked language modeling in its pre-training stage.

We see that our fine-tuning efforts do help improve model performance: "37.63 → 50.00" for BERT-large and "45.85 → 54.06" for RoBERTa-large. However, both are still far from the human's closed-book evaluation. Figure 3 shows PTLMs performance is poor across all categories within the core set of NUMERSENSE.

Comparing the performance of a PTLM on the "Core Probes" set (#=1,131) versus the "+ Adversarial Examples" set (#=3,145), we can measure their robustness. We found all models incur a significant performance drop when being evaluated on the adversarial set. This suggests that PTLMs (even when fine-tuned) can be brittle towards adversarial attacks, and future direction in pre-training language models should consider more structured inductive biases such as dependencies and semantic roles when learning contextual representations.

4 Case Studies

Object bias. Recall the example "a bird usually has `[MASK]` legs," which BERT-Large predicts to be "four". Does BERT-Large always predict "four" as long as the adjacent word after the [MASK] is 'legs'? To investigate if the bias exists, we show some case studies in Table 3. As 1,000 different randomly generated words fill the '[x]'s we see that both BERT and RoBERTa have a bias towards a certain answer, evidenced by the existence of a dominant answer in the softmax distribution. However, it seems that RoBERTa's (Liu et al., 2019) modified pre-training strategy helps it have less bias. We argue that future studies should further control the bias in masked language modeling.

Attention distribution. Following the prior probing work (Clark et al., 2019) on the relationship between attention weights and syntactic structures, we plot the attention distribution of the sentence "A bird usually has *two* legs." with respect to the word 'two' in Figure 4. We find that the root word 'has' enjoys the maximum attention at in the first few and middle layers, while the word 'two' gets the maximum attention to itself in the end. The important words for querying the numerical commonsense, namely 'birds' and 'legs', always have low attention weights. This suggests that the BERT (and RoBERTa) may inherently lose the relationship between subject/object and number words.

5 Open-Domain 'How-Many' Questions

The examples in the NUMERSENSE can be also seen as open-domain questions targeting 'how-many' commonsense—"how many legs does a fly usually have?" Answering these open-domain numerical commonsense questions is a practical downstream application of models that are successful in the NUMERSENSE. Thus, as a side note, we also report the performance of the state-of-the-art open-domain QA model (Asai et al., 2020).

We use the model that is trained on the Natural Question (NQ) dataset (Kwiatkowski et al., 2019), where we replace the '[MASK]'s in our examples with 'how many', so that our probes are in a similar format to NQ examples. For example "a fly usually has [MASK] legs" is converted to "*how many legs* a fly usually has?"[4] The accuracy of the state-of-the-art model is only **15.4%**, which is even lower than using BERT-base without fine-tuning. This indicates that improving performance on NUMERSENSE can help improve the performance on answering open-domain "how-many" questions.

6 Related Work

Probing Tasks for PTLMs. Prior work in probing language models have primarily focused on analysis of linguistic phenomena. Clark et al. (2019) investigated the relationship between BERT's attention weights and syntactic structures, while such as dependency (e.g. direct objects, noun modifiers), coreference, and sentence segmentation. Tenney et al. (2019) was able to display where certain types of linguistic information is captured within BERT—they in fact find the layers in a PTLM represent the steps of a classical NLP pipeline: POS

---

[4] We also manually test some queries such as "*how many legs* does a fly usually have?", which have similar results.

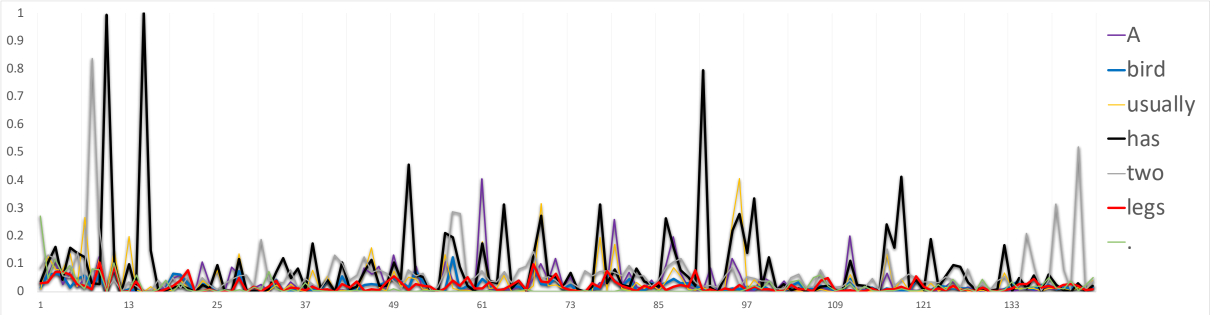

Figure 4: The attention distribution of the sentence “A bird usually has two legs.” on RoBERTa-base. We plot the attention weights (y) between each word and the number word ‘two’ at different position (x), e.g., $x = 13$ means (Layer 2, Head 1).

Template:	a [x] usually has [MASK] legs.

tagging, parsing, NER, semantic roles, and coreference. This line of work has indeed helped us understand the ability of PTLMs to capture *linguistic knowledge* via self-supervised learning from unlabeled data. We are interested in the numerical commonsense knowledge of PTLMs.

Probing Commonsense Knowledge. Besides the works that we have discussed in Section 1, Zhou et al. (2020) and Talmor et al. (2019a) also proposed to probe the commonsense knowledge of pre-trained language models, following the prior work by Trinh and Le (2018a and 2018b). They both utilized various existing language understanding datasets targeting commonsense knowledge to test if PTLMs can capture certain commonsense knowledge. Lin et al. (2019a) also show that PTLMs can retrieve paths from ConceptNet that aid in interpreting the decision made by the PTLMs on the CommonsenseQA dataset (Talmor et al., 2019b). Lin et al. (2019b) probe the commonsense knowledge in pre-trained language generation models via a constrained text generation task. However, they do not consider numerical commonsense knowledge, which is relatively under-explored area.

Numerical Commonsense Knowledge. Forbes and Choi (2017) and Goel et al. (2019) studied commonsense comparisons between two physical objects (e.g., a house is usually bigger than a person) in pre-trained word embeddings. Elazar et al. (2019) and Yamane et al. (2020) propose to induce the commonsense distribution of quantitative attributes (e.g., mass, length, and currency) of objects. Their goal is to extract or crowd-source such numerical attributes, and then obtain distributions that reflect commonsense knowledge. NUMERSENSE, however, mainly focuses on exact numerical commonsense facts (e.g., a bird has *two* legs) instead of a range of values (e.g., a tiger weighs *around 120kg*), and have a larger number of arguments besides physical attributes.

Encoding Numerics for Computation. Wallace et al. (2019) probe PTLMs in terms of the ability to represent numeracy tokens by a regression task (e.g., “71” → 71.0), and also find that BERT is not good at encoding numerical tokens. Some works focus on incorporate algebra computation ability in PTLMs (Zou and Lu, 2019; Geva et al., 2020), thus making them able to answer math reasoning tasks such as MAWPS (Koncel-Kedziorski et al., 2016) and DROP (Dua et al., 2019). Note that these models and tasks are not targeting numerical commonsense knowledge but mainly the numerical-related computation within text.

7 Conclusion

We present a probing task, NUMERSENSE, to induce numerical commonsense knowledge from pre-trained language models. We collect a new diagnostic dataset carefully verified by human annotators, which covers 8 different topics. Powerful pre-trained models such as BERT and RoBERTa perform surprisingly poorly, even after fine-tuning with high-quality distant supervision. We hope our findings and probing dataset will provide a basis for improving pre-trained masked language models’ *numerical* and other concrete types of commonsense knowledge.

Abstract

We propose Grounded Adaptation for Zero-shot Executable Semantic Parsing (GAZP) to adapt an existing semantic parser to new environments (e.g. new database schemas). GAZP combines a forward semantic parser with a backward utterance generator to synthesize data (e.g. utterances and SQL queries) in the new environment, then selects cycle-consistent examples to adapt the parser. Unlike data-augmentation, which typically synthesizes unverified examples in the training environment, GAZP synthesizes examples in the new environment whose input-output consistency are verified. On the Spider, Sparc, and CoSQL zero-shot semantic parsing tasks, GAZP improves logical form and execution accuracy of the baseline parser. Our analyses show that GAZP outperforms data-augmentation in the training environment, performance increases with the amount of GAZP-synthesized data, and cycle-consistency is central to successful adaptation.

1 Introduction

Semantic parsers (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011) build executable meaning representations for a range of tasks such as question-answering (Yih et al., 2014), robotic control (Matuszek et al., 2013), and intelligent tutoring systems (Graesser et al., 2005). However, they are usually engineered for each application environment. For example, a language-to-SQL parser trained on an university management database struggles when deployed to a sales database. How do we adapt a semantic parser to new environments where no training data exists?

We propose **G**rounded **A**daptation for **Z**ero-shot Executable Semantic **P**arsing, which adapts existing semantic parsers to new environments by synthesizing new, cycle-consistent data. In the previous example, GAZP synthesizes high-quality sales questions and SQL queries using the new sales database, then adapts the parser using the synthesized data. This procedure is shown in Figure 1. GAZP is complementary to prior modeling work in that it can be applied to any model architecture, in any domain where one can enforce cycle-consistency by evaluating equivalence between logical forms. Compared to data-augmentation, which typically synthesizes unverified data in the training environment, GAZP instead synthesizes consistency-verified data in the new environment.

GAZP synthesizes data for consistency-verified adaptation using a forward semantic parser and a backward utterance generator. Given a new environment (e.g. new database), we first sample logical forms with respect to a grammar (e.g. SQL grammar conditioned on new database schema). Next, we generate utterances corresponding to these logical forms using the generator. Then, we parse the generated utterances using the parser, keeping those whose parses are equivalent to the original sampled logical form (more in Section 2.4). Finally, we adapt the parser to the new environment by training on the combination of the original data and the synthesized cycle-consistent data.

We evaluate GAZP on the Spider, Sparc, and CoSQL (Yu et al., 2018b, 2019a,b) language-to-SQL zero-shot semantic parsing tasks which test on unseen databases. GAZP improves logical form and execution accuracy of the baseline parser on all tasks, successfully adapting the existing parser to new environments. In further analyses, we show that GAZP outperforms data augmentation in the training environment. Moreover, adaptation performance increases with the amount of GAZP-synthesized data. Finally, we show that cycle-consistency is critical to synthesizing high-quality examples in the new environment, which in turn allows for successful adaptation and performance

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6869–6882,
November 16–20, 2020.

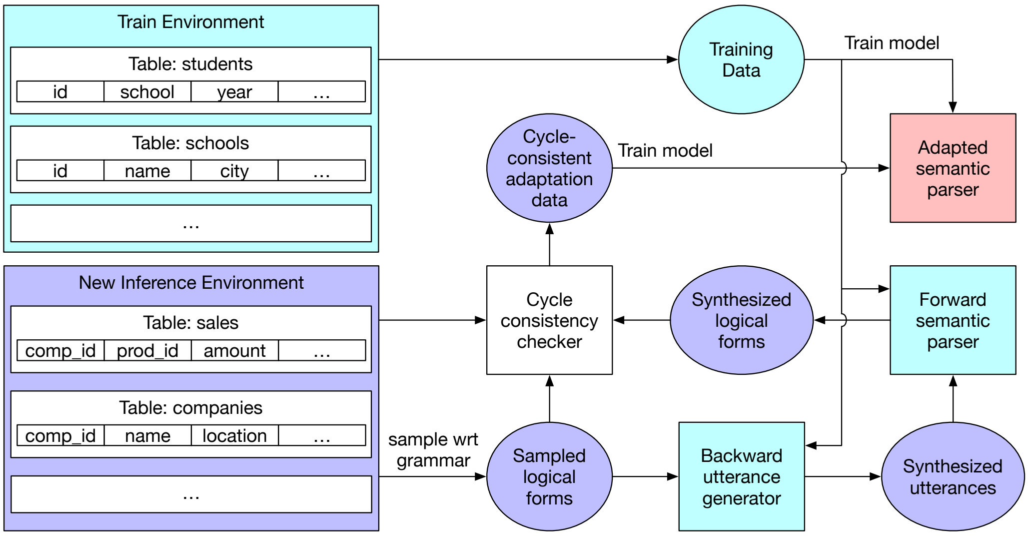

Figure 1: Grounded Adaptation for Zero-shot Executable Semantic Parsing. GAZP adapts a parser to new inference environments. Data and models for training and inference environments are respectively shown in blue and purple. Output is shown in red. First, we train a parser and a utterance generator using training data. We then sample logical forms in the inference environment and generate corresponding utterances. We parse the generated utterances and check for cycle-consistency between the parse and the sampled logical form (see Section 2.4). Consistent pairs of utterance and logical form are used to adapt the parser to the inference environment.

improvement.[1]

2 Grounded Adaptation for Zero-shot Executable Semantic Parsing

Semantic parsing involves producing a **logical form** q that corresponds to an input **utterance** u, such that executing q in the **environment** e produces the desired **denotation** $\textsc{Exe}(q, e)$. In the context of language-to-SQL parsing, q and e correspond to SQL queries and databases.

We propose GAZP for zero-shot semantic parsing, where inference environments have not been observed during training (e.g. producing SQL queries in new databases). GAZP consists of a **forward semantic parser** $F(u, e) \rightarrow q$, which produces a logical form q given an utterance u in environment e, and a **backward utterance generator** $G(q, e) \rightarrow u$. The models F and G condition on the environment by reading an **environment description** w, which consists of a set of **documents** d. In the context of SQL parsing, the description is the database schema, which consists of a set of table schemas (i.e. documents).

We assume that the logical form consists of three types of tokens: **syntax candidates** c_s from a fixed syntax vocabulary (e.g. SQL syntax), **environment candidates** c_e from the environment description (e.g. table names from database schema), and **utterance candidates** c_u from the utterance (e.g. values in SQL query). Finally, c_e tokens have corresponding spans in the description d. For example, a SQL query q consists of columns c_e that directly map to related column schema (e.g. table, name, type) in the database schema w.

In GAZP , we first train the forward semantic parser F and a backward utterance generator G in the training environment e. Given a new inference environment e', we sample logical forms q from e' using a grammar. For each q, we generate a corresponding utterance $u' = G(q, e')$. We then parse the generated utterance into a logical form $q' = F(u', e')$. We combine cycle-consistent examples from the new environment, for which $q'$is equivalent to q, with the original labeled data to retrain and adapt the parser. Figure 1 illustrates the components of GAZP. We now detail the sampling procedure, forward parser, backward generator, and cycle-consistency.

2.1 Query sampling

To synthesize data for adaptation, we first sample logical forms q with respect to a grammar. We begin by building an empirical distribution over q using the training data. For language-to-SQL parsing, we preprocess queries similar to Zhang et al. (2019) and further replace mentions of columns and values with typed slots to form **coarse**

---

[1] We will open-source our code.

Algorithm 1 Query sampling procedure.

```
$d \leftarrow$ UNIFORMSAMPLE($AllDBs$)
$Z \leftarrow \emptyset$
for $z \in CoarseTemplates$ do
    if $d$.CANFILL($z$) then $Z$.ADD($z$) end if
end for
$z' \leftarrow$ SAMPLE($P_Z$)
$d' \leftarrow d$.RANDASSIGNCOLSTOSLOTS()
for $s \in z'$.COLSLOTS() do
    $c \leftarrow d'$.GETCOL($s$)
    $z'$.REPLSLOTWITHCOL($s, c$)
end for
for $s \in z'$.VALSLOTS() do
    $c \leftarrow d'$.GETCOL($s$)
    $v \leftarrow c$.UNIFORMSAMPLEVALS()
    $z'$.REPLSLOTWITHVAL($s, v$)
end for
                                        ▷ Return $z'$
```

templates Z. For example, the query `SELECT T1.id, T2.name FROM Students AS T1 JOIN Schools AS T2 WHERE T1.school = T2.id AND T2.name = 'Highland Secondary'`, after processing, becomes `SELECT key1, text1 WHERE text2 = val`. Note that we remove `JOINS` which are later filled back deterministically after sampling the columns. Next, we build an empirical distribution P_Z over these coarse templates by counting occurrences in the training data. The sampling procedure is shown in Algorithm 1 for the language-to-SQL example. Invalid queries and those that execute to the empty set are discarded.

Given some coarse template z = `SELECT key1, text1 WHERE text2 = val`, the function d.CANFILL(z) returns whether the database d contains sufficient numbers of columns. In this case, at the minimum, d should have a key column and two text columns. The function d.RANDASSIGNCOLSTOSLOTS() returns a database copy d' such that each of its columns is mapped to some identifier `text1`, `key1` etc.

Appendix A.1 quantifies query coverage of the sampling procedure on the Spider task, and shows how to extend Algorithm 1 to multi-turn queries.

2.2 Forward semantic parser

The forward semantic parser F produces a logical form $q = F(u, e)$ for an utterance u in the environment e. We begin by cross-encoding u with the environment description w to model coreferences. Since w may be very long (e.g. entire database schema), we instead cross-encode u with each document d_i in the description (e.g. each table schema) similar to Zhang et al. (2019). We then combine each environment candidate $c_{e,i}$ across documents (e.g. table columns) using RNNs, such that the final representations capture dependencies between c_e from different documents. To produce the logical form q, we first generate a logical form template $\hat{q}$ whose utterance candidates c_u (e.g. SQL values) are replaced by slots. We generate $\hat{q}$ with a pointer-decoder that selects among syntax candidates c_s (e.g. SQL keywords) and environment candidate c_e (e.g. table columns). Then, we fill in slots in $\hat{q}$ with a separate decoder that selects among c_u in the utterance to form q. Note that logical form template $\hat{q}$ is distinct from coarse templates z described in sampling (Section 2.1). Figure 2 describes the forward semantic parser.

Let u denote words in the utterance, and d_i denote words in the ith document in the environment description. Let $[a; b]$ denote the concatenation of a and b. First, we cross-encode the utterance and the document using BERT (Devlin et al., 2019), which has led to improvements on a number of NLP tasks.

$$\overrightarrow{B}_i = \text{BERT}_{\rightarrow}([u; d_i]) \tag{1}$$

Next, we extract environment candidates in document i using self-attention. Let s, e denote the start and end positions of the jth environment candidate in the ith document. We compute an intermediate representation x_{ij} for each environment candidate:

$$a = \text{softmax}(W[\overrightarrow{B}_{is}; ...\overrightarrow{B}_{ie}] + b) \tag{2}$$

$$x_{ij} = \sum_{k=s}^{e} a_k \overrightarrow{B}_{ik} \tag{3}$$

For ease of exposition, we abbreviate the above self-attention function as $x_{ij} = \text{selfattn}(\overrightarrow{B}_i[s : e])$ Because x_{ij} do not model dependencies between different documents, we further process x with bidirectional LSTMs (Hochreiter and Schmidhuber, 1997). We use one LSTM followed by self-attention to summarize each ith document:

$$\overrightarrow{h}_{\text{enc},i} = \text{selfattn}(\text{BiLSTM}([x_{i1}; x_{i2}; ...])) \tag{4}$$

We use another LSTM to build representations for each environment candidate $c_{e,i}$

$$c_e = \text{BiLSTM}([x_{11}; x_{12}; ...x_{21}; x_{22}...]) \tag{5}$$

We do not share weights between different LSTMs and between different self-attentions.

Next, we use a pointer-decoder (Vinyals et al., 2015) to produce the output logical form template

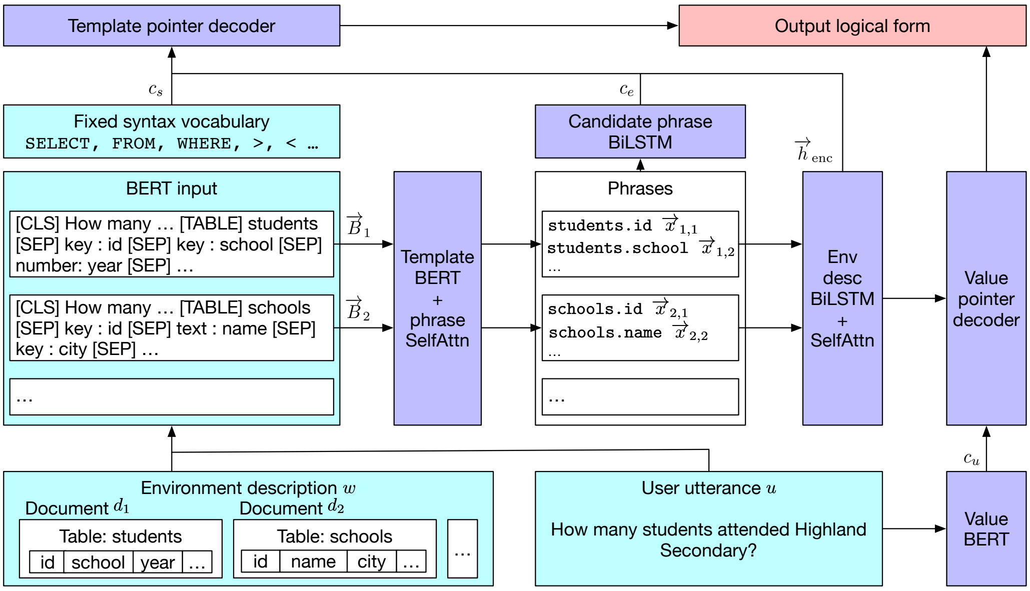

Figure 2: Forward semantic parser. Model components are shown in purple, inputs in blue, and outputs in red. First, we cross-encode each environment description text and the utterance using BERT. We then extract document-level phrase representations for candidate phrases in each text, which we subsequently encode using LSTMs to form input and environment-level candidate phrase representations. A pointer-decoder attends over the input and selects among candidates to produce the output logical form.

$\hat{q}$ by selecting among a set of candidates that corresponds to the union of environment candidates c_e and syntax candidates c_s. Here, we represent a syntax token using its BERT word embedding. The representation for all candidate representations $\vec{c}$ is then obtained as

$$\vec{c} = [c_{e,1}; c_{e,2}; ...c_{s,1}; c_{s,2}; ...] \qquad (6)$$

At each step t of the decoder, we first update the states of the decoder LSTM:

$$h_{\text{dec},t} = \text{LSTM}(\vec{c}_{\hat{q}_{t-1}}, h_{\text{dec},t-1}) \qquad (7)$$

Finally, we attend over the document representations given the current decoder state using dot-product attention (Bahdanau et al., 2015):

$$\begin{aligned} \hat{a}_t &= \text{softmax}(h_{\text{dec},t}\vec{h}_{\text{enc}}^{\intercal}) && (8) \\ v_t &= \sum_i \hat{a}_{t,i}\vec{h}_{\text{enc},i} && (9) \end{aligned}$$

The score for the ith candidate $\vec{c}_i$ is

$$\begin{aligned} o_t &= \hat{W}[h_{\text{dec},t}; v_t] + \hat{b} && (10) \\ s_{t,i} &= o_t\vec{c}_i^{\intercal} && (11) \\ \hat{q}_t &= \text{argmax}(s_t) && (12) \end{aligned}$$

Value-generation. The pervious template decoder produces logical form template $\hat{q}$, which is not executable because it does not include utterance candidates c_u. To generate full-specified executable logical forms q, we use a separate value pointer-decoder that selects among utterance tokens. The attention input for this decoder is identical to that of the template decoder. The pointer candidates c_u are obtained by running a separate BERT encoder on the utterance u. The produced values are inserted into each slot in $\hat{q}$ to form q.

Both template and value decoders are trained using cross-entropy loss with respect to the ground-truth sequence of candidates.

2.3 Backward utterance generator

The utterance generator G produces an utterance $u = G(q, e)$ for the logical form q in the environment e. The alignment problem between q and the environment description w is simpler than that between u and w because environment candidates c_e (e.g. column names) in q are described by corresponding spans in w (e.g. column schemas in database schema). To leverage this deterministic alignment, we augment c_e in q with relevant spans from w, and encode this augmented logical form $\tilde{q}$. The pointer-decoder selects among words c_v from a fixed vocabulary (e.g. when, where, who) and words $c_{\tilde{q}}$ from $\tilde{q}$. Figure 3 illustrates the backward utterance generator.

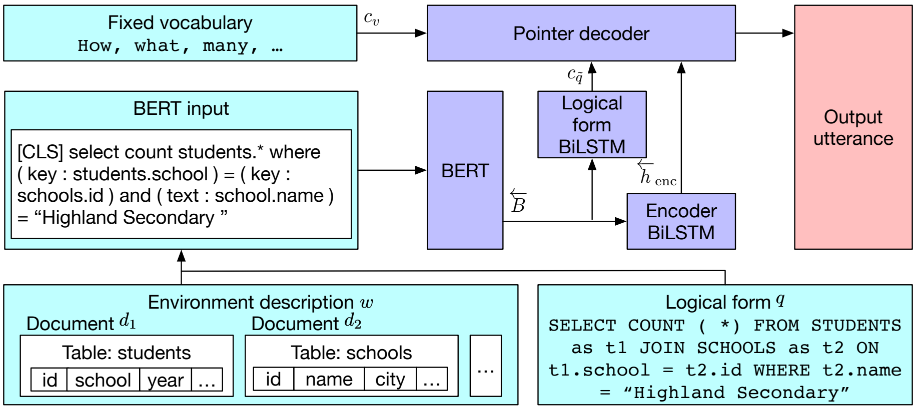

Figure 3: Backward utterance generator. Model components are shown in purple, inputs in blue, and outputs in red. First, we encode the input logical form along with environment description for each of its symbols. we subsequently encode using LSTMs to form the input and environment-level candidate token representations. A pointer-decoder attends over the input and selects among candidate representations to produce the output utterance.

First, we encode the logical form using BERT.

$$\overleftarrow{B} = \text{BERT}_{\leftarrow}(\tilde{q}) \tag{13}$$

Next, we apply a bidirectional LSTM to obtain the input encoding $\overleftarrow{h}_{\text{enc}}$ and another bidirectional LSTM to obtain representations of tokens in the augmented logical form $c_{\tilde{q}}$.

$$\overleftarrow{h}_{\text{enc}} = \text{BiLSTM}(\overleftarrow{B}) \tag{14}$$

$$c_{\tilde{q}} = \text{BiLSTM}(\overleftarrow{B}) \tag{15}$$

To represent c_v, we use word embeddings from $\text{BERT}_{\leftarrow}$. Finally, we apply a pointer-decoder that attends over $\overleftarrow{h}_{\text{enc}}$ and selects among candidates $\overleftarrow{c} = [c_{\tilde{q}}; c_v]$ to obtain the predicted utterance.

2.4 Synthesizing cycle-consistent examples

Having trained a forward semantic parser F and a backward utterance generator G in environment e, we can synthesize new examples with which to adapt the parser in the new environment e'. First, we sample a logical form q using a grammar (Algorithm 1 in Section 2.1). Next, we predict an utterance $u' = G(q, e')$. Because G was trained only on e, many of its outputs are low-quality or do not correspond to its input q. On their own, these examples (u', q) do not facilitate parser adaptation (see Section 3.1 for analyses).

To filter out low-quality examples, we additionally predict a logical form $q' = F(u', e')$, and keep only examples that are **cycle consistent** — the synthesized logical form q' is equivalent to the originally sampled logical form q in e'. In the case of SQL parsing, the example is cycle-consistent if executing the synthesized query $\text{EXE}(q', e')$ results in the same denotation (i.e. same set of database records) as executing the original sampled query $\text{EXE}(q, e')$. Finally, we combine cycle-consistent examples synthesized in e' with the original training data in e to retrain and adapt the parser.

3 Experiments

We evaluate performance on the Spider (Yu et al., 2018b), Sparc (Yu et al., 2019b), and CoSQL (Yu et al., 2019a) zero-shot semantic parsing tasks. Table 1 shows dataset statistics. Figure 4 shows examples from each dataset. For all three datasets, we use preprocessing steps from Zhang et al. (2019) to preprocess SQL logical forms. Evaluation consists of **exact match over logical form templates** (EM) in which values are stripped out, as well as **execution accuracy** (EX). Official evaluations also recently incorporated **fuzz-test accuracy** (FX) as tighter variant of execution accuracy. In fuzz-testing, the query is executed over randomized database content numerous times. Compared to an execution match, a fuzz-test execution match is less likely to be spurious (e.g. the predicted query coincidentally executes to the correct result). FX implementation is not public as of writing, hence we only report test FX.

Spider. Spider is a collection of database-utterance-SQL query triplets. The task involves producing the SQL query given the utterance and the database. Figure 2 and 3 show preprocessed input for the parser and generator.

Sparc. In Sparc, the user repeatedly asks questions that must be converted to SQL queries

(b) Example from CoSQL.

Figure 4: Examples from (a) Spider and (b) CoSQL. Context and output are respectively shown in purple and blue. We do not show Sparc because its data format is similar to CoSQL, but without user dialogue act prediction and without response generation. For our experiments, we produce the output logical form given the data, utterance, and the previous logical form if applicable. During evaluation, the previous logical form is the output of the model during the previous turn (i.e. no teacher forcing on ground-truth previous output).

	Spider	Sparc	CoSQL
# database	200	200	200
# tables	1020	1020	1020
# utterances	10,181	4298	3007
# logical forms	5,693	12,726	15,598
multi-turn	no	yes	yes

Table 1: Dataset statistics.

by the system. Compared to Spider, Sparc additionally contains prior interactions from the same user session (e.g. database-utterance-query-previous query quadruplets). For Sparc evaluation, we concatenate the previous system-produced query (if present) to each utterance. For example, suppose the system was previously asked "where is Tesla born?" and is now asked "how many people are born there?", we produce the utterance `[PREV] SELECT birth_place FROM people WHERE name = 'Tesla' [UTT] how many people are born there ?` For training and data synthesis, the ground-truth previous query is used as generation context for forward parsing and backward utterance generation.

CoSQL. CoSQL is combines task-oriented dialogue and semantic parsing. It consists of a number of tasks, such as response generation, user act prediction, and state-tracking. We focus on state-tracking, in which the user intent is mapped to a SQL query. Similar to Zhang et al. (2019), we restrict the context to be the previous query and the current utterance. Hence, the input utterance and environment description are obtained in the same way as that used for Sparc.

3.1 Results

We primarily compare GAZP with the baseline forward semantic parser, because prior systems produce queries without values which are not executable. We include one such non-executable model, EditSQL (Zhang et al., 2019), one of the top parsers on Spider at the time of writing, for reference. However, EditSQL EM is not directly comparable because of different outputs.

Due to high variance from small datasets, we tune the forward parser and backward generator using cross-validation. We then retrain the model with early stopping on the development set using hyperparameters found via cross-validation. For each task, we synthesize 100k examples, of which ~40k are kept after checking for cycle-consistency. The adapted parser is trained using the same hyperparameters as the baseline. Please see appendix A.2 for hyperparameter settings. Appendix A.3 shows examples of synthesized adaptation examples and compares them to real examples.

Table 2 shows that adaptation by GAZP results in consistent performance improvement across Spider, Sparc, and CoSQL in terms of EM, EX, and FX. We also examine the performance breakdown across query classes and turns (details in appendix A.4). First, we divide queries into difficulty classes based on the number of SQL components, selections, and conditions (Yu et al., 2018b). For example, queries that contain more components such as `GROUP`, `ORDER`, `INTERSECT`,

Model	Spider					Sparc					CoSQL				
	dev		test			dev		test			dev		test		
	EM	EX	EM	EX	FX	EM	EX	EM	EX	FX	EM	EX	EM	EX	FX
EditSQL	57.6	n/a	53.4	n/a	n/a	47.2	n/a	47.9	n/a	n/a	39.9	n/a	40.8	n/a	n/a

nocycle	55.6	52.3	97655	41.1	40.0	81623	30.7	30.8	78428
syntrain	54.8	52.1	39721	47.4	45.2	44294	38.7	34.3	31894
EM consistency	**61.6**	56.9	35501	48.4	45.9	43521	41.9	37.7	31137

Table 3: Ablation performance on development sets. For each one, 100,000 examples are synthesized, out of which queries that do not execute or execute to the empty set are discarded. "nocycle" uses adaptation without cycle-consistency. "syntrain" uses data-augmentation on training environments. "EM consistency" enforces logical form instead of execution consistency.

nested subqueries, column selections, and aggregators, etc are considered to be harder. Second, we divide multi-turn queries into how many turns into the interaction they occur for Sparc and CoSQL (Yu et al., 2019b,a). We observe that the gains in GAZP are generally more pronounced in more difficult queries and in turns later in the interaction. Finally, we answer the following questions regarding the effectiveness of cycle-consistency and grounded adaptation.

Does adaptation on inference environment outperform data-augmentation on training environment? For this experiment, we synthesize data on training environments instead of inference environments. The resulting data is similar to data augmentation with verification. As shown in the "syntrain" row of Table 3, retraining the model on the combination of this data and the supervised data leads to overfitting in the training environments. A method related to data-augmentation is jointly supervising the model using the training data in the reverse direction, for example by generating utterance from query (Fried et al., 2018; Cao et al., 2019). For Spider, we find that this dual objective (57.2 EM) underperforms GAZP adaptation (59.1 EM). Our results indicate that adaptation to the new environment significantly outperforms augmentation in the training environment.

How important is cycle-consistency? For this experiment, we do not check for cycle-consistency and instead keep all synthesized queries in the inference environments. As shown in the "nocycle" row of Table 3, the inclusion of cycle-consistency effectively prunes ~60% of synthesized examples, which otherwise significantly degrade performance. This shows that enforcing cycle-consistency is crucial to successful adaptation.

In another experiment, we keep examples that have consistent logical forms, as deemed by string match (e.g. $q == q'$), instead of consistent denotation from execution. The "EM consistency" row of Table 3 shows that this variant of cycle-consistency also improves performance. In particular, EM consistency performs similarly to execution consistency, albeit typically with lower execution accuracy.

How much GAZP synthesized data should one use for grounded adaptation? For this experiment, we vary the amount of cycle-consistent syn-

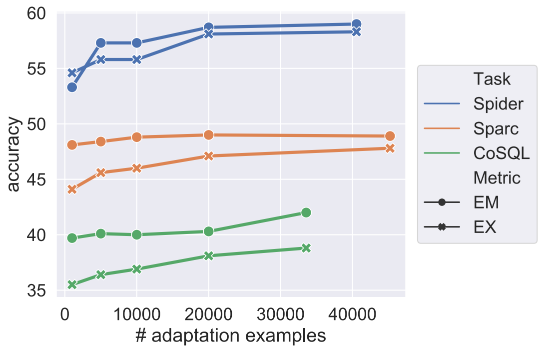

Figure 5: Effect of amount of synthesized data on adaptation performance on the development set. EM and EX denote template exact match and logical form execution accuracy, respectively. The x-axis shows the number of cycle-consistent examples synthesized in the inference environments (e.g. all databases in the development set).

thesized data used for adaptation. Figure 5 shows that that adaptation performance generally increases with the amount of synthesized data in the inference environment, with diminishing return after 30-40k examples.

4 Related work

Semantic parsing. Semantic parsers parse natural language utterances into executable logical forms with respect to an environment (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Liang et al., 2011). In zero-shot semantic parsing, the model is required to generalize to environments (e.g. new domains, new database schemas) not seen during training (Pasupat and Liang, 2015; Zhong et al., 2017; Yu et al., 2018b). For language-to-SQL zero-shot semantic parsing, a variety of methods have been proposed to generalize to new databases by selecting from table schemas in the new database (Zhang et al., 2019; Guo et al., 2019). Our method is complementary to these work — the synthesis, cycle-consistency, and adaptation steps in GAZP can be applied to any parser, so long as we can learn a backward utterance generator and evaluate logical-form equivalence.

Data augmentation. Data augmentation transforms original training data to synthesize artificial training data. Krizhevsky et al. (2017) crop and rotate input images to improve object recognition. Dong et al. (2017) and Yu et al. (2018a) respectively paraphrase and back-translate (Sennrich et al., 2016; Edunov et al., 2018) questions and documents to improve question-answering. Jia and Liang (2016) perform data-recombination in the training domain to improve semantic parsing. Hannun et al. (2014) superimpose noisy background tracks with input tracks to improve speech recognition. Our method is distinct from data-augmentation in the following ways. First, we synthesize data on logical forms sampled from the new environment instead of the original environment, which allows for adaptation to the new environments. Second, we propose cycle-consistency to prune low-quality data and keep high-quality data for adaptation. Our analyses show that these core differences from data-augmentation are central to improving parsing performance.

Cycle-consistent generative adversarial models (cycle-GANs). In cycle-GAN (Zhu et al., 2017; Hoffman et al., 2018), a generator forms images that fools a discriminator while the discriminator tries distinguish generated images from naturally occurring images. The the adversarial objectives of the generator and the discriminator are optimized jointly. Our method is different from cycle-GANs in that we do not use adversarial objectives and instead rely on matching denotations from executing synthesized queries. This provides an exact signal compared to potentially incorrect outputs by the discriminator. Morevoer, cycle-GANs only synthesize the input and verify whether the input is synthesized (e.g. the utterance looks like a user request). In contrast, GAZP synthesizes both the input and the output, and verifies consistency between the input and the output (e.g. the utterance matches the query).

5 Conclusion and Future work

We proposed GAZP to adapt an existing semantic parser to new environments by synthesizing cycle-consistent data. GAZP improved parsing performance on three zero-shot parsing tasks. Our analyses showed that GAZP outperforms data augmentation, performance improvement scales with the amount of GAZP-synthesized data, and cycle-consistency is central to successful adaptation.

In principle, GAZP applies to any problems that lack annotated data and differ between training and inference environments. One such area is robotics, where one trains in simulation because it is prohibitively expensive to collect annotated trajectories in the real world. In future work, we will consider how to interpret environment specifications to facilitate grounded adaptation in these other areas.

A Appendix

A.1 Coverage and multi-turn sampling

When we build an empirical distribution over templates on the training set of Spider, we observe a 85% coverage of dev set templates. That is, 85% of dev set examples have a query whose template occurs in the training set. In other words, while this simple template-filling sampling scheme doesn't provide full coverage over the dev set as a complex grammar would, it covers a large portion of examples.

For Sparc and CoSQL, the sampling procedure is similar to Algorithm 1. However, because there are two queries (one previous, one current), we first sample a previous query z'_1 from $P_{\text{temp}}(z)$, then sample the current query z'_2 from $P_{\text{temp}}(z|z'_1)$. As before, the empirical template distributions are obtained by counting templates in the training set.

A.2 Hyperparameters

Dropout location	Forward parser		
	Spider	Sparc	CoSQL
post-BERT	0.1	0.1	0.1
post-enc LSTMs	0.1	0.3	0.1
pre-dec scorer	0.1	0.1	0.3

Table 4: Dropout rates for the forward parser.

Dropout location	Backward generator		
	Spider	Sparc	CoSQL
post-BERT	0.1	0.3	0.1
post-enc LSTMs	0.1	0.1	0.1
pre-dec scorer	0.1	0.1	0.3

Table 5: Dropout rates for the backward generator.

We use 300-dimensional LSTMs throughout the model. The BERT model we use is DistilBERT (Sanh et al., 2020), which we optimize with Adam (Kingma and Ba, 2015) with an initial learning rate of $5e-5$. We train for 50 epochs with a batch size of 10 and gradient clipping with a norm of 20. We use dropout after BERT, after encoder LSTMs, and before the pointer scorer. The values for these dropouts used by our leaderboard submissions are shown in Table 4 and Table 5. For each task, these rates are tuned using 3-fold cross-validation with a coarse grid-search over values $\{0.1, 0.3\}$ for each dropout with a fixed seed.

A single training run of the forward parser took approximately 16 hours to run on a single NVIDIA Titan X GPU. Each task required 3 folds in addition to the final official train/dev run. For each fold, we grid-searched over dropout rates, which amounts to 8 runs. In total, we conducted 27 runs on a Slurm cluster. Including pretrained BERT parameters, the final forward parser contains 142 million parameters. The final backward utterance generator contains 73 million parameters.

Table 6: Examples of synthesized queries

A.3 Synthesized examples

In order to quantify the distribution of synthesized examples, we classify synthesized queries according to the difficulty criteria from Spider (Yu et al., 2018b). Compared to the Spider development set, GAZP-synthesized data has an average of 0.60 vs. 0.47 joins, 1.21 vs. 1.37 conditions, 0.20 vs. 0.26 group by's, 0.23 vs. 0.25 order by's, 0.07 vs. 0.04 intersections, and 1.25 vs. 1.32 selection columns per query. This suggests that GAZP queries are similar to real data.

Moreover, we example a random sample of 60 synthesized examples. Out of the 60, 51 are correct. Mistakes come from aggregation over wrong columns (e.g. "has the most course" becomes `order by sum T2.grade`) and underspecification (e.g. "lowest of the stadium who has the lowest age"). There are grammatical errors (e.g. "that has the most" becomes "that has been most"), but most questions are fluent and sensible (e.g. "find the name and district of the employee that has the highest evaluation bonus"). A subset of these queries are shown in Table 6.

Table 10: Turn breakdown for Sparc test set

In addition to the main experiment results in Table 2 of Section 3.1, we also examine the performance breakdown across query classes and turns.

GAZP improves performance on harder queries. First, we divide queries into difficulty classes following the classification in Yu et al. (2018b). These difficulty classes are based on the number of SQL components, selections, and conditions. For example, queries that contain more SQL keywords such as `GROUP BY`, `ORDER BY`, `INTERSECT`, nested subqueries, column selections, and aggregators, etc are considered to be harder. Yu et al. (2018b) shows examples of SQL queries in the four hardness categories. Note that **extra** is a catch-all category for queries that exceed qualifications of **hard**, as a result it includes artifacts (e.g. set exclusion operations) that may introduce other confounding factors. Tables 7, 8, and 9 respectively break down the performance of models on Spider, Sparc, and CoSQL. We observe that the gains in GAZP are generally more pronounced in more difficult queries. This finding is consistent across tasks (with some variance) and across three evaluation metrics.

One potential explanation for this gain is that the generalization problem is exacerbated in more

		turn 1	turn 2	turn 3	turn 4+
count		548	533	372	351

Table 11: Turn breakdown for CoSQL test set.

difficult queries. Consider the example of language-to-SQL parsing, in which we have trained a parser on an university database and are now evaluating it on a sales database. While it is difficult to produce simple queries in the sales database due to ta lack of training data, it is likely even more difficult to produce nested queries, queries with groupings, queries with multiple conditions, etc. Because GAZP synthesizes queries — including difficult ones — in the sales database, the adapted parser learns to handle these cases. In contrast, simpler queries are likely easier to learn, hence adaptation does not help as much.

GAZP improves performance in longer interactions. For Sparc and CoSQL, which include multi-turn interactions between the user and the system, we divide queries into how many turns into the interaction they occur. This classification in described in Yu et al. (2019b) and Yu et al. (2019a). Tables 10 and 11 respectively break down the performance of models on Sparc and CoSQL. We observe that the gains in GAZP are more pronounced in turns later in the interaction. Against, this finding is consistent not only across tasks, but across the three evaluation metrics.

A possible reason for this gain is that the conditional sampling procedure shown in Algorithm 1 improves multi-turn parsing by synthesizing multi-turn examples. How much additional variation should we expect in a multi-turn setting? Suppose we discover T coarse-grain templates by counting the training data, where each coarse-grain template has S slots on average. For simplicity, let us ignore value slots and only consider column slots. Given a new database with N columns, the number of possible filled queries is on the order of $O\left(T \times \binom{S}{N}\right)$. For K turns, the number of possible queries sequences is then $O\left(\left(T \times \binom{S}{N}\right)^K\right)$. This exponential increase in query variety may improve parser performance on later-turn queries (e.g. those with a previous interaction), which in turn reduce cascading errors throughout the interaction.

An Imitation Game for Learning Semantic Parsers from User Interaction

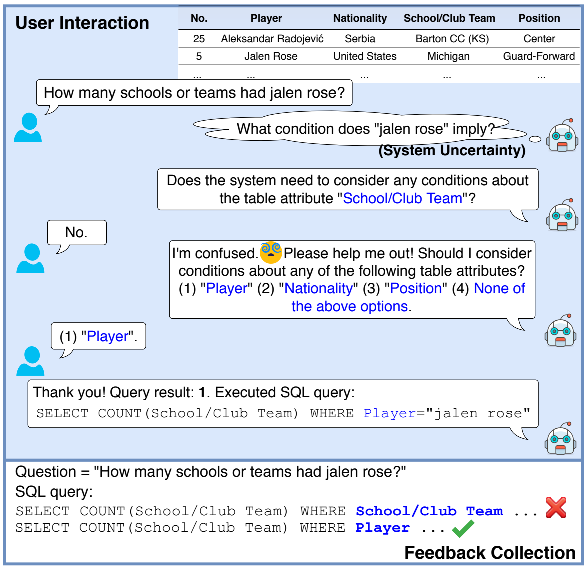
Abstract

Despite the widely successful applications, building a semantic parser is still a tedious process in practice with challenges from costly data annotation and privacy risks. We suggest an alternative, human-in-the-loop methodology for learning semantic parsers directly from users. A semantic parser should be introspective of its uncertainties and prompt for user demonstrations when uncertain. In doing so it also gets to imitate the user behavior and continue improving itself autonomously with the hope that eventually it may become as good as the user in interpreting their questions. To combat the sparsity of demonstrations, we propose a novel *annotation-efficient imitation learning* algorithm, which iteratively collects new datasets by mixing demonstrated states and confident predictions and retrains the semantic parser in a Dataset Aggregation fashion (Ross et al., 2011). We provide a theoretical analysis of its cost bound and also empirically demonstrate its promising performance on the text-to-SQL problem.[1]



No.	Player	Nationality	School/Club Team	Position
25	Aleksandar Radojević	Serbia	Barton CC (KS)	Center
5	Jalen Rose	United States	Michigan	Guard-Forward
...	...	...	...	...

How many schools or teams had jalen rose?

What condition does "jalen rose" imply?

Does the system need to consider any conditions about the table attribute "School/Club Team"?

No.

I'm confused. Please help me out! Should I consider conditions about any of the following table attributes? (1) "Player" (2) "Nationality" (3) "Position" (4) None of the above options.

(1) "Player".

Thank you! Query result: **1**. Executed SQL query:

```
SELECT COUNT(School/Club Team) WHERE Player="jalen rose"
```

Question = "How many schools or teams had jalen rose?"
SQL query:

```
SELECT COUNT(School/Club Team) WHERE School/Club Team ...
SELECT COUNT(School/Club Team) WHERE Player ...
```

Figure 1: A semantic parser proactively interacts with the user in a friendly way to resolve its uncertainties. In doing so it also gets to imitate the user behavior and continue improving itself autonomously with the hope that eventually it may become as good as the user in interpreting their questions.

1 Introduction

Semantic parsing has found tremendous applications in building natural language interfaces that allow users to query data and invoke services without programming (Woods, 1973; Zettlemoyer and Collins, 2005; Berant et al., 2013; Yih et al., 2015; Su et al., 2017; Yu et al., 2018). The life cycle of a semantic parser typically consists of two stages: (1) *bootstrapping*, where we keep collecting labeled data via trained annotators and/or crowdsourcing for model training until it reaches commercial-grade performance (e.g., 95% accuracy on a surrogate test set), and (2) *fine-tuning*, where we deploy the system, analyze the usage, and collect and annotate new data to address the identified problems or emerging needs. However, it poses several challenges for scaling up or building semantic parsers for new domains: (1) *high bootstrapping cost* because mainstream neural parsing models are data-hungry and the annotation cost of semantic parsing data is relatively high, (2) *high fine-tuning cost* from continuously analyzing usage and annotating new data, and (3) *privacy risks* arising from exposing private user data to annotators and developers (Lomas, 2019).

In this paper, we suggest an alternative methodology for building semantic parsers that could potentially address all the aforementioned problems. The key is to involve human users in the learning loop. A semantic parser should be introspective of its uncertainties (Dong et al., 2018) and proac-

tively prompt for demonstrations from the user, who knows the question best, to resolve them. In doing so, the semantic parser can accumulate targeted training data and continue improving itself autonomously without involving any annotators or developers, hence also minimizing privacy risks. The bootstrapping cost could also be significantly reduced because an interactive system needs not to be almost perfectly accurate to be deployed. On the other hand, such interaction opens up the black box and allows users to know more about the reasoning underneath the system and better interpret the final results (Su et al., 2018). A human-in-the-loop methodology like this also opens the door for domain adaptation and personalization.

This work builds on the recent line of research on interactive semantic parsing (Li and Jagadish, 2014; Chaurasia and Mooney, 2017; Gur et al., 2018; Yao et al., 2019b). Specifically, Yao et al. (2019b) provide a general framework, MISP (Model-based Interactive Semantic Parsing), which handles uncertainty modeling and natural language generation. We will leverage MISP for user interaction to prove the feasibility of the envisioned methodology. However, existing studies only focus on interacting with users to resolve uncertainties. None of them has fully addressed the crucial problem of *how to continually learn from user interaction*, which is the technical focus of this study.

One form of user interaction explored for learning semantic parsers is asking users to validate the execution results (Clarke et al., 2010; Artzi and Zettlemoyer, 2013; Iyer et al., 2017). While appealing, in practice it may be a difficult task for real users because they would not need to ask the question if they knew the answer in the first place. We instead aim to learn semantic parsers from fine-grained interaction where users only need to answer simple questions covered by their background knowledge (Figure 1). However, learning signals from such fine-grained interactions are bound to be sparse because the system needs to avoid asking too many questions and overwhelming the user, which poses a challenge for learning.

To tackle the problem, we propose NEIL, a novel *aNnotation-Efficient Imitation Learning* algorithm for learning semantic parsers from such sparse, fine-grained demonstrations: The agent (semantic parser) only requests for demonstrations when it is uncertain about a state (parsing step). For certain/confident states, actions chosen by the current policy are deemed correct and are executed to continue parsing. The policy is updated iteratively in a Dataset Aggregation fashion (Ross et al., 2011). In each iteration, all the state-action pairs, demonstrated or confident, are included to form a new training set and train a new policy in a supervised way. Intuitively, using confident state-action pairs for training mitigates the sparsity issue, but it may also introduce training bias. We provide a theoretical analysis and show that, under mild assumptions, the impact of the bias and the quality of the NEIL policy can be controlled by tuning the policy initialization and confidence estimation accuracy.

We also empirically compare NEIL with a number of baselines on the text-to-SQL parsing task. On the WikiSQL (Zhong et al., 2017) dataset, we show that, *when bootstrapped using only 10% of the training data,* NEIL *can achieve almost the same test accuracy (2% absolute loss) as the full expert annotation baseline, while requiring less than 10% of the annotations that the latter needs*, without even taking into account the different unit cost of annotations from users vs. domain experts. We also show that the quality of the final policy is largely determined by the quality of the initial policy, which provides empirical support for the theoretical analysis. Finally, we demonstrate that NEIL can generalize to more complex semantic parsing tasks such as Spider (Yu et al., 2018).

2 Related Work

Interactive Semantic Parsing. Our work extends the recent idea of leveraging system-user interaction to improve semantic parsing on the fly (Li and Jagadish, 2014; He et al., 2016; Chaurasia and Mooney, 2017; Su et al., 2018; Gur et al., 2018; Yao et al., 2019a,b; Elgohary et al., 2020; Zeng et al., 2020; Semantic Machines et al., 2020). Gur et al. (2018) built a neural model to identify and correct error spans in generated queries via dialogues. Yao et al. (2019b) formalized a model-based intelligent agent MISP, which enables user interaction via a policy probability-based uncertainty estimator, a grammar-based natural language generator, and a multi-choice question-answer interaction design. More recently, Elgohary et al. (2020) crowdsourced a dataset for fixing incorrect SQL queries using free-form natural language feedback. Semantic Machines et al. (2020) constructed a contextual semantic parsing dataset where agents could trigger conversations to handle exceptions such as ambiguous or incomplete user commands. In this work, we seek to continually improve semantic parsers from such user interaction, a topic that is not carefully studied by the aforementioned work.

Interactive Learning from Feedback. Learning interactively from user feedback has been studied in many NLP tasks (Sokolov et al., 2016; Wang et al., 2016, 2017; Nguyen et al., 2017; Gao et al., 2018; Abujabal et al., 2018; Hancock et al., 2019; Kreutzer and Riezler, 2019). Most relevant to us, Hancock et al. (2019) constructed a self-feeding chatbot that improves itself from user satisfied responses and their feedback on unsatisfied ones.

In the field of semantic parsing, Clarke et al. (2010); Artzi and Zettlemoyer (2013); Iyer et al. (2017) learned semantic parsers from binary user feedback on whether executing the generated query yields correct results. However, often times (especially in information-seeking scenarios) it may not be very practical to expect end users able to validate the denotation correctness (e.g., consider validating an execution result "*103*" for the question "*how many students have a GPA higher than 3.5*" from a massive table). Active learning is also leveraged to save human annotations (Duong et al., 2018; Ni et al., 2020). Our work is complementary to this line of research as we focus on learning interactively from end users (not "teachers").

Imitation Learning. Traditional imitation learning algorithms (Daumé et al., 2009; Ross and Bagnell, 2010; Ross et al., 2011; Ross and Bagnell, 2014) iteratively execute and train a policy by collecting expert demonstrations for every policy decision. Despite its efficacy, the learning demands costly annotations from experts. In contrast, we save expert effort by selectively requesting demonstrations. This idea is related to active imitation learning (Chernova and Veloso, 2009; Kim and Pineau, 2013; Judah et al., 2014; Zhang and Cho, 2017). For example, Judah et al. (2014) assumed a "teacher" and actively requested demonstrations for most informative trajectories in the unlabeled data pool. Similar to us, Chernova and Veloso (2009) solicited demonstrations only for uncertain states. However, their algorithm simply abandons policy actions that are confident, leading to sparse training data. Instead, our algorithm utilizes confident policy actions to combat the sparsity issue and is additionally provided with a theoretical analysis.

Concurrent with our work, Brantley et al. (2020) studied active imitation learning for structured prediction tasks such as named entity recognition. Our work instead focuses on semantic parsing, which presents a unique challenge of *integrality*, i.e., the output sequence (a semantic parse) could only be correct *as a whole* (as opposed to *partially* correct) in order to yield the correct denotation. We therefore propose a new cost function (Section 5) to theoretically analyze the factors that affect the efficacy of learning semantic parsers via imitation.

3 Preliminaries

Formally, we assume the semantic parsing model generates a semantic parse by executing a sequence of actions a_t (parsing decisions) at each time step t. In practice, the definition of an action depends on the specific semantic parsing model, as we will illustrate shortly. A state s_t is then defined as a tuple of $(q, a_{1:t-1})$, where q is the initial natural language question and $a_{1:t-1} = (a_1, ..., a_{t-1})$ is the current partial parse. In particular, the initial state $s_1 = (q, \phi)$ contains only the question. Denote a semantic parser as $\hat{\pi}$, which is a *policy function* (Sutton and Barto, 2018) that takes a state s_t as input and outputs a probability distribution over the action space. The semantic parsing process can be formulated as sampling a *trajectory* τ by alternately observing a state and sampling an action from the policy, i.e., $\tau = (s_1, a_1 \sim \hat{\pi}(s_1)$, ..., $s_T, a_T \sim \hat{\pi}(s_T))$, assuming a trajectory length T. The probability of the generated semantic parse becomes: $p_{\hat{\pi}}(a_{1:T}|s_1) = \prod_{t=1}^{T} p_{\hat{\pi}}(a_t|s_t)$.

An interactive semantic parser typically follows the aforementioned definition and requests the user's validation of a specific action a_t. Based on the feedback, a correct action a_t^* can be inferred to replace the original a_t. The parsing process continues with a_t^* afterwards.

In this work, we adopt MISP (Yao et al., 2019b) as the back-end interactive semantic parsing framework, given that it is a principled framework for this purpose and can generalize to various kinds of semantic parsers and logical forms. However, we note that our proposed algorithm is not limited to MISP; it instead depicts a general algorithm for learning semantic parsers from user interaction. We illustrate the application of MISP to a sketch-based parser, SQLova (Hwang et al., 2019), as follows. More details and another example of how it applies to a non-sketch-based parser EditSQL (Zhang et al., 2019) can be found in Appendix B.1.

Example. Consider the SQLova parser, which generates a query by filling "slots" in a pre-defined SQL sketch "`SELECT Agg SCol WHERE WCol OP VAL`". To complete the SQL query in Figure 1, it first takes three steps: `SCol`="`School/Club Team`" (a_1), `Agg`="`COUNT`" (a_2) and `WCol`="`School/Club Team`" (a_3). MISP detects that a_3 is uncertain because its probability is lower than a pre-specified threshold. It validates a_3 with the user and corrects it with `WCol`="`Player`" (a_3^*). The parsing continues with `OP`="`=`" (a_4) and `VAL`="`jalen rose`" (a_5). Here, the trajectory length $T = 5$.

4 Learning Semantic Parsers from User Interaction

In this section, we present NEIL, an *aNnotation-Efficient Imitation Learning* algorithm that trains a parser from user interaction, without requiring a large amount of user feedback (or "annotations"). This property is particularly important for end user-facing systems in practical use. Note that while we apply NEIL to semantic parsing in this work, in principle it can also be applied to other structured prediction tasks (e.g., machine translation).

4.1 An Imitation Learning Formulation

Under the interactive semantic parsing framework, a learning algorithm intuitively can aggregate (s_t, a_t^*) pairs collected from user interactions and trains the parser to enforce a_t^* under the state $s_t = (q, a_{1:t-1})$. However, this is not achievable by conventional supervised learning since the training needs to be conducted in an *interactive* environment, where the partial parse $a_{1:t-1}$ is generated by the parser itself.

Instead, we formulate it as an imitation learning problem (Daumé et al., 2009; Ross and Bagnell, 2010). Consider the user as a *demonstrator*, then the derived action a_t^* can be viewed as an *expert demonstration* which is interactively sampled from the demonstrator's policy (or *expert policy*) π^*,[2] i.e., $a_t^* \sim \pi^*(s_t)$. The goal of our algorithm is thus to train policy $\hat{\pi}$ to imitate the expert policy π^*. A general procedure is described in Algorithm 1 (Line 1–9), where $\hat{\pi}$ is learned iteratively for every m user questions. In each iteration, the policy is retrained on an aggregated training data over the past iterations, following the Dataset Aggregation fashion in (Ross et al., 2011).

Algorithm 1 The NEIL Algorithm

```
Input: Initial training data $D_0$, policy confidence threshold $\mu$.
Output: A trained policy $\hat{\pi}$.
 1: Initialize $D \leftarrow D_0$.
 2: Initialize $\hat{\pi}_1$ by training it on $D_0$.
 3: for $i = 1$ to $N$ do
 4:     Observe $m$ user questions $q_j, j \in [1, m]$;
 5:     $D_i \leftarrow \bigcup_{j=1}^{m}$ PARSE&COLLECT$(\mu, q_j, \hat{\pi}_i, \pi^*)$;
 6:     Aggregate dataset $D \leftarrow D \bigcup D_i$;
 7:     Train policy $\hat{\pi}_{i+1}$ on $D$ using Eq. (1).
 8: end for
 9: return best $\hat{\pi}_i$ on validation.

10: function PARSE&COLLECT$(\mu, q, \hat{\pi}_i, \pi^*)$
11:     Initialize $D'_i \leftarrow \emptyset$, $s_1 = (q, \phi)$.
12:     for $t = 1$ to $T$ do
13:         Preview action $a_t = \arg\max_a \hat{\pi}_i(s_t)$;
14:         if $p_{\hat{\pi}_i}(a_t|s_t) \geq \mu$ then
15:             $w_t \leftarrow 1$;
16:             Collect $D'_i \leftarrow D'_i \bigcup \{(s_t, a_t, w_t)\}$;
17:             Execute $a_t$;
18:         else
19:             Trigger user interaction and derive expert demonstration $a_t^* \sim \pi^*(s_t)$;
20:             $w_t \leftarrow 1$ if $a_t^*$ is valid; 0 otherwise;
21:             Collect $D'_i \leftarrow D'_i \bigcup \{(s_t, a_t^*, w_t)\}$;
22:             Execute $a_t^*$.
23:         end if
24:     end for
25:     return $D'_i$.
26: end function
```

4.2 Annotation-efficient Imitation Learning

Consider parsing a user question and collecting training data using the parser $\hat{\pi}_i$ in the i-th iteration (Line 5). A standard imitation learning algorithm such as DAGGER (Ross et al., 2011) usually requests expert demonstration a_t^* for every state s_t in the sampled trajectory. However, it requires a considerable amount of user annotations, which may not be practical when interacting with end users.

Instead, we propose to adopt an *annotation-efficient* learning strategy in NEIL, which saves user annotations by *selectively* requesting user interactions, as indicated in function PARSE&COLLECT. In each parsing step, the system first previews whether it is confident about its own decision a_t (Line 13–14), which is determined when its probability is no less than a threshold, i.e., $p_{\hat{\pi}_i}(a_t|s_t) \geq$

---

[2] We follow the imitation learning literature and use "expert" to refer to the imitation target, but the user in our setting by no means needs to be a "domain (SQL) expert".

μ.[3] In this case, the algorithm executes and collects its own action a_t (Line 15–17); otherwise, a system-user interaction will be triggered and the derived demonstration $a_t^* \sim \pi^*(s_t)$ will be collected and executed to continue parsing (Line 19–22).

Denote a collected state-action pair as $(s_t, \tilde{a}_t)$, where $\tilde{a}_t$ could be a_t or a_t^* depending on whether an interaction is requested. To train $\hat{\pi}_{i+1}$ (Line 7), our algorithm adopts a *reduction-based* approach similar to DAGGER and reduces imitation learning to iterative supervised learning. Formally, we define our training loss function as a *weighted* negative log-likelihood:

$$\mathcal{L}(\hat{\pi}_{i+1}) = -\frac{1}{|D|} \sum_{(s_t, \tilde{a}_t, w_t) \in D} w_t \log p_{\hat{\pi}_i}(\tilde{a}_t | s_t), \quad (1)$$

where D is the aggregated training data over i iterations and w_t denotes the weight of $(s_t, \tilde{a}_t)$.

We consider assigning weight w_t in three cases: (1) For confident actions a_t, we set $w_t = 1$. This essentially treats the system's own confident actions as gold decisions, which resembles self-training (Scudder, 1965; Nigam and Ghani, 2000; McClosky et al., 2006). (2) For user-confirmed decisions (*valid demonstrations* a_t^*), such as enforcing a `WHERE` condition on "`Player`" in Figure 1, w_t is also set to 1 to encourage the parser to imitate the correct decisions from users. (3) For uncertain actions that cannot be addressed via human interactions (*invalid demonstrations* a_t^*, which are identified when the user selects "None of the above options" in Figure 1), we assign $w_t = 0$. This could happen when some of the incorrect precedent actions are not fixed. For example, in Figure 1, if the system missed correcting the `WHERE` condition on "`School/Club Team`", then whatever value it generates after "`WHERE School/Club Team=`" is wrong, and thus any action a_t^* derived from human feedback would be invalid. In this case, the system selects the next available option without further validation and continues parsing.

A possible training strategy to handle case (3) may set w_t to be negative, similar to Welleck et al. (2020). However, empirically we find this strategy fails to train the parser to correct its mistake in generating "`School/Club Team`" but rather disturbs the model training. By setting $w_t = 0$, the impact of unaddressed actions is removed from training. A similar solution is also adopted in Petrushkov et al. (2018); Kreutzer and Riezler (2019). As shown in Section 6, this way of training weight assignment enables stable improvement in iterative model learning while requiring fewer user annotations.

5 Theoretical Analysis

While NEIL enjoys the benefit of learning from a small amount of user feedback, one crucial question is whether it can still achieve the same level of performance as the traditional supervised approach (which trains a policy on full expert annotations, if one could afford that and manage the privacy risk). In this section, we prove that the performance gap between the two approaches is mainly determined by the learning policy's probability of trusting a confident action that turns out to be wrong, which can be controlled in practice.

Our analysis follows prior work (Ross and Bagnell, 2010; Ross et al., 2011) to assume a unified trajectory length T and an infinite number of training samples in each iteration (i.e., $m = \infty$ in Algorithm 1), such that the state space can be full explored by the learning policy. An analysis under the "finite sample" case can be found in Appendix A.5.

5.1 Cost Function for Analysis

Unlike typical imitation learning tasks (e.g., Super Tux Kart (Ross et al., 2011)), in semantic parsing, there exists only one gold trajectory semantically identical to the question.[4] Whenever a policy action is different from the gold one, the whole trajectory will not yield the correct semantic meaning and the parsing is deemed failed. In other words, a well-performing semantic parser should be able to keep staying in the correct trajectory during the parsing. Therefore, for theoretical analysis, we only analyze a policy's performance when it is conditioned on a *gold partial parse*, i.e., $s_t \in d_{\pi^*}^t$, where $d_{\pi^*}^t$ is the state distribution in step t when executing the expert policy π^* for first t-1 steps. Let $\ell(s, \hat{\pi}) = 1 - p_{\hat{\pi}}(a = a^*|s)$ be the loss of $\hat{\pi}$ making a mistake at state s. We define the *cost* (i.e., the inverse *test-time* quality) of a policy as:

$$J(\hat{\pi}) = T\mathbb{E}_{s \sim d_{\pi^*}}\big[\ell(s, \hat{\pi})\big], \quad (2)$$

where $d_{\pi^*} = \frac{1}{T}\sum_{t=1}^{T} d_{\pi^*}^t$ denotes the average expert state distribution (assuming time step t is a

---

[3] The metric is shown effective for interactive semantic parsing in Yao et al. (2019b). Other confidence measures can also be explored, as we will discuss in Section 7.

[4] We assume a canonical order for swappable components in a parse. In practice, it may be possible, though rare, for one question to have multiple gold parses.

random variable uniformly sampled from $1 \sim T$). A detailed derivation is shown in Appendix A.1.

The *better* a policy $\hat{\pi}$ is, the *smaller* this cost becomes. Note that, by defining Eq. (2), we simplify the analysis from evaluating *the whole trajectory sampled from* $\hat{\pi}$ (as we do in experiments) to evaluating *the expected single-step loss of* $\hat{\pi}$ *conditioned on a gold partial parse*. This cost function makes the analysis easier and meanwhile reflects a consistent relative performance among algorithms for comparison. Next, we compare our NEIL algorithm with the supervised approach by analyzing the upper bounds of their costs.

5.2 Cost Bound of Supervised Approach

A fully supervised system trains a parser on expert-annotated $(q, a^*_{1:T})$ pairs, where the gold semantic parse $a^*_{1:T}$ can be viewed as generated by executing the expert policy π^*. This gives the policy $\hat{\pi}_{sup}$:

$$\hat{\pi}_{sup} = \arg\min_{\pi \in \Pi} \mathbb{E}_{s \sim d_{\pi^*}}[l(s, \pi)],$$

where Π is the policy space induced by the model architecture. A detailed derivation in Appendix A.2 shows the cost bound of the supervised approach:

Theorem 5.1. *For supervised approach, let* $\epsilon_N = \min_{\pi \in \Pi} \mathbb{E}_{s \sim d_{\pi^*}}[l(s, \pi)]$, *then* $J(\hat{\pi}_{sup}) = T\epsilon_N$.

The theorem gives an exact bound (as shown by the equality) since the supervised approach, given the "infinite sample" assumption, trains a policy under the same state distribution d_{π^*} as the one being evaluated in the cost function (Eq. (2)).

5.3 Cost Bound of NEIL Algorithm

Recall that, in each training iteration, NEIL samples trajectories by executing actions from both the previously learned policy $\hat{\pi}_i$ and the expert policy π^* (when an interaction is requested). Let π_i denote such a "mixture" policy. We derive the following cost bound of a NEIL policy $\hat{\pi}$:

$$J(\hat{\pi}) \le \frac{T}{N} \sum_{i=1}^{N} \big[\mathbb{E}_{s \sim d_{\pi_i}}[\ell(s, \hat{\pi}_i)] + \ell_{max} ||d_{\pi_i} - d_{\pi^*}||_1\big].$$

The bound is determined by two terms. The first term $\mathbb{E}_{s \sim d_{\pi_i}}[\ell(s, \hat{\pi}_i)]$ calculates the expected training loss of $\hat{\pi}_i$. Notice that, while the policy is *trained* on states induced by the mixture policy ($s \sim d_{\pi_i}$), what matters to its *test-time* quality is the policy's performance conditioned on a gold partial parse ($s \sim d_{\pi^*}$ in Eq. (2)). This state discrepancy, which does not exist in the supervised approach, explains the performance loss of NEIL, and is bounded by the second term $\ell_{max}||d_{\pi_i} - d_{\pi^*}||_1$, the weighted L_1 distance between d_{π_i} and d_{π^*}. To bound the two terms, we employ a "no-regret" assumption (Kakade and Tewari, 2009; Ross et al., 2011, see Appendix A.3–A.4 for details), which gives the theorem:

Theorem 5.2. *For the proposed* NEIL *algorithm, if* N *is* $\tilde{O}(T)$, *there exists a policy* $\hat{\pi} \in \hat{\pi}_{1:N}$ *s.t.* $J(\hat{\pi}) \le T\big[\epsilon_N + \frac{2T\ell_{max}}{N}\sum_{i=1}^{N} e_i\big] + O(1)$.

Here, $\epsilon_N = \min_{\pi \in \Pi} \frac{1}{N}\sum_{i=1}^{N} \mathbb{E}_{s \sim d_{\pi_i}}[\ell(s, \pi)]$ denotes the best expected policy loss in *hindsight*, and e_i denotes the probability that $\hat{\pi}_i$ does not query the expert policy (i.e., being confident) but its own action is wrong under d_{π^*}.

We note that a no-regret algorithm requires convexity of the loss function (Hazan et al., 2007; Kakade and Tewari, 2009), which is not satisfied by neural network-based semantic parsers. In general, proving theorems under a non-convex case is not trivial. Therefore, we follow the common practice (e.g., Kingma and Ba (2015); Reddi et al. (2018)) to theoretically analyze the convex case while empirically demonstrating the performance of our NEIL algorithm with non-convex loss functions (i.e., when it applies to neural semantic parsers). More accurate regret bound for non-convex cases will be studied in the future.

Remarks. Compared with the supervised approach (Theorem 5.1), NEIL's cost bound additionally contains a term of $\frac{1}{N}\sum_{i=1}^{N} e_i$, which, as we expect, comes from the aforementioned state discrepancy. Intuitively, if a learning policy frequently executes its own but wrong actions in training, the resulting training states d_{π_i} will greatly deviate from the gold ones d_{π^*}.

This finding inspires us to restrict the performance gap by reducing the learning policy's error rate *when it does not query the expert*. Empirically this can be achieved by: (1) *Accurate confidence estimation*, so that actions deemed confident are generally correct, and (2) *Moderate policy initialization*, such that in general the policy is less likely to make wrong actions throughout the iterative training. For (1), we set a high confidence threshold μ=0.95, which is demonstrated reliable for MISP (Yao et al., 2019b). We then empirically validate (2) in experiments.

6 Experiments

In this section, we conduct experiments to demonstrate the annotation efficiency of our NEIL algorithm and that it can train semantic parsers for high performance when the parsers are reasonably initialized, which verifies our theoretical analysis.

6.1 Experimental Setup

We compare various systems on the WikiSQL dataset (Zhong et al., 2017). The dataset contains large-scale annotated question-SQL pairs (56,355 pairs for training) and thus serves as a good resource for experimenting iterative learning. For the base semantic parser, we choose SQLova (Hwang et al., 2019), one of the top-performing models on WikiSQL, to ensure a reasonable model capacity in terms of data utility along iterative training.

We experiment each system with three parser initialization settings, using 10%, 5% and 1% of the total training data. During iterative learning, questions from the remaining training data arrive in a random order to simulate user questions and we simulate user feedback by directly comparing the synthesized query with the gold one. In each iteration, all systems access exactly the same user questions. Depending on how they solicit feedback, each system collects a different number of annotations. At the end of each iteration, we update each system by retraining its parser on its accumulated annotations and the initial training data, and report its *(exact) query match accuracy* on the test set. We also report the *accumulated number of annotations* that each system has requested after each training iteration, in order to compare their annotation efficiency.

In experiments, we consider every 1,000 user questions as one training iteration (i.e., m=1,000 in Algorithm 1). We repeat the whole iterative training for three runs and report average results. *Reproducible details* are included in Appendix B.

6.2 System Comparison

We denote our system as **MISP-NEIL** since it leverages MISP in the back end of NEIL. We compare it with the traditional supervised approach (denoted as **Full Expert**). To investigate the skyline capability of our system, we also present a variant called **MISP-NEIL***, which is *assumed* with perfect confidence measurement and interaction design, so that it can precisely identify and correct its mistakes during parsing. This is implemented by allowing the system to compare its synthesized query with the gold one. Note that this is not a realized automatic system; we show its performance as an upper bound of MISP-NEIL.

On the other hand, although execution feedback-based learning systems (Clarke et al., 2010; Artzi and Zettlemoyer, 2013; Iyer et al., 2017) may not be very practical for end users, we include them nonetheless in the interest of a comprehensive comparison. This leads to two baselines. The **Binary User** system requests binary user feedback on whether *executing* the generated SQL query returns correct database results and collects only queries with correct results to further improve the parser. The **Binary User+Expert** system additionally collects full expert SQL annotations when the generated SQL queries do not yield correct answers.

Given the completely different nature of annotations from Binary User (which validate the *denotation*) and those from Full Expert and MISP-NEIL (which validate a semantic parse's *constituents*), there may not exist a universally fair way to convert one's annotation consumption into the other's. Therefore, in the following sections, we only present and discuss Binary User(+Expert) in terms of their parsing accuracy under different training iterations. To give an estimation of their annotation efficiency for reference, we design a compromised annotation calculation metric for Binary User(+Expert) and include their results on WikiSQL validation set in Appendix C.

Finally, while our MISP-NEIL and the aforementioned baselines all leverage feedback from users or domain experts, an interesting question is how much gain they could obtain compared with using no annotation or feedback at all. To this end, we compare the systems with a **Self Train** baseline (Scudder, 1965; Nigam and Ghani, 2000; McClosky et al., 2006). In each iteration, this baseline collects SQL queries generated *by itself* as the new gold annotations for further training. We additionally apply a confidence threshold to improve the collection quality, i.e., only SQL queries with probability $p_{\tilde{\pi}}(a_{1:T}|s_1)$ greater than 0.5 are included. This strategy empirically leads to better performance. Intuitively, we expect Self Train to perform no better than any other systems in our experiments, since no human feedback is provided to correct mistakes in its collection.

6.3 Experimental Results

We evaluate each system by answering two research questions (RQs):

- *RQ1: Can the system improve a parser without requiring a large amount of annotations?*

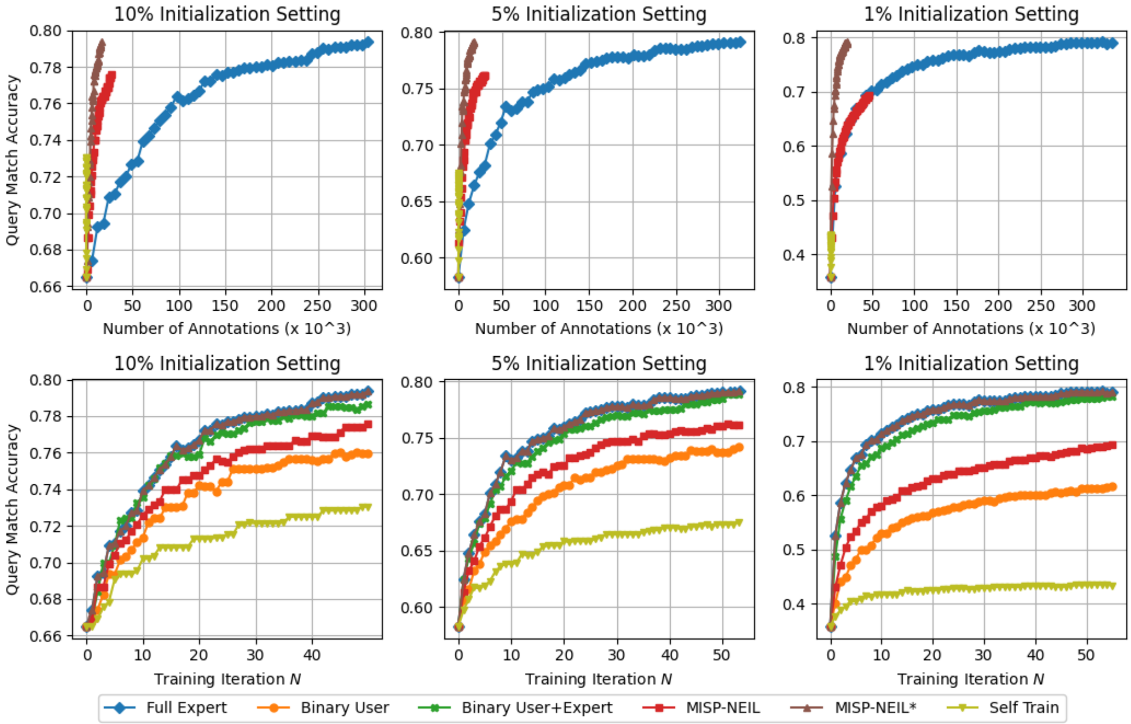

Figure 2: Parsing accuracy on WikiSQL test set when systems are trained with various numbers of user/expert annotations (top) and for different iterations (bottom). We experiment with three initialization settings, using 10%, 5% and 1% of the training data respectively. Results on validation set can be found in Appendix C.

- *RQ2: For interactive systems, while requiring weaker supervision, can they train the parser to reach a performance comparable to the traditional supervised system?*

For *RQ1*, we measure the number of *user/expert* annotations that a system requires to train a parser. For Full Expert, this number equals the trajectory length of the gold query (e.g., 5 for the query in Figure 1); for MISP-NEIL and MISP-NEIL*, it is the number of user interactions during training. Note that while we do not differentiate the actual (e.g., time/financial) cost of users from that of experts in this aspect, we emphasize that our system enjoys an additional benefit of collecting training examples from a much cheaper and more abundant source. For Self Train, the number of annotations is always zero since it does not request any human feedback for the online user questions.

Our results in Figure 2 (top) demonstrate that MISP-NEIL consistently consumes a comparable or smaller amount of annotations to train the parser to reach the same parsing accuracy. Figure 5 in Appendix further shows that, on average, it requires no more than one interaction for each user question along the training. Particularly in the 10% initialization setting, MISP-NEIL uses less than 10% of the total annotations that Full Expert needs in the end. Given the limited size of WikiSQL training set, the simulation experiments currently can only show MISP-NEIL's performance under a small number of annotations. However, we expect this gain to continue as it receives more user questions in the long-term deployment.

To answer *RQ2*, Figure 2 (bottom) compares each system's accuracy after they have been trained for the same number of iterations. The results demonstrate that when a semantic parser is moderately initialized (10%/5% initialization setting), MISP-NEIL can further improve it to reach a comparable accuracy as Full Expert (0.776/0.761 vs. 0.794 in the last iteration). In the extremely weak 1% initialization setting (using only around 500 initial training examples), all interactive learning systems suffer from a huge performance loss. This is consistent with our finding in theoretical analysis (Section 5). In Appendix C.2, we plot the value of e_i, the probability that $\hat{\pi}_i$ makes a confident but wrong decision given a gold partial parse, showing that a better initialized policy generally obtains a smaller e_i throughout the training and thus a tighter cost bound.

Our system also surpasses Binary User. We find that the inferior performance of Binary User is mainly due to the “spurious program” issue (Guu et al., 2017), i.e., a SQL query having correct execution results can still be incorrect in terms of semantics. MISP-NEIL circumvents this issue by directly validating the *semantic meaning* of intermediate parsing decisions. The performance of Binary User+Expert is close to Full Expert as it has additionally involved expert annotations on a considerable number of user questions, which on the other hand also leads to extra annotation overhead.

When it is assumed with perfect interaction design and confidence estimator, MISP-NEIL* shows striking superiority in both aspects. Since it always corrects wrong decisions immediately, MISP-NEIL* can collect and derive the same training examples as Full Expert, and thus trains the parser to Full Expert’s performance level in Figure 2 (bottom). However, it requires only 6% of the annotations that Full Expert needs (Figure 2, top). These observations imply large room for MISP-NEIL to be improved in the future.

Finally, we observe that all feedback-based learning systems outperform Self Train dramatically (Figure 2, bottom). This verifies the benefit of learning from human feedback.

6.4 Generalize to Complex SQL Queries

We next investigate whether MISP-NEIL can generalize to the complex SQL queries in the Spider dataset (Yu et al., 2018), which can contain complicated keywords like `GROUP BY`. For the base semantic parser, we choose EditSQL (Zhang et al., 2019), one of the open-sourced top models on Spider. Given the small size of Spider (7,377 question-SQL pairs for training after data cleaning; see Appendix B.3 for details), we only experiment with one initialization setting, using 10% of the training set. Since EditSQL does not predict the specific values in a SQL query (e.g., “`jalen rose`” in Figure 1), we cannot execute the generated query to simulate the binary execution feedback. Therefore, we only compare our system with Full Expert and Self Train. Parsers are evaluated on Spider Dev set since its test set is not publicly available.

Figure 3 (top) shows that MISP-NEIL and MISP-NEIL* consistently achieve comparable or better annotation efficiency while enjoying the advantage of learning from end user interaction. We expect this superiority to continue as the systems receive more user questions beyond Spider. Meanwhile, we also notice that the gain is smaller and MISP-NEIL suffers from a large performance loss compared with Full Expert (Figure 3, bottom), due to the poor parser initialization and the SQL query complexity. This can be addressed via adopting better interaction designs and more accurate confidence estimation, as shown by MISP-NEIL*. Similarly as in WikiSQL experiments, Self Train performs worse than human-in-the-loop learning systems, as there is no means to correct wrong predictions in its collected annotations.

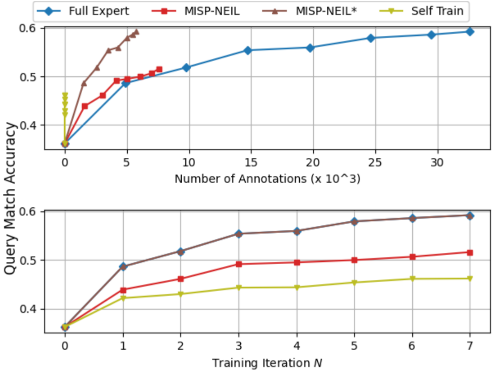

Figure 3: Parsing accuracy on Spider Dev set when systems are trained with various numbers of user/expert annotations and for different iterations.

7 Conclusion and Future Work

Our work shows the possibility of continually learning semantic parsers from fine-grained end user interaction. As a pilot study, we experiment systems with simulated user interaction. One important future work is thus to conduct large-scale user studies and train parsers from real user interaction. This is not trivial and has to account for uncertainties such as noisy user feedback. We also plan to derive a more realistic formulation of user/expert annotation costs by analyzing real user statistics (e.g., average time spent on each question).

In experiments, we observe that neural semantic parsers tend to be overconfident and training them with more data does not mitigate this issue. In the future, we will look into more accurate confidence measure via neural network calibration (Guo et al., 2017) or using machine learning components (e.g., answer triggering (Zhao et al., 2017) or a reinforced active selector (Fang et al., 2017)).

Finally, we believe our algorithm can be applied to save annotation effort for other NLP tasks, especially the low-resource ones (Mayhew et al., 2019).

A Theoretical Analysis in Infinite Sample Case

In this section, we give a detailed theoretical analysis to derive the cost bounds of the supervised approach and our proposed NEIL algorithm (Section 4). Following Ross et al. (2011), we first focus the proof on an *infinite* sample case, which assumes an infinite number of samples to train a policy in each iteration (i.e., $m = \infty$ in Algorithm 1), such that the state space in training can be full explored by the learning policy.

As an overview, we start the analysis by introducing the "cost function" we use to analyze each policy in Appendix A.1, which represents an inverse quality of a policy. In Appendix A.2, we derive the bound of the cost of the supervised approach. Appendix A.3 and Appendix A.4 then discuss the cost bound of our proposed NEIL algorithm. Finally, in Appendix A.5, we show the cost bound of NEIL in *finite* sample case.

A.1 Cost Function for Analysis

In a semantic parsing task, whenever a policy action is different from the gold one, the whole trajectory cannot yield the correct semantic meaning and the parsing is deemed failed. Therefore, we analyze a policy's performance only when it is conditioned on *a gold partial parse*. Intuitively, a policy with better quality should have a higher parsing accuracy under a gold partial parse, so that it is more likely to sample a completely correct trajectory in inference time.

Given a question q and denoting $a^*_{1:t}$ as the gold partial trajectory sampled by the expert policy π^*, we first define the *cost* of sampling a partial trajectory $a_{1:t} = (a_1, ..., a_t)$ as:

$$C(q, a_{1:t}) = \begin{cases} 0 & \text{if } a_{1:t} = a^*_{1:t} \\ 1 & \text{otherwise} \end{cases}.$$

In other words, a sampled partial trajectory is correct if and only if it is the same as the gold partial parse. Based on this definition, we further define the expected cost of policy $\hat{\pi}$ *in a single time step* t (given the question q) as:

$$\begin{aligned} C^t_{\hat{\pi}}(q) &= \mathbb{E}_{a_{1:t-1}\sim\pi^*}\mathbb{E}_{a_t\sim\hat{\pi}}[C(q, a_{1:t})] \\ &= \mathbb{E}_{a_{1:t-1}\sim\pi^*}[1 - p_{\hat{\pi}}(a_t = a^*_t|q, a_{1:t-1})]. \end{aligned}$$

Here, $a_{1:t-1} \sim \pi^*$ denotes a gold partial parse till the (t-1)-th step, which is obtained by executing the expert policy π^* for the first t-1 steps (given q), and $p_{\hat{\pi}}(a_t = a^*_t|q, a_{1:t-1})$ denotes the probability that $\hat{\pi}$ samples action a^*_t given a question q and a partial parse $a_{1:t-1}$. By taking an expectation over all questions $q \in \mathcal{Q}$, we have the following derivations:

$$\begin{aligned} \mathbb{E}_{q\in\mathcal{Q}}[C^t_{\hat{\pi}}(q)] &= \mathbb{E}_{q\in\mathcal{Q},a_{1:t-1}\sim\pi^*}[1-p_{\hat{\pi}}(a_t=a^*_t|q,a_{1:t-1})] \\ &= \mathbb{E}_{s_t\sim d^t_{\pi^*}}[1-p_{\hat{\pi}}(a_t=a^*_t|s_t)]. \end{aligned}$$

The second equality holds by the definition $s_t = (q, a_{1:t-1})$, and $d^t_{\pi^*}$ is the "expert state distribution" in step t when executing the expert policy π^* for first t-1 steps. In this analysis, we follow Ross and Bagnell (2010); Ross et al. (2011) to assume a unified decision length T. By summing up the above expected cost over the T steps, we define the *cost* (i.e., the inverse *test-time* quality) of policy $\hat{\pi}$:

$$\begin{aligned} J(\hat{\pi}) &= \sum_{t=1}^{T} \mathbb{E}_{q\in\mathcal{Q}}[C^t_{\hat{\pi}}(q)] \\ &= \sum_{t=1}^{T} \mathbb{E}_{s_t\sim d^t_{\pi^*}}[1 - p_{\hat{\pi}}(a_t = a^*_t|s_t)]. \end{aligned}$$

Denote $\ell(s, \hat{\pi}) = 1 - p_{\hat{\pi}}(a = a^*|s), a \sim \hat{\pi}(s), a^* \sim \pi^*(s)$ as the "single-step loss function", which is bounded within $[0, 1]$, then the cost of policy $\hat{\pi}$ can be simplified as:

$$\begin{aligned} J(\hat{\pi}) &= \sum_{t=1}^{T} \mathbb{E}_{s_t\sim d^t_{\pi^*}}\left[\ell(s_t, \hat{\pi})\right] \\ &= T\mathbb{E}_{t\sim\mathcal{U}(1,T)}\mathbb{E}_{s_t\sim d^t_{\pi^*}}\left[\ell(s_t, \hat{\pi})\right] \\ &= T\mathbb{E}_{s\sim d_{\pi^*}}\left[\ell(s, \hat{\pi})\right], \end{aligned} \quad (3)$$

where $d_{\pi^*} = \frac{1}{T}\sum_{t=1}^{T} d^t_{\pi^*}$ is the average expert state distribution, when we assume the time step t to be a random variable under the uniform distribution $\mathcal{U}(1, T)$ (the second equality).

A.2 Cost Bound of Supervised Approach

In this section, we analyze the cost bound of the supervised approach. Recall that the supervised approach trains a policy $\hat{\pi}$ using the standard supervised learning algorithm with supervision from π^* at every decision step. Therefore, it finds the best policy $\hat{\pi}_{sup}$ on infinite samples as:

$$\hat{\pi}_{sup} = \arg\min_{\pi\in\Pi} \mathbb{E}_{s\sim d_{\pi^*}}[\ell(s, \pi)], \quad (4)$$

where Π denotes the policy space induced by the model architecture, and the expectation over s is sampled from the whole d_{π^*} state space because of the "infinite sample" assumption. The supervised approach thus obtains the following cost bound:

$$\begin{aligned} J(\hat{\pi}_{sup}) =& T\mathbb{E}_{s\sim d_{\pi^*}}[\ell(s,\hat{\pi}_{sup})] \\ =& T\min_{\pi\in\Pi}\mathbb{E}_{s\sim d_{\pi^*}}[\ell(s,\pi)]. \end{aligned}$$

This gives the following theorem:

Theorem A.1. *For supervised approach, let* $\epsilon_N = \min_{\pi\in\Pi}\mathbb{E}_{s\sim d_{\pi^*}}[\ell(s,\pi)]$*, then* $J(\hat{\pi}_{sup}) = T\epsilon_N$*.*

The cost bound of the supervised approach represents its exact performance as implied by the equality. This is because the approach trains a policy (Eq. (4)) under the same state distribution d_{π^*} (given the "infinite sample" assumption) as in evaluation (Eq. (3)). As we will show next, the proposed NEIL algorithm breaks this consistency while enjoying the benefit of high annotation efficiency, which explains the performance gap.

A.3 No-regret Assumption

Before showing the cost bound of our NEIL algorithm, we introduce a "no-regret" assumption (Kakade and Tewari, 2009; Ross et al., 2011) that is leveraged in the derivation.

Assumption A.1. *No-regret assumption. Define* $\ell_i(\pi) = \mathbb{E}_{s\sim d_{\pi_i}}[l(s,\pi)]$ *and* $\epsilon_N = \min_{\pi\in\Pi}\frac{1}{N}\sum_{i=1}^{N}\ell_i(\pi)$*, then*

$$\frac{1}{N}\sum_{i=1}^{N}\ell_i(\hat{\pi}_i) - \epsilon_N \le \gamma_N$$

for $\lim_{N\to\infty}\gamma_N = 0$ *(usually* $\gamma_N \in \tilde{O}(\frac{1}{N})$*).*

This assumption characterizes an important policy learning pattern: As a policy is trained for an infinite number of iterations, on average, its expected training loss ($\frac{1}{N}\sum_{i=1}^{N}\ell_i(\hat{\pi}_i)$) will converge to the loss of the best policy in hindsight (ϵ_N). In our scenario, this assumption implies that, while our policy is trained on online labels from both the expert policy π^* (when it is queried) and the previously learned policy $\hat{\pi}_i$ (when the agent is confident), it still gradually fits to the best policy over the same state space in training (d_{π_i}). In other words, the likely noisy labels from $\hat{\pi}_i$ do not harm the model fitting to the expert policy in general.

Many no-regret algorithms (Hazan et al., 2007; Kakade and Tewari, 2009) that guarantee $\gamma_N \in \tilde{O}(\frac{1}{N})$ require convexity or strong-convexity of the loss function. However, the loss function used in our application, which is built on the top of a deep neural network model, does not satisfy this requirement. In general, proving theorems under a non-convex case is not trivial. In this analysis, we follow the common practice (see Kingma and Ba (2015); Reddi et al. (2018) for example) to theoretically analyze the convex case while empirically demonstrating the non-convex case. A more accurate regret bound for non-convex neural networks (which may result in a slower γ_N convergence speed with respect to N) can be studied in the future.

A.4 Cost Bound of NEIL Algorithm

As shown in Algorithm 1, NEIL produces a sequence of policies $\hat{\pi}_{1:N} = (\hat{\pi}_1, \hat{\pi}_2, ..., \hat{\pi}_N)$, where N is the number of training iterations, and returns the one with the best test-time performance on validation set as $\hat{\pi}$. In training, the algorithm executes actions from both the learning policy $\hat{\pi}_i$ (when the model is confident) and the expert policy π^*. We denote this "mixture" policy as π_i. Then for the first N iterations, we have the cost bound of NEIL as:

$$\begin{aligned} J(\hat{\pi}) =& \min_{\hat{\pi}'\in\hat{\pi}_{1:N}} T\mathbb{E}_{s\sim d_{\pi^*}}\left[\ell(s,\hat{\pi}')\right] \\ \le& \frac{T}{N}\sum_{i=1}^{N}\mathbb{E}_{s\sim d_{\pi^*}}\left[\ell(s,\hat{\pi}_i)\right] \\ \le& \frac{T}{N}\sum_{i=1}^{N}\left[\mathbb{E}_{s\sim d_{\pi_i}}[\ell(s,\hat{\pi}_i)] + \ell_{max}||d_{\pi_i} - d_{\pi^*}||_1\right]. \end{aligned} \tag{5}$$

From the last inequality, we can see that the cost bound of NEIL is restricted by two terms. The first term $\mathbb{E}_{s\sim d_{\pi_i}}[\ell(s,\hat{\pi}_i)]$ denotes the expected loss of $\hat{\pi}_i$ under the states induced by π_i *during training* (under the "infinite sample" assumption, as mentioned in the beginning of the analysis). By applying the no-regret assumption (Assumption A.1), this term can be bound by $\frac{1}{N}\sum_{i=1}^{N}\mathbb{E}_{s\sim d_{\pi_i}}[\ell(s,\hat{\pi}_i)] \le \epsilon_N + \gamma_N$. Here, $\epsilon_N = \min_{\pi\in\Pi}\frac{1}{N}\sum_{i=1}^{N}\ell_i(\pi)$ denotes the best expected training loss in hindsight.

The second term denotes the L_1 distance between state distributions induced by π_i and π_i^*, weighted by the maximum loss value l_{max} that $\hat{\pi}_i$ encounters over the training. As we notice, unlike the supervised approach, NEIL *trains* a policy under d_{π_i}, while what matters to its *test-time* quality is its performance on the state distribution d_{π^*} (Eq. (3)). This discrepancy explains the performance loss of our algorithm compared to the supervised approach and is bounded by the aforementioned L_1 distance. To further bound this term, we define e_i as the probability that $\hat{\pi}_i$ makes a confident (i.e., without querying the expert policy) but wrong action under d_{π^*}, and introduce the following lemma:

Lemma A.1. $||d_{\pi_i} - d_{\pi^*}||_1 \leq 2Te_i$.

Proof. Let β_{it} be the probability of querying the expert policy under $d^t_{\pi^*}$, $\tilde{\epsilon}_{it}$ the error rate of $\hat{\pi}_i$ under $d^t_{\pi^*}$ (w.r.t. π^*), and d any state distribution besides d_{π^*}. We can then express d_{π_i} by:

$$\begin{aligned} d_{\pi_i} = &\prod_{t=1}^{T}(\beta_{it} + (1-\beta_{it})(1-\tilde{\epsilon}_{it}))d_{\pi^*} \\ &+ (1 - \prod_{t=1}^{T}(\beta_{it} + (1-\beta_{it})(1-\tilde{\epsilon}_{it})))d. \end{aligned}$$

The distance between d_{π_i} and d_{π^*} thus becomes

$$\begin{aligned} &||d_{\pi_i} - d_{\pi^*}||_1 \\ =&(1 - \prod_{t=1}^{T}(\beta_{it} + (1-\beta_{it})(1-\tilde{\epsilon}_{it})))||d - d_{\pi^*}||_1 \\ \leq&2(1 - \prod_{t=1}^{T}(\beta_{it} + (1-\beta_{it})(1-\tilde{\epsilon}_{it}))) \\ \leq&2\sum_{t=1}^{T}[1 - (\beta_{it} + (1-\beta_{it})(1-\tilde{\epsilon}_{it}))] \\ \leq&2\sum_{t=1}^{T}[\tilde{\epsilon}_{it}(1-\beta_{it})] \\ \leq&2\sum_{t=1}^{T}e_{it} \\ =&2Te_i. \end{aligned}$$

The second inequality uses $1 - \prod_{t=1}^{T} x_t \leq \sum_{t=1}^{T}(1 - x_t)$, which holds when $x_t \in [0, 1]$. $\square$

By applying Assumption A.1 and Lemma A.1 to Eq. (3), we derive the following inequality:

$$J(\hat{\pi}) \leq T\big[\gamma_N + \epsilon_N + \frac{2T\ell_{max}}{N}\sum_{i=1}^{N} e_i\big].$$

Given a large enough N ($N \in \tilde{O}(T)$), by the no-regret assumption, we can further simplify the above as:

$$J(\hat{\pi}) \leq T\big[\epsilon_N + \frac{2T\ell_{max}}{N}\sum_{i=1}^{N} e_i\big] + O(1),$$

which leads to our theorem:

Theorem A.2. *For the proposed* NEIL *algorithm, if N is $\tilde{O}(T)$, there exists a policy $\hat{\pi} \in \hat{\pi}_{1:N}$ s.t. $J(\hat{\pi}) \leq T\big[\epsilon_N + \frac{2T\ell_{max}}{N}\sum_{i=1}^{N} e_i\big] + O(1)$.*

By comparing Theorem A.1 and Theorem A.2, it is obvious that the performance gap between NEIL and the supervised approach is bounded by the term around $\frac{1}{N}\sum_{i=1}^{N} e_i$. We discuss its implications in Section 5 and show that, in practice, this performance gap can be controlled by carefully initializing the policy and choosing a more accurate confidence estimator.

Discussion about MISP-NEIL*. In experiments, we consider a skyline instantiation of NEIL, called MISP-NEIL*. This instantiation is assumed with perfect confidence estimation and interaction design, such that it can precisely detect and correct its intermediate mistakes during parsing. Therefore, MISP-NEIL* presents an upper bound performance (i.e., the *tightest* cost bound) of NEIL. This can be interpreted theoretically. In fact, for MISP-NEIL*, e_i is always zero since the system has ensured that its policy action is correct when it does not query the expert policy. In this case, $d_{\pi_i} = d_{\pi^*}$, so $\epsilon_N = \min_{\pi\in\Pi}\frac{1}{N}\sum_{i=1}^{N}\mathbb{E}_{s\sim d_{\pi^*}}[l(s,\pi)] = \min_{\pi\in\Pi}\mathbb{E}_{s\sim d_{\pi^*}}[l(s,\pi)]$. Therefore, according to Theorem A.2, MISP-NEIL* has a cost bound of:

$$J(\hat{\pi}) \leq T\epsilon_N + O(1),$$

where $\epsilon_N = \min_{\pi\in\Pi}\mathbb{E}_{s\sim d_{\pi^*}}[l(s,\pi)]$.

By comparing this bound with the cost bound in Theorem A.1, it is observed that MISP-NEIL* shares the same cost bound as the supervised approach (except for the inequality relation and the constant). This is explainable since MISP-NEIL* indeed collects exactly the same training labels as the supervised approach.

A.5 Cost Bound of NEIL Algorithm in Finite Sample Case

The theorem in the previous section holds when the algorithm observes infinite trajectories in training. However, in practice, NEIL observes the training loss from only a finite set of m trajectories in each iteration. For this consideration, in the following discussion, we provide a proof of the cost bound of NEIL under the finite sample case.

Denote D_i as the m trajectories collected in the i-th iteration and $\ell_i(\hat{\pi}_i) = \mathbb{E}_{s\sim D_i}[\ell(s,\hat{\pi}_i)]$. Applying the no-regret assumption (Assumption A.1) allows us to bound the average expected policy training loss: $\frac{1}{N}\sum_{i=1}^{N}\mathbb{E}_{s\sim D_i}\big[\ell(s,\pi_i)\big] - \tilde{\epsilon}_N \leq \tilde{\gamma}_N$, where $\tilde{\epsilon}_N = \min_{\pi\in\Pi} \frac{1}{N}\sum_{i=1}^{N} \mathbb{E}_{s\sim D_i}\big[\ell(s,\pi)\big]$ denotes the loss of the best policy in hindsight on the finite samples.

Following Eq. (5), we need to switch the derivation from the expected loss of $\hat{\pi}_i$ over d_{π_i} (i.e., $\mathbb{E}_{s\sim d_{\pi_i}}[\ell(s,\hat{\pi}_i)]$) to that over D_i (i.e., $\mathbb{E}_{s\sim D_i}[\ell(s,\hat{\pi}_i)]$), the actual state distribution that $\hat{\pi}_i$ is trained on. To fill this gap, we introduce Y_{ij} to denote the difference between the expected loss of $\hat{\pi}_i$ under d_{π_i} and the average loss of $\hat{\pi}_i$ under the j-th sample trajectory with π at iteration i. The random variables Y_{ij} over all $i \in \{1, 2, ..., N\}$ and $j \in \{1, 2, ..., m\}$ are all zero mean, bounded in $[-\ell_{max}, \ell_{max}]$ and form a martingale in the order of $Y_{11}, Y_{12}, ..., Y_{1m}, Y_{21}, ..., Y_{Nm}$. By Azuma-Hoeffding's inequality (Azuma, 1967; Hoeffding, 1994), $\frac{1}{mN}\sum_{i=1}^{N}\sum_{j=1}^{m} Y_{ij} \leq \ell_{max}\sqrt{\frac{2\log(1/\delta)}{mN}}$ with probability $1-\delta$. Following the derivations in Eq. (5) and by introducing Y_{ij}, with probability of $1-\delta$, we obtain the following inequalities by definition:

$$
\begin{aligned}
&J(\hat{\pi}) \\
\leq& \frac{T}{N}\sum_{i=1}^{N}\left[\mathbb{E}_{s\sim d_{\pi_i}}[\ell(s,\hat{\pi}_i)] + \ell_{max}||d_{\pi_i} - d_{\pi^*}||_1\right] \\
\leq& \frac{T}{N}\sum_{i=1}^{N}\Big[\mathbb{E}_{s\sim D_i}[\ell(s,\hat{\pi}_i)] + \ell_{max}||d_{\pi_i} - d_{\pi^*}||_1\Big] \\
&+ \frac{T}{mN}\sum_{i=1}^{N}\sum_{j=1}^{m} Y_{ij} \\
\leq& \frac{T}{N}\sum_{i=1}^{N}\Big[\mathbb{E}_{s\sim D_i}[\ell(s,\hat{\pi}_i)] + \ell_{max}||d_{\pi_i} - d_{\pi^*}||_1\Big] \\
&+ \ell_{max}T\sqrt{\frac{2\log(1/\delta)}{mN}} \\
\leq& T\Big[\tilde{\gamma}_N + \tilde{\epsilon}_N + \ell_{max}\sqrt{\frac{2\log(1/\delta)}{mN}} \\
&+ \frac{2\ell_{max}T}{N}\sum_{i=1}^{N} e_i\Big].
\end{aligned}
$$

Notice that we need mN to be at least $\tilde{O}(T^2 log(1/\delta))$, so that $\tilde{\gamma_N}$ and $l_{max}\sqrt{\frac{2\log(1/\delta)}{mN}}$ are negligible. This leads to the following theorem:

Theorem A.3. *For the proposed* NEIL *algorithm, with probability at least* $1-\delta$*, when* mN *is* $\tilde{O}(T^2 log(1/\delta))$*, there exists a policy* $\hat{\pi} \in \hat{\pi}_{1:N}$ *s.t.* $J(\hat{\pi}) \leq T[\tilde{\epsilon}_N + \frac{2l_{max}T}{N}\sum_{i=1}^{N} e_i] + O(1)$.

The theorem shows that the cost of NEIL can still be bounded in the finite sample setting. Comparing this bound with the bound under the infinite sample setting, we can observe that the bound is still related to e_i, the probability that $\hat{\pi}_i$ takes a confident but incorrect action under d_{π^*}.

B Implementation Details

B.1 Interactive Semantic Parsing Framework

Our system assumes an interactive semantic parsing framework to collect user feedback. In experiments, this is implemented by adapting MISP (Yao et al., 2019b), an open-sourced framework[5] that has demonstrated a strong ability to improve test-time parsing accuracy. In this framework, an agent is comprised of three components: a world model that wraps the base semantic parser and a feedback incorporation module to interpret user feeds and update the semantic parse, an error detector that decides whether to request for user intervention, and an actuator that delivers the agent's request by asking a natural language question, such that users without domain expertise can understand.

We follow MISP's instantiation for text-to-SQL tasks to adopt a probability-based uncertainty estimator as the error detector, which triggers user interactions when the probability of the current decision is lower than a threshold. The actuator is instantiated by a grammar-based natural language generator. We use the latest version of MISP that allows multi-choice interactions to improve the system efficiency, i.e., when the parser's current decision is validated as wrong, the system presents multiple alternative options for user selection. An additional "None of the above options" option is included in case all top options from the system are wrong. Figure 1 shows an example of the user interaction. From there, the system can derive a correct decision to address its uncertainty (e.g., taking "`Player`" as a `WHERE` column).

As a general interactive semantic parsing framework, MISP has its advantage of being generalizable to different kinds of semantic parsers (as long as their parsing process can be formulated as taking a sequence of actions in their respective action space) and various logical forms (e.g., lambda expressions). Although it could be non-trivial to instantiate such an interactive system, we note that it is a one-time effort for all datasets of the same logical form.

Example of Non-sketch-based Parsers. In addi-

---

[5] `https://github.com/sunlab-osu/MISP`.

tion to the example of the SQLova parser (Hwang et al., 2019) that we provide in Section 3, here we show how the EditSQL parser (Zhang et al., 2019) is formulated under MISP. Unlike SQLova, EditSQL does not assume any SQL sketch; it instead generates a SQL query "token by token".[6] Consider the SQL query in Figure 1. EditSQL takes actions: a_1="`SELECT`", a_2="`COUNT`", a_3="`(`", a_4="`School/Club Team`", a_5="`)`", etc. Therefore, the action space of EditSQL consists of all SQL keywords, grammatical constituents (e.g., "`(`"), and available table columns. In this case, MISP only validates semantically meaningful actions (including aggregators, operators, column names, etc.) while skipping others (including trivial symbols like "`(`" and most SQL keywords[7]).

User Simulator. Our experiments train each system with simulated user feedback. To this end, we build a user simulator similar to the one used by Yao et al. (2019b) in MISP, which can access the ground-truth SQL queries. It gives yes/no answer or selects a choice by directly comparing the sampled policy action with the true one in the gold query. When the true option is not presented within the system provided choices, the user is simulated to select "None of the above options".

B.2 WikiSQL Experiment Details

Dataset&Model. Our main experiments consider the WikiSQL benchmark dataset (Zhong et al., 2017),[8] which contains 56,355/8,421/15,878 question-SQL query pairs in the training/validation/test set. We use exactly the same data split as Zhong et al. (2017).

We choose SQLova (Hwang et al., 2019), one of the open-sourced[9] top-performing semantic parser on WikiSQL, as the base parser, which ensures reasonable model capability to study continual learning. Hyper-parameters are set the same as the ones recommended by the SQLova authors on their GitHub repository,[10] except that we use a learning rate of 1e-5 for fine-tuning the BERT model. Empirically we found out this relatively larger learning rate can greatly accelerate the model learning without affecting the model performance significantly. The total number of model parameters is around 118M, with 110M from BERT-Base (Uncased)[11] and 8M from the SQLova parser side.

Early stop is used to accelerate model training in each training iteration. Specifically, we stop model training if it does not show improvement on the validation set for a consecutive number of epochs. We set this number to 10 before the 30-th training iteration when the total training data is in a relatively small size, and decay it to 5 after the 30-th iteration. We follow SQLova when preprocessing the WikiSQL data.

Experimental Setup. We study a "continual learning" problem and experiment various systems with three initialization settings, as suggested by our theoretical analysis (Section 5). Specifically, we use 10% (5,636 pairs), 5% (2,818 pairs), and 1% (564 pairs) of the total training data for parser initialization, respectively.

In each initialization setting, the remaining training data is used to simulate user questions that a system receives after deployment. The user questions come in a random order. We repeat three random runs (i.e., three random orders of user questions) and report the average system performance. Notice that, we ensure each system receive the same user question (but may have different user feedback depending on their interaction designs) during iterative training, for a fair comparison. Systems update (retrain) their base semantic parsers periodically for every 1,000 user questions.

Metrics. In the end of each iteration, we evaluate the system's performance, including:

- Parsing accuracy. We measure the query match accuracy (i.e., logical form accuracy) using the script from SQLova implementation.
- An accumulated number of user/expert annotations (introduced in Section 6.3). Different systems request different kinds of user/expert annotations. Therefore, even when serving the user on the same user question, different systems require different numbers of annotations. This metric sums up the total number of annotations that each system has requested after each training iteration.

Calculating the aforementioned metrics allow us to plot Figure 2 and Figure 4.

---

[6] EditSQL considers a column name as a single "token", although it may actually contain several words (e.g., `School/Club Team`).

[7] Except `WHERE`, `GROUP BY`, `ORDER BY` and `HAVING`; see Appendix B.3 for details.

[8] `https://github.com/salesforce/WikiSQL`.

[9] `https://github.com/naver/sqlova`.

[10] `https://github.com/naver/sqlova#running-code`.

[11] `https://github.com/google-research/bert#pre-trained-models`.

Compute. We complete experiments on Nvidia GeForce RTX 2080Ti (11GB). Models are all implemented using PyTorch.[12] The run time for each training iteration varies depending on the accumulated training data size. To finish the 50+ iterations of (re-)training, each system takes around 15 days. In the weak 1% initialization case, the Binary User baseline takes less time (around 10 days), since most of its predicted queries are wrong and thus are not included into its training data.

B.3 EditSQL Experiment Details

Data&Model. The Spider dataset (Yu et al., 2018) contains 8,421 question-SQL pairs for training and 1,034 pairs for validation.[13] The test set is not publicly available and is thus not used in our experiments.

We choose EditSQL (Zhang et al., 2019) as the base semantic parser,[14] since it is one of the open-sourced state-of-the-art models on Spider. All hyper-parameters are set following (Zhang et al., 2019). Pre-trained BERT model is also used. Totally there are around 120M parameters in the model, with 110M from the BERT-Base (Uncased)[15] and 10M from the EditSQL parser side. Early stop is additionally used to accelerate model training. Specifically, we stop model training when it does not show improvement on validation for 5 consecutive epochs.

In the data preprocessing step, EditSQL transforms each gold SQL query into a sequence of tokens, where the `From` clause is removed and each column `Col` is prepended by its paired table name, i.e., `Tab.Col`. However, we observe that sometimes this transformation is not convertible. For example, consider the question "what are the first name and last name of all candidates?" and its gold SQL query: "`SELECT T2.first_name , T2.last_name FROM candidates AS T1 JOIN people AS T2 ON T1.candidate_id = T2.person_id`". EditSQL transforms this query into : "`select people.first_name , people.last_name`". The transformed sequence accidentally removes the information about table `candidates` in the original SQL query, leading to semantic meaning inconsistent with the question. When using such erroneous sequences as the gold targets in model training, we cannot simulate consistent user feedback, e.g., when the user is asked whether her query is relevant to the table `candidates`, the simulated user cannot give an affirmative answer based on the transformed sequence. To avoid inconsistent user feedback, we remove question-SQL pairs whose transformed sequence is inconsistent with the original gold SQL query, from the training data. This can be easily done by using EditSQL's post-processing script to convert a preprocessed sequence back to the SQL format. Only when the converted query is the same as the original one, the transformation is consistent. This reduces the size of the training set from 8,421 to 7,377. The validation set is kept untouched for fair evaluation.

The implementation of interactive semantic parsing for EditSQL is the same as Section B.1, except that, in order to cope with the complicated structure of Spider SQL queries, for columns in `WHERE`, `GROUP BY`, `ORDER BY` and `HAVING` clauses, we additionally provide an option for the user to "remove" the clause, e.g., removing a `WHERE` clause by picking the "The system does not need to consider any conditions." option. We also adjust the "semantic unit" definition in MISP[16] to deal with the autoregressive decoding of EditSQL. For example, instead of asking first about a `SELECT` column and then about its aggregator, we define one semantic unit to inquire about both the column and its aggregator.

To instantiate NEIL, the confidence threshold μ is 0.995 as we observe that EditSQL tends to be overconfident.

Experimental Setup. We experiment with one initialization setting, using 10% of the total training data (i.e., 737 question-SQL pairs), and systems update (retrain) their base semantic parsers periodically for every 1,000 user questions as in WikiSQL experiments. We report system performance averaged over three random runs (i.e., three random orders of user questions).

We also tried using more training data for initialization. However, since the total training data in Spider is very limited in size, more initialization data means fewer data for simulating online

user questions and conducting continual learning. This leads to less clear experimental observations (e.g., even the Full Expert system shows fluctuation, probably due to data redundancy or an issue with model architecture capability). Therefore, we only focus on the 10% initialization setting.

Metrics. We measure each system similarly as in WikiSQL experiments. For parsing performance, we calculate the exact match accuracy using scripts from the EditSQL implementation.

Compute. We complete experiments on Nvidia GeForce RTX 2080Ti (11GB). Models are implemented using PyTorch. The run time for each training iteration varies depending on the accumulated training data size. Finishing the whole iterative learning takes around 5 days for all systems.

C Additional Experimental Results

C.1 Additional SQLova Results

Figure 4 shows different systems' performance on WikiSQL validation set. For Binary User(+Expert), it is hard to quantify "one annotation", which varies according to the actual database size and the query difficulty. As a compromise, we approximate this number by calculating it in the same way as Full Expert, with the assumption that in general validating execution results is as hard as validating the SQL query itself.

We also show in Figure 5 the average number of annotations (i.e., user interactions) that MISP-NEIL requires per question during the iterative training. Overall, as the base parser is further trained, our system tends to request fewer user interactions. In most cases throughout the training, the system requests no more than one user interaction, demonstrating the annotation efficiency of our NEIL algorithm.

C.2 Connection to Theoretical Analysis

As we proved in Section 5, the performance gap between our proposed NEIL algorithm and the supervised approach is mainly decided by $\frac{1}{N}\sum_{i=1}^{N} e_i$, an average probability that $\hat{\pi}_i$ makes a confident but wrong decision under d_{π^*} (i.e., given a gold partial parse) over N training iterations. More specifically, from our proof of Lemma A.1, e_i can be expressed as:

$$e_i = \frac{1}{T}\sum_{t=1}^{T} e_{it} = \frac{1}{T}\sum_{t=1}^{T} \tilde{\epsilon}_{it}(1-\beta_{it}),$$

where $\tilde{\epsilon}_{it}$ denotes policy $\hat{\pi}_i$'s conditional error rate under $d^t_{\pi^*}$ when it does not query the expert (i.e., being confident about its own action) at step t, and $1-\beta_{it}$ denotes the probability that $\hat{\pi}_i$ does not query the expert under $d^t_{\pi^*}$. $\tilde{\epsilon}_{it}(1-\beta_{it})$ thus represents a joint probability that $\hat{\pi}_i$ makes confident but wrong action under $d^t_{\pi^*}$ at step t.

To show a reflection of our theoretical analysis on the experiments, we present the values of the following three variables during training: (1) $\tilde{\epsilon}_i = \frac{1}{T}\sum_{t=1}^{T} \tilde{\epsilon}_{it}$, the average value of $\tilde{\epsilon}_{it}$ over T time steps. A smaller $\tilde{\epsilon}_i$ implies a lower conditional error rate and thus a smaller e_i and a smaller performance gap. (2) $\beta_i = \frac{1}{T}\sum_{t=1}^{T} \beta_{it}$, the average value of β_{it} over T time steps. A smaller β_i (i.e., a larger $1-\beta_i$) means a smaller probability that $\hat{\pi}_i$ queries the expert (i.e., being more confident). This could lead to a larger e_i and thus a larger performance gap. (3) e_i as defined previously. A smaller e_i indicates a smaller performance gap between our algorithm and the supervised approach.

We plot the results of our MISP-NEIL system (based on SQLova) in Figure 6. For all initialization settings, we observe that the base parser tends to make more confident actions under a gold partial parse (i.e., decreasing β_i) when it is trained for more iterations. Meanwhile, the error rate of its confident actions under a gold partial parse is also reduced (i.e., decreasing $\tilde{\epsilon}_i$). When combining the two factors, e_i is shown to keep decreasing, implying that with more iterations that the parser is trained, it gets a tighter cost bound and better performance.

Finally, we notice that a differently initialized parser can end up with different performance. This is reasonable since a better initialized parser presumably should have a better overall error rate. This is also consistent with our observation in the main experimental results (Section 6.3).

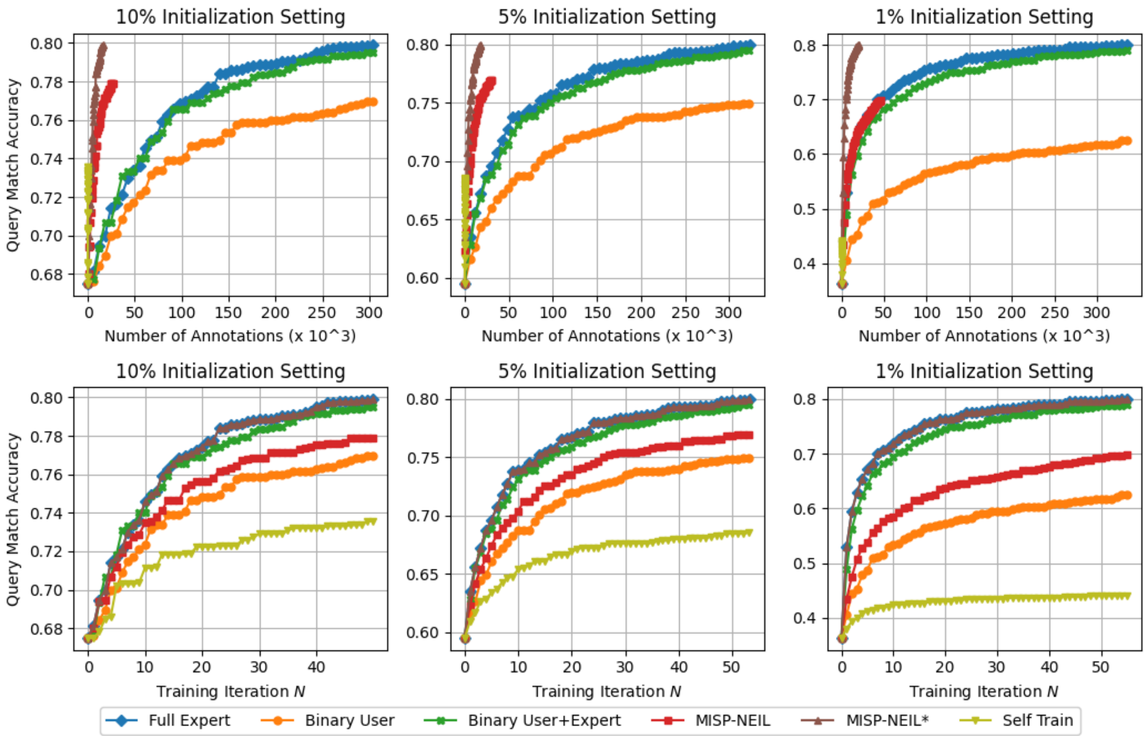

Figure 4: Parsing accuracy on WikiSQL validation set when systems are trained with various numbers of user/expert annotations (top) and for different iterations (bottom). We experiment systems with three initialization settings, using 10%, 5% and 1% of the training data respectively.

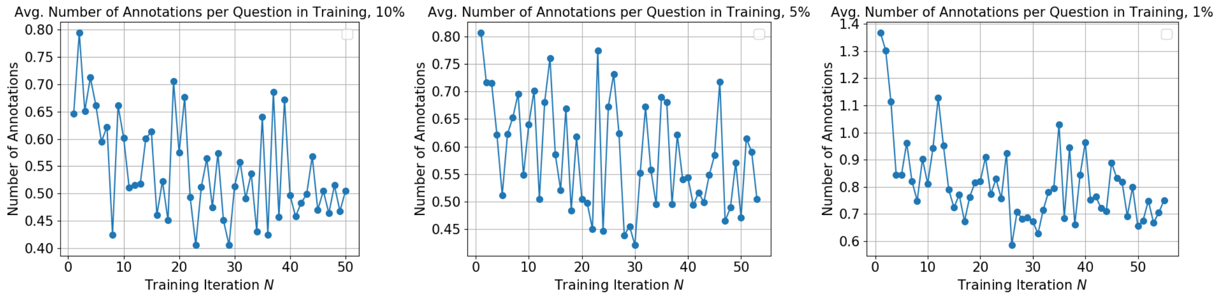

Figure 5: Average number of user annotations/interactions that MISP-NEIL requests for each user question during iterative training (on WikiSQL), when the parser is initialized using 10%, 5% and 1% of training data.

Abstract

Context-dependent text-to-SQL task has drawn much attention in recent years. Previous models on context-dependent text-to-SQL task only concentrate on utilizing historical user inputs. In this work, in addition to using encoders to capture historical information of user inputs, we propose a database schema interaction graph encoder to utilize historicalal information of database schema items. In decoding phase, we introduce a gate mechanism to weigh the importance of different vocabularies and then make the prediction of SQL tokens. We evaluate our model on the benchmark SParC and CoSQL datasets, which are two large complex context-dependent cross-domain text-to-SQL datasets. Our model outperforms previous state-of-the-art model by a large margin and achieves new state-of-the-art results on the two datasets. The comparison and ablation results demonstrate the efficacy of our model and the usefulness of the database schema interaction graph encoder.

1 Introduction

The Text-to-SQL task aims to translate natural language texts into SQL queries. Users who do not understand SQL grammars can benefit from this task and acquire information from databases by just inputting natural language texts. Previous works (Li and Jagadish, 2014; Xu et al., 2017; Yu et al., 2018a; Bogin et al., 2019b; Huo et al., 2019) focus on context-independent text-to-SQL generation. However, in practice, users usually interact with systems for several turns to acquire information, which extends the text-to-SQL task to the context-dependent text-to-SQL task in a conversational scenario. Throughout the interaction, user inputs may omit some information that appeared before. This phenomenon brings difficulty for context-dependent text-to-SQL task.

Recently, context-dependent text-to-SQL task has attracted more attention. Suhr et al. (2018) conduct experiments on ATIS dataset (Dahl et al., 1994). Besides, two cross-domain context-dependent datasets SParC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a) are released. Cross-domain means databases in test set differ from that in training set, which is more challenging.

EditSQL (Zhang et al., 2019) is the previous state-of-the-art model on SParC and CoSQL datasets and it focuses on taking advantages of previous utterance texts and previously predicted query to predict the query for current turn. Table 1 shows the user inputs, ground truth queries and predicted queries of EditSQL for an interaction. In the second turn, EditSQL views “Kacey” as the name of a dog owner. However, since the context of the interaction is about dogs, “Kacey” should be the name of a dog. This example shows that a model using only historical information of user inputs may fail to keep context consistency and maintain thematic relations.

According to (Yu et al., 2019b) and (Yu et al., 2019a), to maintain thematic relations, users may change constraints, ask for different attributes for the same topic when they ask the next questions. Thus, database schema items (i.e., *table.column*) in current turn should have relation with items in previous turn. For example, in Table 1, the second question x^2 adds a constraint of the name and asks for the age of a dog instead of the numbers of all dogs. The corresponding database schema items *Dogs.age* and *Dogs.name* in y^2 belong to the same table as *Dogs.** in previous query y^1. Therefore, we propose to take historical information about database schema items into consideration.

In particular, we first construct a graph based on corresponding database, where graph nodes are database schema items and graph edges are primary-foreign keys and column affiliation. Short

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6903–6912,
November 16–20, 2020. ©2020 Association for Computational Linguistics

x^1	how many dogs on the table
$\tilde{y}^1$	SELECT count (*) FROM Dogs
y^1	SELECT count (*) FROM Dogs
x^2	what is the age of Kacey
$\tilde{y}^2$	SELECT T2.age FROM owners as T1 JOIN Dogs AS T2 ON T1.owner_id = T2.owner_id WHERE T1.first_name = 1
y^2	SELECT age FROM dogs WHERE name = “Kacey”
x^3	which dog is highest weight on table – Do you want the name of the dog with the highest weight? – exactly
$\tilde{y}^3$	SELECT name FROM dogs ORDER BY weight DESC limit 1
y^3	SELECT name FROM dogs ORDER BY weight DESC limit 1
x^4	What is the size code of BUL – Did you mean the size code of dogs with a breed code BUL? – exactly
$\tilde{y}^4$	SELECT size_code FROM dogs WHERE breed_code = 1
y^4	SELECT size_code FROM dogs WHERE breed_code = “BUL”

Table 1: An example interaction. x^i is the input sequence in i-th turn and y^i is the corresponding ground truth query. $\tilde{y}^i$ means that query is predicted by a model, which is EditSQL here.

distance between graph nodes appearing in previous query and current query can reveal the context consistency since there is usually an edge between the different attributes of the same topic. We then propose a database schema interaction graph encoder to model database schema items together with historical items. Empirical results on two large cross-domain context-dependent text-to-SQL datasets - SParC and CoSQL show that our schema interaction graph encoder contributes to modeling context consistency and our proposed model with database schema interaction graph encoder substantially outperforms the state-of-the-art model.

Our main contributions are summarized as follows:

- Previous models failed to keep context consistency and predict queries in a conversation scenario. To remedy this, we propose a database schema interaction graph encoder for database schema encoding and it can keep context consistency for the context-dependent text-to-SQL task. Our implementations are public available [1].
- Our model with the database schema interaction graph encoder achieves new state-of-the-art performances on development and test sets of two cross-domain context-dependent text-to-SQL datasets, SparC and CoSQL.

2 Related Work

Many studies have focused on context-independent text-to-SQL task. Zhong et al. (2017) split the vocabulary and use reinforcement learning. Xu et al. (2017) propose a sketched-based model, which decomposes the token prediction process into SELECT-clause prediction and WHERE-clause prediction, aiming at taking previous predictions into consideration. Yu et al. (2018a) further employ a tree-based SQL decoder so as to decode SQL queries with the help of SQL grammar. In order to encode database schemas, schemas are regarded as graphs and graph neural networks have been applied (Bogin et al., 2019a,b). Guo et al. (2019) design an intermediate representation to bridge the gap between natural language texts and SQL queries. Choi et al. (2020) utilize a sketch-based slot filling approach to synthesize SQL queries. Wang et al. (2019) attempt to align the database columns and their mentions in user inputs by using a relation-aware self attention.

Recently, context-dependent text-to-SQL task has drawn people’s attention. In-domain context-dependent benchmarks ATIS (Suhr et al., 2018) have been proposed. For ATIS, Suhr et al. (2018) utilize a sequence to sequence framework. Besides, they introduce an interaction-level encoder for incorporating historical user inputs and a segment copy mechanism to reduce the length of generation. Later, two large and complex cross-domain context-dependent dataset SParC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a) are proposed. In order to tackle cross-domain context-dependent text-to-SQL task, Zhang et al. (2019) propose the EditSQL model in order to capture features from historical user inputs, variant database schemas and previously predicted SQL query. EditSQL achieves the state-of-the-art performance on the two cross-domain datasets. Compared to EditSQL, our work further explore a new way to employ historical information of database schemas.

---

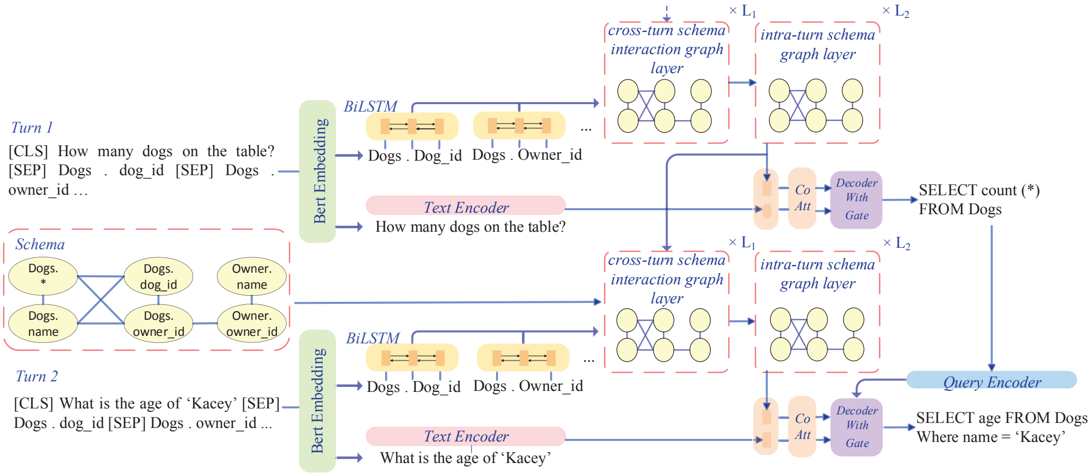

Figure 1: Overview of our IGSQL model. Modules with the same color share the same parameters.

3 Problem Setup

We define X as a series of natural language utterances of an interaction (i.e., user inputs), Y as corresponding ground-truth SQL queries, S as the set of database schema items (*table.column*) and R as the set of relations between schema items (primary-foreign keys and column affiliation). Let $X = \{x^1, x^2, ..., x^{|X|}\}$, where $|X|$ is the number of utterances. x^i is the i-th utterance and x^i_j is the j-th token of it. y^i is the i-th SQL query corresponding to x^i and y^i_j is the j-th token of y^i. S consists of schema items $\{S^1, ..., S^{|S|}\}$, where $|S|$ is the number of database schema items. At turn i, the model should make use of current and previous utterances $\{x^1, x^2, ..., x^i\}$, database schema items S and their relations R to predict a SQL query $\tilde{y}^i$. The objective of the model is to maximize the probability of $\prod_{i=1}^{|I|} P(y^i|x^1, x^2, ..., x^i)$.

4 IGSQL Model

Our model adopts an encoder-decoder framework with attention mechanism. Figure 1 shows the architecture of our model. The model have four main components: (1) a database schema interaction graph encoder, which consists of cross-turn schema interaction graph layers and intra-turn schema graph layers, (2) a text encoder that captures historical information of user inputs, (3) a co-attention module that updates outputs of text encoder and database schema interaction graph encoder, and (4) a decoder with a gated mechanism to weight the importance of different vocabularies. In addition, the model also uses BERT embedding.

We will first introduce the BERT embedding in Section 4.1, and then introduce our database schema interaction graph encoder in Section 4.2, text encoder and co-attention module in Section 4.3 and decoder in Section 4.4.

4.1 BERT Embedding

BERT (Devlin et al., 2019) is a pre-trained language model. Employing BERT output as embeddings of user inputs and database schema items has proved effective in context-dependent text-to-SQL task (Hwang et al., 2019; Guo et al., 2019; Wang et al., 2019; Choi et al., 2020). Therefore, we leverage BERT to get the embeddings of user inputs and database schema items as other context-dependent text-to-SQL models do. We concatenate user inputs and database schema items by separating with a "[SEP]" token following (Hwang et al., 2019). The output of BERT model is used as the embeddings of user inputs and schema items.

4.2 Database Schema Interaction Graph Encoder

As shown in Table 1, previous model mistakes "Kacey" as the name of a dog owner. However, the interaction is all about dogs and "Kacey" should be the name of a dog. It shows that previous model does not perform well in modeling context consistency of an interaction.

For two database schema items appearing in two adjacent turns, short distance of items in the graph can reveal the context consistency. For example, the distance between *Dogs.∗* [2] and correct item *Dogs.name* is 1. Distance between *Dogs.∗* and wrong item *owners.name* is 3.

---

[2] *table.∗* is considered a special column in table.

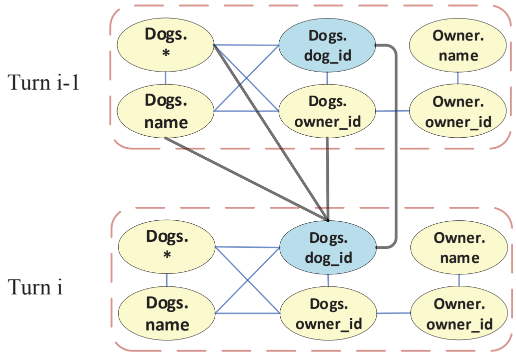

Figure 2: Database Schema Interaction Graph. We add black edges into the graph when we want to update the representation of the blue node (*Dogs.dog_id*) at turn i.

Therefore, we propose a database schema interaction graph encoder based on the database schema graph, attempting to model context consistency by using historical schema representations. The database schema interaction graph encoder consists of L_1 cross-turn schema interaction graph layers and L_2 intra-turn schema graph layers (L_1 and L_2 are hyper-parameters). Cross-turn schema interaction graph layers update schema item representations by using that in previous turn. Intra-turn schema graph layers further aggregate adjacent item representations in the same turn.

4.2.1 Graph Construction and Schema Items Encoding

We first introduce how we construct a graph based on database schema. We use database schema items as nodes. Each node has an edge linking to itself. There is an undirected edge between node t and node j according to relation set R if one of the following condition is satisfied: 1) node t and node j are the foreign-primary key pair; 2) node t and node j belong to the same table. We define the edge set as E.

A schema item *table.column* is divided into *"table"*, *"."* and *"column"*. We use a BiLSTM with BERT embedding to encode tokens and average hidden state vectors of BiLSTM as the embedding of the schema item. The embedding of the j-th schema item at i-th turn is noted as r_j^i.

4.2.2 Cross-turn Schema Interaction Graph Layer

Figure 2 shows an example of the database schema interaction graph. The graph only allows node t in previous turn to update node j in current turn, when the distance between node t and node j in the original graph constructed in Section 4.2.1 is less than or equal to 1. For example, if we want to update the representation of *Dogs.dog_id* at turn i, we add edges linking *Dogs.**, *Dogs.name*, *Dogs.owner_id* and *Dogs.dog_id* at turn $i-1$ to *Dogs.dog_id* at turn i.

Note that we have L_1 cross-turn schema interaction graph layers for turn i. At the l-th layer, we obtain updated representation $z_t^{i,l}$ of the t-th schema item by using attention on outputs of the L_2 intra-turn schema graph layers at previous turn $\{g_t^{i-1,L_2}\}_{t=1}^{|S|}$ (which will be introduced in next subsection) and representations of previous layer $\{z_t^{i,l-1}\}_{t=1}^{|S|}$. We use item embedding r_t^i as the initial representation $z_t^{i,0}$. For simplicity, we omit turn index i and layer index l in the formulas of attention mechanism except the input $z_t^{i,l-1}$, g_t^{i-1,L_2} and output $z_t^{i,l}$.

At the l-th layer, we first use a feed-forward neural network with leakyReLU activation function for non-linear transformation. We use FFN to denote the feed-forward neural network with leakyReLU activation function.

$$\begin{aligned} u_t &= \text{FFN}(z_t^{i,l}) \\ \hat{u}_t &= \text{FFN}(g_t^{i-1,L_2}) \end{aligned} \tag{1}$$

We then apply attention mechanism as follows.

$$\begin{aligned} \xi_{t,j} &= \begin{cases} (u_t)^T W_1 u_j / \sqrt{d_1}, & [t,j] \in E \\ -\infty, & [t,j] \notin E \end{cases} \\ \hat{\xi}_{t,j} &= \begin{cases} (u_t)^T W_2 \hat{u}_j / \sqrt{d_1}, & [t,j] \in E \\ -\infty, & [t,j] \notin E \end{cases} \\ \alpha_{t,j} &= \frac{exp(\xi_{t,j})}{\sum_v exp(\xi_{t,v}) + \sum_k exp(\hat{\xi}_{t,k})} \\ \hat{\alpha}_{t,j} &= \frac{exp(\hat{\xi}_{t,j})}{\sum_v exp(\xi_{t,v}) + \sum_k exp(\hat{\xi}_{t,k})} \\ \tilde{u}_t &= \sum_j \alpha_{t,j} u_j + \sum_j \hat{\alpha}_{t,j} \hat{u}_j \end{aligned} \tag{2}$$

where d_1 is the dimension of u_t. W_1 and W_2 are weight matrices. $\alpha_{t,j}$ and $\hat{\alpha}_{t,j}$ are the attention scores. $\tilde{u}_t$ is the t-th output vector of attention.

Following (Vaswani et al., 2017; Veličković et al., 2017), we extend attention mechanism to multi-head attention. We also add a sub-layer of feed-forward neural network with residual connection as in Transformer.

$$z_t^{i,l} = z_t^{i,l-1} + \text{FFN}(z_t^{i,l-1} + \tilde{u}_t) \quad (3)$$

where $z_t^{i,l}$ is the final output of layer l. There are L_1 cross-turn schema interaction graph layers and thus z_t^{i,L_1} is the final output of cross-turn schema interaction graph layers for the t-th schema item.

4.2.3 Intra-turn Schema Graph Layer

There are L_2 intra-turn schema graph layers following cross-turn schema interaction graph layers. In each intra-turn schema graph layer, we use almost the same attention mechanism as in the cross-turn schema interaction graph layer, except that we use the original graph constructed in Section 4.2.1. Since the original graph does not contain nodes in previous turn, the intra-turn schema graph layer can only update node representation by aggregating adjacent node representations in the same turn.

At each intra-turn schema graph layer layer l of turn i, it takes output vectors in previous layer $g_t^{i,l-1}$ as inputs and its output is $g_t^{i,l}$. $g_t^{i,0}$ is z_t^{i,L_1}. We then use attention mechanism to aggregate information. We also add a sub-layer of FFN and residual connection. For simplicity, we omit the turn index i and layer index l in attention except input $g_t^{i,l-1}$ and output $g_t^{i,l}$.

$$\begin{aligned}
\mu_t &= \text{FFN}(g_t^{i,l-1}) \\
\tau_{t,j} &= \begin{cases} (\mu_t)^T W_3 \mu_j / \sqrt{d_2}, & [t,j] \in E \\ -\infty, & [t,j] \notin E \end{cases} \\
\beta_{t,j} &= \frac{exp(\tau_{t,j})}{\sum_k exp(\tau_{t,k})} \\
\tilde{\mu}_t &= \sum_j \beta_{t,j} \mu_j \\
g_t^{i,l} &= g_t^{i,l-1} + \text{FFN}(g_t^{i,l-1} + \tilde{\mu}_t)
\end{aligned} \quad (4)$$

where W_3 is a weight matrix and d_2 is the dimension of μ_t. $\beta_{t,j}$ is the attention score of the j-th node to the t-th node. $\tilde{\mu}_t$ is the attention output. $g_t^{i,l}$ is the output of t-th schema item at layer l of turn i. Besides, We also extend attention to multi-head attention.

The final output of intra-turn schema graph layers for the t-th schema item is g_t^{i,L_2}.

4.3 Text Encoder and Co-Attention Module

We use a BiLSTM to encode tokens of an utterance text with BERT embedding. In order to capture interaction history, we add an LSTM as interaction encoder and utilize turn-level attention, following (Zhang et al., 2019). The final representation of the t-th token in utterance i is denoted as h_t^i.

We also add a co-attention module between text tokens and schema items following (Zhang et al., 2019). The schema item vector $\tilde{g}_t^i$ used in decoding phase is the concatenation of g_t^{i,L_2} and its corresponding attention vector over text. The representation of input text tokens $\tilde{h}_t^i$ used in decoding phase is the concatenation of h_t^i and its corresponding attention vector over schema items. Due to page limit, we omit the details here, which can be found in (Zhang et al., 2019).

4.4 Decoder

In decoding phase, we first encode previously predicted query with a BiLSTM. We then exploit a LSTM decoder with attention (Bahdanau et al., 2015) to capture features from input text's token vectors, schema item vectors and previously predicted SQL query vectors. At j-th time step, We use attention on text token's vector $\tilde{h}_t^i$, database schema vector $\tilde{g}_t^i$ and previously predicted SQL token's vector q_t. We thus get three context vectors. The final context vector c_j is the concatenation of these three context vectors.

We follow (Suhr et al., 2018) to make prediction of SQL tokens based on SQL reserved words, database schema items and previous predicted SQL tokens. We also add a gate mechanism to introduce the importance of these three vocabularies. For simplicity, we omit turn index i in decoder step except $\tilde{y}_j^i$.

The gate mechanism is introduced to measure the importance of three vocabularies.

$$\begin{aligned}
\tilde{o}_j &= \tanh(W_o([o_j; c_j] + b_o) \\
\zeta_m &= \sigma(W_m \tilde{o}_j + b_m) \\
m &\in \{res, sch, que\}
\end{aligned} \quad (5)$$

where o_j is the j-th hidden vector of the LSTM decoder. c_j is the context vector. $[;]$ is the concatenation operator and $\tilde{o}_j$ is the non-linear transformation of $[o_j; c_j]$. σ is the sigmoid function. res, sch, que represent SQL reserved words, database schema items and previously predicted SQL tokens respectively and $\zeta_{res}, \zeta_{sch}, \zeta_{que}$ represent the importance of these three kinds of tokens.

	SParC	CoSQL
cross-domain	✓	✓
Interaction	4298	3007
Train	3034	2164
Dev	422	292
Test	842	551
User Questions	12726	15598
Databases	200	200
Tables	1020	1020
Vocab	3794	9585
Avg Turn	3.0	5.2

Table 2: Statistics of SParC, CoSQL

We then predict SQL tokens as follows.

$$\begin{aligned} p_1(\tilde{y}^i_j = w) &= \frac{1}{Z} exp(\zeta_{res} \cdot \mathbf{w}^T (W_{res}\tilde{o}_j + b_{res})) \\ p_2(\tilde{y}^i_j = S_t) &= \frac{1}{Z} exp(\zeta_{sch} \cdot (\tilde{g}^i_t W_{sch}\tilde{o}_j) \\ p_3(\tilde{y}^i_j = \tilde{y}^{i-1}_t) &= \frac{1}{Z} exp(\zeta_{que} \cdot (q_t W_{que}\tilde{o}_j)) \end{aligned} \tag{6}$$

where $\mathbf{w}$ is the one-hot vector of word w. q_t and $\tilde{g}^i_t$ are query vector and schema item vector that are mentioned before. The final generation probability $p(\tilde{y}^i_j)$ is $p_1(\tilde{y}^i_j) + p_2(\tilde{y}^i_j) + p_3(\tilde{y}^i_j)$. Z is the normalization factor that ensures $\sum_{v \in V} p(v)$ is 1, where V is the whole vocabulary. The loss function is $\sum_i \sum_j -log(p(y^i_j))$

5 Implementation Details

We use Adam optimizer (Kingma and Ba, 2015) to optimize the loss function. The initial learning rate except BERT model is 1e-3, while the initial learning rate of BERT model is 1e-5. We use learning rate warmup over the first 1000 steps. The learning rate will be multiplied by 0.8 if the loss on development set increases and the token accuracy on development set decreases. The number of cross-turn schema interaction graph layer L_1 is 2, while the number of intra-turn schema graph layer L_2 is 1. The dimensions d_1 and d_2 are both 300. For encoder and decoder, the hidden size of the one layer LSTM and BiLSTM are 300. Besides, we use batch re-weighting to reweigh the loss function following (Suhr et al., 2018). For BERT embedding, following EditSQL, we use the pre-trained BERT base model in order to make fair comparison.

6 Experiments

6.1 Experiment Setup

Datasets. We conduct experiments on two large-scale cross-domain context-dependent SQL generation datasets, SParC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a). In comparison with previous context-dependent dataset ATIS (Dahl et al., 1994), SParC and CoSQL are more complex since they contain more databases and adopt a cross-domain task setting, where the databases of training set differ from that of development set and test set. Statistics of SParC and CoSQL are shown in Table 2.

Evaluation Metrics. Yu et al. (2018b) introduce exact set match accuracy to replace string match accuracy by taking queries with same constraints but different orders as the same query. In SParC and CoSQL, we use question match accuracy and interaction match accuracy as evaluation metrics. Question match accuracy is the average exact set match accuracy over all questions, while interaction match accuracy is the average exact set match accuracy over all interactions.

Baseline Models. We compare our model with following baseline models.

- **Context dependent Seq2Seq (CD S2S).** This model is originated in (Suhr et al., 2018) for ATIS dataset. Yu et al. (2019b) adapt this model to cross-domain setting by adding a BiLSTM to encode schema items and modifying the decoder to generate different schema items according to databases.

- **SyntaxSQL-con.** This model is originated in (Yu et al., 2018a), which utilizes SQL grammars for decoder. Yu et al. (2019b) adapt this model to context-dependent setting by adding LSTM encoders to encode historical user inputs and historical SQL queries.

- **EditSQL.** The model is proposed by (Zhang et al., 2019). In addition to modules for encoding historical user inputs and corresponding SQL queries, it also contains a copy mechanism to copy tokens from previous SQL queries.

6.2 Experiment Results

Results of these baseline models and our proposed IGSQL model are shown in Table 3. Our model surpasses the previous state-of-the-art model EditSQL.

Method	SParC Dev		SParC Test		CoSQL Dev		CoSQL Test	
	Ques	Int	Ques	Int	Ques	Int	Ques	Int
CD S2S	21.9	8.1	23.2	7.5	13.8	2.1	13.9	2.6

Extra	12.8	18.8	9.3	10.3

Table 5: Exact match accuracy w.r.t. different hardness level on development sets.

IGSQL achieves substantial improvement on question match accuracy by 3.5, 3.3 points on SParC development and test sets and 4.2, 1.7 points on CoSQL development and test sets, respectively. As for interaction match accuracy, IGSQL improves by 3, 4.2 points on SParC development and test sets, and 3.5, 1.3 points on CoSQL development and test sets. Results demonstrate the effectiveness of our model.

Table 4 shows the exact match accuracy of interaction with respect to different turn number. In both datasets, performances on interactions with one turn improve less. In SParC, performances on interactions with two turns and four turns improve the most, while in CoSQL, performances on interaction with two turns and larger than four turns improve the most. These results demonstrate that our database schema interaction graph encoder contributes to modeling schema items in conversational scenarios.

Table 5 lists the exact match accuracy with respect to different hardness level. Results in the table show that performance at each hardness level improves. The results indicate that capturing historical database schema information can not only improve the accuracy of easy questions, but also answer harder questions more accurately.

6.3 Ablation Study

In order to verify the usefulness of our database schema interaction graph encoder, we conduct several ablation experiments as follows.

w/o cross-turn schema interaction graph layer. In this experiment, we discard cross-turn schema interaction graph layers. In this setting, our model cannot encode historical database schema information.

w/o intra-turn schema graph layer. In this experiment, we discard intra-turn schema graph layers to examine whether these layers are useful.

GRU interaction layer. One of the most common way to employ historical information of database schema items is to update node representation directly from historical vector of the same node. For example, in Figure 2, we can use a GRU by taking representation of *Dogs.dog_id* at turn $i-1$ and its BERT embedding at turn i as input. The output of GRU is the vector of *Dogs.dog_id* at turn i. In this experiment, we use a GRU to replace cross-turn schema interaction graph layers.

Fully-connected interaction layer. To examine the effectiveness of our design of schema interaction graph, we make experiment that replaces the schema interaction graph with fully connected graph. Taking Figure 2 as an example, to update representation of blue node at turn i, there are edges connecting blue node at turn i to all nodes at turn $i-1$.

Since the test sets of SParC and CoSQL are not public, we carry out the ablation experiments only on development sets of these two datasets. Table 6 shows the results of ablation experiments. Our full model achieves about 2 points improvement compared with the model without cross-turn schema in-

Method	SParC		CoSQL	
	Ques Match	Int Match	Ques Match	Int Match
IGSQL	50.7	32.5	44.1	15.8
w/o cross-turn schema interaction graph layer	47.6(-3.1)	29.5(-3.0)	41.9(-2.2)	14.0(-1.8)
w/o intra-turn schema graph layer	50.2(-0.5)	31.1(-1.4)	42.9(-1.2)	14.0(-1.8)
GRU interaction layer	48.2(-2.5)	29.2(-3.3)	41.0(-3.1)	14.1(-1.7)
Fully-connected interaction layer	48.2(-2.5)	29.0(-3.5)	42.0(-2.1)	13.0(-2.8)

Table 6: Ablation study on development sets. Numbers in brackets are performance differences compared to IGSQL.

x^1	Which cartoon aired first?
EditSQL	SELECT title FROM cartoon ORDER BY original_air_date LIMIT 1
IGSQL	SELECT title FROM cartoon ORDER BY original_air_date LIMIT 1
y^1	SELECT title FROM cartoon ORDER BY original_air_date LIMIT 1
x^2	What was the last cartoon to air?
EditSQL	SELECT T1.title FROM cartoon AS T1 JOIN tv_channel AS T2 ON T1.channel = T2.id JOIN tv_series AS T3 ON T2.id = T3.channel ORDER BY T3.air_date LIMIT 1
IGSQL	SELECT title FROM cartoon ORDER BY original_air_date DESC LIMIT 1
y^2	SELECT title FROM cartoon ORDER BY original_air_date DESC LIMIT 1
x^3	What channel was it on?
EditSQL	SELECT channel FROM tv_series ORDER BY air_date LIMIT 1
IGSQL	SELECT channel FROM cartoon ORDER BY original_air_date DESC LIMIT 1
y^3	SELECT channel FROM cartoon ORDER BY original_air_date DESC LIMIT 1
x^4	What is the production code?
EditSQL	select T1.production_code FROM cartoon AS T1 JOIN tv_channel AS T2 ON T1.channel = T2.id JOIN tv_series AS T3 ON T2.id = T3.channel ORDER BY T3.air_date LIMIT 1
IGSQL	SELECT production_code FROM cartoon ORDER BY original_air_date DESC LIMIT 1
y^4	SELECT production_code FROM cartoon ORDER BY original_air_date DESC LIMIT 1

Table 7: An example of an interaction in CoSQL. x^i is the input sequence at i-th turn and y^i is the corresponding ground truth query. We show the predictions of EditSQL and IGSQL and mark the differences with red color.

teraction graph layers and the model with GRU interaction layer. Besides, our model achieves about 1 point improvement compared with the model without intra-turn schema graph layers. These results indicate that our cross-turn and intra-turn schema graph layers are very helpful.

The difference between cross-turn schema interaction graph layer and fully-connected interaction layer is how we add edges between nodes at turn $i-1$ and turn i. Compared to fully-connected interaction layer, the schema interaction graph introduces a distance restriction when adding edges. Our model with schema interaction graph performs substantially better, which shows that our design of schema interaction graph can significantly help our model to keep context consistency.

6.4 Case Study

In Table 7, we show an interaction with four turns. We also provide the predictions of EditSQL and IGSQL and mark the differences with red color. After the first turn, EditSQL confuses *cartoon.original_air_date* with *tv_series.air_date*. Our proposed IGSQL model successfully obtains answers in the correct order by taking historical information of database schema items into account.

7 Conclusion and Future work

In this paper, we focus on context-dependent cross-domain SQL generation task. We find that previous state-of-the-art model only takes historical user inputs and previously predicted query into consideration, but ignores the historical information of database schema items. Thus we propose a model named IGSQL to model database schema items in a conversational scenario. Empirical results demonstrate the efficacy of our model. We also conduct ablation experiments to reveal the significance of our database schema interaction graph encoder. For future work, we will explore methods attempting to solve hard and extra hard questions.

Abstract

In Natural Language Interfaces to Databases systems, the text-to-SQL technique allows users to query databases by using natural language questions. Though significant progress in this area has been made recently, most parsers may fall short when they are deployed in real systems. One main reason stems from the difficulty of fully understanding the users' natural language questions. In this paper, we include human in the loop and present a novel parser-independent interactive approach (PIIA) that interacts with users using multi-choice questions and can easily work with arbitrary parsers. Experiments were conducted on two cross-domain datasets, the WikiSQL and the more complex Spider, with five state-of-the-art parsers. These demonstrated that PIIA is capable of enhancing the text-to-SQL performance with limited interaction turns by using both simulation and human evaluation.

1 Introduction

The past few years have witnessed a burgeoning interest in the study of text-to-SQL, the essential technique for Natural Language Interfaces to Databases (NLIDB) systems (Guo et al., 2019; Hwang et al., 2019; He et al., 2019a; Bogin et al., 2019a,b). By converting natural language (NL) questions into executable forms (i.e., Structured Query Language or SQL), text-to-SQL parsers relieve users from the burden of learning about techniques behind the queries. Though significant progress has been made in this field, most parsers are still less than desirable when deployed in real NLIDB systems. As users are not experts in database querying, a central challenge for the parsers is to fully understand the users' NL questions.

Since users are who know the questions best, interacting with them has been seen as a promising way to tackle the above challenge in real NLIDB systems. Early works tried to get users involved in checking SQL queries (Li and Jagadish, 2014; Iyer et al., 2017; Yaghmazadeh et al., 2017), which are impracticable in real systems, as they can only succeed if users have a very good knowledge of SQL. In another attempt to involves users, Gur et al. (2018) proposed to interact with non-expert users by multi-choice questions. However, this approach is designed for relatively simple scenarios and cannot be easily applied to more complex ones. More recently, Yao et al. (2019) took an important step forward by measuring uncertainty of neural-based parsers and altering the behavior of them. However, as far as we know, most parsers in real systems are equipped with elaborate rules instead of using fully neural methods (Dhamdhere et al., 2017; Gliozzo et al., 2013; Lai et al., 2014). Moreover, in some situations, parsers are supplied by third parties, making it impossible to alter them. Therefore, assuming parsers are a black box, it is indispensable to conduct research on an interactive approach for enhancing the text-to-SQL technique in complex scenarios.

In this paper, we propose a **P**arser-**I**ndependent **I**nteractive **A**pproach (PIIA) to interact with human users and help parsers better understand NL questions. To achieve this goal, we devised three modules: (1) *Error Locator* employs an alignment method to help parsers locate uncertain tokens in the NL questions. (2) *Question Generator* designs multi-choice questions in natural language for users, which offers a pleasant interactive experience. (3) *NL Modifier* rewrites the NL questions according to the users' feedback and produces more legible questions to facilitate downstream parsing. Our major contributions are:

- We propose a novel interactive approach, named PIIA, to enhance the text-to-SQL for complex

SQL queries in a cross-domain scenario.

- The interaction process in PIIA is user-friendly that asks multi-choice questions and reduces the number of questions as much as possible.
- PIIA is designed as a parser-independent approach that can easily collaborate with arbitrary base parsers and be deployed in real systems.
- We conduct a series of experiments with five base parsers on two large cross-domain datasets that demonstrate the effectiveness of PIIA by using both simulation and human evaluation.

2 Methodology Overview

While querying databases in an NLIDB system, users pose a natural language question that is denoted as $\mathbf{x}$. The text-to-SQL parser takes $\mathbf{x}$ as input and predicts a SQL query, which is denoted as $\mathbf{y}$. The system then executes the predicted SQL and returns the result. As mentioned, users are not experts in database querying, so they may pose natural language questions with inexplicit expressions. To better understand the difficulties caused by inexplicit expressions, we carefully analyzed 300 mistakes made by IRNet (Guo et al., 2019), one of the state-of-the-art parsers on the Spider dataset (Yu et al., 2018b). We found that in 47.3% of the cases the parser couldn't understand database-related information, such as table and column names as well as values. Thus, we build PIIA upon parsers that can interactively revise inexplicit expressions in $\mathbf{x}$ with the help of users' feedback, thus enhancing the performance of text-to-SQL.

Our proposed PIIA, shown schematically in Figure 1, works between the user and the text-to-SQL parser and it consists of three modules, Error Locator, Question Generator and NL Modifier. After receiving $\mathbf{x}$ and $\mathbf{y}$, the Error Locator helps the parser find a set of uncertain tokens in $\mathbf{x}$. For each uncertain token, the Question Generator creates a natural language multi-choice question. After interactively asking the user all the multi-choice questions, the PIIA agent collects all the answers (i.e., the user's selections). Then, the NL Modifier corrects $\mathbf{x}$ based on the answers and obtains a more legible question $\hat{\mathbf{x}}$. Finally, by feeding modified question $\hat{\mathbf{x}}$ into the text-to-SQL parser, we can get a new predicted SQL query $\hat{\mathbf{y}}$. Compared to $\mathbf{x}$, $\hat{\mathbf{x}}$ combines user's feedback and contains clearer semantics. Hence $\hat{\mathbf{y}}$ is likely more accurate than $\mathbf{y}$. Note that, our PIIA agent will not read the contents of the databases (i.e., values) due to privacy concerns. Details of the three modules are presented in Sections 3, 4 and 5.

3 Error Locator

The goal of Error Locator is to detect the tokens in $\mathbf{x}$ that are hardly understood by the parser. These are called *Uncertain Tokens*, and in most cases are related to database information, such as table and column names as well as values. When the parser fails to understand them, the uncertain tokens will be mistranslated or ignored. Since the parser is a black box, the only information we can get from it is the predicted SQL. Hence, we devise a method to compare the NL question $\mathbf{x}$ with the predicted SQL $\mathbf{y}$. All the informative tokens in $\mathbf{x}$ may align with the corresponding tokens in $\mathbf{y}$, while the unaligned tokens in $\mathbf{x}$ are extracted as uncertain tokens. To this end, we firstly restate the predicted SQL $\mathbf{y}$ to an NL question $\mathbf{x}'$ through *SQL-to-Text Restatement*, and then perform *Token-to-Token Alignment* between $\mathbf{x}$ and $\mathbf{x}'$.

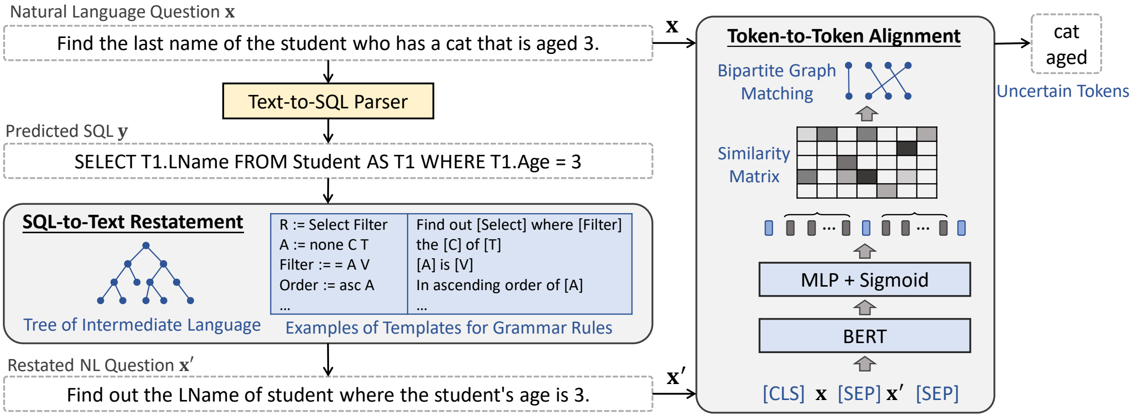

Figure 3: Illustration of Error Locator with a real case from IRNet on the Spider dataset. The NL question $\mathbf{x}$ is parsed to SQL $\mathbf{y}$, and then converted to restated NL question $\mathbf{x}'$ via SQL-to-text restatement. Then, a token-to-token alignment similarity matrix between $\mathbf{x}$ and $\mathbf{x}'$ is computed to detect uncertain tokens (i.e., cat and aged).

3.1 SQL-to-Text Restatement

Compared to aligning an NL question with a SQL query, the alignment of two NL questions is more reasonable because it utilizes a similar linguistic structure and can make better use of pre-trained models (e.g., BERT). Thus, before the alignment, we restate the predicted SQL $\mathbf{y}$ into a natural language question $\mathbf{x}'$. Previous work has proposed sequence-to-sequence based methods (Guo et al., 2018) that cannot ensure the restatement correctness. In contrast, we carefully design a template-based SQL-to-text method that solves this problem because the restatement correctness and integrality are critical for the alignment process.

Since SQL is execution-oriented, its clauses are about database operations. Some of the clauses may not be expressed in the users' NL questions, such as `GROUPBY` and `JOIN`. To bridge the gap between natural language and SQL, we design an intermediate language that is inspired by Guo et al. (2019) and whose grammar is shown in Figure 2. The predicted SQL can be easily converted into the intermediate language, which can be naturally represented by a hierarchical tree structure. Each tree node corresponds to a grammar rule. For each kind of grammar rule, we design a few natural language templates to describe it. Thus, we can recursively convert the tree into a natural language question. As for nested SQL queries, we utilize subordinate clauses with "that/which" to handle the subqueries. The SQL-to-text restatement is depicted on the left of Figure 3, along with a concrete example. We also give some examples of templates in the figure. Finally, the restated $\mathbf{x}'$ has the same semantics of SQL $\mathbf{y}$ and is independent of database internal operations.

3.2 Token-to-Token Alignment

Given the user NL question $\mathbf{x}$ and the restated NL question $\mathbf{x}'$, we perform the token-to-token alignment between them and find out the uncertain tokens in $\mathbf{x}$. As shown on the right of Figure 3, we adopt BERT (Devlin et al., 2019) as the encoder. BERT is pre-trained on a large corpus and equipped with the ability to encode sentences on the basis of contextual information. The input of BERT is the concatenation of the two questions with "[CLS]" and "[SEP]". Each token obtains an output vector from BERT, which is fed into a trainable Multi-Layer Perceptron (MLP) layer to further distill useful information. Assuming that $\mathbf{x}$ has N tokens and $\mathbf{x}'$ has M tokens, we can denote that $\mathbf{x} = (x_1, x_2, \ldots, x_N)$ and $\mathbf{x}' = (x'_1, x'_2, \ldots, x'_M)$. The output embeddings of tokens in $\mathbf{x}$ and $\mathbf{x}'$ can respectively be denoted by

$$\begin{aligned} H &= (\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_N) \quad \in \mathbb{R}^{d \times N}, \\ U &= (\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_M) \quad \in \mathbb{R}^{d \times M}, \end{aligned} \tag{1}$$

where d is the output embedding size.

Based on H and U, we employ the cosine similarity to derive a token-level similarity matrix $A \in \mathbb{R}^{N \times M}$, where each entry A_{nm} indicates the similarity between x_n and x'_m:

$$A_{nm} = \frac{\mathbf{h}_n^\top \cdot \mathbf{u}_m}{||\mathbf{h}_n|| \cdot ||\mathbf{u}_m||}. \tag{2}$$

The alignment between $\mathbf{x}$ and $\mathbf{x}'$ can be obtained using the similarity scores in A. After removing stop words and words from SQL-to-text restatement templates, we regard the similarity scores as the weights of a bipartite graph and apply the Hungarian maximum matching algorithm to find an optimized token-level one-to-one alignment. Finally, the tokens in $\mathbf{x}$ with alignment scores less than the threshold p are extracted as uncertain tokens. It is also important to note that a schema-aware post-processing is operated on these scores. Since the tokens that appear more than once in the database schema may confuse the alignment process, the post-processing aims to give addition bias and help Error Locator detect potential uncertain tokens[1].

3.3 Training Process

Since the annotations of token-to-token alignment are not available, fully supervised learning is infeasible. Inspired by the work of Legrand et al. (2016), we solve this problem by leveraging negative sampling to generate training data and adopt a weakly supervised training strategy. Concretely, we collect several pairs $(\mathbf{x}, \mathbf{x}'_{pos})$. $\mathbf{x}$ is the user NL question and $\mathbf{x}'_{pos}$ is the corresponding positive restated NL question restated from the ground truth SQL of $\mathbf{x}$. For each $(\mathbf{x}, \mathbf{x}'_{pos})$ pair, we generate negative restated NL questions $\mathbf{x}'_{neg}$ in two ways: random sampling, where we randomly pick an $\mathbf{x}'$ from other pairs as $\mathbf{x}'_{neg}$; and perturbed sampling, where we generate an $\mathbf{x}'_{neg}$ by replacing column names or/and value tokens in $\mathbf{x}'_{pos}$. The random samples are vastly different from $\mathbf{x}'_{pos}$, and the common tokens in positive and negative samples are uninformative (e.g., stop words). This kind of $\mathbf{x}'_{neg}$ helps distinguish the informative and uninformative tokens. The perturbed samples have the same uninformative tokens with $\mathbf{x}'_{pos}$, and help model to focus on the alignment of informative tokens. We generate 50 random samples and 50 perturbed samples for each $(\mathbf{x}, \mathbf{x}'_{pos})$ pair.

By generating negative samples, we obtain the training data composed of triples $(\mathbf{x}, \mathbf{x}'_{pos}, \mathbf{x}'_{neg})$. The intuition behind the weakly supervised training is that $\mathbf{x}$ is more similar to $\mathbf{x}'_{pos}$ than $\mathbf{x}'_{neg}$. We measure the sentence-level similarity by averaging the token-level similarities:

$$s(\mathbf{x}, \mathbf{x}') = \frac{1}{N} \sum_{n=1}^{N} \max_{m=1}^{M} A_{nm}. \tag{3}$$

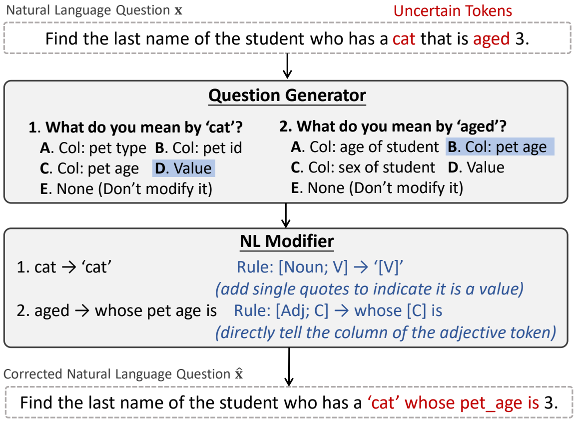

Figure 4: Question Generator and NL Modifier: an example. Shaded options in the multi-choice questions are selected by the user.

Then, our goal is to increase $s(\mathbf{x}, \mathbf{x}'_{pos})$ and decrease $s(\mathbf{x}, \mathbf{x}'_{neg})$. We employ hinge loss to maximize the margin of the two scores, which is also accompanied by L^1-norm on two corresponding similarity matrices to make them sparse. The loss function is:

$$\begin{aligned} L = &\max\big(0, m - (s(\mathbf{x}, \mathbf{x}'_{pos}) - s(\mathbf{x}, \mathbf{x}'_{neg}))\big) \\ &+ \lambda \left(|A_{pos}|_1 + |A_{neg}|_1 \right), \end{aligned} \tag{4}$$

Where m is the margin and λ balances the hinge loss and the L^1-norm.

4 Question Generator

For each uncertain token detected by the Error Locator, the PIIA agent interacts with the user to get a more explicit explanation. Instead of asking the user to explain the uncertain token directly, we provide an NL multi-choice question. As users are non-expert and unfamiliar with database operations, simply picking an option is more natural and friendly. Thus, the Question Generator is designed to generate a multi-choice question for each uncertain token[2], i.e., "What do you mean by that?" as shown in Figure 4.

To make a multi-choice question, a set of candidate options are generated. As analyzed in Section 2, most of the uncertain tokens are related to database information. Thus, for each uncertain token in an NL question, we find out the corresponding database and add all the column and table

---

[1] We lower the alignment score of a token (denoted as S) by the number of its occurrences (denoted as C) in the database schema (the score is lowered to S/C).

[2] During interaction, after getting an answer to a multi-choice question, we check the remaining uncertain tokens. If an uncertain token exists in the answer, we delete the corresponding multi-choice question to avoid repeating.

names into the candidate set. Additionally, we observe that some uncertain tokens are about aggregation operations, so we also add the aggregation operations into the candidate set, such as *min*, *max* and *sum*. As a result, the set is quite large, especially for complex databases. For example, the set size can be larger than 40 in the Spider dataset.

Hence, we devise a ranking method to find out the options with the highest correlations to the uncertain token. Concretely, for each candidate option (denoted by $\mathbf{w}$), we calculate its similarity score with the uncertain token (denoted by z). As each candidate option is a span with one or more tokens, we adopt both lexical and semantic similarities. $\mathbf{w}$ and z are pre-processed with lemmatization. Then the Jaccard distance between them is computed for lexical similarity, which is the number of common tokens divided by the number of unique tokens in them. For semantic similarity, we present each token as an embedding vector (i.e., GloVe (Pennington et al., 2014)) and employ the Euclidean distance between $\mathbf{w}$ and z. The embedding vector of a span is the average embedding over tokens in the span. All the candidate options are ranked by the summation of these two similarity scores, and three of them are picked as options. Additionally, we add two more options, *Value* and *None*, to each multi-choice question. *Value* indicates that z is related to a value in the database. *None* means that either the token does not need modification or all the other options are not related. The *None* option is essential as it prevents uncertain tokens from being modified unexpectedly. This alleviates the need for Error Locator to make exact error detection and ensures a higher recall rate. Following the example in Figure 3, we show the question generation process in Figure 4. As we can observe, the multi-choice questions are easy to be understood by non-expert users, and the provided options are reasonable. After interacting with users, the PIIA agent gets the information that “cat” is a value, and “aged” indicates the column “pet_age”.

5 NL Modifier

The last module of PIIA is the NL Modifier, which corrects NL questions with the users’ feedback, i.e., how users answer the multi-choice questions. The most straightforward way is to directly replace the uncertain tokens with the selected options. However, it is not always reasonable. Since the uncertain tokens can be not only nouns but also verbs or adjectives, directly replacing verbs or adjectives may cause incoherence. To avoid this problem, we carefully design several modifier rules according to different POS tags, option types, and user NL question contexts. As mentioned in Section 4, there are four option types: column name, table name, aggregation, and value. A concrete example is shown in Figure 4, where we also list the modifier rules that are applied. Since the noun “cat” is selected as a value, the single quotes are added. It is easier for the parser to recognize it as a value because values are always equipped with single quotes in the dataset. Moreover, as there are multiple columns about age in the database, the adjective “aged” is modified to “whose pet_age is” to make the column name easier to identify. Finally, the corrected NL question $\hat{\mathbf{x}}$ is fed into the text-to-SQL parser. More modifier rules and examples are shown in Table 3.

PIIA is designed to modify the user NL questions instead of the predicted SQLs. Modifying the predicted SQLs is more straightforward but impracticable. We conducted several surveys and found non-expert users had difficulty giving high-quality responses to modify SQLs directly, even for simple SQLs. Note that, the uncertain tokens found by PIIA are the unaligned tokens in NL questions, so the users’ feedback to uncertain tokens cannot be used to modify the corresponding SQLs.

6 Experiments

In this section, we firstly introduce the experimental setup. Then we assess PIIA by using both simulation and human evaluation, and finally we perform a closer analysis of PIIA.

6.1 Experimental Setup

We conduct experiments on two cross-domain text-to-SQL datasets with five base parsers.

The **WikiSQL** dataset (Zhong et al., 2017) collects 24,241 cross-domain single-table databases from Wikipedia and contains 80,654 hand-annotated pairs of NL questions and SQL queries. The SQL queries are relatively simple with only `SELECT` and `WHERE` clauses. Two parsers are selected: (1) **SQLova** (Hwang et al., 2019), currently the best open-sourced parser on WikiSQL, uses table-aware and context-aware representations of questions to generate SQL queries. (2) **SQLNet** (Xu et al., 2017) applies sequence-to-set prediction and employs a sketch-based approach to predict SQL queries. We report our PIIA results on the test set, which contains 15,878 samples.

The **Spider** dataset (Yu et al., 2018b) is a human-labeled text-to-SQL dataset that consists of 10,181 NL questions and 5,693 unique complex SQL queries on 200 databases with multiple tables. It covers 138 different domains and is much more complex than the WikiSQL dataset because it has a greater number of complex questions and nested SQL queries. Three parsers are selected: (1) **IRNet** (Guo et al., 2019), currently the state-of-the-art open-sourced parser on Spider, employs the coarse-to-fine framework (Dong and Lapata, 2018) and designs an intermediate language. (2) **IRNet+BERT** takes BERT as NL encoder to enhance the performance of basic IRNet. (3) **SyntaxSQLNet** (Yu et al., 2018a) employs a SQL specific syntax tree based decoder and table-aware column attention encoders. The test set is not publicly available, so we evaluate PIIA on the development set, which contains 1,034 samples.

In Error Locator, the similarity threshold is set to be the average score of all the $(\mathbf{x}, \mathbf{x}')$ pairs in the training triples $\mathcal{X} = \{(\mathbf{x}, \mathbf{x}'_{pos}, \mathbf{x}'_{neg})\}$ as follows:

$$p = \frac{1}{2|\mathcal{X}|} \sum_{(\mathbf{x}, \mathbf{x}'_{pos}, \mathbf{x}'_{neg}) \in \mathcal{X}} \left(s(\mathbf{x}, \mathbf{x}'_{pos}) + s(\mathbf{x}, \mathbf{x}'_{neg}) \right) .$$

This threshold score is generally lower than alignment scores of certain tokens and higher than that of uncertain tokens, which can help to distinguish certain and uncertain token alignment. For hyper-parameters, we set $m = 1$ and $\lambda = 0.5$. As for the NL Modifier, the NLTK pos tagging model (Loper and Bird, 2002) is employed for pre-processing.

6.2 Simulation Evaluation

We build a simulator to interact with the PIIA agent, which aims to give ideal selections for multi-choice questions. We report the results achieved by five base parsers.

Simulator The simulator chooses options on behalf of the real user. Given an NL question with T uncertain tokens, PIIA asks a multi-choice question with K options for each token. The simulator enumerates all K^T possible combinations of options and feeds them into the NL Modifier and the parser to get SQL queries. If one of these SQL queries is the same as the ground truth SQL, the simulator obtains the ideal selection. Otherwise, the PIIA fails to correct the NL question. Since it is too time-consuming to enumerate all K^T combinations, we only rank and simulate the top 100. Concretely, we firstly filter out options whose tokens do not appear in the ground truth SQL. Then we provide a score to each left option, as Question Generator does in Section 4. Finally, the overall score for a combination is computed by summing up all the option scores in the combination.

	Models	SQLAcc	ExeAcc	Avg.#T
WikiSQL	SQLova	80.7	86.2	N/A
	+PIIA	**84.9**	**88.9**	**1.3**
	SQLNet	61.7	68.0	N/A
	+PIIA	**68.4**	**73.2**	**1.7**
Spider	IRNet	53.2	N/A	N/A
	+PIIA	**59.3**	N/A	**2.9**
	IRNet+BERT	61.9	N/A	N/A
	+PIIA	**63.4**	N/A	**2.4**
	SyntaxSQLNet	27.2	N/A	N/A
	+PIIA	**34.2**	N/A	**3.4**

Table 1: Simulation results of PIIA on the WikiSQL test set and the Spider development set.

Model Comparison We evaluate PIIA with the simulator on both WikiSQL and Spider datasets. The results are shown in Table 1. For the WikiSQL dataset, we report the accuracy of SQL exact matching (SQLAcc) and the accuracy of execution (ExeAcc). We can observe that PIIA boosts the performance for both base parsers with fewer than two average interaction turns (Avg.#T). The absolute SQLAcc improvements for SQLova and SQLNet are 4.2% and 6.7% respectively, while the absolute ExeAcc improvements are 2.7% and 5.2%. The results on SQLNet are competitive with those of DailSQL (Gur et al., 2018), a parser-independent method designed for simple SQL. However, on average, PIIA interacts with users by 1.7 turns, while DialSQL needs about 4.8. This indicates that PIIA is quite efficient and able to enhance text-to-SQL with only a few interaction turns.

Similar performance boosts can be observed on the Spider dataset, which has more complex multi-table SQL queries. As execution results are not available, we only report the results of SQLAcc. The improvements on IRNet, IRNet+BERT and SyntaxSQLNet again demonstrate the effectiveness of PIIA. PIIA can also enhance the parser integrated with BERT, which further proves the necessity of PIIA. After interacting with users, PIIA provides the revised NL questions in a form that

Models	w/o PIIA	PIIA(H)	PIIA(S)	Avg.#T
IRNet	49.0	52.7	54.7	2.8
IRNet+BERT	60.7	62.2	62.7	2.4

Table 2: SQL Accuracy of human evaluation (H) and simulation (S) on 300 samples.

is easier for parsers to understand. The average interaction turns are about three, a number users find acceptable. Fewer interaction turns are required by better parsers. Additionally, a smaller improvement is obtained with a better parser, as better parsers know NL questions better. PIIA is effective because it utilizes the feedback provided by users, who know the questions best, thus leading to a further narrowing of the gap between parsers and users.

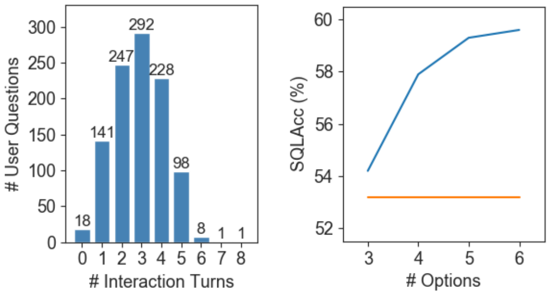
6.3 Human Evaluation

We carry out the evaluation of PIIA with real users. The human evaluation is performed on the more complex Spider dataset and with two state-of-the-art parsers, i.e., IRNet and IRNet+BERT. We randomly sample 300 NL questions from the Spider development set and invite 30 volunteers majoring in liberal arts to interact with the PIIA agent. Each NL question is evaluated by three volunteers, all of whom are non-expert without any background knowledge of SQL queries. We provide them with the NL questions and the corresponding databases, and they interact with PIIA by answering the multi-choice questions.

The SQLAcc results of the human evaluation are shown in Table 2. By interacting with real users, PIIA boosts the overall SQLAcc of both IRNet and IRNet+BERT by an absolute improvement of 3.7% and 1.5%, respectively. This indicates that PIIA provides a friendly way to interact with non-expert users, who are therefore able to understand the multi-choice questions and give proper answers. The average numbers of interaction turns are 2.8 and 2.4, respectively, which the users find acceptable. We also analyze the gap between human evaluation and simulation and find that some of the NL questions are ambiguous, making it hard for real users to distinguish similar options.

6.4 Closer Analysis

We use the IRNet parser on the Spider dataset to provide a closer analysis of PIIA. Similar observations can be obtained with other parsers.



(a)

(b)

Figure 5: (a) Turn distribution and (b) SQLAcc w.r.t number of options by IRNet+PIIA on the Spider development set. Orange line in (b) indicates the result without PIIA.

Number of Turns In interactive systems, the number of interaction turns mostly determines whether users have a positive experience as too many turns may tire them out. With that in mind, we figure out the distribution of the number of turns (i.e., the number of multi-choice questions) over the Spider development set. The distribution is shown in Figure 5(a) with the average number being 2.9. As observed, the interaction process finishes in four turns in nearly 90% of the cases. Only 10 out of 1,034 cases require an interaction process with more than five turns, which indicates PIIA is able to process such a complex dataset with high efficiency. We also analyze the cases correctly modified by the simulation and find that about 40% of the multi-choice questions get the *None* answer, which is an acceptable percentage. Additionally, the performance of our Error Locator is adequate. Though there are an average of 12.4 tokens in each NL question on the Spider development set, the Error Locator is able to find about three uncertain tokens out of them effectively.

Number of Options Providing a greater number of options in multi-choice questions increases the chances of including the correct one, thus enhancing the performance of the system. With more options, however, users have to make more effort. Therefore, we conduct experiments to analyze the influence of the number of options on the SQLAcc under simulation, as shown in Figure 5(b). The curve tends to be smooth after five options, meaning that this number is reasonable and able to balance the number of options and the need for correct ones. It's worth mentioning that each question contains two necessary options, i.e., *None* and *Value*,

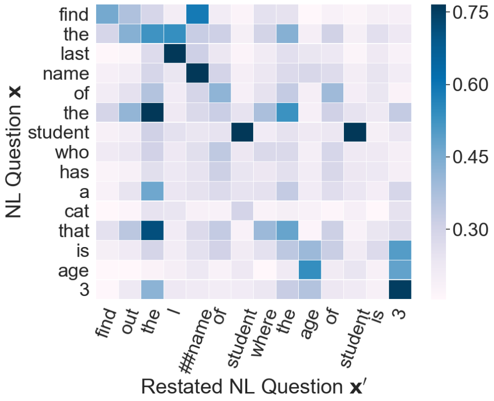


Figure 6: The similarity matrix of a real case.

so that the least number of options is three.

Similarity Matrix The Error Locator module is responsible for calculating a similarity matrix A between a user's NL question $\mathbf{x}$ and a restated NL question $\mathbf{x}'$. Following the example in Figure 3, we show the similarity matrix in Figure 6. "last name" is evidently more similar to the column name "lname" than to the others, which meets our expectations. Two uncertain tokens are extracted, namely "cat" and "age". They are not stop words, and their scores don't reach the threshold. Since the token "cat" is not expressed in the restated NL question, it has a low similarity score. Although "age" appears in the restated NL question, it exists in two column names in the database, i.e., "age" from the table "student" and "pet_age" from the table "pet". Thus the score of "age" is reduced and falls below the threshold.

Modifier Rules We carefully design the modifier rules for the NL Modifier based on the uncertain tokens and the selected options. Concretely, we take into consideration the types of options (column, table, value, or aggregation), the POS taggings of the uncertain tokens, and the contexts of the uncertain tokens. As shown in Table 1, PIIA with the NL Modifier improves the efficacy of IRNet SQLAcc from 53.2% to 59.3%. Instead of using the NL Modifier, we try a straightforward way to modify the NL questions that involves directly replacing the uncertain tokens with selected options. With this approach, the simulated SQLAcc stands at 54.8%, a result that is much worse than what PIIA can achieve with the NL Modifier, thus proving that our module is indispensable.

Case Study Table 3 shows more real cases of users' NL questions and corrected NL questions along with the corresponding modifier rules. The words in bold are uncertain tokens and their corrections. Though IRNet wrongly parses these six cases, PIIA manages to solve them correctly. The first five cases are modified by rules for nouns, verbs, and adjectives that are related to the column names in the databases. Different rules are applied to add the column names into NL questions, making it more explicit for the parser to understand them. Case 6 shows an example of how to modify the aggregation operator and the value-related tokens. PIIA revises the inexplicit NL questions by interacting with users. Equipped with the PIIA agent, the performance of the base parser is improved.

7 Related Works

The works most related to ours are those investigating interactive semantic parsing. For instance, DailSQL, proposed by Gur et al. (2018), aims to detect error spans and their categories based on an encoder-decoder architecture. But it is designed for relatively simple scenarios. In this research area, another impressive work involves a model-based interaction system, which detects uncertain tokens and asks questions relying on inner parser states (Yao et al., 2019). Unlike these studies, however, we design a parser-independent interactive approach that can also perform cross-domain complex SQL queries. In the field of applied systems, Gao et al. (2015) focused on user interface designing and proposed an interactive semantic parsing system called Datatone. In contrast to them, our main contribution lies in the realm of technology. Another topic our method related to is query reformulation. The idea of query reformulation is explored by Ray et al. (2018) and Rastogi et al. (2019), while they apply this idea in other domains with different scenarios. Our work is also related to semantic parsing, the process of converting natural language utterances into logical forms. Sequence-to-sequence methods are widely applied to solve this task (Berant et al., 2013; Dong and Lapata, 2016; Finegan-Dollak et al., 2018; Su et al., 2018). To reduce search space for decoding, several works employed intermediate representations to generate abstract representations (Cheng et al., 2017; Goldman et al., 2018; Dong and Lapata, 2018). Although these methods have achieved an impressive performance in experimental studies, there is still a long way to go before they can be successfully

1	User NL question:	List the creation year, name and **budget** of each department.
	Corrected NL question:	List the creation year, name and **budget in billions** of each department.
	Modifier Rule:	*[Noun; C] → [C] (replace the token with the whole column name)*
2	User NL question:	What are the **first names** of all the different drivers in alphabetical order?
	Corrected NL question:	What are the **forename** of all the different drivers in alphabetical order?
	Modifier Rule:	*[Noun; C] → [C] (detect the phrase and replace it with the whole column name)*
3	User NL question:	What is the type of the document **named** "David CV"?
	Corrected NL question:	What is the document type code of the document **whose name is** "David CV"?
	Modifier Rule:	*[Verb; C] → whose [C] is (directly tell the column name of the verb token)*
4	User NL question:	Where is the club "Hopkins Student Enterprises" **located**?
	Corrected NL question:	Where is the club "Hopkins Student Enterprises" **'s location**?
	Modifier Rule:	*[Verb; C] → 's [C] (directly tell the column name of the verb token, when the token is in the end of the sentence)*
5	User NL question:	Show the enrollment and primary_conference of the **oldest** college.
	Corrected NL question:	Show the enrollment and primary_conference of the **oldest founded** college.
	Modifier Rule:	*[Adj; C] → [Adj] [C] (directly add the column name of the adjective token)*
6	User NL question:	Give the **mean** GNP and total population of nations which are considered **US territory**.
	Corrected NL question:	Give the **average** GNP and total population of nations which are considered **'US territory'**.
	Modifier Rule:	*[Agg] → [Agg] (replace the aggregation token with the most similar aggregation word)* *[Noun; V] → '[V]' (add single quotes to indicate it is a value)*

Table 3: Cases by IRNet+PIIA on Spider. Texts highlighted in gray indicate column names in the databases.

applied in real systems.

Works dealing with the task of weakly supervised word alignment are also related to our research because our Error Locator module performs the same task. Some examples include the work of Liu and Sun (2015), who proposed a latent-variable log-linear model for word alignment, the research of Legrand et al. (2016), who used pairwise training with negative sampling to train the alignment model, and a study that introduced a gradient-based alignment method for machine translation (He et al., 2019b).

8 Conclusion and Future Work

We propose a parser-independent interactive approach, PIIA, to enhance the text-to-SQL process in NLIDB systems. PIIA interacts with users via multi-choice questions and can be built on arbitrary parsers. Experimental results show this approach leads to significant performance boosts on two cross-domain datasets with five different base parsers. In the future, we are interested in distilling and reusing the common knowledge from users' selections.

Abstract

Due to the lack of labeled data, previous research on text-to-SQL parsing mainly focuses on English. Representative English datasets include ATIS, WikiSQL, Spider, etc. This paper presents DuSQL, a larges-scale and pragmatic Chinese dataset for the cross-domain text-to-SQL task, containing 200 databases, 813 tables, and 23,797 question/SQL pairs. Our new dataset has three major characteristics. First, by manually analyzing questions from several representative applications, we try to figure out the true distribution of SQL queries in real-life needs. Second, DuSQL contains a considerable proportion of SQL queries involving row or column calculations, motivated by our analysis on the SQL query distributions. Finally, we adopt an effective data construction framework via human-computer collaboration. The basic idea is automatically generating SQL queries based on the SQL grammar and constrained by the given database. This paper describes in detail the construction process and data statistics of DuSQL. Moreover, we present and compare performance of several open-source text-to-SQL parsers with minor modification to accommodate Chinese, including a simple yet effective extension to IRNet for handling calculation SQL queries.

1 Introduction

In the past few decades, a large amount of research has focused on searching answers from unstructured texts given natural questions, which is also known as the question answering (QA) task (Burke et al., 1997; Kwok et al., 2001; Allam and Haggag, 2012; Nguyen et al., 2016). However, a lot of high-quality knowledge or data are actually stored in databases in the real world. It is thus extremely useful to allow ordinary users to directly interact with databases via natural questions. To meet this need, researchers have proposed the text-to-SQL task with released English datasets for model training and evaluation, such as ATIS (Iyer et al., 2017), GeoQuery (Popescu et al., 2003), WikiSQL (Zhong et al., 2017), and Spider (Yu et al., 2018b).

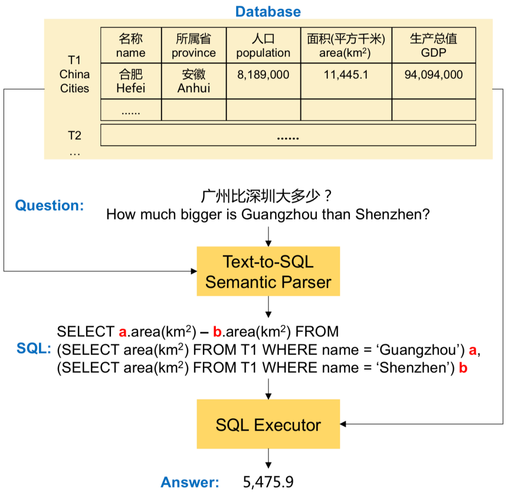

Figure 1: Illustration of the text-to-SQL task.

Formally, given a natural language (NL) question and a relational database, the text-to-SQL task aims to produce a legal and executable SQL query that leads directly to the correct answer, as depicted in Figure 1. A database is composed of multiple tables and denoted as DB $= \{T_1, T_2, ..., T_n\}$. A table is composed of multiple columns and denoted as $T_i = \{col_1, col_2, ..., col_m\}$. Tables are usually linked with each other by foreign keys.

The earliest datasets include ATIS (Iyer et al., 2017) , GeoQuery (Popescu et al., 2003), Restaurants (Tang and Mooney, 2001), Academic (Li and Jagadish, 2014), etc. Each dataset only has a single database containing a certain number of tables. All question/SQL pairs of train/dev/test sets are generated against the same database. Many interesting approaches are proposed to handle those datasets (Iyer et al., 2017; Yaghmazadeh et al., 2017; Finegan-Dollak et al., 2018).

However, real-world applications usually in-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6923–6935,
November 16–20, 2020. ©2020 Association for Computational Linguistics

volve more than one database, and require the model to be able to generalize to and handle unseen databases during evaluation. To accommodate this need, the WikiSQL dataset is then released by Zhong et al. (2017). It consists of 80,654 question/SQL pairs for 24,241 single-table databases. They propose a new data split setting to ensure that databases in train/dev/test do not overlap. However, they focus on very simple SQL queries containing one SELECT statement with one WHERE clause. In addition, Sun et al. (2020) released TableQA, a Chinese dataset similar to the WikiSQL dataset.

Yu et al. (2018b) released a more challenging Spider dataset, consisting of 10,181 question/SQL pairs against 200 multi-table databases. Compared with WikiSQL and TableQA, Spider is much more complex due to two reasons: 1) the need of selecting relevant tables; 2) many nested queries and advanced SQL clauses like GROUP BY and ORDER BY.

As far as we know, most existing datasets are constructed for English. Another issue is that they do not refer to the question distribution in real-world applications during data construction. Taking Spider as an example. Given a database, annotators are asked to write many SQL queries from scratch. The only requirement is that SQL queries have to cover a list of SQL clauses and nested queries. Meanwhile, the annotators write NL questions corresponding to SQL queries. In particular, all these datasets contain very few questions involving calculations between rows or columns, which we find are very common in real applications.

This paper presents DuSQL, a large-scale and pragmatic Chinese text-to-SQL dataset, containing 200 databases, 813 tables, and 23,797 question/SQL pairs. Specifically, our contributions are summarized as follows.

- In order to determine a more realistic distribution of SQL queries, we collect user questions from three representative database-oriented applications and perform manual analysis. In particular, we find that a considerable proportion of questions require row/column calculations, which are not included in existing datasets.

- We adopt an effective data construction framework via human-computer collaboration. The basic idea is automatically generating SQL queries based on the SQL grammar and constrained by the given database. For each SQL query, we first generate a pseudo question by traversing it in the execution order and then ask annotators to paraphrase it into a NL question.

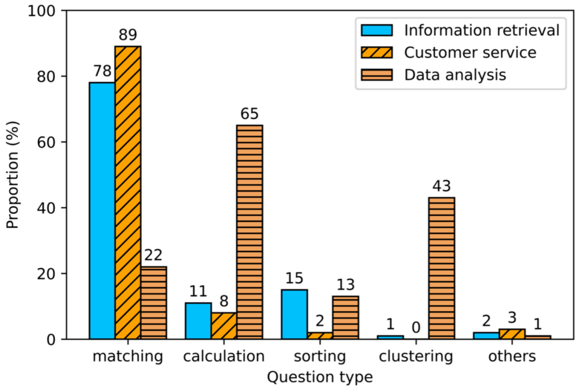

Figure 2: The SQL query distributions of the three applications. Please kindly note that a query may belong to multiple types.

- We conduct experiments on DuSQL using three open-source parsing models. In particular, we extend the state-of-the-art IRNet (Guo et al., 2019) model to accommodate the characteristics of DuSQL. Results and analysis show that DuSQL is a very challenging dataset. We will release our data at `https://github.com/luge-ai/luge-ai/tree/master/semantic-parsing`.

2 SQL Query Distribution

As far as we know, existing text-to-SQL datasets mainly consider the complexity of SQL syntax when creating SQL queries. For example, WikiSQL has only simple SQL queries containing SELECT and WHERE clauses. Spider covers 15 SQL clauses including SELECT, WHERE, ORDER BY, GROUP BY, etc, and allows nested queries.

However, to build a pragmatic text-to-SQL system that allows ordinary users to directly interact with databases via NL questions, it is very important to know the SQL query distribution in real-world applications, from the aspect of user need rather than SQL syntax. Our analysis shows that Spider mainly covers three types of SQL queries, i.e., matching, sorting, and clustering, whereas WikiSQL only has matching queries. Neither of them contains the calculation type, which we find composes a large portion of questions in certain real-world applications.

To find out the SQL query distribution in real-life applications, we consider the following three representative types of database-oriented applications, and conduct manual analysis against user questions. We ask annotators to divide user questions into five categories (see Appendix B for details), i.e., *matching*, *sorting*, *clustering*, *calculation*, and *others*.

Information retrieval applications. We use Baidu, the Chinese search engine, as a typical information retrieval application. Nowadays, search engines are still the most important way for web users to acquire answers. Thanks to the progress in knowledge graph research, search engines can return structured tables or even direct answers from infobox websites such as Wikipedia and Baidu Encyclopedia. From one-day Baidu search logs, we randomly select 1,000 questions for which one of returned top-10 relevant web sites is from infobox websites. Then, we manually classify each question into the above five types.

Customer service robots. Big companies build AI robots to answer questions of customers, which usually require the access to industrial databases. We provide a free trial API[1] to create customer service robots for developers. With the permission of the developers, we randomly select 1,500 questions and corresponding databases from their created robots. These questions cover multiple domains such as banks, airlines, and communication carriers, etc.

Data analysis robots. Every day, innumerous tables are generated, such as financial statements, business orders, etc. To perform data analysis over such data, companies hire professionals to write SQL queries. Obviously, it is extremely useful to build robots that allow financial experts to directly perform data analysis using NL questions. We collect 500 questions from our data analysis robot.

Figure 2 shows the query distributions of the three applications. It is obvious that calculation questions occupy a considerable proportion in all three applications. For customer service robots, users mainly try to search information, and therefore most questions belong to the matching type. Yet, 8% questions require calculation SQL queries to be answered. For data analysis robots, calculation questions dominate the distribution, since users try to figure out useful clues behind the data.

To gain more insights, we further divide calculation questions into three subtypes according to the SQL syntax, i.e., row calculation, column calculation, and calculation with a constant. Figure 3 shows some examples.

Row Calculation

How much bigger is Guangzhou than Shenzhen?

SELECT a.area(km^2) - b.area(km^2) FROM

(SELECT area(km^2) FROM T1 WHERE name = ‘Guangzhou’) a,

(SELECT area(km^2) FROM T1 WHERE name = ‘Shenzhen’) b

Column Calculation

What is the population density of Hefei?

SELECT population / area(km^2) FROM T1 WHERE name = ‘Hefei’

Calculation with a Constant

How old is Jenny?

SELECT curdate - birthday FROM student WHERE name = ‘Jenny’

How far is Beijing’s population from 23 million?

SELECT 23000000 - population FROM T1 WHERE name = ‘Beijing’

Figure 3: Examples in the calculation type, including questions and SQL queries. The first example of *calculation with a constant* is based on a database that has a “student” table with the schema of {*name, birthday, height, age*}. Other examples are based on the database in Figure 1.

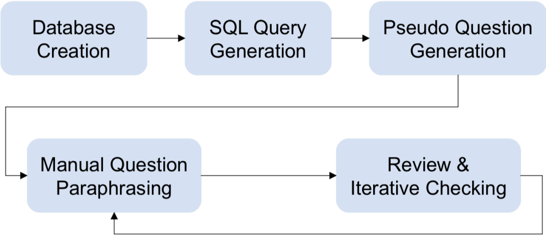

Figure 4: The construction workflow of DuSQL.

3 Corpus Construction

Building a large-scale text-to-SQL dataset with multi-table databases is extremely challenging. First, though there are a large amount of independent tables on the Internet, connections among the tables are usually unavailable. Therefore, great efforts are needed to create multi-table databases. Second, it is usually difficult to obtain NL questions against certain databases. Third, given a question and the corresponding database, we need proficient annotators to write a SQL query for the question who understand both the database schema and the SQL syntax.

Different from previous works, which usually rely on human to create both NL questions and SQL queries (Yu et al., 2018b), we build our dataset via a human-computer collaboration way,

---

[1] The API is publicly available at `https://ai.baidu.com/unit/v2#/innovationtec/home`.

as illustrated in Figure 4. The key idea is to automatically generate SQL queries paired with pseudo questions given a database. Then pseudo questions are paraphrased to NL questions by humans. Finally, to guarantee data quality, low-confidence SQL queries and NL questions detected according to their overlapping and similarity metrics, and are further checked by humans.

3.1 Database Creation

Most of mature databases used in industry are not publicly available. So we collect our databases mainly from the Internet. However, databases available on the Internet are in the form of independent tables, which need to be linked with other tables. We create databases in three steps: table acquisition, table merging, and foreign key creation.

We collect websites to crawl tables, ensuring that they cover multiple domains. As the largest Chinese encyclopedia, Baidu Baike contains more than 17 million entries across more than 200 domains. We start with all the entries in Baike as the initial sites, and extend the collection based on the reference sites in each entry page. We keep sites where tables are crawled. The final collection contains entries of Baike, annual report websites[2], vertical domain websites[3], and other websites such as community forums[4]. Table 1 shows the data distribution regarding database sources.

Source	Proportion
Baike	40.3
Vertical domain websites	31.3
Annual report	23.4
Others	5.0

Table 1: The distribution of database sources.

To make a domain correspond to a database, we merge tables with the same schema to a new table with a new schema, e.g., tables about China cities with the schema of $\{population, area, ...\}$ are merged to a new table with the schema of $\{termid, name, population, area, ...\}$, where $termid$ is randomly generated as primary key and $name$ is the name of the city. Meanwhile, we add a type for each column according to the form of its value, where the column type consists of text, number and date.

We create foreign keys between two tables via entity linking, e.g., a table named "Livable cities in 2019" with the schema of {*city_name, ranker, ...*} joins to a table named "China cities" with the schema of {*term_id, name, area, ...*} through the links of entities in "city_name" and "name". According to foreign keys, all tables are split into separate graphs, each of which consists of several joined tables. We choose 200 graphs to create databases, and manually check and correct foreign keys for each database.

Overall, we create 200 databases with 813 tables, covering about 70% of Baike entries from more than 160 domains such as movies, actors, cities, animals, foods, etc. Since some tables are sensitive, we use the column header of each table, and populate it with randomly selected values from the original table.

3.2 Automatic Generation of SQL Queries

Given a database, we want to generate as many common SQL queries as possible. Both manually writing SQL queries and quality-checking take a significant amount of time. Obviously, SQL queries can be automatically generated from the grammar. We utilize production rules from the grammar to automatically generate SQL queries, instead of asking annotators to write them. According to the difficulty[5] and semantic correctness of a SQL query, we prune the rule paths in the generation. Then, we sample the generated SQL queries according to the distribution in Figure 2 and carry out the follow-up work based on them.

As illustrated in Figure 5, the SQL query can be represented as a tree using the rule sequence of {*SQLs = SQL, SQL = Select Where, Select = SELECT A, Where = WHERE Conditions, ...*}, all of which are production rules of the grammar. Guided by the SQL query distributions in real applications, we design production rules to ensure that all common SQL queries can be generated, e.g., the rule of {*C = table.column mathop table.column*} allows calculations between columns or rows. By exercising every rule of the grammar, we can generate SQL queries covering patterns of different complexity.

We consider two aspects in the automatic SQL generation: the difficulty and semantic correct-

---

[2] QuestMobile, 199it, tianyancha, etc.

[3] State Statistical Bureau, China Industrial Information Network, Shopping websites, Booking websites, etc.

[4] Baidu Tieba, Newsmth, Hupu, etc.

[5] We observe that very complex queries are rare in search logs. Since our SQL queries are automatically generated, without complexity control, the proportion of complex queries would dominate the space, thus deviating from the real query distribution.

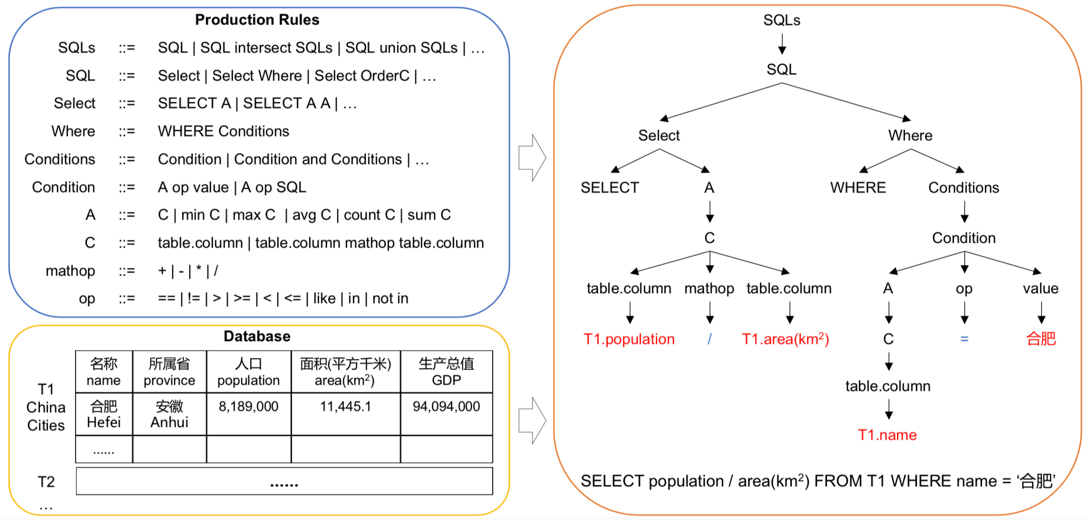

Figure 5: An example of SQL query generation from the grammar. We show a part of production rules (all rules are shown in Appendix A). The leaf nodes in red are from the database.

ness of a SQL query. To control the difficulty of the generated queries, we make some restrictions based on our analysis on real-life questions: first, a SQL query contains only one nested query; second, there are no more than three conditions in a where clause and no more than four answers in a select statement; third, a SQL query has at most one math operation; forth, most text values are from databases[6]. To ensure the semantics correctness of the generated query, we abide by preconditions of each clause and expression in the generation, e.g., the expression of {A > SQL} requires that the nested SQL returns a number value. The full list of preconditions is shown in Appendix C.

Under these requirements, we generate a large amount of candidate SQL queries against 200 databases. Among them, only a tiny proportion of SQL queries are of the calculation type, since only few columns support calculation operations. We keep all queries in the calculation type, randomly select ones with sorting and clustering types of the same size, and select ones with the matching type[7] of three times the size. We make sure that these selected queries are spread across all 200 databases. Then these queries are used as input for the follow-up work.

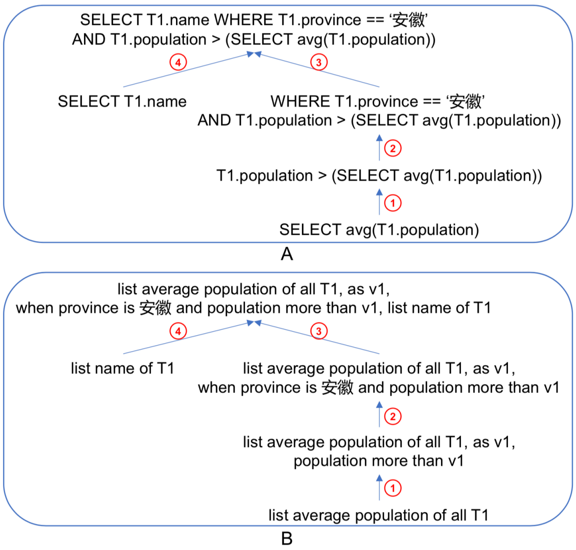

Figure 6: An example of the pseudo question generation according to the execution order of the SQL query. The numbers in circles represent the order of execution.

3.3 Semi-automatic Generation of Questions

For each SQL query, we automatically generate a pseudo question to explain it. Then pseudo questions are shown to annotators who can understand them and paraphrase them to NL questions without looking at databases and SQL queries.

We generate a pseudo question for a SQL query according to its execution order. As shown in Figure 6, the entire pseudo question of the SQL query consists of pseudo descriptions of all clauses according to their execution orders. The pseudo description of a clause consists of pseudo descriptions of all its components. We give a description

---

[6] The text values in a SQL query are from the database to reduce the difficulty of SQL prediction. We plan to remove this restriction in the next release version of DuSQL.

[7] Including combinations of matching type and other types, e.g., the SQL query of {SELECT ... WHERE ... ORDER BY ... } represents the combination of matching and sorting types.

for each component, e.g., *list* for *SELECT*, *average* for the aggregator of *avg*. Appendix D shows the descriptions for all components. To ensure that the pseudo question is clear and reflects the meaning of the SQL query, intermediate variables are introduced to express sub-SQL queries, e.g., "v1" in the example of Figure 6 represents the result of the nested query and is used as a value in other expressions.

We ask two annotators[8] to reformulate pseudo questions into NL questions[9], and filter two kinds of questions: 1) incomprehensible ones which are semantically unclear; 2) unnatural ones which are not the focus of humans[10]. During the process of paraphrasing, 6.7% of question/SQL pairs are filtered, among which 76.5% are complex queries. Then we ask other annotators to check the correctness of reformulated questions, and find 8% of questions are inaccurate.

3.4 Review and Checking

To guarantee data quality, we automatically detect low-quality question/SQL pairs according to the following evaluation metrics.

- **Overlap**. To ensure the naturalness of our questions, we calculate the overlap between the pseudo question and the corresponding NL question. The question with an overlap higher than 0.6 is considered to be of low quality.
- **Similarity**. To ensure that the question contains enough information for the SQL query, we train a similarity model based on question/SQL pairs. The question with a similarity score less than 0.8 is considered to be of low quality.

In the first round, about 18% of question/SQL pairs are of low quality. We ask annotators to check these pairs and correct the error pairs. This process iterates through the collaboration of human and computer until the above metrics no longer changing. It iterates twice in the construction of DuSQL.

3.5 Dataset Statistics

We summarize the statistics of DuSQL and other cross-domain datasets in Table 2, and give some examples in Figure 7. DuSQL contains enough question/SQL pairs for all common types. WikiSQL and TableQA are simple datasets, only containing matching questions. Spider and CSpider (Min et al., 2019) mainly cover matching, sorting, clustering and their combinations. There are very few questions in the calculation type, and all of them only need column calculations. Spider does not focus on questions that require the common knowledge and math operation. According to our analysis in Figure 2, the calculation type is very common, accounting for 8% to 65% in different applications. DuSQL, a pragmatic industry-oriented dataset, conforms to the distribution of SQL queries in real applications. Meanwhile, DuSQL is larger, twice the size of other complex datasets. DuSQL contains 200 databases, covering about 70% of entries in Baike and more than 160 domains, e.g., cities, singers, movies, animals, etc. We provide content for each database. All the values of a SQL query can be found in the database, except for numeric values. All table and column names in the database are clear and self-contained. In addition, we provide English schema for each database, including table names and column headers.

哪些城市首套房首付比例不少于20%？
Which cities have a down payment ratio no less than 20% for the first home?

```
SELECT 名称 FROM 城市 WHERE 首套房首付比例 >= 0.2
SELECT} name FROM city WHERE down_payment_ratio_first >= 0.2
```

占地最大的3个图书馆位于哪个城市？具体哪里？
Which cities are the 3 largest libraries located in? Where is the location?

```
SELECT T2.名称, T1.地址 FROM 图书馆 AS T1 JOIN 城市 AS T2
   ON T1.所属城市id = T2.词条id ORDER BY T1.面积 DESC LIMIT 3
SELECT T2.name, T1.address FROM library AS T1 JOIN city AS T2
   ON T1.city_id = T2.termid ORDER BY T1.area DESC LIMIT 3
```

哪些学校本科就业学生数等于所有高校本科就业人数的平均值？
For which university, the number of graduates for direct employment is equal to the average of all universities?

```
SELECT 名称 FROM 高校 WHERE 本科毕业人数 - 继续深造人数
   = (SELECT avg (本科毕业人数 - 继续深造人数) FROM 高校 )
SELECT name FROM college WHERE graduate_number - further_number
   = (SELECT avg (graduate_number - further_number) FROM college)
```

既有相关电视剧又有相关电影的皇帝有哪些？
List the emperors who appear both in TV dramas and movies?

```
(SELECT 帝王id FROM 电视剧) INTERSECT (SELECT 帝王id FROM 电影)
(SELECT emperor_id FROM tv) INTERSECT (SELECT emperor_id FROM movie)
```

Figure 7: SQL query examples.

4 Benchmark Approaches

All existing text-to-SQL works focus on English datasets. Considering that DuSQL is the most similar with Spider, we choose the following three representative publicly available parsers as our benchmark approaches, to understand the performance of existing approaches on our new Chinese dataset.

---

[8] They are full-time employees and familiar with SQL language. Meanwhile, they have lots of experience in annotating QA data.

[9] Some values in SQL queries are rewritten as synonyms.

[10] E.g., "*When province is Sichuan, list the total rank of these cities.*" for the SQL query {SELECT sum(rank) From T2 WHERE province = 'Sichuan'} is considered as an unnatural question, as *the total rank* would not be asked by humans.

Dataset	Size	DB	Table/DB	Matching	Sorting	Clustering	Calculation			Others
							Column	Row	Constant	
WikiSQL	80,654	26,251	1	80,654	0	0	0	0	0	0
TableQA	49,974	5,291	1	49,974	0	0	0	0	0	0
Spider	9,693	200	5.1	6,450	863	1,059	13	0	0	1,308
CSpider	9,691	166	5.3	6,448	862	1,048	13	0	0	1,318
Ours	23,797	200	4.1	6,440	2,276	3,768	1,760	1,385	1,097	7,071

Table 2: Statistics and comparisons of all existing cross-domain text-to-SQL datasets. The statistics of Spider are based on published data, only containing train and development sets. *Others* consists of combinations between matching, sorting and clustering types.

We also extend the state-of-the-art IRNet model of Guo et al. (2019) to accommodate the two characteristics of our data, i.e., calculation questions and the need of value prediction.

Seq2Seq+Copying (Zhong et al., 2017) incorporates the database schemas into the model input and uses a copying mechanism in the decoder.

SyntaxSQLNet (Yu et al., 2018a) proposes a SQL syntax tree-based network to generate SQL structures, and uses generation path history and table-aware column attention in the decoder.

IRNet (Guo et al., 2019) designs an intermediate representation called SemQL for encoding higher-level abstraction structures than SQL, and then uses a grammar-based decoder (Yin and Neubig, 2017) to synthesize a SemQL query. At present, IRNet reports the state-of-the-art results on Spider dataset.

Both SyntaxSQLNet and IRNet utilize a grammar to guide SQL generation and conduct experiments on Spider dataset. However, neither of their grammars can handle calculation questions. Another major difference between our dataset and Spider is that our evaluation metric (see Section §5) also considers value prediction, since values in a SQL query are from the corresponding question or database both of which are available inputs to the model. Please refer to our discussion in Section §3 for details. Due to the characteristics of our dataset, all the three models perform poorly on DuSQL. Therefore, we extend the IRNet model to accommodate DuSQL as follows.

Firstly, we extend the grammar of SemQL to accommodate the two characteristics of our dataset, as shown in Figure 8. The production rules in bold are added to parse calculation questions. Other production rules are modified based on original rules to support value prediction (Due to space limitation, we attach the full list of extended grammar in Appendix F.). Then we use all the n-grams of length 1-6 in the question to match database cells or number/date to determine candidate values for the predicated SQL query. The values are used in the same way as the columns and tables in the IR-Net model.

$$
\begin{array}{rcl}
\boldsymbol{Z} & ::= & +\,R\,R \mid -\,R\,R \mid \times\,R\,R \mid \div\,R\,R \\
\mathit{Filter} & ::= & =A\,V \mid !\!=A\,V \mid >A\,V \mid <A\,V \\
 & & \mid >=A\,V \mid <=A\,V \mid \mathit{like}\,A\,V \\
\mathit{Superlative} & ::= & \mathit{des}\,A\,V \mid \mathit{asc}\,A\,V \\
\boldsymbol{A} & ::= & \mathit{max}\,\mathit{MathA} \mid \mathit{min}\,\mathit{MathA} \mid \mathit{count}\,\mathit{MathA} \\
 & & \mid \mathit{sum}\,\mathit{MathA} \mid \mathit{avg}\,\mathit{MathA} \mid \mathit{none}\,\mathit{MathA} \\
\boldsymbol{MathA} & ::= & +\,A\,A \mid -\,A\,A \mid \times\,A\,A \mid \div\,A\,A \\
\boldsymbol{V} & ::= & \mathit{value}
\end{array}
$$

Figure 8: The extended grammar for SemQL.

5 Experiments

Data Settings Following WikiSQL, we split our dataset into train/dev/test in a way so that databases are non-overlapping among the three subsets. In other words, all question/SQL pairs for the same database are in the same subset. This is also referred to as cross-domain parsing problem, since some database schemes in dev/test do not appear in train. At last, 200 databases are split into 160/17/23, and 23,979 question/SQL pairs are split into 18,602/2,039/3,156.

Evaluation Metrics Evaluation metrics for the text-to-SQL task include component matching, exact matching, and execution accuracy. Component matching (Yu et al., 2018b) uses F1 score to evaluate the performance of the model on each clause. Exact matching, namely the percentage of questions whose predicted SQL query is equivalent to the gold SQL query, is widely used in text-to-SQL tasks. Execution accuracy, namely the percentage of questions whose predicted SQL query obtains the correct answer, assumes that each SQL query has an answer.

We use exact matching as the main metric, and follow Xu et al. (2017) and Yu et al. (2018b) to

Methods	Calculation				Matching	Sorting	Clustering	Others
	Column	Row	Constant	All				
IRNet	0	0	0	0	25.0	32.8	34.2	8.7
IRNetExt	22.0	34.3	37.9	29.7	52.1	68.7	60.8	52.5

Table 3: Performances of different SQL query types.

Methods	w/o values		w/ values	
	Dev	Test	Dev	Test
Seq2SeqCopying	6.6	3.9	2.6	1.9
SyntaxSQLNet	14.6	8.6	7.1	5.2
IRNet	38.4	34.2	18.4	15.4
IRNetExt	59.8	54.3	56.2	50.1
w/o calculation	50.2	48.2	46.6	45.6
w/o value	50.1	43.5	19.4	17.9

Table 4: Performance of the benchmark approaches.

handle the “ordering issue”. Finally, we give the model performance with (w) and without (w/o) value evaluation.

Main results. Table 4 shows performance of the benchmark approaches. The performance of Seq2SeqCopying is the lowest. It uses the copying mechanism to reduce errors posed by out-of-domain words in the databases of test set. But it predicts lots of invalid SQL queries with grammatical errors, since its decoder does not consider SQL structures at all.

SyntaxSQLNet and IRNet outperform Seq2SeqCopying by utilizing a grammar from SQL structures to guide SQL generation. In particular, IRNet utilize SemQL as an abstraction representation of SQL queries. However, neither of the two vanilla models handles calculation questions and value directions properly. The basic IRNet achieves only 34.2/15.4 accuracy on the test set w/o and w/ value evaluation.

We can see that by simply extending IRNet to parse calculation questions and predict values, the IRNetExt model achieves much higher accuracy (54.3/50.1).

Ablation study. We perform ablation study to gain more insights on the contribution of our extensions. As shown in table 4, the accuracy on test set drops 4.5 by excluding production rules from the grammar of SemQL. The accuracy of calculation type is 0, which composes 20.7% of the questions in the test set. After excluding the prediction of values, the test performance drops significantly for two reasons. First, there are a large number of questions that contain values, accounting for about 75% in the dev set and 70% in the test set. Second, the generation of where clauses can be improved by leveraging the column-cell relationship.

Analysis. Table 3 shows performance of different SQL query types. Firstly, the grammar extension is effective, the accuracy of all types is significantly improved. Second, the accuracy of calculation type is lower than that of other types, as many calculation questions require incorporating common knowledge, e.g., *age = dateOfDeath - dateOfBirth*. How to represent and incorporate such knowledge into the model is very challenging. Third, questions requiring common knowledge perform poorly, as they need understanding rather than matching, such as the matching issue of “the oldest” and “age”.

6 Related Work

Semantic parsing. Semantic parsing aims to map NL utterances into semantic representations, such as logical forms (Liang, 2013), SQL queries (Tang and Mooney, 2001), Python code (Ling et al., 2016), etc. In order to facilitate model training and evaluation, researchers release a variety of datasets. ATIS and GeoQuery are two popular early datasets originally in logical forms, and are converted into SQL queries (Iyer et al., 2017; Popescu et al., 2003). As two recently released datasets, WikiSQL (Zhong et al., 2017) and Spider (Yu et al., 2018b) have attracted extensive research attention. It is also noteworthy that Min et al. (2019) propose the CSpider dataset by translating English questions of Spider into Chinese.

Data construction methods. As discussed in Section §3, creating a large-scale semantic parsing dataset is extremely challenging. To construct Spider, Yu et al. (2018b) ask annotators to write both questions and SQL queries given a database. Both Iyer et al. (2017) and Herzig and Berant (2019) assume that the database and questions are given and try to reduce the effort of creating semantic representations. Our data construction is most closely related to Overnight (Wang et al., 2015), who proposes to automatically generate logical forms based on a hand-crafted grammar and ask annotators to paraphrase pseudo questions into NL questions. Overnight focuses on logic form (LF) based semantic representation, while our work on SQL representation. The differences are two-fold. First, databases of Overnight are much simpler, composed of a set of entity-property-entity triples. Second, LF operations of Overnight are much simpler, consisting of only matching and aggregation operations, such as count, min, max. Our dataset is more complex and thus imposes more challenges on the data construction.

Text-to-SQL parsing approaches. Seq2Seq models achieve the state-of-the-art results on single-database datasets such as ATIS and GeoQuery (Dong and Lapata, 2016). With the release of WikiSQL dataset, researchers make efforts to handle unseen databases by using database schema as inputs. Two mainstream approaches are the Seq2Seq model with copy mechanism (Sun et al., 2018) and the Seq2Set model (Xu et al., 2017). With BERT representations (Devlin et al., 2019), the execution accuracy exceeds 90% (He et al., 2019; Guo and Gao, 2019).

For the more challenging Spider dataset with multi-table databases, Guo et al. (2019) introduces an intermediate representation (SemQL) for SQL queries, and uses a grammar-based decoder to generate SemQL, reporting state-of-the-art performance. Bogin et al. (2019) proposes to encode the database schema with graph neural network. Recently, Wang et al. (2019) proposes RATSQL to use relation-aware self-attention to better encode the question and database schema simultaneously.

7 Conclusion

We present the first large-scale and pragmatic Chinese dataset for cross-domain text-to-SQL parsing. Based on the analysis on questions from real-world applications, our dataset contains a considerable proportion of questions that require row/column calculations. We extend the state-of-the-art IRNet model on Spider to accommodate DuSQL, and obtain substantial performance boost. Yet, there is still a large room for improvement, especially on calculation questions which usually require incorporation of common-sense knowledege into the model. For future work, we will continually improve the scale and quality of our dataset, to facilitate future research and to meet the need of database-oriented applications.

Figure 9: The production rules for SQL generation.

A The Grammar for SQL Generation

Figure 9 shows production rules used for SQL generation. All kinds of SQL queries can be generated by exercising each rule, e.g., the rule of {*Condition = A op SQL*} for nested query generation, the rule of {*C = table.column1 mathop table.column2*} and {*C = table1.column mathop table2.column*}for calculation query generation.

B Query Type Definition

Question classification is mostly based on the operations used in corresponding SQL queries. Matching means the answer can be directly obtained from the database. Sorting means we need to sort the returned results or only return top-k results. Clustering means we have to perform aggregations (count, min/max, etc.) on each cluster. Calculation means we need to calculate between columns or rows to get the answer. Other usually corresponds to questions requiring reasoning or subjective questions, e.g., "*Is Beijing bigger than Shanghai?*", and "*Is the ticket expensive?*". Figure 10 shows some examples for types in Figure 2, except for the calculation type (shown in Figure 3) and other type which do not have corresponding SQL queries.

Matching

List cities with a population less than 10 million.

SELECT name FROM T1 WHERE population < 10000000

Sorting

Give the top 5 cities with the largest population.

SELECT name FROM T1 ORDER BY population DESC LIMIT 5

Clustering

Give the total population of each province.

SELECT province, sum(population) FROM T1 GROUP BY province

Figure 10: Examples of types in Figure 2. All of them are based on the database in Figure 1.

C Preconditions in SQL Generation

To ensure the semantic correctness of the generated SQL query, we define the preconditions for each production rule, and abide by these preconditions in the SQL query generation.

- For the generation of SQL query with multiple SQLs, e.g., {*SQLs ::=SQL union SQLs*}: the columns in the select clause of the previous SQL match the columns in the select clause of the subsequent SQL, i.e., the columns of the two select clauses are the same or connected by foreign keys.

- For the rule of generating *GroupC*: the *C* is generated from the rule of {*C ::= table.column*}, where the column can perform the clustering operation, that is to say, the table can be divided into several sub-tables according to the values of this column.

- For the rule of {*Condition ::= A op value*}: $op \in \{<, <=, >, >=, =, !=, like\}$. If $op \in \{<, <=, >, >=\}$, *A* and *value* must be in the type of number or date. If *op* is *like*, *A* must be in text type.

- For the rule of {*Condition ::= A op SQL*}: $op \in \{<, <=, >, >=, =, !=, in, not\ in\}$. If $op \in \{<, <=, >, >=, =, !=\}$, *A* and *SQL* must be in the type of number, and {>= *min*, <= *max*} are invalid. If $op \in \{in, not\ in\}$, *SQL* must return a set.

- For the rule of generating *A*: {*avg C* | *sum C*} require the *C* is in number type, {*min C* | *max C*} require the *C* is in number or date type, and {*count C*} requires the *C* is in text type.

Dataset	Size	DB	Table/DB	Order	Group	Having	Nest	Calculation		
								Column	Row	Constant
WikiSQL	80,654	26,251	1	0	0	0	0	0	0	0
TableQA	49,974	5,291	1	0	0	0	0	0	0	0
Spider	10,181	200	5.1	1,335	1,491	388	844	13	0	0
CSpider	9,691	166	5.3	1,052	1,123	505	913	13	0	0
Ours	23,797	200	4.1	4,959	3,029	3,432	2,208	1,760	1,385	1,097

Table 5: Comparisons of cross-domain text-to-SQL datasets. The statistics of Spider are from Yu et al. (2018b). The statistics of CSpider are based on the released data.

- For the rule of {*C ::= t1.column mathop t2.column*}: the two columns are of the same type, either number or date. Then we have to make sure that the columns are comparable based on rules built by search log analysis.

- For the rule of {*C ::= t1.column1 mathop t1.column2*}: the numerical units of these two columns can perform corresponding mathematical operations, e.g., *CNY/per* × *person* = *CNY.*

D Descriptions of SQL Components

We provide a description for each basic component, as follows:

- The descriptions for aggregators of {*min, max, count, sum, avg*} are {*minimum, maximum, the number of, total, average*}.

- The descriptions for operators of {=, *!*=, >, >=, <, <=, *like, in, not in*} are based on the column type. The descriptions for {=, *!*=, *like, in, not in*} with the text type are {*is, is not, contain, in, not in*}, descriptions for {=, *!*=, >, >=, <, <=} with the number type are {*is equal to, is not equal to, more than, no less than, less than, no more than*}, and descriptions for {=, *!*=, >, >=, <, <=} with the date type are {*in, not in, after, in or after, before, in or before*}.

- The descriptions for math operators of {+, -, *, /} are {*sum, difference, product, times*}.

- The descriptions for the condition relations {*and, or*} are {*and, or*}.

- The descriptions for {*asc, desc*} are {*in the ascending, in the descending*}.

- The descriptions for columns, tables, and values are equal to themselves.

Meanwhile, we provide the description for each production rule, as shown in Figure 12.

```
          Z  ::=  intersect R R | union R R | except R R | R
                  | + R R | − R R | × R R | ÷ R R
          R  ::=  Select | Select Filter

Abstract

On the WikiSQL benchmark, state-of-the-art text-to-SQL systems typically take a slot-filling approach by building several dedicated models for each type of slots. Such modularized systems are not only complex but also of limited capacity for capturing inter-dependencies among SQL clauses. To solve these problems, this paper proposes a novel extraction-linking approach, where a unified extractor recognizes all types of slot mentions appearing in the question sentence before a linker maps the recognized columns to the table schema to generate executable SQL queries. Trained with automatically generated annotations, the proposed method achieves the first place on the WikiSQL benchmark.

1 Introduction

Text-to-SQL systems generate SQL queries according to given natural language questions. Text-to-SQL technology is very useful as it can empower humans to naturally interact with relational databases, which serve as foundations for the digital world today. As a subarea of semantic parsing (Berant et al., 2013), text-to-SQL is known to be difficult due to the flexibility in natural language.

Recently, by the development of deep learning, significant advances have been made in text-to-SQL. On the WikiSQL (Zhong et al., 2018) benchmark for multi-domain, single table text-to-SQL, state-of-the-art systems (Hwang et al., 2019; He et al., 2019) can predict more than 80% of entire SQL queries correctly. Most of such systems take a sketch-based approach (Xu et al., 2018) that builds several specialized modules, each of which is dedicated to predicting a particular type of slots, such as the column in `SELECT`, or the filter value in `WHERE`. Such dedicated modules are complex and often fall short of capturing inter-dependencies among SQL sub-clauses, as each type of slots is modeled separately. To deal with these drawbacks, this paper formulates text-to-SQL as mention extraction and linking problems in a sequence labeling manner (Section 2). In this new formulation, the key to synthesizing SQL is to extract the *mentions* of SQL slots and the *relations* between them. Consider the question and its corresponding SQL query in example (1), with the headers in the schema being {LANE, NAME, NATIONALITY, SPLIT (50M), TIME}.

(1) a. **Question**: What is the total sum of 50m splits for Josefin Lillhage in lanes above 8?
b. **SQL**: `SELECT SUM` (Split (50m)) `FROM` some_table `WHERE` Name = 'Josefin Lillhage' `AND` Lane $>$ 8

We can see that many SQL elements, or *slots*, such as `column` names of SPLIT (50M) and LANE, `values` like "Josefin Lillhage" and 8, as well as operators $>$ are mentioned with words similar in form and/or meaning. Moreover, the relations between the slot mentions, such as <lanes, above, 8> forming a filter condition, are represented by proximity in linear order or other linguistic cues. Thus, the recognition of the mentions and their relations would mostly reconstruct the intended SQL query from natural language question.

To this end, we leverage one unified BERT-based (Devlin et al., 2019) extractor (Section 2.1) to recognize the slot mentions as well as their relations, from the natural language questions. The output of the extractor can be deterministically translated into pseudo SQLs, before a BERT-based linker (Section 2.2) maps the column mentions to the table headers to get executable SQL queries. A major challenge to the proposed method is the absence of manual annotation of mentions and relations. Thus

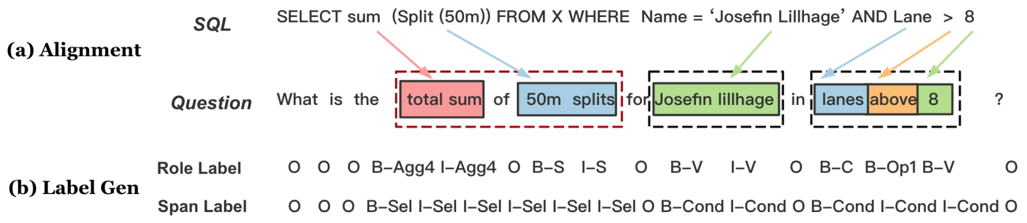

Figure 1: **Question sentence as mentions and relation of SQL slots.** (a) The mention of SQL slots (pink: the aggregation function, blue:columns, green: operators, yellow: values) and their relations (select relation and filter relation are shown in dashed rectangle). (b) Representing mentions with role labels and relations with span labels.

we propose an automatic annotation method (Section 2.4) based on aligning tokens in a SQL with corresponding question. Also, preliminary results show that the prediction of aggregation function (AGG) restricts model performance, which induces us to put forward AGG prediction enhancement (AE) method inspired by Brill (1995). Trained with such annotations and applied AE method, the proposed method can already achieves the first place on the WikiSQL benchmark.

The main contribution of this paper is the mention and relation extraction-based approach to text-to-SQL task. To the best of our knowledge, this is the *first* work that formulates the task as sequence labeling-based extraction plus linking, which enjoys the advantage of structural simplicity and interdependency awareness. In addition, we also propose an automatic method to generate annotations. Such annotations can be useful for developing novel methods for text-to-SQL, such as question decomposition-based approaches.

Role Type	**F-Labels**	**Example**
select column	S	*splits*: B-S
where column	C	*lanes*: I-C
value	V	*8*: B-V
agg. function	AGGi	*sum*: I-AGG4
operator	OPi	*above*:B-OP1
Span Type	**F-Label**	**Example**
SELECT span	Sel	*sum*:I-Sel
FILTER span	Cond	*lanes*:B-Cond

Table 1: **Labels for mention *roles* & relation *spans*.**

2 Method

2.1 Extractor

The extractor recognizes (1) *slot mentions*, including the SELECT column with aggregation function, WHERE columns with corresponding values and operators; and (2) *slot relations*, namely associating each WHERE column with its operator and value. Most of the SQL slots are mentioned in the question, as shown in Figure 1(a). As for the slot relations, note that the column, value and operator that form a filter condition relation usually appear in adjacency in the question, such as *in lanes above 8* in the example. Thus, the extraction of the relations is equivalent to the labeling of the corresponding *text span*. As shown in Figure 1(b), the extraction of mentions and relations can be represented by tagging each token in the question by a set of BIO labels. Formally, the label $l \in \{T \times \{B, I\}, O\}$, where $\times$ denotes the Cartesian product of T, the set of functional labels, and the set of positional label of {B, I}, where B and I means the beginning and the continuation of a particular annotation $t \in T$, respectively. The standing alone O label is assigned to tokens that are outside of any type of annotation of interest. For our task, we define two sets of labels: (a) the SQL *role labels* representing the slot mentions; (b) the *span labels* representing the slot relations, both of which are shown in Table 1. With these defined label set, the recognition of both slot mentions and slot relations are formulated as *sequence labeling*.

Extractor Model The model first encodes the question text and the table headers. As pre-trained language models such as BERT achieve state-of-the-art performance on various NLP tasks including sequence labeling, we adopt BERT to get contextualized representations for both role and span labeling. Similar to state-of-the-art methods for text-to-SQL such as SQLova (Hwang et al., 2019), we concatenate the question text along with the table header as input for BERT, in the form of $q_1, q_2, .., q_L$, `[SEP]`, $c_{1,1}, c_{1,2}, ...$, `[SEP]`, $c_{2,1}, ..., c_{M,1} ...$, where Q ($|Q| = L$) is the question while $C = c_1, .., c_M$ ($|C| = M$) are the table headers. Each header c_i may have multiple tokens, thus the 2-d indexes of $c_{i,j}$ being used.

Special `SEP` token is inserted between different headers c_i as well as between the question sentence Q and the first header c_1. As the labeling is w.r.t. the question sentence, the conditional random filed (CRF) (Lafferty et al., 2001) layer only is applied to the question segment. The full model is described as in equation (1), where BERT denotes the BERT model while CRF denotes a CRF layer.

$$\begin{aligned} Q^{\mathrm{B}}; C^{\mathrm{B}} &= \mathrm{BERT}([Q; C]) \\ Q^{att} &= \mathrm{Attention}(Q^{\mathrm{B}}, C^{\mathrm{B}}, C^{\mathrm{B}}) + Q^{\mathrm{B}} \\ L &= \mathrm{CRF}(W^L Q^{att}) \end{aligned} \tag{1}$$

Before the BERT representations are fed to the CRF layer, they first go through an *attention layer* (Bahdanau et al., 2014), which encodes the question tokens with columns in the schema. The resulting representation is added to the original token representation in an element-wise manner. Finally, the resulting token representations are fed to the CRF layer, which yields the label sequence. As the two labeling tasks can benefit each other, we fine-tune BERT in a multi-task learning way.

2.2 Schema Linking as Matching

The column mentions in the question sentence often differ with the the canonical column names in the table schema in terms of string forms, as shown in Figure 1, where SPLIT (50M) is mentioned as *50m splits* and NAME is not mentioned at all. The latter case is *implicit mention* of column, as only the value for the column, *Josefin Lillhage*, appears in the question. Such case is challenging yet not uncommon. To convert mention and relation extraction results to SQL, we need a schema linking module to link explicit and implicit column mentions to its canonical column names in the table schema. Formally, we define the linker as a text matching model, i.e. estimating a function $f([C_i; span; Q]) \rightarrow \{0, 1\}$, where C_i is a header in the table schema, $span$ is the either an extracted column mention (for linking explicit column mention) or an extracted value v (for linking implicit column mention). Special tokens of `[W]` and `[S]` are used to distinguish SELECT spans from FILTER spans. Again, BERT is used as the underlying model for its state-of-the-art performance on text matching. The matching procedure can be described as in equation (2).

$$\begin{aligned} v_i^{\mathrm{CLS}} &= \mathrm{BERT}([span; C_i]) \\ P(i) &= \mathrm{Sigmoid}(W v^{\mathrm{CLS}}) \end{aligned} \tag{2}$$

2.3 AGG prediction enhancement

Analysis of preliminary results suggests that aggregation function (AGG) prediction is a bottleneck for our system, which is partly attributed to the findings by Hwang et al. (2019) that AGG annotations in WikiSQL have up to 10% of errors. In such case, as our extractor model has to take care of other types of slots, these extra constraints make it more challenging for our model to fit flawed data, compared with a dedicated AGG classifier, as in most SOTA methods. Another reason may be that no all the aggregation functions are grounded to particular tokens. Given the characteristic of the data and the possible limitation of the information extraction-based model, we improve the AGG results over the original model, using only simple association signals in the training data. To this end, we adopt transformation-based learning algorithm (Brill, 1995) to update the AGG predictions based on association rules in the form of "change AGG from x to x', given certain word tuple occurrences." Such rules are mined and ranked from the training data by the algorithm.

2.4 Automatic Annotation via Alignment

A challenge for training the extractor is that benchmark datasets have no role or span annotations. Since manual annotations are costly, we resort to automatic ways. The idea is to annotate mentions by aligning the SQL slots in the query to tokens in the question. Figure 1 depicts such alignments with arrows and colors. Specifically, the proposed method is a two-step procedure. The first step is *alignment*, which runs two pass of aligning. The first pass conducts exact and partial string match to recognize values and some of the columns, while the second pass aligns the remaining SQL slots, by training a statistical aligner with the training set of the data. For this purpose, we choose Berkeley aligner (Liang et al., 2006), which works by estimating the co-occurrence of tokens in the parallel corpora, which are the question-SQL pairs in our case. As statistical aligner can occasionally yield null-alignment for a few tokens, we use another unsupervised word and semantic similarity-based algorithm (Perez et al., 2020) to complement the missing alignments. The second step is *label generation*, where the roles are generated according to aligned elements, while the span labels are assigned by considering minimal text span that covers all the elements in a SELECT/WHERE clause.

3 Experiment

Dataset and Metric. We use the largest human-annotated text-to-SQL dataset, WikiSQL Zhong et al. (2018), which consists of 80,654 pairs of questions and human-verified SQL queries. Tables appeared either in train or dev set will never appear in the test set. Two metrics in Zhong et al. (2018) are adopt for evaluating the SQL query synthesis accuracy: (1) *Logical Form Accuracy*, denoted as LF, where LF = # of SQL queries with correct logic form / total # of SQL queries; and (2) *Execution Accuracy*, denoted as EX, where EX = # of SQL queries with correct execution / total # of SQL queries. Execution guidance decoding (EG) (Wang et al., 2018) is used, following previous work.

Implementation Details. We use StanfordNLP (Qi et al., 2018) for tokenization. The word embeddings are randomly initialized by BERT, and fine-tuned during the training. Adam is used (Kingma and Ba, 2014) to optimize the model with default hyper-parameters. We choose uncased BERT-base pre-trained model with default settings due to resource limitations. The training procedures follows Hwang et al. (2019). Codes are implemented in Pytorch 1.3 and will be made publicly available [1].

3.1 Results

We compare our method with notable models that have reported results on WikiSQL task, including Seq2SQL(Zhong et al., 2018), SQLNet(Xu et al., 2018), TypeSQL(Yu et al., 2018a), Coarse-to-Fine(Dong and Lapata, 2018), SQLova(Hwang et al., 2019), X-SQL(He et al., 2019) and HydraNet (Lyu et al., 2020) in Table 2. Without EG, our method with BERT-base outperforms most of existing methods, including SQLova with BERT-large and MT-DNN (Liu et al., 2019a)-based X-SQL, and ranks right after HydraNet, which is based on RoBerTa (Liu et al., 2019b) large. Lyu et al. (2020) shows that RoBERTa large outperform BERT large in their setting and Liu et al. (2019a) shows MT-DNN also outperforms BERT in many tasks. Despite disadvantage in underlying pre-trained language model, our model achieves competitive results.

Model	Dev		Test	
	LF	EX	LF	EX
Seq2SQL	49.5	60.8	48.3	59.4
SQLNet	63.2	69.8	61.3	68.0
TypeSQL	68.0	74.5	66.7	73.5
Coarse-to-Fine	72.5	79.0	71.7	78.5
SQLova	81.6	87.2	80.7	86.2
X-SQL	83.8	89.5	83.3	88.7
HydraNet	83.6	**89.1**	83.8	**89.2**
this work - AE	81.1	86.5	81.1	86.5
this work	**84.6**	88.7	**84.6**	88.8
SQLova+EG	84.2	90.2	83.6	89.6
X-SQL+EG	86.2	92.3	86.0	91.8
HydraNet+EG	86.6	92.4	86.5	92.2

this work$_{EG}$	**87.9**	**92.6**	**87.8**	**92.5**

Table 2: **Accuracy of previous and this work**.

For the results with the EG in Table 2, our method outperforms all the existing methods, including SQLova, X-SQL and HydraNet, leading to new state-of-the-art in the SQL accuracies in terms of both logic form and execution. Table 3 shows the slot type-wise results, where our method achieves new state-of-the-art results on the W$_{col}$, W$_{val}$ and W$_{op}$ accuracies. Since the operators and values are directly derived from the extractor, such results are evidence for the effectiveness of our extraction-based approach. Before applying AGG enhancement (*AE*), the bottleneck of our method is on AGG prediction. We close such gap with *AE* using only word co-occurrence features. The improved AGG accuracy also leads to the new state-of-the-art for the overall SQL results. A limitation of our sequence labeling-based approach is that it performs passably on some questions with nested span structures, as in the question "When does the train [arriving at [Bourne]$_{\text{DEST}}$ at 11.45]$_{\text{TIME}}$ departure?" Since sequence labeling captures flat structures in nature, such cases raise challenges similar to the situation in nested NER.

Model	S$_{col}$	S$_{agg}$	W$_{no.}$	W$_{col}$	W$_{op}$	W$_{val}$

Estimating Annotation Quality. The quality of automatic annotation can be estimated in an *oracle extractor* setting, where the automatically annotated labels, instead of the extractor prediction, are fed to the linker. In this setting, the logic form and execution accuracy on the dev set reaches 92.8% and 94.2%, respectively, which are the ceiling for our approach. Note that such ceiling is above the human-level accuracy reported in Hwang et al. (2019), suggesting that the quality of the automatic annotation is reasonably good.

4 Related Work

Semantic parsing (Berant et al., 2013) is to map natural language utterances to machine-interpretable representations, such as logic forms (Dong and Lapata, 2016), program codes (Yin and Neubig, 2017), and SQL queries (Zhong et al., 2018). Text-to-SQL is a sub-area of semantic parsing, which is widely studied in recent years. Earlier work (Dong and Lapata, 2016; Krishnamurthy et al., 2017; Zhong et al., 2018; Sun et al., 2018; Wang et al., 2018) follow a neural sequence-to-sequence paradigm (Sutskever et al., 2014) with attention mechanism (Bahdanau et al., 2014). Pointer networks (Vinyals et al., 2015) are also commonly adopted. These sequence-to-sequence approaches often suffer the "ordering issue" since they are designed to fit an ordered sequence, while the conditions in WHERE-clause are unordered in nature.

SQLNet (Xu et al., 2018) introduces sketch-based method, which decomposes the SQL synthesis into several independent classification sub-tasks, including select-aggregation/column and where-number/column/operator/value. Except where-value, which is usually predicted by a pointer network, all the other sub-tasks use their own dedicated classifiers to make predictions. These sketch-based models raise challenges in training, deployment and maintenance. Moreover, each sub-module solves its own classification problem, without considering the dependencies with SQL elements modeled by other sub-modules. Recent advances (Yu et al., 2018a; Dong and Lapata, 2018; Hwang et al., 2019; He et al., 2019) follow this approach and achieve comparative results on WikiSQL, mostly by using pre-trained language models as the encoder.

While our sequence labeling method is also based on pre-trained language model, it differs from state-of-the-art methods in that it explicitly extracts mentions from the questions and can benefit from inter-dependency modeling between extracted mentions. The mentions for values, operators and corresponding columns often appear in proximity in the question, thus the sequence labeling model can better capture their dependencies and benefits the recognition for all of them, as experiment results suggest. Furthermore, our extractor-linker architecture is also much simpler than sketch-based methods.

Recent trend (Krishnamurthy et al., 2017; Guo et al., 2019; Wang et al., 2020; Choi et al., 2020) in academia starts to shift to multi-table and complex queries setting of text-to-SQL, as in the Spider task (Yu et al., 2018b). State-of-the art methods on Spider typically fall into two categories: *grammar-based approach* (Guo et al., 2019; Wang et al., 2020), and *sketch-based approach*, such as RYANSQL (Choi et al., 2020) and RECPARSER (Zeng et al., 2020). The latter ones have slot prediction modules similar to SQLNet for the WikiSQL, while recursion modules are introduced to handle the generation of complex SQL sketches, a characteristic in Spider but absent in WikiSQL. At a high level, our method is along the same line of SQLNet-RYANSQL, yet differs with them, as our method extracts slots in a unified way rather than using dedicated modules to predict each slot type. We can extend our method to the Spider task by following existing sketch construction methods as in RYANSQL, while replacing their slot classification modules with our extractor-linker methods.

5 Conclusion and Future Work

Thanks to the simple, unified model for mention and relation extraction and its capacity for capturing inter mention dependencies, the proposed method proves to be a promising approach to text-to-SQL task. Equipped with automatic-generated labels and AGG enhancement method, our model achieves state-of-the-art results on the WikiSQL benchmark. Since the current automatic-generated annotations are still noisy, it is useful to further improve the automatic annotation procedure. We also plan to extend our approach to cope with multi-table text-to-SQL task Spider.

Abstract

In existing sophisticated text-to-SQL models, schema linking is often considered as a simple, minor component, belying its importance. By providing a schema linking corpus based on the Spider text-to-SQL dataset, we systematically study the role of schema linking. We also build a simple BERT-based baseline, called **S**chema-**L**inking SQL (SLSQL) to perform a data-driven study. We find when schema linking is done well, SLSQL demonstrates good performance on Spider despite its structural simplicity. Many remaining errors are attributable to corpus noise. This suggests schema linking is the crux for the current text-to-SQL task. Our analytic studies provide insights on the characteristics of schema linking for future developments of text-to-SQL tasks.[1]

1 Introduction

Structured Query Language (SQL), while exact and powerful, suffers from a complex grammar presenting significant challenges for laymen to write queries. Automatically parsing natural language into SQL (text-to-SQL) thus has huge potential, as it would enable lay users to mine the world's structured data using natural language queries.

To achieve practical text-to-SQL workflow, a model needs to correlate natural language queries with the given database. Therefore, **schema linking** is considered helpful for text-to-SQL parsing (Guo et al., 2019; Bogin et al., 2019b; Dong et al., 2019; Wang et al., 2020). Here, schema linking means identifying references of columns, tables and condition values in natural language queries. For example, for the question "Find the names of schools that have a donation with amount above 8.5" (shown with relevant tables in Figure 1), "name" is a *column reference* to `school.name`, "donation" a *table reference* to `endowment`, and "8.5" and "sale" are *value references*, corresponding to the condition values in the SQL query.

Existing solutions largely treat *schema linking* as a minor component implemented with simple string matching (Guo et al., 2019; Yu et al., 2018a; Lin et al., 2019) heuristics to support sophisticated text-to-SQL models. An exception is Dong et al. (2019), which framed schema linking as a task to be solved by sequential tagging. While they did show the importance of schema linking, how it contribute to text-to-SQL task performance remains unanswered as there is no annotated corpus to analyze.

To address these shortcomings, we perform an in-depth study on the role of schema linking in text-to-SQL parsing. Intuitively, schema linking helps both *cross-domain generalizability* and *complex SQL generation*, which have been identified as the current bottlenecks of the text-to-SQL task (Finegan-Dollak et al., 2018; Yu et al., 2018c). By *cross-domain generalizability*, we refer to the proper separation of training and testing instances and databases, requiring a model to infer against with arbitrary databases where the schema and the domain are previously unknown. This means the model must be aware of what tables and columns are involved in the question — exactly what schema linking does. Schema linking indirectly addresses the *complex SQL generation* challenge: the writing of SQL queries comprising a mixture of `select`, `group by`, and nested clauses. Generating such queries requires the modeling of complex semantic dependencies in the input and to manage complex SQL grammar during decoding. As discussed in Dong et al. (2019), detecting and removing domain-specific words from the model's purview allows the model to focus on learning syntactic conversion between natural language and SQL, reducing the

Find the names of schools that have a donation with amount above 8.5.

```
select t2.name
from endowment as t1 join school as t2
on t1.school_id = t2.id
where t1.amount > 8.5
```

Show the ids and details of the investors who have a transaction with type code "sale".

```
select t1.id , t1.details
from investors as t1 join transactions as t2
on t1.id = t2.investor_id
where t2.type_code = "sale"
```

Figure 1: Two examples of schema linking. Column, table and value references are marked in red, yellow and green, respectively. The arrows of column and table references indicate their respective referents in the schema. For value references, the arrows point to the columns they compare with.

input's syntactic sparsity. For example, if we view the words linked with the schema as placeholders, the two natural language queries in Figure 1 can be deemed syntactically similar.

To perform a systematic data-driven study, we annotate and contribute ground truth schema linking data for the publicly-available training and development set of the Spider dataset (Yu et al., 2018c). We then build a simple BERT baseline, named **S**chema-**L**inking SQL (SLSQL), which links the schema in a natural language query and parses the SQL query with awareness of the predicted schema linking results. We systematically compare several variants of SLSQL, each of which utilizes schema linking differently. We find that schema linking always leads to better SQL parsing performance. But the performance of schema linking is far from perfect, even under supervised learning ($\leq$ 0.83 F1). To maximize the potential of schema linking, we study how SLSQL performs during inference when provisioned with oracle schema linking results (i.e., ground truth annotation). As such, we find our simple SLSQL model performs impressively on Spider — the remaining gap is largely due to corpus noise, including inconsistent patterns and errors in the dataset. This evidence points to schema linking as a critical task for text-to-SQL parsing, and also provides an indicative upper bound on performance on the Spider dataset. Interestingly, our analyses on the failure cases caused by model deficiencies reveal advanced challenges on the text-to-SQL task like *deep logical reasoning* and *extremely complex structure* (*c.f.* Section 5). Our annotated data enables us to address these challenges without the interference of the current noisy schema linker.

In summary, we contribute an annotation of schema linking and in-depth analyses on the role of schema linking in the text-to-SQL task. We identify schema linking as a crux for the further improvement of text-to-SQL parsing. Our analyses provide insights to advance the understanding of text-to-SQL parsing, facilitating future research on the areas of problem identification, dataset construction and model evaluation.

2 Related Work

Text-to-SQL Parsing: Text-to-SQL parsing has been long studied in past decades (Finegan-Dollak et al., 2018; Yu et al., 2018c). Early text-to-SQL systems rely heavily on complicated rules and handcrafted feature engineering (Zhong et al., 2017; Finegan-Dollak et al., 2018). Fortunately, the research progress has been largely accelerated in recent years thanks to both large-scale text-to-SQL datasets (Zhong et al., 2017; Yu et al., 2018c) and interests in neural modeling (Xu et al., 2017; Dong and Lapata, 2018; Sun et al., 2018; Yu et al., 2018b; Guo et al., 2019; Wang et al., 2020). With years of studies, current research on this task focuses on addressing cross-domain generalizability and generating complex SQL queries. To improve cross-domain generalizability, advanced representations of the schema and the queries are explored, e.g., graph-based schema representations (Bogin et al., 2019b,a), contextualized question representations (Hwang et al., 2019; Guo et al., 2019) and relation-aware self-attention (Wang et al., 2020). As for the complex SQL query generation, approaches are proposed to constrain the output with SQL grammar, e.g., modular decoders for separate SQL clauses (Yu et al., 2018b), intermediate language representation (Guo et al., 2019), recursive decoding for nested queries (Lee, 2019), schema-dependent grammar for SQL decoding (Lin et al., 2019), etc. Unlike their perspective, this work calls attention to schema linking, which we consider is the crux for the text-to-SQL task and yet to be sufficiently studied.

Schema Linking: The idea of schema linking has been broadly studied in similar tasks like entity linking in the field of knowledge graphs (Fu et al., 2020; Wu et al., 2019; Rijhwani et al., 2019; Logeswaran et al., 2019) and slot filling in dialogue systems (Xu and Hu, 2018; Ren et al., 2018; Nouri and Hosseini-Asl, 2018; Rastogi et al., 2017), where ample annotated data and models have been proposed to address their specific properties. In the general domain of semantic parsing, it has been demonstrated that decoupling underlying structure with lexicon benefits cross-domain semantic parsing (Su and Yan, 2017; Herzig and Berant, 2018). However, when it comes to the text-to-SQL problem, many existing approaches treat schema linking as a minor pre-processing procedure using simple heuristics, such as string matching between natural language utterances and column/table names (Guo et al., 2019; Yu et al., 2018a; Lin et al., 2019). As discussed in Dong et al. (2019), such simple heuristics are difficult to accurately identify columns/tables involved in a natural language utterance and well understand the relation between an utterance and the corresponding database schema. Therefore, they make the first step towards treating schema linking as an individual research problem. Nevertheless, due to the lack of direct schema linking supervision, they achieve limited improvement on the challenging Spider dataset, further illustrating the difficulties of this problem. Unlike these prior approaches, more recent models (Bogin et al., 2019a,b; Wang et al., 2020) integrate schema linking as a learnable component into the network, which brings significant improvements. In this work, we take one step further along this line to perform a thorough study by conducting schema linking annotation, discussing its importance and revealing its unique characteristics.

3 Schema Linking Annotation

To support a data-driven and systematical study, we annotate the schema linking information for each instance in the training and development set of Spider (Yu et al., 2018c) (the test set is hidden), the largest and most challenging text-to-SQL dataset so far. A simple way is conducting automatic annotation by matching table/column names and values in a ground truth SQL query against its corresponding natural language query. However, such automatic annotation method can bring much noise that would potentially hinder the model performance. Therefore, we annotate the dataset combining both automatic and manual processing.

Automatic Annotation: We first programmatically annotate the schema linking for easy cases to reduce the manual work. The string matching strategy we use is inspired by Guo et al. (2019). We first generate n-grams for each natural language query and only keep those with a length less than 6. For each condition value in a ground truth SQL query, we label the n-gram which it exactly matches. After labeling all n-grams matching with SQL condition values, we enumerate all unlabeled n-grams in the ascending order of length. If an n-gram contains all tokens in a column name, we label and regard this n-gram as a reference to that column. This process deals with cases where a column name is exactly mentioned or slightly paraphrased (e.g., column "type code" mentioned as "code of type"). However, a column/table name can also partially occur (e.g., column "type code" mentioned as "code"). To deal with such cases, we enumerate all unlabeled n-grams in descending order of length. If an n-gram contains any token in a column name, we label it as the reference to the corresponding column. Table reference labeling is conducted similarly.

Manual Annotation: We then recruit three computer science majors to further manually refine the automatic annotation. They are trained with a detailed annotation guideline and 50 trial samples. One is allowed to start after getting all trial samples correctly annotated. During the process, strict quality control is conducted by calculating their inter-annotator agreement (IAA)[2]. Specifically, the dataset is divided into 10 batches where instances in each batch are equally distributed to the annotators with 5% overlap. We accept a batch if the IAA is higher than 0.7 (at least 70% of the instances have exactly the same annotation by all three annotators); otherwise, the annotators are required to re-examine their annotations individually. Once a batch of annotation is accepted, we let the annotators discuss their disagreed annotations and come up with a final agreed result.

---

[2] In this work, we treat one instance as *agreed* if the three annotators have exactly the same annotations on it.

Category	Precision	Recall	F1
column	0.682	0.897	0.775
table	0.867	0.744	0.801
value	0.997	0.845	0.915

Table 1: The micro-average precision, recall and F1 of the automatic annotation using our final manual annotated data as the ground truth.

Analysis: To evaluate how noisy and coarse the automatic annotation is, we calculate its F1 score by treating the manually improved result as the ground truth (see Table 1). For value reference, some missing annotations are caused by abbreviation. For example, the text span "assistant professor" in a natural language query is abbreviated as `rank="AsstProf"` in the corresponding ground truth SQL query. For column and table reference, an issue is that it cannot deal with columns and tables are not textually referred to in the corresponding utterance. For example, the column `elevation` is mentioned as "altitude" in a sentence. Other issues of the automatic annotation are largely caused by similar column/table names.

4 Model

To conduct an in-depth study of the role of schema linking, we develop the SLSQL model, as depicted in Figure 2. It comprises a base model (the left part), which is based on the encoder–decoder structure, and an explicit schema linking component (the right part). While many sophisticated models have been proposed, we adopt this structure to leverage its simplicity to systematically analyze the factor of schema linking. In our experiments, we will study different variants of this structure by configuring the model in various ways.

Before the detailed model description, we first introduce our mathematical notations. We denote the natural language query Q as $Q = \{q_i\}_{i=1}^{|Q|}$, where q_i indicates the i^{th} token of Q and $|Q|$ indicates the length. Similarly, we denote the database schema E as $E = \{e_i\}_{i=1}^{|E|}$. It is the concatenation of a special token `[none]`, the name of each table and the names of its columns. Here, `[none]`, which we treat as a special element in the schema, is designed for schema linking — if a word in Q does not link to any column or table, it links to this token. In addition, we use MLP to mean multilayer perceptron, $\oplus$ to represent the concatenation operation, and bold symbols to denote dense representations.

4.1 Base Model

We now detail the base model which consists of an encoder and a decoder. The encoder (part ① in Figure 2) processes the input (i.e., Q and E) into hidden representation (denoted as $\boldsymbol{h}$) and the decoder (part ② in Figure 2) generates the SQL query (i.e, S) accordingly.

Encoder: Following (Hwang et al., 2019; Guo et al., 2019; Zhang et al., 2019), we concatenate the input query Q and database schema E to an integrated sequence as input for BERT (Devlin et al., 2019) to generate embeddings for each question token and element in the schema (namely $\boldsymbol{Q} = \{\boldsymbol{q_i}\}_{i=1}^{|Q|}$ and $\boldsymbol{E} = \{\boldsymbol{e_i}\}_{i=1}^{|E|}$) and the overall representation for the input as $\boldsymbol{h}$. Here, $\boldsymbol{E}$ consists of embeddings of all the columns/tables and the special token `[none]`. The embedding of the special token `[CLS]` in BERT is taken as $\boldsymbol{h}$. Formally, we have:

$$\{\texttt{[CLS]}, Q, E\} \rightarrow \boldsymbol{h}, \{\boldsymbol{q_i}\}_{i=1}^{|Q|}, \{\boldsymbol{e_i}\}_{i=1}^{|E|}. \tag{1}$$

Note that, in this representation, the schema linking information has also been captured by the multilayer self-attention implicitly. However, we argue the explicit supervisions are required. While a plausible solution is to use the relation-aware encoding proposed by Wang et al. (2020) to do this, we later propose a simpler solution to facilitate our analytical study.

Decoder: Inspired by the prior work (Yin and Neubig, 2017; Dong and Lapata, 2016, 2018; Zhang et al., 2019), we adopt a two-step decoder to generate the SQL query from the hidden representation $\boldsymbol{h}$. We first generate a coarse SQL query S', namely a SQL sequence without aggregate functions, using a GRU network (Cho et al., 2014). We then synthesize the final SQL query S based on S'. The ② part in Figure 2 illustrates the generation of aggregate functions for the column `budget` during the decoding process.

4.2 Schema Linking Extension

To study the role of schema linking, we extend the encoder to explicitly capture the schema linking information. It works in two steps: in step 1.1, we learn the explicit schema linking based on our annotation; in step 1.2, we learn $\boldsymbol{h}$, the overall representation for the input, by integrating our explicit schema linking results.

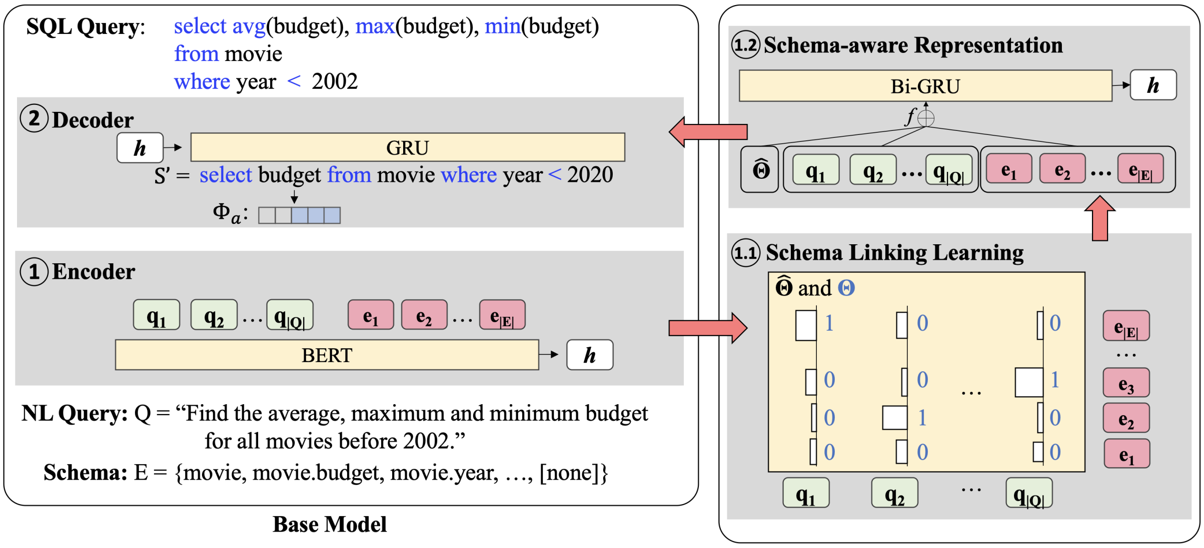

Figure 2: Schematic of our SLSQL model. The left part illustrates the base model, an encoder–decoder framework commonly used in the text-to-SQL task. The right part shows our extension of schema liking component.

Schema Linking Learning: We denote the ground truth schema linking distribution as Θ and the estimated one as $\hat{\Theta}$. We denote the linking probability of the token q_i and the schema element e_j as $\hat{\mathcal{P}}_{i,j}$, which is calculated as

$$\hat{\mathcal{P}}_{i,j} = softmax\Big[MLP(\boldsymbol{q_i} \oplus \boldsymbol{e_j})\Big] \tag{2}$$

where $1 \leq i \leq |Q|$ and $1 \leq j \leq |E|$. Therefore, the estimated schema linking distribution is formulated as $\hat{\Theta} = \{\hat{\mathcal{P}}_{i,j}\}_{1 \leq i \leq |Q|, 1 \leq j \leq |E|}$. The loss function of the schema linking step is defined as

$$\begin{aligned}\mathcal{L} = -\frac{1}{|Q||E|} \sum_{i=1}^{|Q|} \sum_{j=1}^{|E|} \big[\mathcal{P}_{i,j} \log \hat{\mathcal{P}}_{i,j} \\ +(1-\mathcal{P}_{i,j}) \log(1-\hat{\mathcal{P}}_{i,j})\big],\end{aligned} \tag{3}$$

where $\mathcal{P}_{i,j} \in \Theta$ is the ground truth value for each pair of q_i and e_j.

Schema-aware Representation: In step 1.2, we learn the schema-aware representation (i.e., $\boldsymbol{h}$) based on the predicted schema linking results (i.e., $\hat{\Theta}$), Q, and E. To cover the temporal relation, we use a bi-directional GRU to generate $\boldsymbol{h}$. Thus, the schema-aware representation is learned from

$$\boldsymbol{h} = \text{Bi-GRU}\Big[f(\hat{\Theta}, \boldsymbol{Q}, \boldsymbol{E})\Big], \tag{4}$$

where f is the reference mechanism. It is calculated by concatenating the embedding of q_i and the embedding of the schema element (including `[none]`) it likely links with. We here implemented it in a soft manner through weighted average embedding. Specifically,

$$f(\hat{\Theta}, \boldsymbol{Q}, \boldsymbol{E}) = \{\boldsymbol{q_i} \oplus \sum_{j=1}^{|E|} \hat{\mathcal{P}}_{i,j} \boldsymbol{e_j}\}_{i=1}^{|Q|}. \tag{5}$$

5 Experiments

In this section, we conduct systematic studies on the role of schema linking in text-to-SQL parsing. We examine several variants of SLSQL and thoroughly analyze the experimental results, providing detailed analyses and discussions to shed light on its unique characteristics.

5.1 Experiment Settings

Dataset: We conduct the experiments on the Spider (Yu et al., 2018c) dataset, a large-scale benchmark for cross-domain complex text-to-SQL task. Spider consists of 11,840 examples which are split into training (size: 7,000), development (size: 2,134) and test set (size: 1,034), covering 138 different domains. In addition, SQL queries in the dataset are categorized into four difficulty levels based on the number of SQL keywords. Models are evaluated using the official *exact matching accuracy* metric of Spider. We conduct ablation studies on the development set since the test set is used for scoring models on the leaderboard and is not publicly accessible.

Model Variants: To study the contribution of schema linking to the text-to-SQL parsing problem, we examine the following variants of SLSQL, each with one way of utilizing the schema linking information. To facilitate discussions, the model described in Section 4 is referred to as **default** in this section.

- **base model:** To evaluate the impact of explicit schema linking, we use the *base* model, as a variant, whose encoder is defined as EQ. (1) and followed by the decoder directly. Note there is no schema linking component in this variant.
- **auto:** To validate the advance of the manual annotation, we build this variant, which is trained with the automatic schema linking annotation in EQ. (3) instead of the manual annotation.
- **hard reference**: As introduced in Section 4.2, we generate schema-aware representation using reference mechanism f. Here, we further build this variant using hard reference concatenation. Specifically, instead of computing weighted average embeddings of all database schema elements as described in EQ. (5), we concatenate a question token embedding $\boldsymbol{q_i}$ with $\boldsymbol{e_j}$ which is the embedding of the schema element with the highest linking probability, i.e. $\hat{\mathcal{P}}_{i,j}$, to validate whether a different way of integrating schema linking information impacts the performance.
- **oracle:** To explore the maximum potential benefit of schema linking to the text-to-SQL task, we design the *oracle* variant. In this variant, we remove the schema liking learning component (step 1.1 in Figure 2), connect the encoder part with step 1.2 directly, and replace the estimated distribution $\hat{\Theta}$ with the ground truth distribution Θ in EQ. (4), namely, $\boldsymbol{h} = \text{Bi-GRU}\big[f(\Theta, \boldsymbol{Q}, \boldsymbol{E})\big]$. Like the *auto* variant, we build the *oracle_auto* variant using the automatic annotation instead.

Implementation Details: We use Stanford CoreNLP (Manning et al., 2014) to preprocess the corpus. We implement SLSQL in PyTorch (Paszke et al., 2017). We use the pre-trained uncased BERT-Base model with 12 layers provided by Wolf et al. (2019). We use Adam (Kingma and Ba, 2014) with the learning rate set to 5×10^{-5} and batch size set to 4. Considering the ablation studies have to be conducted on the development set due to the model submission policy of Spider (at most 2 models are allowed for evaluation on the hidden test set), all hyperparameters are tuned on the training set. The model converges within 20 epochs.

Model		**SL**	**Dev**	**Test**
SLSQL	default	0.81	61.4	55.0
	hard_ref	0.80	60.8	55.7
	base	-	57.4	-
	auto	0.77	59.2	-
	oracle	1.0	**72.4**	-
	oracle_auto	0.83	65.7	-
GlobalGNN (Bogin et al., 2019b)		-	52.7	47.4
EditSQL (Zhang et al., 2019)		-	57.6	53.4
IRNet (Guo et al., 2019)		-	61.9	54.7
Bertrand-DR (Kelkar et al., 2020)		-	57.9	54.6
RYANSQL (Choi et al., 2020)		-	70.6	60.6
RATSQL (Wang et al., 2020)		-	69.7	**65.6**

Table 2: Exact matching accuracy of our model variants and other recently published text-to-SQL models which are evaluated on Spider. The *default* and *hard_ref* variants are evaluated on the hidden test set. For each variant, we report their overall schema linking F1 score (denoted as **SL**) on the development set by treating the manual annotation as the ground truth.

5.2 Overall Performance Analysis

Table 2 shows the performance of SLSQL and other recent models evaluated on Spider. We can observe that there is a strong positive correlation between the schema linking performance and the exact matching accuracy. For example, without schema linking, SLSQL-*base* has the lowest exact matching accuracy among all variants. By comparing the three variants with a trained schema linking component (*default*, *hard_ref* and *auto*), we find that training SLSQL models with higher quality annotations leads to better performance (*default* & *hard_ref* v.s. *auto*), while using soft or hard concatenation for propagating schema linking information does not make a significant difference (*default* v.s. *hard_ref*). As expected, feeding SLSQL with Θ rather than $\hat{\Theta}$ during inference leads to a significantly higher result (*oracle* and *oracle_auto*). Similarly, using the manual annotation instead of the automatic annotation for the oracle setting largely improves the model performance.

We also list top models on the Spider leaderboard for reference in Table 2. As we do not aim at putting effort in building sophisticated models, our *default* and *hard_ref* variants cannot compete with the state-of-the-art models like RYANSQL (Choi et al., 2020) and RATSQL (Wang et al., 2020). However, the *oracle* variant shows that a simple model has the potential to sharply outperform these strong models (on the development set), by improving schema linking performance, which shows an important future direction. We will have further discussions on this issue in Section 5.5.

Variant	easy	medium	hard	extra	all
default	79.6	66.6	49.4	33.5	61.4
hard_ref	79.2	66.4	48.9	31.8	60.8
base	77.6	60.0	47.1	31.8	57.4
auto	77.2	64.1	48.3	31.2	59.2
oracle	**89.5**	**75.1**	**66.1**	**46.4**	**72.4**
oracle_auto	86.0	70.2	53.4	36.5	65.7

Table 3: Exact matching accuracy by difficulty on the development set of Spider.

Reference	Precision	Recall	F1
column	0.826	0.820	0.823
table	0.806	0.840	0.822
value	0.773	0.741	0.757

Table 4: Schema linking results of different references categories on the development set of Spider. Precision, recall and F1 scores are micro-averaged.

World Knowledge	Ex.1	Q:	How many languages are spoken in Aruba?
		G:	`country.name` - *value*
		P:	`countrylanguage.language` - *value*
	Ex.2	Q:	. . . in African countries that are republics?
		G:	`country.government_form` - *colum*
		P:	*none*
Semantic Understanding	Ex.3	Q:	. . . average rank for winners in all matches?
		G:	`matches.winner_rank` - *column*
		P:	`ranking.rank` - *column*
	Ex.4	Q:	. . . names of students who have no friends?
		G:	`highschooler` - *table*
		P:	*none*
Type Error	Ex.5	Q:	List all the student details . . .
		G:	`student.other_student_details` - *column*
		P:	`student` - *table*

Table 5: Representative erroneous schema linking predictions. Notations Q, G, P stand for question, ground truth and prediction, respectively. Reference types are in italics and *none* means not being a reference.

5.3 Can Schema Linking Help Manage Complex Queries?

To have further insights on how schema linking can help complex queries, we investigate detailed model performance under different difficulty levels. Table 3 presents the result. We can observe that, generally schema linking helps boost the performance of SLSQL across all different difficulty levels (*base* v.s. other variants). More accurate schema linking predictions lead to more significant accuracy improvements. For example, the *oracle* variant, which has access to the manual annotation, achieves the highest score on all different difficulty levels. Besides, *default* and *hard_ref* outperform the *auto* variant trained with automatic annotation on all difficulty levels, thanks to the higher quality of schema linking annotation.

5.4 Schema Linking Performance Analyses

To have a better understanding of the schema linking task itself, we test its performance for SLSQL-*default* and list some representative wrong predictions, as shown in Table 4 and Table 5. We observe that, with the model trained with explicit supervision, the F1 scores for column, table and value linking are still far from satisfactory, demonstrating that schema linking is not an easy task and requires future efforts to improve.

Particularly, linking value references with the schema is the most difficult part as its F1 score is the lowest. We find most of wrong value predictions are due to the lack of world knowledge. As shown in Ex.1, the model mistakenly predicts Aruba as a language instead of a country. In Ex.2, the model fails to understand that "republic" is a government form. We find that, despite using BERT as underlying language understanding module, the model still has difficulty in dealing with some of such value reference linking. To help the model accurately link value references with the schema, a solution can be scanning the content stored in the database, as applied in some prior work (Bogin et al., 2019b; Wang et al., 2020), to facilitate the model inference. The motivation behind it is that "Aruba" occurs in the column `country.name` instead of `countrylangauge.language` or `city.name`. However, in real scenarios, database contents are not always accessible to text-to-SQL models and condition values mentioned in human utterances do not necessarily exist in the database (Zhong et al., 2017). An alternative solution can be looking for external knowledge resources which easily identify that the word "republic" is related to "government form", as adopted in Guo et al. (2019). Nevertheless, such solution relies heavily on the quality and availability of knowledge resources, making the model less portable for practical use. Most of the remaining errors have commonalities with wrong table/column reference linking, in terms of causes.

When it comes to column and table reference linking, we find the error sources are complex, which mainly include failing to capture semantic relations between words and tables/columns and predicting other linking types. We observe that sometimes the model is biased towards predicting columns/tables that exactly occur in an utterance while neglecting more global information. As shown in Ex.3, the model links the word "rank" to the column `ranking.rank` while the correct choice should be `matches.winner_rank` if considering more global information. In addition to neglecting global semantic information, failing to capture semantic similarity between words is another cause of errors such as the case shown in Ex.4. We find that some of such issues are caused by the WordPiece tokenization (Wu et al., 2016) in BERT. For example, it tokenizes "highschooler" as "highs ##cho ##ole ##r" while tokenizing "high schooler" as "high school ##er", which is the cause of this case. Besides, columns can have common words with their table names, making the model mistakenly predict some part of a column reference as a table reference (or vice versa) in some cases like Ex.5. However, with such linking errors, the model usually is still able to finally generate desired SQL queries, which means they typically are not as harmful as other errors described above.

Fortunately, many of the aforementioned problems have been extensively studied in similar tasks such as zero-shot entity linking in knowledge graph tasks (Wu et al., 2019; Logeswaran et al., 2019; Rijhwani et al., 2019; Fu et al., 2020) and domain adaptive slot filling in dialogue system domains (Xu and Hu, 2018; Rastogi et al., 2017; Ren et al., 2018; Nouri and Hosseini-Asl, 2018). With annotated data, there is an ample room to transfer these approaches, which are mostly based on supervised learning, to the schema linking problem for further improving the text-to-SQL parsing ability.

5.5 Error Analysis of the Oracle Variant

To further investigate what the remaining problems lie on, provided that schema linking can be done perfectly, we conduct error analyses using the *oracle* variant. We randomly sample 100 error instances on the development set. We analyze the errors and classify them into three categories: *Correct Equivalent*, *Corpus Error* and *Model Incapability*. Considering many examples in the dataset have textually similar questions, erroneous predictions having the same cause are counted once during analysis. This process is repeated for five times and we take the average percentage for each error type. We find many errors are due to the the corpus noises, namely the first two error types. Table 6 provides representative examples for each category. We now detail the three error categories.

Correct Equivalent: One SQL query can have several semantic equivalents with different writing patterns. We find that in the Spider dataset, it is not always consistent that which of such patterns is given as the ground truth. We identify some SQL queries generated by SLSQL are actually semantically correct while treated as wrong predictions due to not only co-existence of different SQL writing patterns in the training set but also the exact matching evaluation. According to our manual verification, such false negative samples take up around 30% of the sampled errors. Ex.1 shows a case where two SQL queries are semantically equivalent, despite different writing patterns. There are also some inconsistent patterns in particular clauses like `group by`, as illustrated in Ex.2. Such errors suggest that either pattern consistency or more flexible, robust evaluation metric should be focused on for future dataset construction.

Corpus Error: After carefully examining each sampled errors, we also identify around 26% of them are caused by incorrectly annotated example in the dataset, e.g., wrong ground truth SQL queries, incomprehensible utterances, problematic database schemas, etc. As shown in Ex.3, "greater area than that of any country" is indeed logically equivalent to "greater than the maximum area of all countries", while the ground truth SQL query means "greater area than that of some countries". Some of these errors are even hard to identify as incorrect ground truth at first glance. Ex.4 looks like a correct equivalent case while actually the ground truth SQL query is wrong. Moreover, we find typos in natural language queries can lead to incorrect SQL queries. For example, one instance has a text span "the sname of every sing" in the natural language query which we believe should be "the name of every song". While better data annotations definitely result in better SQL parsing performance, such errors suggest a robust text-to-SQL parser should be tolerant of noises like typos and grammatical errors, which is an important but overlooked problem for real application.

Model Incapability: Even with oracle schema linking annotation, SLSQL is yet to be perfect. We find about 44% of the failing instances are due to modeling incapability. Many problems lie in the requirement of *deep logical reasoning* and *extremely complex structure*. Considering the case shown in Ex.5, the model directly translates the word "and"

Correct Equivalent (29.6%)	Ex.1	Q:	What are the names of people who **do not play poker**?
		G:	select name from people where people_id **not in** (select people_id from poker_player)
		P:	select people.name from people **except** select people.name from poker_player join people
	Ex.2	Q:	For **each shop**, return the number of employees working there and the name of the shop.
		G:	select count(∗), t2.name from hiring as t1 join shop as t2 on t1.shop_id = t2.shop_id group by t2.**name**
		P:	select shop.name, count(∗) from shop join hiring on hiring.shop_id = shop.shop_id group by shop.**shop_id**
Corpus Error (26.3%)	Ex.3	Q:	Which countries have **greater area than that of any country** in Europe?
		G:	select name from country where surface_area > (select **min**(surface_area) from country where continent = 'Europe')
		P:	select name from country where surface_area > (select **max**(surface_area) from country where continent = 'Europe')
	Ex.4	Q	Find the number of concerts happened in the stadium **with the highest capacity**.
		G:	select **count**(∗) from concert as t1 join stadium as t2 order by t2.capacity **desc limit 1**
		P:	select count(∗) from stadium join concert where stadium.capacity = (select max(capacity) from stadium)
Model Incapability (44.1%)	Ex.5	Q:	What is the total surface area of the continents Asia **and** Europe?
		G:	select sum(surface_area) from country where continent = 'Asia' **or** continent = 'Europe'
		P:	select sum(surface_area) from country where continent = 'Asia' **and** continent = 'Europe'
	Ex.6	Q:	How many countries speak **both** English and Dutch?
		G:	select count(∗) from (select t1.name from country as t1 join countrylanguage as t2 where t2.language = 'English' intersect select t1.name from country as t1 join countrylanguage as t2 where t2.language = 'Dutch')
		P:	select count(∗) from countrylanguage where countrylanguage.language = 'English' intersect select count(∗) from countrylanguage where countrylanguage.language = 'Dutch'

Table 6: Representative examples of the three error types and their average percentages during sampling. Notations Q, G and P stand for question, ground truth and prediction, respectively. Some `on` clauses are omitted for display.

into the SQL keyword *and*, leading to a SQL query with contradictory conditions. Although this query is classified as "medium" by the Spider evaluation script, it is actually difficult as it requires a model to perform logic reasoning based on the understanding that a country cannot be in Asia and Europe at the same time. A similar case is "singers with birth year before 1945 and after 1955" where a numeric comparison is required to avoid generating contradictory `where` conditions. Ex.6 is a case of extremely complex structure where three logical steps are required to synthesize the SQL query, i.e., 1) selecting English-speaking countries and Dutch-speaking countries; 2) finding their intersection using `intersect`; and 3) counting the intersection size with an outer query. Unfortunately, the model writes a plausible but wrong SQL query.

Discussion: The above results and analyses suggest that, with schema linking well solved, even a simple BERT baseline can capture quite a large portion of the patterns in the Spider dataset. This indicates that schema linking is the crux for current research on text-to-SQL task, providing an appealing perspective to this task. Also, through experiments and analyses with schema linking annotation, some previously unnoticed challenges like *deep logical reasoning* and *extremely complex structure* have emerged, also pointing further research directions. Such problems were interwoven with schema linking problems in the original Spider dataset. Our schema linking annotation makes it possible for such problems to be separately approached without the interference of database schemas.

6 Conclusion

We critically examine the role of schema linking for the text-to-SQL task. To support model-independent and thorough studies, we invest human resources to annotate schema references and contribute a high-quality, large-scale schema linking corpus. Experimenting with our designed Schema Linking SQL (SLSQL) model, we demonstrate that more accurate schema linking conclusively leads to better text-to-SQL parsing performance. Importantly, given oracular schema references, a simple BERT model like SLSQL can achieve an impressive performance. Our experiments show that schema linking, often overlooked as simple preprocessing, is actually a requisite for good SQL parsing performance, providing an intriguing perspective for future improvements on this task. Our study sheds light on the characteristics of text-to-SQL parsing for future efforts including advanced modeling, problem identification, dataset construction and model evaluation.

A Model Details

A.1 Encoder Implementation

For each example, we concatenate all the column/table names, a special token `[none]` and the natural language query, separated by `[SEP]`, as the input sequence to BERT. Here the special token `[none]` is designed for the subsequent schema reference resolution that we will introduce later. For each column, we concatenate the column name with its table name, separated by a dedicated symbol `[#]`, as its canonical string representation. If a word is tokenized into multiple pieces by the BERT tokenizer, the embedding of the first piece is taken as the corresponding word embedding. Representations of columns and tables are computed through a GRU (Cho et al., 2014) which takes as input their word embeddings generated by BERT.

A.2 Decoder Implementation

The decoder of SLSQL is largely based on the work of Zhang et al. (2019) and uses the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015). For ease of readability, we define the attention function $attention(\mathrm{Q}, \mathrm{K})$ as follows:

$$\begin{aligned} \text{score}_i &= \mathrm{QWK}_i \\ \alpha &= softmax(\text{score}) \\ \text{output} &= \sum_i \alpha_i \mathrm{K}_i \end{aligned} \tag{6}$$

where $\mathbf{W}$ is a learnable weight. At each decoding step t, we generate the next hidden state $\mathbf{h}_{t+1}$ as follows:

$$\mathbf{h}_{t+1} = \mathrm{GRU}\big([\mathbf{k}_t; \mathbf{s}_t; \mathbf{c}_t]\big) \tag{7}$$

where $\mathbf{k}_t$ is the embedding of the clause keyword at step t, which can be `select`, `from`, `where`, etc. We denote the embedding of the generated SQL query token at step t as $\mathbf{s}_t$. The context vector $\mathbf{c}_t$ is the concatenation the context of column/table and the context of natural language question.

$$\mathbf{c}_t = [\mathbf{c}_t^{\text{col/tbl}}; \mathbf{c}_t^{\text{q}}] \tag{8}$$

Here, the context of column/table $\mathbf{c}_t^{\text{col/tbl}}$ is obtained as follows:

$$\begin{aligned} \mathbf{e}_{i,j}^{\text{q}} &= [\mathbf{e}_i; \mathbf{q}_j; \mathbf{f}_i] \\ \tilde{\mathbf{e}}_i^{\text{q}} &= attention(\mathbf{k}_{t-1}, \mathbf{e}_i^{\text{q}}) \\ \mathbf{c}_t^{\text{col/tbl}} &= attention(\mathbf{h}_t, \tilde{\mathbf{e}}^{\text{q}}) \end{aligned} \tag{9}$$

where $\mathbf{e}_i$ is the embedding of i-th column/table. Here, $\mathbf{f}_i$ is a feature vector that consists of binary features such indicating whether i-th column/table is a primary key or a foreign key column, etc. We have the context of question as follows:

$$\mathbf{c}_t^{\text{q}} = attention(\mathbf{h}_t, \tilde{\mathbf{q}}) \tag{10}$$

where $\tilde{\mathbf{q}}$ is the reference-aware question representation. At the decoding step t, the SQL query token $\mathbf{y}_t$ is predicted as follows.

$$\begin{aligned} \text{score}_i^{\text{col/tbl}} &= MLP\big([\mathbf{h}_t; \tilde{\mathbf{e}}_i^{\text{q}}; \mathbf{c}_t^{\text{q}}]\big) \\ \text{score}^{\text{kw}} &= MLP\big([\mathbf{h}_t; \mathbf{c}_t^{\text{q}}]\big) \\ P(\mathbf{y}_t) &= softmax\big([\text{score}^{\text{col/tbl}}; \text{score}^{\text{kw}}]\big) \end{aligned} \tag{11}$$

If $\mathbf{y}_t$ is a clause keyword (e.g., `select`, `from`, `where`, etc.), we set $\mathbf{k}_{t+1}$ as the embedding of $\mathbf{y}_t$. Otherwise, it will remain as is. If $\mathbf{y}_t$ is a column in `select`, `group by`, or `having` clause, we predict its aggregate functions as follows:

$$\begin{aligned} \text{score}_{\text{agg}} &= MLP\big([\mathbf{h}_t; \tilde{\mathbf{e}}_i^{\text{q}}]\big) \in \mathbb{R}^5 \\ P_{\text{agg}}(j) &= sigmoid\big(\text{score}_j^{\text{agg}}\big) \end{aligned} \tag{12}$$

where j is the index of the five aggregate functions.

A.3 Inference Constraints

During inference, syntax-based constraints are applied to prune the prediction space. For example, `having` can never come before `group by`. Since columns with aggregate functions are reduced into a single token in the target SQL sequence, we can determine the type of the next token before it is generated. For example, a column comes after a `select` token or a comma (`,`). To this end, a transition function constructed by scanning over the dataset is used to further prune the prediction space in Formula 11.

A Multi-Task Incremental Learning Framework with Category Name Embedding for Aspect-Category Sentiment Analysis

NLP Group, Gridsum
{daizehui,pengcheng01,chenhuajie,dingyadong}@gridsum.com

Abstract

(T)ACSA tasks, including aspect-category sentiment analysis (ACSA) and targeted aspect-category sentiment analysis (TACSA), aims at identifying sentiment polarity on predefined categories. Incremental learning on new categories is necessary for (T)ACSA real applications. Though current multi-task learning models achieve good performance in (T)ACSA tasks, they suffer from catastrophic forgetting problems in (T)ACSA incremental learning tasks. In this paper, to make multi-task learning feasible for incremental learning, we proposed Category Name Embedding network (**CNE**-net). We set both encoder and decoder shared among all categories to weaken the catastrophic forgetting problem. Besides the origin input sentence, we applied another input feature, i.e., category name, for task discrimination. Our model achieved state-of-the-art on two (T)ACSA benchmark datasets. Furthermore, we proposed a dataset for (T)ACSA incremental learning and achieved the best performance compared with other strong baselines.

1 Introduction

Sentiment analysis has become an increasingly popular natural language processing (NLP) task in academia and industry. It provides real-time feedback on consumer experience and their needs, which helps producers to offer better services. To deal with the presence of multiple categories in one document, **(T)ACSA** tasks, including aspect-category sentiment analysis (**ACSA**) and targeted aspect-category sentiment analysis (**TACSA**), were introduced.

The main purpose for ACSA task is to identify sentiment polarity (i.e. positive, neutral, negative and none) of an input sentence upon specific predefined categories (Mohammad et al., 2018; Wu et al., 2018). For example, as shown in Table 1, giving an input sentence "Food is always fresh and hot-ready to eat, but it is too expensive." and predefined categories {*food*, *service, price*, *ambience* and *anecdotes/miscellaneous*}, the sentiment of category *food* is positive, the polarity regarding to category *price* is negative, while is none for others. In this task, the models should capture both explicit expressions and implicit expressions. For example, the phrase "too expensive" indicates the negative polarity in the *price* category, without a direct indication of "price".

In order to deal with ACSA with both multiple categories and multiple targets, TACSA task was introduced (Saeidi et al., 2016) to analyze sentiment polarity on a set of predefined target-category pairs. An example is shown in Table 1, given targets "restaurant-1" and "restaurant-2", in the case "I like restaurant-1 because it's cheap, but restaurant-2 is too expansive", the category *price* for target "restaurant-1" is positive, but is negative for target "restaurant-2", while is none for other target-category pairs. A mathematical definition for (T)ACSA is given as follows: giving a sentence s as input, a predefined set of targets T and a predefined set of aspect categories A, a model predicts the sentiment polarity y for each target-category pair $\{(t, a) : t \in T, a \in A\}$. For ACSA task, there is only one target t in all (t, a) categories. In this paper, in order to simplify the expression in TACSA, we use predefined categories, which is short for predefined target-category pairs.

Multi-task learning, with shared encoders but individual decoders for each category, is an approach to analyze all the categories in one sample simultaneously for (T)ACSA (Akhtar et al., 2018; Schmitt et al., 2018). Compared with single-task ways (Liang et al., 2019), multi-task approaches utilize category-specific knowledge in training signals from each task and get better performance. However, current multi-task models still suffer from a

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6955–6965,
November 16–20, 2020.

Task	Sentence	Labels
ACSA	Food is always fresh and hot-ready to eat, but it is too expensive	(food,positive), (service, none), (price, negative), (ambience, none) (anecdotes/miscellaneous, none)
TACSA	I like restaurant-1 because it's cheap, but restaurant-2 is too expansive.	(restaurant-1-general, none), (restaurant-1-price,positive), (restaurant-1-location, none), (restaurant-1-safety,none), (restaurant-2-general, none), (restaurant-2-price,negative), (restaurant-2-location, none), (restaurant-2-safety,none)

Table 1: Example and gold standard for (T)ACSA examples.

lack of features such as category name (Meisheri and Khadilkar, 2018). Models with category name features encoded in the model may further improve the performance.

On the other hand, the predefined categories in (T)ACSA task make the application in new categories inflexible, as for (T)ACSA applications, the number of categories maybe varied over time. For example, *fuel consumption, price level, engine power, space* and so on are **source categories** to be analyzed in the gasoline automotive domain. For electromotive domain, source categories in the automotive domain will still be used, while new **target category** such as *battery duration* should also be analyzed. Incremental learning is a way to solve this problem. Therefore, it is necessary to propose an incremental learning task and an incremental learning model concerned with new category for (T)ACSA tasks.

Unfortunately, in the current multi-task learning (T)ACSA models, the encoder is shared but the decoders for each category are individual. This parameter sharing mechanism results in only the shared encoder and target-category-related decoders are finetuned during the finetuning process, while the decoder of source categories remains unchanged. The finetuned encoder and original decoder of source categories may cause catastrophic forgetting problem in the origin categories. For real applications, high accuracy is excepted in source categories and target categories. Based on the previous researches that decoders between different tasks are usually modeled by mean regularization (Evgeniou and Pontil, 2004) , an idea comes up to further make the decoders the same by sharing the decoders in all categories to decrease the catastrophic forgetting problem. But here raises another question, how to identify each category in the encoder and decoder shared network? In our approach, we solve the category discrimination problem by the input category name feature.

In this paper, we proposed a multi-task category name embedding network (**CNE**-net). The multi-task learning framework makes full use of training signals from all categories. To make it feasible for incremental learning, both encoder and decoders for each category are shared. The category names were applied as another input feature for task discrimination. We also present a new task for (T)ACSA incremental learning. In particular, our contribution is three-folded:

(1) We proposed a multi-task **CNE**-net framework with both encoder and decoder shared to weaken catastrophic forgetting problem in multi-task learning (T)ACSA model.

(2) We achieved state-of-the-art on the two (T)ACSA datasets, SemEval14-Task4 and Sentihood.

(3) We proposed a new task for incremental learning in (T)ACSA. By sharing both encoder layers and decoder layers of all the tasks, we achieved better results compared with other baselines both in source categories and in the target category.

2 Related Work

2.1 Aspect-category Sentiment Analysis

(T)ACSA task is to predict sentiment polarity on a set of predefined categories. It is able to analyze sentiment in an end-to-end way with explicit expressions or implicit expressions (Mohammad et al., 2018; Wu et al., 2018). The earliest works most concerned on feature engineering (Zirn et al., 2011; Wiebe, 2012; Wagner et al., 2014). Subsequently, Nguyen and Shirai (2015); Wang et al. (2017); Meisheri and Khadilkar (2018) applied neural network models to achieve higher accuracy. Ma et al. (2018) then involved commonsense knowledge as additional features. The current approaches consist of multi-task models (Akhtar et al., 2018; Schmitt et al., 2018), which analyze all the categories simultaneously in one sample to make full use of all the features and labels in the training sample, and single-task models that treat one category in one sample (Jiang et al., 2019).

2.2 Multi-Task Learning

Multi-task learning(MTL) utilizes all the related tasks by sharing the commonalities while learning individual features for each sub-task. MTL has been proven to be effective in many NLP tasks, such as information retrieval (Liu et al., 2015), machine translation (Dong et al., 2015), and semantic role labeling (Collobert and Weston, 2008). For ACSA task, Schmitt et al. (2018) applied MTL framework with a shared LSTM encoder and individual decoder classifiers for each category. The multiple aspects in MTL were handled by constrained attention networks with orthogonal and sparse regularization (Hu et al., 2019).

2.3 Incremental Learning

Incremental learning was inspired by adding new abilities to a model without having to retrain the entire model. For example, Doan and Kalita (2016) presented several random forest models to perform sentiment analysis on customers' reviews. Many domain adaptation approaches utilizing transfer learning suffer from "catastrophic forgetting" problem (French and Chater, 2002). To solve this problem, Rosenfeld and Tsotsos (2017) proposed an incremental learning Deep-Adaption-Network that constrains newly learned filters to be linear combinations of existing ones.

To the best of our knowledge, for (T)ACSA task, few researches concerned with incremental learning in new categories. In this paper, we proposed a (T)ACSA incremental learning task and the **CNE**-net model to solve this problem in a multi-task learning approach with a shared encoder and shared decoders. We also apply category name for task discrimination.

3 Datasets

This section describes the benchmark datasets we used to evaluate our model, the incremental learning task definition, the methodology to prepare the incremental learning dataset, and the evaluation metric.

3.1 Evaluation Benchmark Datasets

We evaluated the performance of the **CNE**-net model on two benchmark datasets, i.e., ACSA task on SemEval-2014 Task4 (Pontiki et al., 2014) and TACSA task on SentiHood (Saeidi et al., 2016).

The **ACSA task** was evaluated on SemEval-2014 Task4, a dataset on restaurant reviews. Our model provides a joint solution for sub-task 3 (Aspect Category Detection) and sub-task 4 (Aspect Category Sentiment Analysis). The sentiment polarities are $y \in Y = \{$positive, neutral, negative, conflict and none$\}$, and the categories are $a \in A = \{$*food*, *service*, *price*, *ambience* and *anecdotes/miscellaneous*$\}$. The conflict label indicates both positive and negative sentiment is expressed in one category (Pontiki et al., 2014).

The **TACSA task** was evaluated on the Sentihood dataset, which describes locations or neighborhoods of London and was collected from question answering platform of Yahoo. The sentiment polarities are $y \in Y = \{$positive, negative and none$\}$, the targets are $t \in T = \{$Location1, and Location2$\}$, and the aspect categories are $a \in A = \{$*general*, *price*, *transit-location*, and *safety*$\}$.

3.2 Evaluation Transfer Learning Datasets

Besides evaluating the model on existing (T)ACSA tasks, we also proposed incremental learning tasks for (T)ACSA[1] in new category based on SemEval-2014 Task4 and Sentihood dataset, respectively.

Firstly, we split the categories into source categories and target categories. For ACSA task, the source categories are $\{$*food*, *price*, *ambience* and *anecdotes/miscellaneous*$\}$, while the target category is $\{$*service*$\}$. For TACSA task, the source categories are $\{$*general*, *transit-location*, and *safety*$\}$, while the target category is $\{$*price*$\}$. This was considered by the amount of data with positive/negative/neutral polarity in this category, as well as the sense of this category for real applications.

---

[1] The dataset can be found at `https://github.com/flak300S/emnlp2020_CNE-net`.

origin ACSA sample	{“text”: “The only thing more wonderful than the food is the service.”, ”sentiment”: {“food”: “Positive”, “service”: “Positive”, “price”: None, “ambience”: None, “anecdotes/miscellaneous”: None } }
ACSA Sample-Source	{“text”: “The only thing more wonderful than the food is the service.”, ”sentiment”: {“food”: “Positive”, “price”: None, “ambience”: None, “anecdotes/miscellaneous”: None } }
ACSA Sample-Target	{“text”: “The only thing more wonderful than the food is the service.”, ”sentiment”: {“service”: “Positive” } }

Table 2: An example for generating ACSA incremental learning task.

Secondly, we prepare training, validation and testing data for incremental learning task by independently splitting the origin training data, validation data and test data into source-category data (**Sample-Source**) containing label only in source categories and target-category data (**Sample-Target**) with target-category label only. For example, as shown in Table 2, in ACSA task, the origin labels {*food*: positive, *service*:positive, *price*:none, *ambience*:none, *anecdotes/miscellaneous*:none} were transformed to {*food*: positive, *price*:none, *ambience*:none, *anecdotes/miscellaneous*:none} in Sample-Source and {*service*:positive} in Sample-Target. The input sentences were kept the same as origin dataset. For other researches to investigate the influence of target-category training data amount quantitatively, we also created incremental learning data by combining all the Sample-Source and sampled Sample-Target. The sampling rate is a range from 0.0 to 1.0.

In this paper, the ACSA incremental learning dataset is created from SemEval14-Task ACSA dataset, and it is called SemEval14-Task-*inc*. The TACSA incremental learning dataset is created from Sentihood TACSA dataset, and it is called Sentihood-*inc*.

3.3 Evaluation Metrics

We evaluated the aspect category extraction (to determine whether the sentiment is none for each category) and sentiment analysis (to predict the sentiment polarity) on the two datasets. For aspect category extraction evaluation, we applied the probability $1 - p$ as the not none probability for each category, where p is the probability of the “none” class in this category. The evaluation metric is the same as Sun et al. (2019). For the origin SemEval-14 Task4 dataset, we use Micro-F1 for category extraction evaluation and accuracy for sentiment analysis evaluation. For the origin Sentihood dataset, we use Macro-F1, strict accuracy, and area-under-curve(AUC) for category extraction evaluation while use AUC, and strict accuracy for sentiment analysis evaluation. When evaluating the incremental learning task, we use the F1 metric (Micro-F1 for SemEval-14 and Macro-F1 for Sentihood) for category extraction and accuracy for sentiment analysis.

4 Approach

In this section, we describe the architecture of **CNE**-net for (T)ACSA task. In BERT classification tasks, the typical approach is feeding sentence “[CLS]tokens in sentence[SEP]” into the model, while the token “[CLS]” is used as a feature for classification. In order to encode category names into BERT model, as well as analyze sentiment polarity of all the categories simultaneously, we made two significant differences from the original BERT, one on the encoder module and another on the decoder module.

4.1 Encoder with Category Name Embedding

In order to get a better category name embedding, as well as to make it feasible for incremental learning cross categories, the category names are encoded into the model, along with the origin sentence like “[CLS] sentence words input [SEP] category1 input [SEP] category2 input [SEP]...[SEP] categoryN input[SEP]”, as shown in the BERT encoder module in Figure 1. In ACSA task, the category names are “{food, service, price, ambiance, and anecdotes/miscellaneous}”, while in TACSA task, the category names are “{location-1 general, location-1 price, location-1 transit-location, location-1 safety, location-2 general, location-2 price, location-2 transit-location, and location-2 safety}”.

We mark output states of the BERT encoder as follows: the hidden state of [CLS] $\vec{h}_{[CLS]} \in \mathbb{R}^d$, the hidden states of words in origin sentences

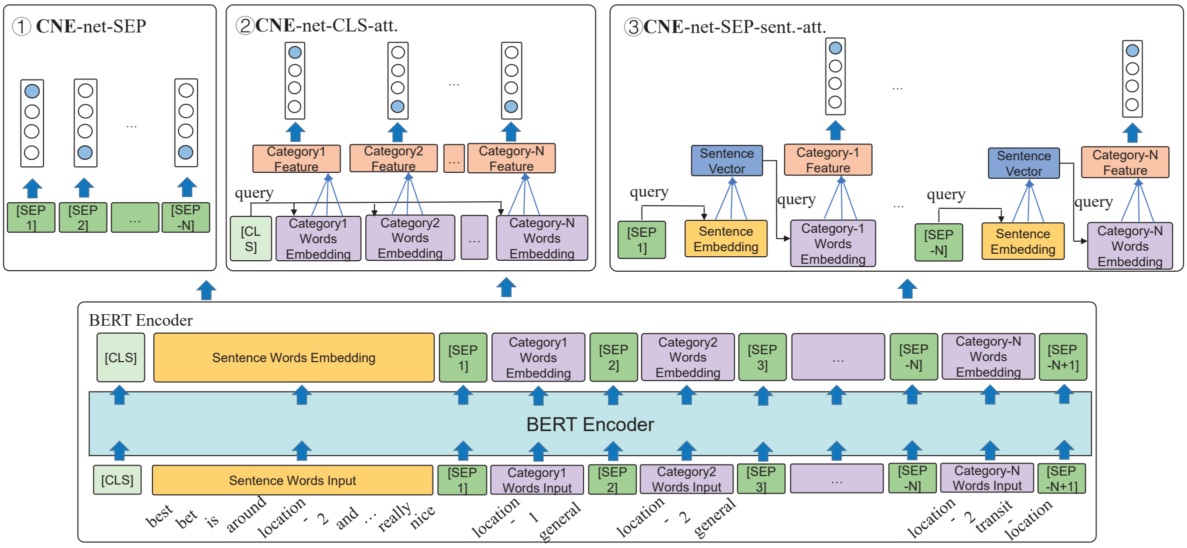

Figure 1: **CNE**-net model architecture

$\mathbf{H}_{sent} \in \mathbb{R}^{L_{sent} \times d}$, the hidden states of separators $\mathbf{H}_{[SEP]} \in \mathbb{R}^{n_{cat} \times d}$, and the hidden states of category words $\mathbf{H}_{cat-i} \in \mathbb{R}^{L_{cat-i} \times d}$ for the i-th category ($0 < i \leq n_{cat}$), where L_{sent} is the length of the input sentence, d is the dimension of hidden states, n_{cat} is the number of categories feed into the model, and L_{cat-i} is the length of the i-th category input words.

4.2 Multi-Task Decoders

We proposed three types of decoder for (T)ACSA task, as shown in Figure 1①,② and ③. These decoders are multi-label classifiers, which apply a softmax classifier for sentiment analysis in each category.

Type 1, **CNE**-net-SEP, as shown in Figure 1①, the separator token $\vec{h}_{[SEP-i]}$ is applied as feature representation for sentiment polarity analysis in each category directly. The probability for each polarity in category *i* is calculated as follows where $\vec{h} = \vec{h}_{[SEP-i]}$:

$$\vec{f_i} = \mathbf{W}_i \cdot \vec{h} + \vec{b_i}; \vec{p_i} = softmax(\vec{f_i}) \qquad (1)$$

where $\vec{f_i} \in \mathbb{R}^s$ is the output logits for category i, $\vec{p_i} \in \mathbb{R}^s$ is the output probability for category i, $\mathbf{W}_i \in \mathbb{R}^{d \times s}$ and $\vec{b_i} \in \mathbb{R}^s$ are randomly initialized parameters to be trained, and s is the number of sentiment classes. $s = 5$ for {positive, neutral, negative, conflict and none} in SemEval14-Task4, while $s = 3$ for {positive, negative and none} in Sentihood dataset. In our approach, $\mathbf{W}_1 = \mathbf{W}_2 = ... = \mathbf{W}_{n_{cat}}$ and $\vec{b}_1 = \vec{b}_2 = ... = \vec{b}_{n_{cat}}$.

Type 2, **CNE**-net-CLS-att., in order to get content-aware category embedding vector, we applied attention mechanism with $\vec{h}_{[CLS]}$ serves as query vector, and $\mathbf{H}_{cat-i}$ serves as both key and value matrix, as shown in Figure 1②. The category embedding vector $\vec{e}_{cat-i}$ for the i-th category is as follows:

$$\vec{e}_{cat_i} = softmax(\vec{h}_{[CLS]} \cdot \mathbf{H}_{cat-i}) \cdot \mathbf{H}_{cat-i} \quad (2)$$

The probability for category *i* in type 2 is calculated following equation(1) where $\vec{h} = \vec{e}_{cat_i}$.

Type 3, **CNE**-net-SEP-sent.-att. applied attention mechanism for both sentence embedding and category name embedding. As it is shown in Figure 1③. Firstly, sentence vector correlated with the *i*-th category is calculated by attention with separator embedding $\vec{h}_{[SEP-i]}$ serving as query, and sentence embedding $\mathbf{H}_{sent}$ serving as key and value matrix. Sentence vector $\vec{h}_{sent-i}$ correlated with the *i*-th category is as follows:

$$\vec{h}_{sent-i} = softmax(\vec{h}_{[SEP-i]} \cdot \mathbf{H}_{sent}) \cdot \mathbf{H}_{sent} \quad (3)$$

Secondly, similar to that in type 2, the category embedding vector $\vec{e}_{cat-i}$ for the *i*-th category calculated by attention mechanism is as follows:

$$\vec{e}_{cat_i} = softmax(\vec{h}_{sent-i} \cdot \mathbf{H}_{cat-i}) \cdot \mathbf{H}_{cat-i} \quad (4)$$

The probability for for category *i* in type 3 is calculated following equation(1) where $\vec{h} = \vec{e}_{cat_i}$.

4.3 Model Training

The **CNE**-net multi-task framework was trained in an end-to-end way by minimizing the sum of cross-entropy loss of all the categories. We employed L_2 regularization to ease over-fitting. The loss function is given as follows:

$$L = -\frac{1}{|D|}\sum_{x,y\in D}\sum_{i=1}^{N}\vec{y}_i \cdot \log \vec{p}_i(x;\theta) + \frac{\lambda}{2}||\theta||_2 \tag{5}$$

where D is the training dataset, N is the number of categories, Y is the sentiment classes $Y = \{positive, neutral, negative, conflict, none\}$ (*neutral* and *conflict* is not included in TACSA task), $\vec{y}_i \in \mathbb{R}^{|Y|}$ is the one-hot label vector for the i-th category with true label marked as 1 and others marked as 0, $\vec{p}_i(x;\theta)$ is the probability for the i-th category, and λ is the L_2 regularization weight. Besides L_2 regularization, we also employed dropout and early stopping to ease over-fitting.

During training incremental learning models, we follow the workflow of the incremental learning application. We firstly train a source-category model with the Sample-Source training data. Then finetuned the source-category model with Sample-Target training data to get incremental learning model.

5 Experiments

5.1 Experiment Settings

The pretrained uncased BERT-base[2] was used as the encoder in **CNE**-net. The number of Transformer blocks is 12, the number of self-attention heads is 12, and the hidden layer size in each self-attention head is 64. The total amount of parameters in BERT encoder is about 110M. The dropout ratio is 0.1 during training, the traning epochs is 10, and the learning rate is 5e-5 with a warm-up ratio of 0.25.

5.2 Compared Methods

We compare the performance of our model with some state-of-the-art models.

For ACSA task:

- XRCE (Brun et al., 2014): a hybrid classifier based on linguistic features.
- NRC-Canada (Kiritchenko et al., 2014): several binary one-vs-all SVM classifiers for this multi-class multi-label classification problem.
- AT-LSTM and ATAE-LSTM (Wang et al., 2016): a LSTM attention framework with aspect word embeddings concatenated with sentence word embeddings.
- BERT-pair-QA-B (Sun et al., 2019): a question answering and natural language inference model based on BERT.
- Multi-task framework (MTL) (Schmitt et al., 2018): a LSTM multi-task learning framework with an individual attention head for each category. To better compare our model with this approach, we changed the encoder to BERT-base.

For TACSA task:

- LR (Saeidi et al., 2016): a logistic regression classfier with linguistic features.
- LSTM-final (Saeidi et al., 2016): a BiLSTM encoder with final states served as feature representation.
- LSTM+TA+SA (Ma et al., 2018): a BiLSTM encoder with complex target-level and sentence-level attention mechanisms.
- SenitcLSTM (Ma et al., 2018): LSTM+TA+SA model upgraded by introducing external knowledge.
- Dmu-Entnet (Liu et al., 2018): model with delayed memory update mechanism to track different targets.
- Recurrent Entity Network (REN) (Ye and Li, 2020): a recurrent entity memory network that employs both word-level information and sentence-level hidden memory for entity state tracking.

In TACSA task, besides these models, we also compared our model with the BERT-pair-QA-B model and MTL model mentioned in ACSA comparison methods.

5.3 Main Results

The performances of compared methods and three types of **CNE**-net are shown in Table 3 (ACSA task) and Table 4 (TACSA task). All the models with BERT encoder (QA-B, MTL and our **CNE**-net) achieved better performance compared with models without BERT encoder (XRCE, NCR-Canada, AT-LSTM, ATAE-LSTM, SenitcLSTM, Dmu_entnet, and REN). Our **CNE**-net performs better compared with QA-B and MTL framework

Table 4: Performance on Sentihood, TACSA task. ("-" means not reported.)

in both ACSA and TACSA tasks. QA-B is a single-task approach, which each category is trained independently. Our **CNE**-net is a multi-task learning framework. It performs better than QA-B by using shared semantic features and sentiment labels in all the categories. **CNE**-net also performs better compared with the MTL model since it encodes the category names as additional features to generate the representation of each category.

Our **CNE**-net-SEP-sent.-att. model achieves state-of-the-art on all the evaluation metrics in both SemEval14-Task4 and Sentihood dataset. The improved extraction F_1 is 0.0080 in the SemEval14-Task4 (increased from 0.9147 in QA-B to 0.9227 in **CNE**-net-SEP-sent.att.), while it is 0.010 in the Sentihood dataset (increased from 0.884 in MTL to 0.894 in **CNE**-net-SEP-sent.att.). The accuracy metrics for sentiment analysis in the SemEval14-Task4 are binary, 3-way and 4way, which refers to accuracy with positive/negative (binary), positive/neutral/negative (3-way) and positive/neutral/negative/conflict (4-way). The improvement of sentiment classification accuracy is 0.012 in SemEval14-Task4 (4-way setting, increased from 0.859 in QA-B to 0.871 in **CNE**-net-SEP-sent.att.), while is 0.004 in the Sentihood dataset (increased from 0.971 in MTL to 0.975 in **CNE**-net-SEP-sent.att.).

CNE-net-SEP uses [SEP] as a feature representation for sentiment classification. It performs the poorest among all three types of **CNE**-net since representation from only [SEP] token does not make full use of sentence information and category information. **CNE**-net-CLS-att. uses [CLS] as sentence representation and applies attention mechanism to build the relationship between sentence representation and the category name hidden states to get sentiment classification feature and achieve better performance. The **CNE**-net-SEP-sent.-att. uses attention twice. The first one is to build category-name-aware sentence embeddings for each category with [SEP] as query and sentence hidden states matrix as key and value, while the second one is to apply each category-name-aware sentence embedding to generate category representation like what we do in **CNE**-net-CLS-att.. This category-name-aware sentence embedding and the sentence-aware category embedding makes it per-

form the best in the three types of **CNE**-net.

5.4 Incremental Learning Results

This section describes the performance in the incremental learning task. We trained the model following incremental learning workflow, as mentioned in section 4.3. We compared the results between mix-training (short as $mix.$) (mixing Sample-Source and Sample-Target) and incremental learning (short as $incre.$), for both extraction F_1 and sentiment accuracy.

Firstly, we compare the performance in target category, i.e. aspect category extraction F_1 (short as $extra.$) and sentiment analysis accuracy (short as $senti.$) from mix-training process and incremental learning. As the target category performance shown in Table 5, there is no significant difference between mix-training and incremental learning for both aspect extraction and sentiment analysis. For example, in SemEval14-Task-*inc*, the extraction F_1 and sentiment accuracy of **CNE**-net-SEP-sent.-att. are 0.936 and 0.930 respectively in mix-training, while they are 0.937 and 0.932 respectively in incremental learning. In Sentihood-*inc*, the extraction F_1 and sentiment accuracy of **CNE**-net-SEP-sent.-att. are 0.952 and 0.919 respectively in mix-training, while they are 0.954 and 0.920 respectively in incremental learning. This indicates incremental learning does not decrease the performance in the target category. Our **CNE**-net-SEP-sent.-att. performs the best in all the models.

Secondly, we compare aspect extraction and sentiment analysis performance in source categories after incremental learning, since both source categories and target categories requires high accuracy. The extraction F_1 and sentiment accuracy of source categories after the incremental learning process as well as in the mix-training process are shown in Table 6. There is no significant difference in sentiment accuracy of source categories after training with incremental learning data. For example, in SemEval14-Task-*inc*, sentiment accuracy of **CNE**-net-SEP-sent.-att. is 0.855 in mix-training, while it is 0.854 in incremental learning. This is probably because of the similar sentiment features between categories, in which the fine-tuning process does not make a great difference.

However, for category extraction, MTL suffers from catastrophic forgetting after fine-tuning. In SemEval14-Task4-*inc*, extraction F_1 of MTL model of source categories decreases from 0.898 in mix-training to 0.698 after incremental learning,

CNE-net-SEP-sent.-att.	SemEval14-Task4-*inc*				Sentihood-*inc*			
	Source Categories		Target Category		Source Categories		Target Category	
	extra.	*senti.*	*extra.*	*senti.*	*extra.*	*senti.*	*extra.*	*senti.*
shared decoder	91.3	85.4	93.7	93.2	86.3	92.3	95.4	92.0
unshared decoder	84.2↓	84.0	93.4	93.0	79.6↓	91.5	94.9	91.6

Table 7: Extraction F_1 and sentiment accuracy after incremental learning of **CNE**-net-SEP-sent.-att. with shared and unshared decoder.

while in Sentihood-*inc*, F_1 metric of MTL model of source categories decreases from 0.870 in mix-training to 0.757 after incremental learning. Fortunately, the QA-B model, as well as our **CNE**-nets, suffer less from this problem. In SemEval14-Task4-*inc*, extraction F_1 metric of **CNE**-SEP-sent.-att. is 0.913 in source categories after fine-tuning, while it is 0.916 in mix-training. In Sentihood-*inc*, extraction F_1 of **CNE**-SEP-sent.-att. is 0.863 in source categories after fine-tuning, while it is 0.877 in mix-training.

5.5 Discussion

We have confirmed the effectiveness of **CNE**-nets for (T)ACSA tasks and (T)ACSA incremental learning tasks. However, there remains a question, why our model suffers less from catastrophic forgetting in incremental learning?

To answer this question, we compare the incremental learning performance of our **CNE**-net-SEP-sent.-att. with a similar model but the decoders in each category are unshared with $\mathbf{W}_1 \neq \mathbf{W}_2 \neq ... \neq \mathbf{W}_{n_{cat}}$ and $\vec{b}_1 \neq \vec{b}_2 \neq ... \neq \vec{b}_{n_{cat}}$ (**CNE**-net-SEP-sent.-att.-unshared) in equation (1) and the results are shown in Table 7. There is no significant difference in target category between the model with shared decoders and the model with unshared decoders, indicating both shared and unshared model is able to get enough feature for category extraction and sentiment analysis in target category. However, it is more important that, in **CNE**-net-SEP-sent.-att.-unshared, the extraction F_1 suffers from a sudden decrease. In SemEval14-Task4-*inc*, extraction F_1 decreases from 0.913 with shared decoder to 0.842 with unshared decoder, while in Sentihood-*inc*, extraction F_1 decreases from 0.863 with shared decoder to 0.796 with unshared decoder.

We believe the decreased extraction F_1 in source categories is due to the unshared decoders for each task, which results in only shared encoder and target-category decoders are fine-tuned during the fine-tuning process. In contrast, the decoder of source categories remains unchanged. The fine-tuned encoder and original source-category decoder is the reason for the catastrophic forgetting problem in the category extraction evaluation. In our shared decoder approach, both encoders and decoders are shared and fine-tuned to weaken the catastrophic forgetting problem.

6 Conclusion

In this paper, in order to make multi-task learning feasible for incremental learning, we proposed **CNE**-net with different attention mechanisms. The category name features and the multi-task learning structure help the model achieve state-of-the-art on ACSA and TACSA tasks. Furthermore, the shared encoder and decoder layers weaken catastrophic forgetting in the incremental learning task. We proposed a task for (T)ACSA incremental learning and achieved the best performance with **CNE**-net compared with other strong baselines. Further research may be concerned with zero-shot learning on new categories.

Abstract

Recently, pre-trained language models mostly follow the pre-train-then-fine-tuning paradigm and have achieved great performance on various downstream tasks. However, since the pre-training stage is typically task-agnostic and the fine-tuning stage usually suffers from insufficient supervised data, the models cannot always well capture the domain-specific and task-specific patterns. In this paper, we propose a three-stage framework by adding a task-guided pre-training stage with selective masking between general pre-training and fine-tuning. In this stage, the model is trained by masked language modeling on in-domain unsupervised data to learn domain-specific patterns and we propose a novel selective masking strategy to learn task-specific patterns. Specifically, we design a method to measure the importance of each token in sequences and selectively mask the important tokens. Experimental results on two sentiment analysis tasks show that our method can achieve comparable or even better performance with less than 50% of computation cost, which indicates our method is both effective and efficient. The source code of this paper can be obtained from `https://github.com/thunlp/SelectiveMasking`.

1 Introduction

Pre-trained Language Models (PLMs) have achieved superior performances on various NLP tasks (Baevski et al., 2019; Joshi et al., 2020; Liu et al., 2019; Yang et al., 2019; Clark et al., 2020) and have attracted wide research interests. Inspired by the success of GPT (Radford et al., 2018) and BERT (Devlin et al., 2019), most PLMs follow the pre-train-then-fine-tuning paradigm, which adopts unsupervised pre-training on large general-domain corpora to learn general language patterns and supervised fine-tuning to adapt to downstream tasks.

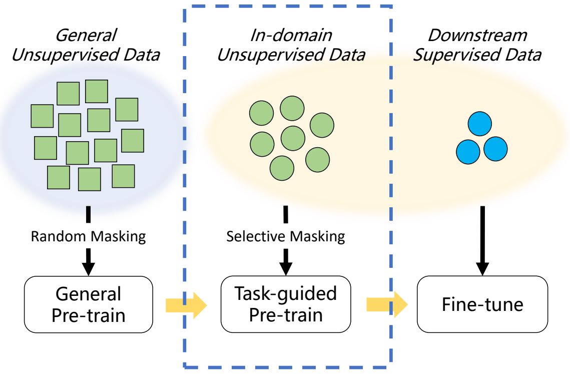

Figure 1: The overall three-stage framework. We add task-guided pre-training between general pre-training and fine-tuning to efficiently and effectively learn the domain-specific and task-specific language patterns.

Recently, Gururangan et al. (2020) shows that learning domain-specific and task-specific patterns during pre-training can be helpful to the models for certain domains and tasks. However, conventional pre-training is aimless with respect to specific downstream tasks, and fine-tuning usually suffers from insufficient supervised data, preventing PLMs from effectively capturing these patterns.

To learn *domain-specific language patterns*, some previous works (Beltagy et al., 2019; Huang et al., 2020) pre-train a BERT-like model from scratch using large-scale in-domain data. However, they are computation-intensive and require large-scale in-domain data, which is hard to obtain in many domains. To learn *task-specific language patterns*, some previous works (Phang et al., 2018) add intermediate supervised pre-training after general pre-training, whose pre-training task is similar to the downstream task but has a larger dataset. However, Wang et al. (2019) shows that this kind of intermediate pre-training often negatively impacts

the transferability to downstream tasks.

To better capture domain-specific and task-specific patterns, we propose a three-stage framework by adding a **task-guided pre-training** stage with selective masking between the general pre-training and fine-tuning. The overall framework is shown in Figure 1. In the stage of task-guided pre-training, the model is trained by masked language modeling (Masked LM) (Devlin et al., 2019) on mid-scale in-domain unsupervised data, which is constructed by collecting other corpora in the same domain. In this way, PLMs can utilize more data to better learn domain-specific language patterns (Alsentzer et al., 2019; Lee et al., 2019; Sung et al., 2019; Xu et al., 2019; Aharoni and Goldberg, 2020). However, the conventional Masked LM randomly masks tokens, which is inefficient to learn task-specific language patterns. Hence, we propose a **selective masking strategy** for task-guided pre-training, whose main idea is selectively masking the important tokens for downstream tasks.

Intuitively, some tokens are more important than others for a specific task and the important tokens vary among different tasks (Ziser and Reichart, 2018; Feng et al., 2018; Rietzler et al., 2020). For instance, in sentiment analysis, sentiment tokens such as “like” and “hate” are critical for sentiments classification (Ke et al., 2020). And, in relation extraction, predicates and verbs are typically more significant. If PLMs can selectively mask and predict the important tokens instead of a mass of random tokens, they can effectively learn task-specific language patterns and the computation cost of pre-training can be significantly reduced.

For the selective masking strategy, we propose a simple method to find important tokens for downstream tasks. Specifically, we define a task-specific score for each token and if the score is lower than a certain threshold, we regard the token as important. However, this method relies on the supervised downstream datasets whose sizes are limited for pre-training. To better utilize mid-scale in-domain unsupervised data as shown in Figure 1, we train a neural network on downstream datasets where the important tokens are annotated using the method mentioned above. This neural network can learn the implicit token-selecting rules, which enables us to select tokens without supervision.

We conduct experiments on two sentiment analysis tasks: MR (Pang and Lee, 2005) and SemEval14 task 4 (Pontiki et al., 2014). Experimental results show that our method is both efficient and effective. Our method can achieve comparable and even better performances than the conventional pre-train-then-fine-tune method with less than 50% of the overall computation cost.

2 Methodology

In this section, we describe task-guided pre-training and selective masking strategy in detail. For convenience, we denote general unsupervised data, in-domain unsupervised data, downstream supervised data as D_{General}, D_{Domain} and D_{Task}. They generally contain about 1000M words, 10M words, and 10K words respectively.

2.1 Training Framework

As shown in Figure 1, our overall training framework consists of three stages:

General pre-training (GenePT) is identical to the pre-training of BERT (Devlin et al., 2019). We randomly mask 15% tokens of D_{General} and train the model to reconstruct the original text.

Task-guided pre-training (TaskPT) trains the model on the mid-scale D_{Domain} with selective masking to efficiently learn domain-specific and task-specific language patterns. In this stage, we apply a selective masking strategy to focus on masking the important tokens and then train the model to reconstruct the input. The details of selective masking are introduced in Section 2.2.

Fine-tuning is to adapt the model to the downstream task. This stage is identical to the fine-tuning of the conventional PLMs.

Since TaskPT enables the model to efficiently learn the domain-specific and task-specific patterns, it is unnecessary to fully train the model in the stage of GenePT. Hence, our overall pre-training time cost of the two pre-training stages can be much smaller than those of conventional PLMs.

2.2 Selective Masking

In our TaskPT, we select important tokens of D_{Task} by their impacts on the classification results. However, this method relies on the supervised labels of D_{Task}. To selectively mask on mid-scale unlabeled in-domain data D_{Domain}, we adopt a neural model to learn the implicit scoring function from the selection results on D_{Task} and use the model to find important tokens of D_{Domain}.

Finding important tokens

We propose a simple method to find important tokens of D_{Task}. Given the n-token input sequence $\boldsymbol{s} = (w_1, w_2, \ldots, w_n)$, we use an auxiliary sequence buffer $\boldsymbol{s}'$ to help evaluating these tokens one by one. At time step 0, $\boldsymbol{s}'$ is initialized to empty. Then, we sequentially add each token w_i to $\boldsymbol{s}'$ and calculate the task-specific score of w_i, which is denoted by $\mathrm{S}(w_i)$. If the score is lower than a threshold δ, we regard w_i as an important token. Note that we will remove previous important tokens from $\boldsymbol{s}'$ to make sure the score is not influenced by previous important tokens.

Assume the buffer at the time step $i-1$ is $\boldsymbol{s}'_{i-1}$. We define the token w_i's score as the difference of classification confidences between the original input sequence $\boldsymbol{s}$ and the buffer after adding w_i, which is denoted by $\boldsymbol{s}'_{i-1}w_i$:

$$\mathrm{S}(w_i) = P(y_{\mathrm{t}} \mid \boldsymbol{s}) - P(y_{\mathrm{t}} \mid \boldsymbol{s}'_{i-1}w_i), \qquad (1)$$

where y_{t} is the target classification label of the input $\boldsymbol{s}$ and $P(y_{\mathrm{t}} \mid *)$ is the classification confidence computed by a PLM fine-tuned on the task. Note that the PLM used here is the model with GenePT introduced in Section 2.1, not a fully pre-trained PLM. In experiments, we set $\delta = 0.05$. The important token criterion $\mathrm{S}(w_i) < \delta$ means after adding w_i, the fine-tuned PLM can correctly classify the incomplete sequence buffer with a close confidence to the complete sequence.

Masking on in-domain unsupervised data

For D_{Domain}, text classification labels needed for computing $P(y_{\mathrm{t}} \mid *)$ are unavailable to perform the method stated above.

To find and mask important tokens of D_{Domain}, we apply the above method to D_{Task} to generate a small scale of data where important tokens are annotated. Then we fine-tune a PLM on the annotated data to learn the implicit rules for selecting the important tokens of D_{Domain}. The PLM used here is also the model with GenePT. The fine-tuning task here is a binary classification to classify whether a token is importent or not. With this fine-tuned PLM as a scoring function, we can efficiently score each token of D_{Domain} without labels and select the important tokens to be masked. After masking the important tokens, D_{Domain} can be used as the training corpus for our task-guided pre-training.

3 Experiments

3.1 Experimental Settings

We evaluate our method on two sentiment analysis tasks: MR (Pang and Lee, 2005) and SemEval14 task 4 restaurant and laptop datasets (Pontiki et al., 2014), using the model architecture of $\mathrm{BERT}_{\mathrm{BASE}}$ in Devlin et al. (2019). Considering the space limit, we only report the results on SemEval14-Restaurant in the main paper. The results on SemEval14-Laptop can be found in the appendix. For simplicity, we abbreviate SemEval14-Restaurant to Sem14-Rest in the rest of the paper.

In GenePT, we adopt BookCorpus (Zhu et al., 2015) and English Wikipedia as our D_{General}. To show that our strategy can significantly reduce the computation cost of pre-training, we choose the model which early stopped at 100k, 200k, and 300k steps and the fully pre-trained model (1M steps).

In TaskPT, we use the pure text of Yelp (Zhang et al., 2015) and Amazon (He and McAuley, 2016) as our in-domain unsupervised data D_{Domain}. These two datasets are both 1000 times larger than MR & Sem14-Rest (D_{Task}), and 100 times smaller than BookCorpus & English Wikipedia (D_{General}).

In fine-tuning, we fine-tune the model for 10 epochs and choose the version with the highest accuracy on the dev set.

3.2 Experimental Results

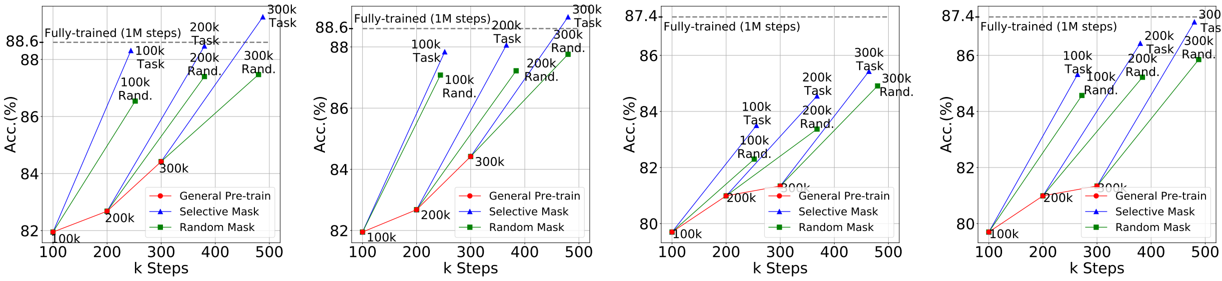
Efficiency

We report our accuracy-pre-training-step lines of all four combinations of downstream tasks and D_{Domain} in Figure 2. Note that since the cost of the selective masking is insignificant compared with that of the task-specific pre-training, it is ignored in Figure 2. The detailed analysis of the computation cost in selective masking can be found in the Appendix. From the experimental results, we can observe that

(1) Our method achieves comparable or even better performances on all 4 settings with less than 50% pre-training costs, which indicates our task-guided pre-training method with selective masking is both efficient and effective.

(2) Our selective masking strategy consistently outperforms the random selecting strategy that most previous works use, which indicates that our selective masking works well for capturing task-specific language patterns.

(3) In the 4 settings, our model performs best in Sem14-Rest + Yelp, in which our model outper-



(a) Sem14-Rest + Yelp (b) Sem14-Rest + Amazon (c) MR + Yelp (d) MR + Amazon

Figure 2: Experimental results on 4 different combinations (Task + D_{Domain}). The y-axis indicates the test accuracy. The x-axis indicates the overall pre-training steps. The general pre-training starts at 0 steps and stops at 100k, 200k and 300k steps, corresponding to the "General Pre-train" line. Then task-guided pre-training or random mask pre-training runs for about 200k steps, corresponding to the "Selective Mask" line and "Random Mask" line.

		MR	Sem14-Rest
w/o Task-guided pre-training		87.37	88.60
Amazon	Random	88.35	90.40
	Selective	**89.51****	**91.56****
Yelp	Random	87.20	90.70
	Selective	**88.15****	**91.87***

Table 1: Test accuracies of models trained with different methods (without task-guided pre-training or task-guided pre-training with different masking strategies) after full general pre-training (1M steps). $*$ and $**$ indicate statistically significant ($p < .05$ and $p < .001$).

Downstream Dataset: MR
Text: Constently **touching**, surprisingly **funny**, semi-surreal ##ist exploration of the **creative** act.
In-domain Dataset: Yelp
Text: **Nice**, clean, simple setup. Limited seating. Cakes are aw ##sum! Very **fresh**. Even have egg ##less cakes. Food is **good** as well. Really like the pan ##ner pan ##ini. Also other items are **worth** checking out.

Table 2: The former one is a sequence masked by our selective method on downstream data. The latter one is a sequence masked by the PLM scoring function. The bold tokens are selected to be masked.

forms the fully pre-trained $\text{BERT}_{\text{BASE}}$ by 1.4% with only half of the training steps. While in MR+Yelp, the model performs worst, in which our accuracy drops 1.94% compared with the fully pre-trained model. This is because the text domains of Sem14-Rest and Yelp are much more similar (both restaurant reviews) than those of MR and Yelp (movie reviews and restaurant reviews). It indicates that the similarity between D_{Domain} and D_{Task} is critical for our task-guided pre-training to capture the domain-specific and task-specific patterns, which is intuitive.

Effectiveness

To evaluate the effectiveness of task-guided pre-training, we continue to pre-train the fully pre-trained $\text{BERT}_{\text{BASE}}$ on the in-domain data. We use the official model in (Devlin et al., 2019) as the fully pre-trained $\text{BERT}_{\text{BASE}}$. From Table 1, we have the following observations:

(1) Compared with the fully trained GenePT, our model with TaskPT achieves significant improvements in 3 settings no matter which kind of masking strategies is used, which shows the task-guided pre-training can help the model to capture the domain-specific and task-specific patterns. In the MR+Yelp setting, the random masking harms the model performance, which indicates not all patterns in D_{Domain} can benefit downstream tasks.

(2) In all settings, our selective masking strategy consistently outperforms the random masking strategy, even on the setting of MR+Yelp. It indicates that our selective masking strategy can still effectively capture helpful task-specific patterns even when the D_{Domain} is not so close to the D_{Task}.

3.3 Case Study

To analyze whether our selective masking strategy can successfully find important tokens, we conduct a case study, as shown in Table 2. In this case, we use MR as the supervised data and Yelp as the unsupervised in-domain data. It shows that our selective masking strategy successfully selects sentiment tokens, which are important for this task, on both supervised and unsupervised data.

4 Conclusion

In this paper, we design task-guided pre-training with selective masking and present a three-stage training framework for PLMs. With task-guided pre-training, models can effectively and efficiently learn domain-specific and task-specific patterns, which benefits downstream tasks. Experimental results show that our methods can achieve better performances with less computation cost. Note that although we only conduct experiments on two sentiment classification tasks using BERT as the base model, our method can easily generalize to other models using masked language modeling or its variants and other text classification tasks.

Besides, there are still two important directions for future work: (1) How to apply task-guided pre-training to general domain data when the in-domain data is limited. (2) How to design more effective strategies to capture domain-specific and task-specific patterns for selective masking.

Appendices

A Cost of Selective Masking

In practice, our selective masking method described in Section 2.2 can be implemented in the following 4 steps:

- **Fine-tune BERT**. Fine-tune a checkpoint after the GenePT on downstream supervised datasets (i.e., MR & SemEval14).
- **Downstream Mask**. Selectively annotate important tokens on downstream supervised datasets using the method stated in “Finding important tokens”.
- **Train NN**. Train a token-level binary classification BERT model from the checkpoint after the GenePT on downstream supervised datasets where important tokens are annotated.
- **In-domain Mask**. Use the token-level binary classification model trained in the **Train NN** step to select important tokens on in-domain unsupervised datasets (i.e., Yelp & Amazon), and mask them.

The additional time cost introduced by the 4 steps in selective masking strategy is shown in Table 3. From the table, we conclude that the extra computation time cost of our selective masking strategy is insignificant compared with the cost saved in the pre-training stage, so we ignore it in the calculation and comparison of pre-training steps.

	MR		SemEval14	
	Yelp	Amazon	Yelp	Amazon
Finetune BERT	10	10	3	3
Downstream Mask	20	20	10	10
Train NN	10	10	3	3
In-domain Mask	40	120	40	120
Sum	70	150	56	136
Saved Cost	2160	2160	2160	2160

Table 3: The comparison between the cost of the 4 steps for tokens selection and that saved by our selective masking method (in minutes). The 1-5 lines are the time for every stage and their summation of token selection. The last line is the saved pre-training time.

In Figure 3, we also illustrate the proportion of different stages according to the time they spend in our experiments. The whole pie is the conventional random-masking pre-training cost and the colored sectors are the time cost of the proposed GenePT, selective masking strategy, and TaskPT. The white sector, as a result, indicates the pre-training time saved in our training framework. From the figures, we can see that the cost of selective masking only contributes a small part of the whole pre-training time and about half of the conventional pre-training cost (about 36 hours in our experiments) is saved with our method.

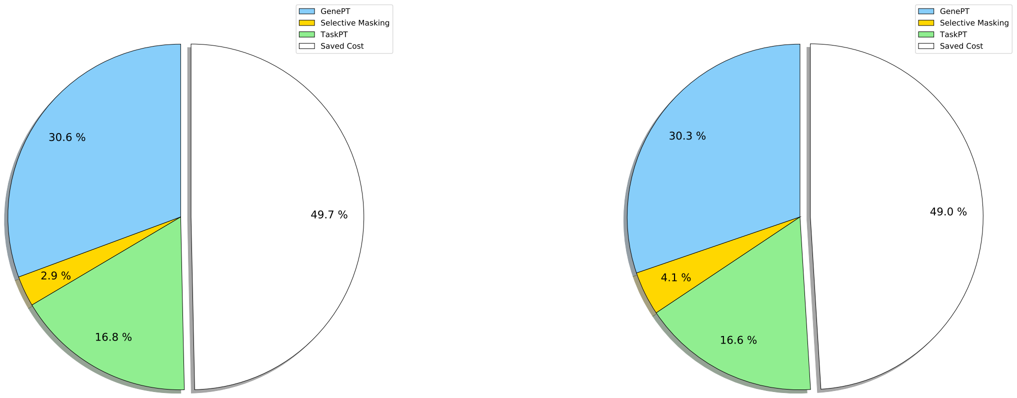
(b) SemEval14 + Amazon



(c) MR + Yelp

(d) MR + Amazon

Figure 3: The proportion of the time cost of different pre-training stages 4 different combinations (Task + D_{Domain}). The whole pie represents the time cost of the conventional pre-training method. The colored sectors represent the time cost of GenePT, selective masking, and TaskPT respectively. The white sector shows the time saved by our training framework.

B Detailed Experimental Setup

B.1 GenePT

We generally followed the pre-training procedure and hyper-parameters of BERT$_{\text{BASE}}$ in (Devlin et al., 2019) except that we set the max tokens number in a sequence to 256 and utilized FP16 precision[1] for efficiency. We pre-trained the model on 4 NVIDIA V100 GPUs. The whole 1M-step training completes in about 3 days and we saved checkpoints at 100k, 200k, and 300k steps during the process.

B.2 Selective Masking.

The implementation details of each steps in selective masking are described as follows.

Fine-tune BERT. We fine-tuned the checkpoint that stopped GenePT at 100k, 200k, 300k, and 1M steps respectively on downstream supervised datasets MR and SemEval14 with the same hyper-parameters. The fine-tuning batch size was 64 with max tokens number 256. The learning rate was 2e-5 and we used 42 as the random seed. We fine-tuned for at most 10 epochs and selected the model with the highest accuracy on valid datasets.

Downstream Mask. We used the models after being fine-tuned on MR and SemEval14 as classifiers to perform the important tokens selecting method on downstream supervised datasets. The sentences were tokenized by the BERT's sub-word

---

[1] `https://github.com/NVIDIA/DeepLearningExamples/tree/master/PyTorch/LanguageModeling/BERT`

tokenizer. We set $\delta = 0.05$ in all circumstances. After the selection, important tokens were annotated as label "1" while others were labeled as "0".

Train NN. We added a token-level binary classification head on the top of the BERT checkpoints after GenePT and fine-tuned them with the annotated data after the Downstream Mask stage. The max sequence length was 128, with batch size 64 and learning rate 1e-5. Besides, to balance the two labels, we set the weight 1.5 for label "1"(important tokens).

In-domain Mask. The NN-based token selection was performed by classifying each token in mid-scale in-domain datasets with the model trained after the **Train NN** stage. If the classification result was "1", then the token was regarded as important and would be masked in the pre-training stage afterward.

B.3 TaskPT

We then continued pre-training the checkpoints after GenePT on selectively masked in-domain datasets. The hyper-parameters were almost the same as that in GenePT, except that we only pre-trained for at most 200k steps.

B.4 Fine-tuning

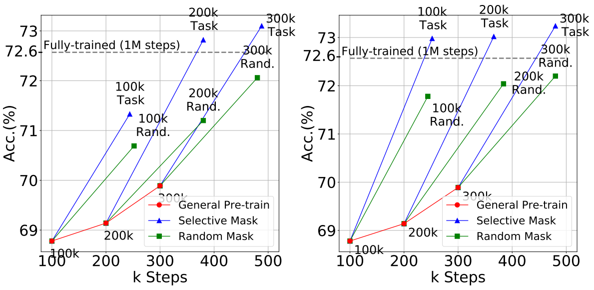
The model after TaskPT was then fine-tuned on downstream datasets MR and SemEval14. The hyper-parameters were generally the same with the **Fine-tune BERT** stage (B.2) except that we averaged the model performance over 10 different random seeds: [13, 43, 83, 181, 271, 347, 433, 659, 727, 859] to provide more convincing results.

C Detailed Datasets Description

We utilized 4 sentiment classification datasets in our experiments. The train/dev/test splits and other statistical information of the 4 datasets are shown in Table 4.

Dataset	Amount	Classes
MR	8534/1078/1050	2
SemEval14	3333/185/973	3
Yelp	700k	5
Amazon	3M	5

Table 4: Datasets statistics. Note that we only use the pure text in the training set of Yelp and Amazon as in-domain unsupervised data



(a) Sem14-Lap + Yelp (b) Sem14-Lap + Amazon

Figure 4: Experimental results on Sem14-Lap + Yelp and Sem14-Lap + Amazon. The y-axis indicates the test accuracy. The x-axis indicates the overall pre-training steps. The general pre-training starts at 0 steps and stops at 100k, 200k and 300k steps, corresponding to the "General Pre-train" line. Then task-guided pre-training or random mask pre-training runs for about 200k steps, corresponding to the "Selective Mask" line and "Random Mask" line.

MR MR[2] is movie-review data for the use in sentiment-analysis experiments. Since the originally released data does not provide train/dev/test split, we randomly sampled 80% of the whole set for training, 10% for validation, and 10% for testing.

SemEval14 SemEval14[3] is the restaurant-domain dataset released by the task 4 in SemEval14 competition. The original task is aspect-based sentiment analysis. To convert it into a conventional sentiment classification task, we concatenated the aspect tokens and text tokens to form a full sentence as the input to the model.

Yelp Yelp[4] is a 5-class sentiment classification dataset of reviews about restaurants obtained from the Yelp Dataset Challenge in 2015. In our experiments, we only used its pure text as in-domain unsupervised data.

Amazon Amazon[5] is composed of different reviews on the Amazon website. Similar to Yelp, we only used its pure text to construct in-domain unsupervised data.

D Results on SemEval14-Laptop

Here we present additional experimental results on the SemEval14 task 4 laptop dataset. We use SemEval14-Laptop as the downstream task dataset and use Yelp and Amazon as in-domain datasets respectively. Similar to Section 3.1, we applied our task-guided pre-training to the BERT$_{\text{BASE}}$ model early stopped pre-training at 100k, 200k, 300k steps to evaluate the efficiency of our method and also continued to pre-train from the fully pre-trained BERT$_{\text{BASE}}$ to evaluate the effectiveness. The accuracy-pre-training-step lines of the efficiency experiment are reported in Figure 4 and the accuracies in the effectiveness experiment are shown in Table 5.

Abstract

Most of the existing pre-trained language representation models neglect to consider the linguistic knowledge of texts, which can promote language understanding in NLP tasks. To benefit the downstream tasks in sentiment analysis, we propose a novel language representation model called SentiLARE, which introduces word-level linguistic knowledge including part-of-speech tag and sentiment polarity (inferred from SentiWordNet) into pre-trained models. We first propose a context-aware sentiment attention mechanism to acquire the sentiment polarity of each word with its part-of-speech tag by querying SentiWordNet. Then, we devise a new pre-training task called label-aware masked language model to construct knowledge-aware language representation. Experiments show that SentiLARE obtains new state-of-the-art performance on a variety of sentiment analysis tasks[1].

1 Introduction

Recently, pre-trained language representation models such as GPT (Radford et al., 2018, 2019), ELMo (Peters et al., 2018), and BERT (Devlin et al., 2019) have achieved promising results in NLP tasks, including sentiment analysis (Xu et al., 2019, 2020; Yin et al., 2020). These models capture contextual information from large-scale corpora via well-designed pre-training tasks. The literature has commonly reported that pre-trained models can be used as effective feature extractors and achieve state-of-the-art performance on various downstream tasks (Wang et al., 2019a).

Despite the great success of pre-trained models, existing pre-training tasks like masked language model and next sentence prediction (Devlin et al., 2019) neglect to consider the linguistic knowledge. Such knowledge is important for some NLP tasks, particularly for sentiment analysis. For instance, existing work has shown that linguistic knowledge including part-of-speech tag (Qian et al., 2015; Huang et al., 2017) and word-level sentiment polarity (Qian et al., 2017) is closely related to the sentiment of longer texts. We argue that pre-trained models enriched with the linguistic knowledge of words will facilitate the understanding of the sentiment of the whole texts, thereby resulting in better performance on sentiment analysis.

There are two major challenges to construct knowledge-aware pre-trained language representation models which can promote the downstream tasks in sentiment analysis: 1) **Knowledge acquisition across different contexts**. Most of the existing work has adopted static sentiment lexicons as linguistic resource (Qian et al., 2017; Chen et al., 2019), and equipped each word with a fixed sentiment polarity across different contexts. However, the same word may play different sentiment roles in different contexts due to the variety of part-of-speech tags and word senses. 2) **Knowledge integration into pre-trained models**. Since the introduced word-level linguistic knowledge can only reflect the local sentiment role played by each word, it is important to deeply integrate knowledge into pre-trained models to construct sentence-level language representation, which can derive the global sentiment label of a whole sentence from local information. How to build the connection between sentence-level language representation and word-level linguistic knowledge is underexplored.

In this paper, we propose a novel pre-trained language representation model called SentiLARE to deal with these challenges. First, to acquire the linguistic knowledge of each word, we label the word with its part-of-speech tag, and obtain the sentiment polarity via a context-aware sentiment

November 16–20, 2020.

attention mechanism over all the matched senses in SentiWordNet (Baccianella et al., 2010). Then, to incorporate linguistic knowledge into pre-trained models, we devise a novel pre-training task called label-aware masked language model. This task involves two sub-tasks: 1) predicting the word, part-of-speech tag, and sentiment polarity at masked positions given the sentence-level sentiment label; 2) predicting the sentence-level label, the masked word and its linguistic knowledge including part-of-speech tag and sentiment polarity simultaneously. We call the first sub-task *early fusion* since the sentiment labels are aforehand integrated as input embeddings, whereas in the second sub-task, the labels are used as *late supervision* to the model in the output layer. These two sub-tasks are expected to establish the connection between sentence-level representation and word-level linguistic knowledge, which can benefit downstream tasks in sentiment analysis. Our contributions are in three folds:

- We investigate the effectiveness of incorporating linguistic knowledge into pre-trained language representation models, and we reveal that injecting such knowledge via pre-training tasks can benefit various downstream tasks in sentiment analysis.

- We propose a novel pre-trained language representation model called SentiLARE. This model derives a context-aware sentiment polarity for each word using SentiWordNet, and adopts a pre-training task named label-aware masked language model to construct sentiment-aware language representations.

- We conduct extensive experiments on sentence-level and aspect-level sentiment analysis (including extraction and classification). Results show that SentiLARE obtains new state-of-the-art performance on a variety of sentiment analysis tasks.

2 Related Work

General Pre-trained Language Models

Recently, pre-trained language representation models including ELMo (Peters et al., 2018), GPT (Radford et al., 2018, 2019), and BERT (Devlin et al., 2019) become prevalent. These models use LSTM (Hochreiter and Schmidhuber, 1997) or Transformer (Vaswani et al., 2017) as the encoder to acquire contextual language representation, and explore various pre-training tasks including masked language model and next sentence prediction (Devlin et al., 2019).

Thanks to the great success of BERT on various NLP tasks, many variants of BERT have been proposed, which mainly fall into four aspects: 1) Knowledge enhancement: ERNIE-Tsinghua (Zhang et al., 2019) / KnowBERT (Peters et al., 2019) explicitly introduces knowledge graph / knowledge base to BERT, while ERNIE-Baidu (Sun et al., 2019b) designs entity-specific masking strategies during pre-training. 2) Transferability: TransBERT (Li et al., 2019) conducts supervised post-training on the pre-trained BERT with transfer tasks to get a better initialization for target tasks. 3) Hyper-parameters: RoBERTa (Liu et al., 2019) measures the impact of key hyper-parameters to improve the under-trained BERT. 4) Pre-training tasks: SpanBERT (Joshi et al., 2020) masks consecutive spans randomly instead of individual tokens, while XLNet (Yang et al., 2019) designs a training objective combining both reconstruction and autoregressive language modeling.

Pre-trained Models for Sentiment Analysis

Another line of work aims to build task-specific pre-trained models via post-training on the task data (Gururangan et al., 2020). For sentiment analysis, BERT-PT (Xu et al., 2019) conducts post-training on the corpora which belong to the same domain of the downstream tasks to benefit aspect-level sentiment analysis. DomBERT (Xu et al., 2020) augments the training samples from relevant domains during the pre-training phase to enhance the performance on the aspect-level sentiment analysis of target domains. SentiBERT (Yin et al., 2020) devises a two-level attention mechanism on top of the BERT representation to capture phrase-level compositional semantics.

Compared with the existing work on pre-trained models for sentiment analysis, our work integrates sentiment-related linguistic knowledge from SentiWordNet (Baccianella et al., 2010) into pre-trained models to construct knowledge-aware language representation, which can benefit a wide range of downstream tasks in sentiment analysis.

Linguistic Knowledge for Sentiment Analysis

Linguistic knowledge such as part of speech and word-level sentiment polarity is commonly used as external features in sentiment analysis. Part of speech is shown to facilitate the parsing of the syntactic structure of texts (Socher et al., 2013). It

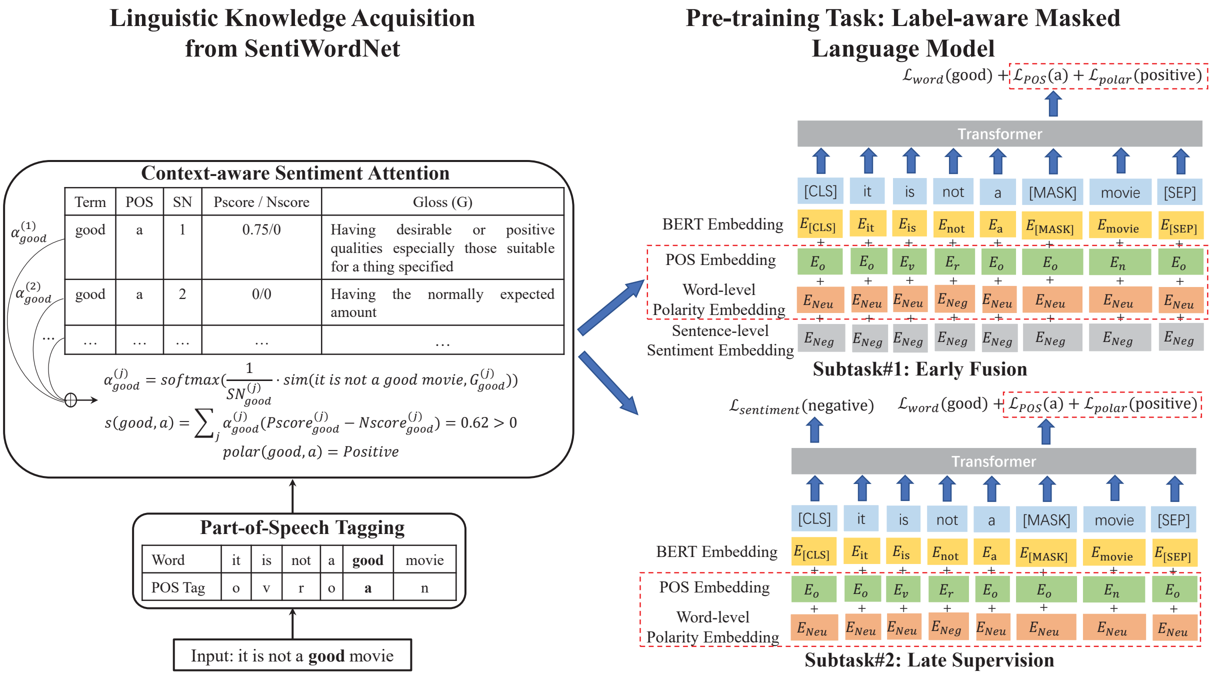

Figure 1: Overview of SentiLARE. This model first labels each word with its part-of-speech tag, and then uses the word and tag to match the corresponding senses in SentiWordNet. The sentiment polarity of each word is obtained by weighting the matched senses with context-aware sentiment attention. During pre-training, the model is trained based on label-aware masked language model including *early fusion* and *late supervision*. Red dotted boxes denote that the linguistic knowledge is used in input embedding or pre-training loss function.

can also be incorporated into all layers of RNN as tag embeddings (Qian et al., 2015). Huang et al. (2017) shows that part of speech can help to learn sentiment-favorable representations.

Word-level sentiment polarity is mostly derived from sentiment lexicons (Hu and Liu, 2004; Wilson et al., 2005). Guerini et al. (2013) obtains the prior sentiment polarity by weighting the sentiment scores over all the senses of a word in SentiWordNet (Esuli and Sebastiani, 2006; Baccianella et al., 2010). Teng et al. (2016) proposes a context-aware lexicon-based weighted sum model, which weights the prior sentiment scores of sentiment words to derive the sentiment label of the whole sentence. Qian et al. (2017) models the linguistic role of sentiment, negation and intensity words via linguistic regularizers in the training objective of LSTM.

3 Model

3.1 Task Definition and Model Overview

Our task is defined as follows: given a text sequence $X = (x_1, x_2, \cdots, x_n)$ of length n , our goal is to acquire the representation of the whole sequence $H = (h_1, h_2, \cdots, h_n)^\top \in \mathbb{R}^{n \times d}$ that captures the contextual information and the linguistic knowledge simultaneously, where d indicates the dimension of representation vectors.

Figure 1 shows the overview of our model, which consists of two steps: 1) Acquiring the part-of-speech tag and the sentiment polarity for each word; 2) Conducting pre-training via label-aware masked language model, which contains two pre-training sub-tasks, i.e., early fusion and late supervision. Compared with existing BERT-style pre-trained models, our model enriches the input sequence with its linguistic knowledge including part-of-speech tag and sentiment polarity, and utilizes label-aware masked language model to capture the relationship between sentence-level language representation and word-level linguistic knowledge.

3.2 Linguistic Knowledge Acquisition

This module obtains the part-of-speech tag and the sentiment polarity for each word. The input of this module is a text sequence $X = (x_1, x_2, \cdots, x_n)$, where $x_i (1 \leq i \leq n)$ indicates a word in the vocabulary. First, our model acquires the part-of-speech tag pos_i of each word x_i via Stanford Log-Linear Part-of-Speech Tagger[2]. For simplicity, we only consider five POS tags including verb (v), noun (n),

---

[2] `https://nlp.stanford.edu/software/tagger.html`

adjective (a), adverb (r), and others (o).

Then, we acquire the word-level sentiment polarity $polar_i$ from SentiWordNet for each pair (x_i, pos_i). In SentiWordNet, we can find m different senses for the pair (x_i, pos_i), each of which contains a sense number, a positive / negative score, and a gloss $(SN_i^{(j)}, Pscore_i^{(j)}, Nscore_i^{(j)}, G_i^{(j)})$, $1 \leq j \leq m$, where SN indicates the rank of different senses, $Pscore/Nscore$ is the positive / negative score assigned by SentiWordNet, and G denotes the definition of each sense. Inspired by the existing work on inferring word-level prior polarity from SentiWordNet (Guerini et al., 2013) and unsupervised word sense disambiguation (Basile et al., 2014), we propose a context-aware attention mechanism which simultaneously considers the sense rank and the context-gloss similarity to determine the attention weight of each sense:

$$\alpha_i^{(j)} = softmax(\frac{1}{SN_i^{(j)}} \cdot sim(X, G_i^{(j)}))$$

where $\frac{1}{SN_i^{(j)}}$ approximates the impact of sense frequency because a smaller sense rank indicates more frequent use of this sense in natural language (Guerini et al., 2013), and $sim(X, G_i^{(j)})$ denotes the textual similarity between the context and the gloss of each sense, which is commonly used as an important feature in unsupervised word sense disambiguation (Basile et al., 2014). To calculate the similarity between X and $G_i^{(j)}$, we encode them with Sentence-BERT (SBERT) (Reimers and Gurevych, 2019) which achieves the state-of-the-art performance on semantic textual similarity tasks, and obtain the cosine similarity between the vectors:

$$sim(X, G_i^{(j)}) = cos(\text{SBERT}(X), \text{SBERT}(G_i^{(j)}))$$

Once we obtain the attention weight of each sense, we can calculate the sentiment score of each pair (x_i, pos_i) by simply weighting the scores of all the senses:

$$s(x_i, pos_i) = \sum_{j=1}^{m} \alpha_i^{(j)} (Pscore_i^{(j)} - Nscore_i^{(j)})$$

Finally, the word-level sentiment polarity $polar_i$ for the pair (x_i, pos_i) can be assigned with $Positive/Negative/Neutral$ when $s(x_i, pos_i)$ is positive / negative / zero, respectively. Note that if we cannot find any sense for (x_i, pos_i) in SentiWordNet, $polar_i$ is assigned with $Neutral$.

3.3 Pre-training Task

Given the knowledge enhanced text sequence $X_k = \{(x_i, pos_i, polar_i)_{i=1}^n\}$, the goal of the pre-training task is to construct the knowledge-aware representation vectors $H = (h_1, \cdots, h_n)^\top$ which can promote the downstream tasks in sentiment analysis. We devise a new supervised pre-training task called label-aware masked language model (LA-MLM), which introduces the sentence-level sentiment label l into the pre-training phase to capture the dependency between sentence-level language representation and individual words. It contains two separate sub-tasks: early fusion and late supervision.

3.3.1 Early Fusion

The purpose of early fusion is to recover the masked sequence conditioned on the sentence-level label, as shown in Figure 1. Assume that $\hat{X}_k$ denotes the knowledge enhanced text sequence with some masked tokens, we can obtain the representation vectors with the input of $\hat{X}_k$ and the sentence-level sentiment label l:

$$(h_{cls}^{EF}, h_1^{EF}, ..., h_n^{EF}, h_{sep}^{EF}) = \text{Transformer}(\hat{X}_k, l)$$

where h_{cls}^{EF} and h_{sep}^{EF} are the hidden states of the special tokens `[CLS]` and `[SEP]`. The input embeddings of $\hat{X}_k$ contains the embedding used in BERT (Devlin et al., 2019), the part-of-speech (POS) embedding and the word-level polarity embedding. Additionally, the embedding of the sentence-level sentiment label l is *early* added to the input embeddings. The model is required to predict the word, part-of-speech tag, and word-level polarity at the masked positions individually, thus the loss function is devised as follows:

$$\mathcal{L}_{EF} = -\sum_{t=1}^{n} m_t \cdot [\log P(x_t|\hat{X}_k, l) + \log P(pos_t|\hat{X}_k, l) + \log P(polar_t|\hat{X}_k, l)]$$

where m_t is an indicator function and equals to 1 iff x_t is masked. The prediction probabilities $P(x_t|\hat{X}_k, l)$, $P(pos_t|\hat{X}_k, l)$ and $P(polar_t|\hat{X}_k, l)$ are calculated based on the hidden state h_t^{EF}. This sub-task explicitly exerts the impact of the global sentiment label on the words and the linguistic knowledge of words, enhancing the ability of our model to explore the complex connection among them.

Task	Input Format	Output Hidden States
Sentence-level Sentiment Classification	`[CLS]` $x_1, \cdots x_n$ `[SEP]`	$h_{\texttt{[CLS]}}$
Aspect Term Extraction	`[CLS]` $x_1 \cdots x_n$ `[SEP]`	$h_1, h_2, \cdots, h_n$
Aspect Term Sentiment Classification	`[CLS]` $a_1 \cdots a_l$ `[SEP]` $x_1 \cdots x_n$ `[SEP]`	$h_{\texttt{[CLS]}}$
Aspect Category Detection	`[CLS]` $x_1 \cdots x_n$ `[SEP]`	$h_{\texttt{[CLS]}}$
Aspect Category Sentiment Classification	`[CLS]` $a_1 \cdots a_l$ `[SEP]` $x_1 \cdots x_n$ `[SEP]`	$h_{\texttt{[CLS]}}$
Text Matching	`[CLS]` $x_1 \cdots x_n$ `[SEP]` $y_1 \cdots y_m$ `[SEP]`	$h_{\texttt{[CLS]}}$

Table 1: Fine-tuning setting of SentiLARE on downstream tasks. Both $x_1 \cdots x_n$ and $y_1 \cdots y_m$ indicate the text sequences, while $a_1 \cdots a_l$ denotes the aspect term / category sequence. The output hidden states are then used in the classification / regression layer.

3.3.2 Late Supervision

The late supervision sub-task aims to predict the sentence-level label and the word information based on the hidden states at `[CLS]` and masked positions respectively, as shown in Figure 1. Similar to early fusion, the representation vectors with the input of $\hat{X}_k$ are obtained as follows:

$$(h_{cls}^{LS}, h_1^{LS}, ..., h_n^{LS}, h_{sep}^{LS}) = \text{Transformer}(\hat{X}_k)$$

In this sub-task, the sentiment label l is used as the *late* supervision signal. Thus, the loss function to simultaneously predict the sentence-level sentiment label, words, and linguistic knowledge of words is shown as follows:

$$\mathcal{L}_{LS} = -\log P(l|\hat{X}_k) - \sum_{t=1}^{n} m_t \cdot [\log P(x_t|\hat{X}_k) + \log P(pos_t|\hat{X}_k) + \log P(polar_t|\hat{X}_k)]$$

where the sentence-level classification probability $P(l|\hat{X}_k)$ is calculated based on the hidden state h_{cls}^{LS}. This sub-task enables our model to capture the implicit relationship among the sentence-level representation at `[CLS]` and word-level linguistic knowledge at masked positions.

Since the two sub-tasks are separate, we empirically set the percentage of pre-training data provided for the late supervision sub-task as 20% and early fusion as 80%. As for the masking strategy, we increase the probability of masking words with positive / negative sentiment polarity from 15% in the setting of BERT to 30% because they are more likely to impact the sentiment of the whole text.

4 Experiment

4.1 Pre-training Dataset and Implementation

We adopted the Yelp Dataset Challenge 2019[3] as our pre-training dataset. This dataset contains 6,685,900 reviews with 5-class review-level sentiment labels. Each review consists of 127.8 words on average.

Since our method can adapt to all the BERT-style pre-trained models, we used RoBERTa (Liu et al., 2019) as the base framework to construct Transformer blocks in this paper, and discussed the generalization ability to other pre-trained models like BERT (Devlin et al., 2019) in the following experiment. The hyper-parameters of the Transformer blocks were set to be the same as RoBERTa-Base due to the limited computational power. Considering the high cost of training from scratch, we utilized the parameters of pre-trained RoBERTa[4] to initialize our model. We also followed RoBERTa to use Byte-Pair Encoding vocabulary (Radford et al., 2019) whose size was 50,265. The maximum sequence length in the pre-training phase was 128, while the batch size was 400. We took Adam (Kingma and Ba, 2015) as the optimizer and set the learning rate to be 5e-5. The warmup ratio was 0.1. SentiLARE was pre-trained on Yelp Dataset Challenge 2019 for 1 epoch with label-aware masked language model, which took about 20 hours on 4 NVIDIA RTX 2080 Ti GPUs.

4.2 Fine-tuning Setting

We fine-tuned SentiLARE to the downstream tasks including sentence-level sentiment classification, aspect-level sentiment analysis, and general text matching tasks in our experiments. We adopted the fine-tuning settings in the existing work (Devlin et al., 2019; Xu et al., 2019), and showed the input format and the output hidden states of each task in Table 1. Note that the input embeddings in all the downstream tasks only contain BERT embedding, part-of-speech embedding and word-level polarity embedding. The hyper-parameters of fine-tuning on different datasets are reported in the Appendix.

---

[3] `https://www.yelp.com/dataset/challenge`

[4] `https://github.com/pytorch/fairseq`

4.3 Baselines

We compared SentiLARE with general pre-trained models, task-specific pre-trained models and task-specific models without pre-training.

General Pre-trained Models: We adopted BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), and RoBERTa (Liu et al., 2019) as general pre-trained baselines. These models achieve state-of-the-art performance on various NLP tasks.

Task-specific Pre-trained Models: We used BERT-PT (Xu et al., 2019), TransBERT (Li et al., 2019), and SentiBERT (Yin et al., 2020) as task-specific pre-trained baselines. Since TransBERT is not originally designed to deal with sentiment analysis tasks, we chose review-level sentiment classification on Yelp Dataset Challenge 2019 as the transfer task, and the downstream tasks in sentiment analysis as the target tasks.

Task-specific Models without Pre-training: We also chose some task-specific baselines without pre-training for corresponding tasks, including SC-SNN (Chen et al., 2019), DRNN (Wang, 2018), ML (Sachan et al., 2019) for sentence-level sentiment classification, DE-CNN (Xu et al., 2018) for aspect term extraction, CDT (Sun et al., 2019a) for aspect term sentiment classification, TAN (Movahedi et al., 2019) for aspect category detection, and AS-Capsules (Wang et al., 2019b) for aspect category sentiment classification.

We evaluated all the pre-trained baselines based on the codes and the model parameters provided by the original papers. For a fair comparison, all the pre-trained models were set to the base version, which possess a similar number of parameters (about 110M). The experimental results were presented with mean values over 5 runs. As for the task-specific baselines without pre-training, we re-printed the results on the corresponding benchmarks from the references.

4.4 Sentence-level Sentiment Classification

Dataset	Amount (Train/Valid/Test)	Length	# classes
SST	8,544 / 1,101 / 2,210	19.2	5
MR	8,534 / 1,078 / 1,050	21.7	2
IMDB	22,500 / 2,500 / 25,000	279.2	2
Yelp-2	504,000 / 56,000 / 38,000	155.3	2
Yelp-5	594,000 / 56,000 / 50,000	156.6	5

Table 2: Statistics of sentence-level sentiment classification (SSC) datasets.

We first evaluated our model on sentence-level sentiment classification benchmarks including Stanford Sentiment Treebank (SST) (Socher et al., 2013), Movie Review (MR) (Pang and Lee, 2005), IMDB (Maas et al., 2011), and Yelp-2/5 (Zhang et al., 2015), which are widely used datasets at different scales. The detailed statistics of these datasets are shown in Table 2, which contain the amount of training / validation / test sets, the average length and the number of classes. Since MR, IMDB, and Yelp-2/5 don't have validation sets, we randomly sampled subsets from the training sets as the validation sets, and evaluated all the pre-trained models with the same data split.

Model	SST	MR	IMDB	Yelp-2	Yelp-5
SOTA-NPT	$55.20^{\sharp}$	$82.50^{\sharp}$	$93.57^{\dagger}$	$97.27^{\ddagger}$	$69.15^{\ddagger}$
BERT	53.37	87.52	93.87	97.74	70.16
XLNet	56.33	89.45	95.27	97.41	70.23
RoBERTa	54.89	89.41	94.68	97.98	70.12
BERT-PT	53.24	87.30	93.99	97.77	69.90
TransBERT	55.56	88.69	94.79	96.73	69.53
SentiBERT	56.87	88.59	94.04	97.66	69.94
SentiLARE	**58.59****	**90.82****	**95.71****	**98.22****	**71.57****

Table 3: Accuracy on sentence-level sentiment classification (SSC) benchmarks (%). SOTA-NPT means the state-of-the-art performance from the baselines without pre-training, where the results marked with $\sharp$, † and ‡ are re-printed from Chen et al. (2019), Sachan et al. (2019) and Wang (2018), respectively. ** indicates that our model significantly outperforms the best pre-trained baselines on the corresponding dataset (t-test, *p-value*$<$ 0.01).

The results are shown in Table 3. We can observe that SentiLARE performs better than the baselines on the sentence-level sentiment classification datasets, thereby indicating the effectiveness of our knowledge-aware representation in sentiment understanding. Compared with vanilla RoBERTa, SentiLARE enhances the performance on all the datasets significantly. This demonstrates that for sentiment analysis tasks, linguistic knowledge can be used to enhance the state-of-the-art pre-trained model via the well-designed pre-training task.

4.5 Aspect-level Sentiment Analysis

Aspect-level sentiment analysis includes aspect term extraction, aspect term sentiment classification, aspect category detection, and aspect category sentiment classification. For aspect term based tasks, we chose SemEval2014 Task 4 for laptop (Lap14) and restaurant (Res14) domains (Pontiki et al., 2014) as the benchmarks, while for aspect category based tasks, we used SemEval2014 Task

Dataset	# sentences (Train/Test)	# terms (Train/Test)	# categories (Train/Test)	# sentiment classes	Amount of ATE (Train/Valid/Test)	Amount of ATSC (Train/Valid/Test)	Amount of ACD (Train/Valid/Test)	Amount of ACSC (Train/Valid/Test)

SentiLARE	**88.22***	**91.15****	**82.16***	**78.70***	**88.32****	**81.63****	**92.22**	**80.71****	**92.97****	**87.30****	**91.29**	**80.00**

Table 5: F1, accuracy (Acc.) and Macro-F1 (MF1.) on four aspect-level sentiment analysis tasks including aspect term extraction (ATE), aspect term sentiment classification (ATSC), aspect category detection (ACD) and aspect category sentiment classification (ACSC) (%). SOTA-NPT means the state-of-the-art performance from the baselines without pre-training, where the results marked with ♯, †, ‡ and ♭ are re-printed from Xu et al. (2018), Sun et al. (2019a), Movahedi et al. (2019) and Wang et al. (2019b), respectively. - means that the results are not reported in the references. * indicates that our model significantly outperforms the best pre-trained baselines on the corresponding dataset (t-test, *p-value*< 0.05), while ** means *p-value*< 0.01.

4 for restaurant domain (Res14) and SemEval2016 Task 5 for restaurant domain (Res16) (Pontiki et al., 2016). The statistics of these datasets are reported in Table 4. We followed the existing work (Xu et al., 2019) to leave 150 examples from the training sets for validation. Since the number of the examples with the *conflict* sentiment label is rather small, we adopted the same setting as the existing work (Tang et al., 2016; Xu et al., 2019) and dropped these examples in the aspect term / category sentiment classification task.

We present the results of aspect-level sentiment analysis in Table 5. We can see that SentiLARE outperforms the baselines on all the four tasks, and most of the improvement margins are significant. Interestingly, in addition to aspect-level sentiment classification, our model also performs well in aspect term extraction and aspect category detection. Since the aspect words are mostly nouns, part-of-speech tags may provide additional knowledge for the extraction task. In addition, the aspect terms can be signaled by neighboring sentiment words. This may explain why our knowledge-aware representation can help to extract (detect) the aspect term (category).

4.6 Ablation Test

To study the effect of the linguistic knowledge and the label-aware masked language model, we conducted ablation tests and presented the results in Table 6. Since the two sub-tasks are separate, the setting of -EF / -LS indicates that the pre-training data were all fed into the late supervision / early fusion sub-task, and -EF-LS denotes that the pre-training task is changed from label-aware masked language model to vanilla masked language model, while the input embeddings still include part-of-speech and word-level polarity embeddings. The -POS / -POL setting means that we removed the part of speech / word-level sentiment polarity in the input embeddings respectively, as well as in the supervision signals of the two sub-tasks. Obviously, -POS-POL indicates the complete removal of linguistic knowledge.

Results in Table 6 show that both the pre-training task and the linguistic knowledge contribute to the improvement over RoBERTa. Compared with early fusion, the late supervision sub-task plays a more important role in the classification tasks which depend on the global representation of the input sequence, such as SSC, ATSC, ACD and ACSC. Intuitively, the late supervision sub-task may learn a meaningful global representation at `[CLS]` by

Task	SSC	ATE	ATSC		ACD	ACSC	
Dataset	SST	Res14	Res14		Res16	Res14	
Model	Acc.	F1	Acc.	MF1.	F1	Acc.	MF1.
RoBERTa	54.89	89.55	86.07	79.21	77.89	90.67	83.81
SentiLARE	**58.59**	**91.15**	**88.32**	**81.63**	**80.71**	**92.97**	**87.30**
- EF	58.44	90.82	87.70	81.11	80.42	92.70	86.42
- LS	57.33	90.88	87.21	80.46	79.74	92.44	86.14
- EF - LS	56.91	90.74	86.95	79.71	78.92	91.32	84.73
- POS	58.15	90.94	87.98	81.38	80.27	92.51	86.61
- POL	57.95	90.63	87.64	81.34	79.40	92.46	86.30
- POS - POL	57.31	90.35	87.59	81.20	79.21	92.21	85.68

Table 6: Ablation test on sentiment analysis tasks. EF / LS / POS / POL denotes early fusion / late supervision / part-of-speech tag / word-level polarity, respectively.

simultaneously predicting the sentence-level sentiment labels and the word knowledge. Thus, it contributes more to the performance on these classification tasks.

As for the impact of linguistic knowledge, the performance of SentiLARE degrades more in the setting of removing the word-level sentiment polarity. This implies that the word-level polarity can help the pre-trained model more to derive the global sentiment in the classification tasks and signal neighboring aspects in the extraction task.

4.7 Analysis on Knowledge Acquisition

To investigate whether our proposed context-aware knowledge acquisition method can help construct knowledge-aware language representation, we compared the context-aware sentiment attention described in §3.2 with a context-free prior polarity acquisition algorithm (Guerini et al., 2013). This algorithm simply acquires a fixed sentiment polarity for each word with its part-of-speech tag by weighting the sentiment score of each sense with the reciprocal of the sense number, regardless of the variety of context. All the other parts of SentiLARE remain unchanged for comparison between these two knowledge acquisition methods.

Task	SSC	ATE	ATSC		ACD	ACSC	
Dataset	SST	Res14	Res14		Res16	Res14	
Model	Acc.	F1	Acc.	MF1.	F1	Acc.	MF1.
SentiLARE (w/ CASA)	**58.59**	**91.15**	**88.32**	**81.63**	**80.71**	**92.97**	**87.30**
SentiLARE (w/ CFPP)	56.86	90.54	88.05	81.26	79.00	92.72	86.59

Table 7: F1, accuracy (Acc.) and Macro-F1 (MF1.) of SentiLARE with context-aware sentiment attention (CASA) or context-free prior polarity (CFPP) on sentiment analysis tasks (%).

Results in Table 7 show that our context-aware method performs better on all the tasks. This demonstrates that our context-aware attention mechanism can help SentiLARE model the sentiment roles of words across different contexts, thereby leading to better knowledge enhanced language representation.

4.8 Analysis on Knowledge Integration

To further demonstrate the importance of label-aware masked language model which deeply integrates linguistic knowledge into pre-trained models, we divided the test set of SST into two subsets according to the number of sentiment words (including positive and negative words determined by linguistic knowledge) in the sentences. Since there are 6.48 sentiment words on average in the sentences of SST's test set, we partitioned the test set into two subsets: *SST-Less* contains the sentences with no more than 7 sentiment words, and *SST-More* includes the other sentences. Intuitively and presumably, the sentences with more sentiment words may include more complex sentiment expressions. We compared three models: RoBERTa which does not use linguistic knowledge, SentiLARE-EF-LS which simply augments input embeddings with linguistic knowledge as described in §4.6, and SentiLARE which deeply integrates linguistic knowledge via the pre-training task.

Model	SST-Less	SST-More
RoBERTa	55.61	53.52
SentiLARE-EF-LS	58.20 (+2.59)	54.49 (+0.97)
SentiLARE	**59.72 (+4.11)**	**56.45 (+2.93)**

Table 8: Accuracy of RoBERTa, SentiLARE-EF-LS, and SentiLARE on two subsets of SST's test set (%).

Results in Table 8 show that SentiLARE-EF-LS already outperforms RoBERTa remarkably on SST-Less by simply augmenting input features with linguistic knowledge. However, on SST-More, SentiLARE-EF-LS only obtains marginal improvement over RoBERTa. As for our model, SentiLARE can consistently outperform RoBERTa and SentiLARE-EF-LS, and the margin between SentiLARE and SentiLARE-EF-LS is more evident on SST-More. This indicates that our pre-training task can help to integrate the local sentiment information reflected by word-level linguistic knowledge into global language representation, and facilitate the understanding of complex sentiment expressions.

4.9 Analysis on Generalization Ability

Generalization to Other Pre-trained Models: To study whether the introduced linguistic knowledge and the proposed pre-training task can improve the performance of other pre-trained models besides RoBERTa, we chose BERT (Devlin et al., 2019) and ALBERT (Lan et al., 2020) as the base framework for evaluation. The experimental settings were set the same as SentiLARE based on RoBERTa.

Task	SSC	ATE	ATSC		ACD	ACSC	
Dataset	SST	Res14	Res14		Res16	Res14	
Model	Acc.	F1	Acc.	MF1.	F1	Acc.	MF1.
BERT	53.37	87.68	83.77	76.06	72.59	88.35	80.40
SentiLARE (w/BERT)	**55.64**	**89.93**	**86.47**	**79.62**	**77.44**	**91.82**	**85.21**
ALBERT	53.67	89.44	84.25	75.96	73.61	89.13	82.18
SentiLARE (w/ALBERT)	**54.75**	**90.63**	**86.56**	**79.17**	**77.74**	**91.00**	**84.27**

Table 9: F1, accuracy (Acc.) and Macro-F1 (MF1.) of BERT, ALBERT, and SentiLARE based on BERT / ALBERT on sentiment analysis tasks (%).

Results in Table 9 show that SentiLARE based on BERT / ALBERT outperforms vanilla BERT / ALBERT on the datasets of all the tasks, which demonstrates that our proposed method can adapt to different BERT-style pre-trained models to benefit the tasks in sentiment analysis.

Dataset	Amount (Train/Valid/Test)	Task Type	# classes
SCT	1,771 / 100 / 1,871	Classification	2
SICK	4,500 / 500 / 4,927	Classification	3
STSb	5,749 / 1,500 / 1,379	Regression	-

Table 10: Statistics of text matching datasets.

Generalization to Other NLP Tasks: Since sentiment is a common feature to improve the tasks of text matching (Cai et al., 2017; Li et al., 2019), we chose three text matching tasks to explore whether our sentiment-aware representations can also benefit these tasks, including story ending prediction, textual entailment, and semantic textual similarity. We evaluated RoBERTa and SentiLARE on the datasets of SCT (Mostafazadeh et al., 2016), SICK (Marelli et al., 2014), and STSb (Cer et al., 2017) for the three tasks respectively. The statistics of these datasets are reported in Table 10. We followed the existing work (Li et al., 2019) to preprocess the SCT dataset, and directly adopted the official version of SICK and STSb datasets.

Task	StoryEndPred	TextEntail	SemTextSim	
Dataset	SCT	SICK	STSb	
Model	Acc.	Acc.	Pear.	Spear.
RoBERTa	90.95	88.22	88.37	87.61
SentiLARE	**92.47**	**89.42**	**89.15**	**88.50**

Table 11: Accuracy (Acc.), Pearson (Pear.) and Spearman (Spear.) correlations of RoBERTa and SentiLARE on the tasks of story ending prediction, textual entailment, and semantic textual similarity (%).

Results in Table 11 show that SentiLARE can enhance the performance of RoBERTa on these text matching tasks. This indicates that sentiment-related linguistic knowledge can be successfully integrated into the pre-trained language representation model to not only benefit the sentiment analysis tasks but also generalize to other sentiment-related NLP tasks. We will explore the generalization of our model to more NLP tasks as future work.

5 Conclusion

We present a novel pre-trained model called SentiLARE for sentiment analysis, which introduces linguistic knowledge from SentiWordNet via context-aware sentiment attention, and adopts label-aware masked language model to deeply integrate knowledge into BERT-style models through pre-training tasks. Experiments show that SentiLARE outperforms state-of-the-art language representation models on various sentiment analysis tasks, and thus facilitates sentiment understanding.

A Experimental Details

A.1 Hyper-parameter Setting

We provided the hyper-parameter search space during pre-training in Table 12. Grid search was used to select hyper-parameters, and the selection criterion was the classification accuracy on the validation set when we fine-tuned the pre-trained model on SST.

We also provided the detailed setting of hyper-parameters during fine-tuning on the datasets of sentiment analysis, including hyper-parameter search space in Table 13 and best assignments in Table 14. Note that we used HuggingFace's Transformers[5] to implement our model, so all the hyper-parameters we reported were consistent with the codes of HuggingFace's Transformers. We utilized manual search to select the best hyper-parameters during fine-tuning. The number of hyper-parameter search trials for each dataset was 20. We used accuracy as our criterion for selection on all the sentiment analysis tasks except aspect term extraction and aspect category detection. For these two tasks, F1 was adopted as the selection criterion.

Hyper-parameter	Search Space
Percentage of Data in EF	*choice*[0,0.2,0.4,0.6,0.8,1]
Masking Probability (Sentiment Words)	*choice*[0.2,0.3,0.4,0.5]
Batch Size	*choice*[400,512]
Training Epoch	*choice*[1,2]
Learning Rate	5e-5
Warmup Ratio	0.1
Sequence Length	128
Maximum Gradient Norm	1.0
Optimizer	Adam
Epsilon (for Adam)	1e-8

Table 12: Hyper-parameter search space of SentiLARE during pre-training. *choice* indicates that the listed numbers will be chosen with the same probability.

Hyper-parameter	Search Space
Learning Rate	*choice*[1e-5,2e-5,3e-5,4e-5,5e-5]
Training Epoch	*uniform-integer*[3,8]
Warmup Step	*uniform-integer*[0,total_step*0.2]
Batch Size	*choice*[12,16,24,32]
Sequence Length	*choice*[128,256,512]
Maximum Gradient Norm	1.0
Optimizer	Adam
Epsilon (for Adam)	1e-8

Table 13: Hyper-parameter search space of SentiLARE on the downstream sentiment analysis tasks. *uniform-integer* means the integers in the interval can be selected uniformly. In the search space of warmup step, total_step denotes the total training steps on different datasets.

A.2 Results on Validation Sets

In addition to the performance on the test set of each dataset which has been reported in the main paper, we also provided the validation performance on the datasets of sentence-level and aspect-level sentiment analysis in Table 15. As mentioned in Appendix A.1, accuracy and F1 were used to select the best hyper-parameters, so we reported the validation performance of all the pre-trained models on these metrics.

A.3 Runtime

The runtime of fine-tuning on different datasets of sentiment analysis was reported in Table 16. We tested all the pre-trained models on 4 NVIDIA RTX 2080 Ti GPUs.

B Case Study

To intuitively show that SentiLARE can integrate linguistic knowledge into pre-trained models to promote sentiment analysis, we provided a case, and visualized the classification probability of all the prefix subsequences truncated at each position in Figure 2. For example, the prediction probability at the position of *small* was acquired by the hidden state of [CLS] obtained by RoBERTa / SentiLARE with the input "[CLS] The restaurant is small [SEP]". Both RoBERTa and SentiLARE were fine-tuned on the Yelp-2 dataset.

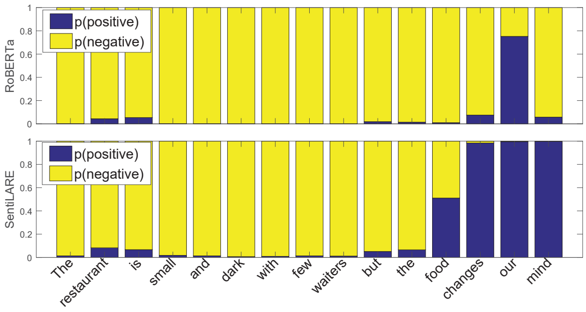

Figure 2: Visualization of the classification probability of RoBERTa and SentiLARE fine-tuned on Yelp-2. The bar indicates the output distribution of RoBERTa and SentiLARE with the input of the prefix subsequence at each position.

Compared with RoBERTa, our model enhanced with word-level linguistic knowledge can successfully capture the sentiment shift caused by the word *change* in this sentence, thereby determining the correct sentence-level sentiment label.

C Analysis on Textual Similarity in Knowledge Acquisition

SentiLARE (w/WordVec)	57.41	90.66	88.10	81.27	80.07	92.75	86.87

Table 17: F1, accuracy (Acc.) and Macro-F1 (MF1.) of SentiLARE with Sentence-BERT (SBERT) or word vectors (WordVec) on sentiment analysis tasks (%).

Since Sentence-BERT is costly to calculate the textual similarity between contexts and glosses, we compared it with another lighter textual similarity algorithm (Basile et al., 2014) which computes the representation vectors of sentences by averaging the embedding vectors of their constituent words. We used 300-dimensional GloVe[6] as the word vectors to obtain textual similarity.

Results in Table 17 show that Sentence-BERT performs better on all the tasks. Nevertheless, static word vectors are more computationally efficient in linguistic knowledge acquisition with acceptable performance drop.

Weakly-Supervised Aspect-Based Sentiment Analysis via Joint Aspect-Sentiment Topic Embedding

Jiaxin Huang, Yu Meng, Fang Guo, Heng Ji, Jiawei Han

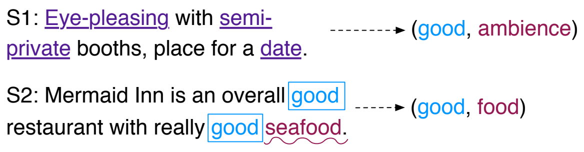
Abstract

Aspect-based sentiment analysis of review texts is of great value for understanding user feedback in a fine-grained manner. It has in general two sub-tasks: (i) extracting aspects from each review, and (ii) classifying aspect-based reviews by sentiment polarity. In this paper, we propose a weakly-supervised approach for aspect-based sentiment analysis, which uses only a few keywords describing each aspect/sentiment without using any labeled examples. Existing methods are either designed only for one of the sub-tasks, neglecting the benefit of coupling both, or are based on topic models that may contain overlapping concepts. We propose to first learn ⟨sentiment, aspect⟩ joint topic embeddings in the word embedding space by imposing regularizations to encourage topic distinctiveness, and then use neural models to generalize the word-level discriminative information by pre-training the classifiers with embedding-based predictions and self-training them on unlabeled data. Our comprehensive performance analysis shows that our method generates quality joint topics and outperforms the baselines significantly (7.4% and 5.1% F1-score gain on average for aspect and sentiment classification respectively) on benchmark datasets[1].

1 Introduction

With the vast amount of reviews emerging on platforms like Amazon and Yelp, aspect-based sentiment analysis, which extracts opinions about certain facets of entities from text, becomes increasingly essential and benefits a wide range of downstream applications (Bauman et al., 2017; Nguyen et al., 2015).

Aspect-based sentiment analysis contains two sub-tasks: Aspect extraction and sentiment polarity classification. The former identifies the aspect covered in the review, whereas the latter decides its sentiment polarity.



S1: Eye-pleasing with semi-private booths, place for a date. → (good, ambience)

S2: Mermaid Inn is an overall good restaurant with really good seafood. → (good, food)

Figure 1: Two sample restaurant reviews. Pure aspect words are in red and wavy-underlined, and general opinion words are in blue and framed in boxes. Words implying both aspects and opinions (which we define as joint topics) are underlined and in purple.

Various methods have been proposed for the task. Neural network models (Liu et al., 2015; Xu et al., 2018) have outperformed rule-based models (Hu and Liu, 2004; Zhuang et al., 2006), but they require large-scale fine-grained labeled data to train, which can be difficult to obtain. Some other studies leverage word embeddings to solve the aspect extraction problem in an unsupervised (He et al., 2017; Liao et al., 2019) or weakly-supervised setting (Angelidis and Lapata, 2018; Karamanolakis et al., 2019), *without* using any annotated documents. In this work, we study the weakly-supervised setting, where only a few keywords are provided for each aspect and sentiment.

We show two sample restaurant reviews in Fig. 1 together with their expected output—aspect and sentiment labels. With a closer look at these two example reviews, we observe that S2 includes a general opinion word "good" and a pure aspect word "seafood", which are separate hints for sentiment and aspect classification respectively. S1, on the other hand, does not address the target with plain and general words, but instead use more specific words like "semi-private" and "date" which are uniquely used when people feel good about the ambience instead of other aspects. Humans can interpret these unique and fine-grained terms as hints for a joint topic of ⟨good, ambience⟩, but this

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6989–6999,
November 16–20, 2020.

is hard for models that are solely trained for one sub-task. If a model can automatically learn the semantics of each joint topic of ⟨sentiment, aspect⟩, it will be able to identify representative terms of the joint topics such as "semi-private" which provide information for aspect and sentiment simultaneously, and will consequently benefit both aspect extraction and sentiment classification. Therefore, leveraging more fine-grained information by coupling the two subtasks will enhance both.

Several LDA-based methods consider learning joint topics (Zhao et al., 2010; Wang et al., 2015; Xu et al., 2012), but they rely on external resources such as part-of-speech (POS) tagging or opinion word lexicons. A recent LDA-based model (García-Pablos et al., 2018) uses pre-trained word embedding to bias the prior in topic models to jointly model aspect words and opinion words. Though working fairly well, topic models are generative models and do not enforce topic distinctiveness—topic-word distribution can largely overlap among different topics, allowing topics to resemble each other. Besides, topic models yield unstable results, causing large variance in classification results.

We propose the **JASen** model for **J**oint **A**spect-**Sen**timent Topic Embedding. Our general idea is to learn a joint topic representation for each ⟨sentiment, aspect⟩ pair in the shared embedding space with words so that the surrounding words of topic embeddings nicely describe the semantics of a joint topic. This is accomplished by training topic embeddings and word embeddings on in-domain corpora and modeling the joint distribution of user-given keywords on all the joint topics. After learning the joint topic vectors, embedding-based predictions can be derived for any unlabeled review. However, these predictions are sub-optimal for sentiment analysis where word order plays an important role. To leverage the expressive power of neural models, we distill the knowledge from embedding-based predictions to convolutional neural networks (CNNs) (Krizhevsky et al., 2012) which perform compositional operations upon local sequences. A self-training process is then conducted to refine CNNs by using their high-confident predictions on unlabeled data.

We demonstrate the effectiveness of **JASen** by conducting experiments on two benchmark datasets and show that our model outperforms all the baseline methods by a large margin. We also show that our model is able to describe joint topics with coherent term clusters.

Our contributions can be summarized as follows: (1) We propose a weakly-supervised method **JASen** to enhance two sub-tasks of aspect-based sentiment analysis. Our method does *not* need any annotated data but only a few keywords for each aspect/sentiment. (2) We introduce an embedding learning objective that is able to capture the semantics of fine-grained joint topics of ⟨sentiment, aspect⟩ in the word embedding space. The embedding-based prediction is effectively leveraged by neural models to generalize on unlabeled data via self-training. (3) We demonstrate that **JASen** generates high-quality joint topics and outperforms baselines significantly on two benchmark datasets.

2 Related Work

The problem of aspect-based sentiment analysis can be decomposed into two sub-tasks: aspect extraction and sentiment polarity classification. Most previous studies deal with them individually. There are various related efforts on aspect extraction (He et al., 2017), which can be followed by sentiment classification models (He et al., 2018). Other methods (García-Pablos et al., 2018) jointly solve these two sub-tasks by first separating target words from opinion words and then learning joint topic distributions over words. Below we first review relevant work on aspect extraction (Sec 2.1) and then turn to studies that jointly extract aspects and sentiment polarity (Sec 2.2).

2.1 Aspect Extraction

Early studies towards aspect extraction are mainly based on manually defined rules (Hu and Liu, 2004; Zhuang et al., 2006), which have been outperformed by supervised neural approaches that do not need labor-intensive feature engineering. While CNN (Xu et al., 2018) and RNN (Liu et al., 2015) based models have shown the powerful expressiveness of neural models, they can easily consume thousands of labeled documents thus suffer from the label scarcity bottleneck.

Various unsupervised approaches are proposed to model different aspects automatically. LDA-based methods (Brody and Elhadad, 2010; Chen et al., 2014) model each document as a mixture of aspects (topics) and output a word distribution for each aspect. Recently, neural models have shown to extract more coherent topics. ABAE (He et al., 2017) uses an autoencoder to reconstruct sentences through aspect embedding and removes irrelevant words through attention mechanisms. CAt (Tulkens and van Cranenburgh, 2020) introduces a single head attention calculated by a Radial Basis Function (RBF) kernel to be the sentence summary. The unsupervised nature of these algorithms is hindered by the fact that the learned aspects often do not well align with user's interested aspects, and additional human effort is needed to map topics to certain aspects, not to mention some topics are irrelevant of interested aspects.

Several weakly-supervised methods address this problem by using a few keywords per aspect as supervision to guide the learning process. MATE (Angelidis and Lapata, 2018) extends ABAE by initializing aspect embedding using weighted average of keyword embeddings from each aspect. ISWD (Karamanolakis et al., 2019) co-trains a bag-of-word classifier and an embedding-based neural classifier to generalize the keyword supervision. Other text classification methods leverage pre-trained language model (Meng et al., 2020b) to learn the semantics of label names or metadata (Zhang et al., 2020) to propagate document labels.

The above methods do not take aspect-specific opinion words into consideration. The semantic meaning captured by a ⟨sentiment, aspect⟩ joint topic preserves more fine-grained information to imply the aspect of a sentence and thus can be used to improve the performance of aspect extraction.

2.2 Joint Extraction of Aspect and Sentiment

Most previous studies that jointly perform aspect and sentiment extraction are LDA-based methods. Zhao et al. (2010) include aspect-specific opinion models along with aspect models in the generative process. Wang et al. (2015) propose a restricted Boltzmann machine-based model that treats aspect and sentiment as heterogeneous hidden units. Xu et al. (2012) adapt LDA by introducing sentiment-related variables and integrating sentiment prior knowledge. All these methods rely on external resources such as part-of-speech (POS) tagging or opinion word lexicons. A more recent study that shares similar weakly-supervised setting with ours is W2VLDA (García-Pablos et al., 2018). They apply Brown clustering (Brown et al., 1992) to separate aspect-terms from opinion-terms and construct biased hyperparameters α and β by embedding similarity. Despite the effectiveness of topic models, they suffer from the drawback of not imposing discriminative constraints among topics—topic-word distribution can largely overlap among different topics, allowing redundant topics to appear and making it hard to classify them. We empirically show the advances of our method by capturing discriminative joint topic representations in the embedding space.

3 Problem Definition

Our weakly-supervised aspect-based sentiment analysis task is defined as follows. The input is a training corpus $\mathcal{D} = \{d_1, d_2, \ldots, d_{|\mathcal{D}|}\}$ of text reviews from a certain domain (e.g., restaurant or laptop) *without* any label for aspects or sentiment. A list of keywords l_a for each aspect topic (denoted as $a \in A$) and l_s for each sentiment polarity (denoted as $s \in S$) are provided by users as guidance. For each unseen review in the same domain, our model outputs a set of $\langle s, a \rangle$ labels.

4 Model

Figure 2 shows the workflow of **JASen**. Our goal is to generate a set of ⟨sentiment, aspect⟩ predictions for each review.

We first learn an embedding space to explicitly represent the semantics of the topics (including both pure aspect/sentiment and joint ⟨sentiment, aspect⟩ ones) as embedding vectors, which are surrounded by the embeddings of the representative words of the topics. We also impose discriminative regularization on the embedding space to push different topics apart. To model the local sequential information which is crucial for sentiment analysis, we use CNN as the classifier by pre-training it on pseudo labels given by the cosine similarity between document embeddings and topic embeddings, and self-training it on unlabeled data to iteratively refine its parameters. Below we introduce the details of **JASen**.

4.1 Joint-Topic Representation Learning

We learn the representations of words and topics on the in-domain corpus by following two principles: (1) distributional hypothesis (Sahlgren, 2008) and (2) topic distinctiveness. The first principle is achieved by an adaptation of the Skip-Gram model (Mikolov et al., 2013) through modeling both local and global contexts of words, and the second is achieved by a series of regularization

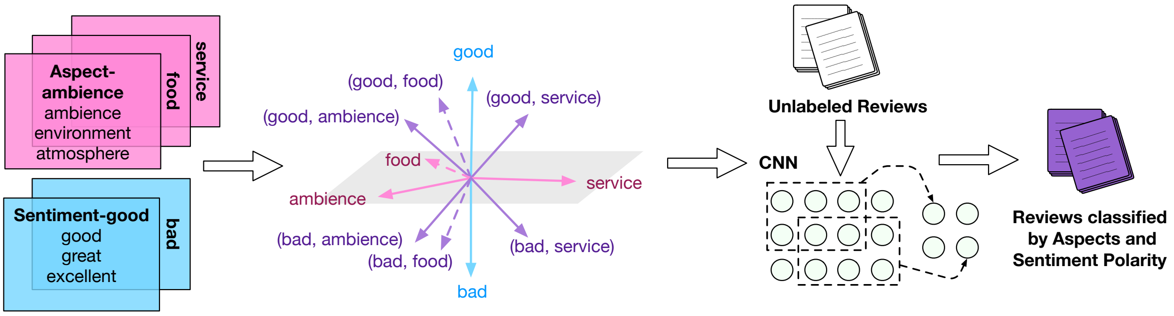

Figure 2: Overview of our model **JASen**. We first leverage the in-domain training corpus and user-given keywords to learn joint topic representation in the word embedding space. The marginal probability of keywords belonging to an aspect/sentiment can be summed up by the joint distribtution over ⟨sentiment, aspect⟩ joint topics. Embedding-based prediction on unlabeled data are then leveraged by neural models for pre-training and self-training.

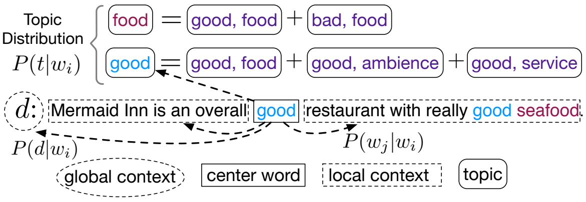

Figure 3: Embedding training.

objectives. Fig. 3 provides the overview of our embedding learning objectives with an example.

Modeling Local and Global Contexts. We learn word embeddings based on the assumption that words with similar contexts have similar meanings, and define contexts to be a combination of location contexts (Mikolov et al., 2013) and global contexts (Meng et al., 2019; Liao et al., 2019; Meng et al., 2020a). The local context of a word w_i refers to other words whose distances are h words or less from w_i. To maximize the probability of seeing the local context of a word w_i, we use the following objective:

$$\mathcal{L}_l = -\sum_{w_i} \sum_{0<|j-i|\le h} \log P(w_j|w_i), \tag{1}$$

where $P(w_j|w_i) \propto \exp(\boldsymbol{v}_j^\top \boldsymbol{u}_i)$, and $\boldsymbol{u}_i, \boldsymbol{v}_j$ are the center and context word embeddings.

The global context (Meng et al., 2019; Liao et al., 2019) of a word w_i refers to the document d where a word appears, based on the motivation that similar documents contain similar-meaning words. We use the following objective for global context:

$$\mathcal{L}_g = -\sum_{d\in\mathcal{D}} \sum_{w_i\in d} \log P(d|w_i), \tag{2}$$

where $P(d|w_i) \propto \exp(\boldsymbol{d}^\top \boldsymbol{u}_i)$.

Regularizing Pure Aspect/Sentiment Topics. To endow the embedding space with discriminative power over the aspect/sentiment categories for better classification performance, we regularize the aspect topic embeddings $\boldsymbol{t}_a$ and sentiment topic embeddings $\boldsymbol{t}_s$ so that different topics are pushed apart. For example, the word "good" in Fig. 3 is a keyword for the sentiment topic *good*, and we aim to place $\boldsymbol{t}_{\text{good}}$ close to the word embedding of "good" in the embedding space while away from other topic embeddings (*i.e.*, $\boldsymbol{t}_{\text{bad}}$). To achieve this, we maximize the probability of using each topic keyword to predict its representing topic:

$$\mathcal{L}_{reg}^{A} = -\sum_{a\in A} \sum_{w_i\in l_a} \log P(t_a|w_i), \tag{3}$$

$$\mathcal{L}_{reg}^{S} = -\sum_{s\in S} \sum_{w_i\in l_s} \log P(t_s|w_i), \tag{4}$$

where l_a, l_s are the keyword lists for aspect a and sentiment s, respectively; $P(t|w_i) \propto \exp(\boldsymbol{u}_i^\top \boldsymbol{t})$. Eqs. (3) and (4) empower the embedding space for classification purpose, that is, words can be "classified" into topics based on embedding similarity. For good initializations of $\boldsymbol{t}_a$ and $\boldsymbol{t}_s$, we use the average word embedding of user-provided keywords for each aspect and sentiment.

Regularizing Joint ⟨Sentiment, Aspect⟩ Topics. Now we examine the joint case, where $|S|\times|A|$ topics are regularized. We connect the learning of joint topic embeddings with pure aspect/sentiment topics by exploring the relationship between marginal distribution and joint distribution:

$$P(t_a|w_i) = \sum_{s\in S} P\left(t_{\langle s,a\rangle}\middle|w_i\right), \tag{5}$$

$$P(t_s|w_i) = \sum_{a\in A} P\left(t_{\langle s,a\rangle}\middle|w_i\right). \tag{6}$$

As an example, Fig. 3 shows that the marginal probability of the keyword "good" belonging to the sentiment topic "good" is equal to the probability sum of it belonging to ⟨good, food⟩, ⟨good, ambience⟩ and ⟨good, service⟩.

The objective for regularizing joint topics $\mathcal{L}_{joint}$ can be derived by replacing $P(t_a|w_i)$ in Eq. (3) with Eq. (5) and $P(t_s|w_i)$ in Eq. (4) with Eq. (6).

We also notice that general opinion words such as "good" (or pure aspect words such as "seafood") are equally irrelevant to the aspect (or sentiment) dimension, so we use a uniform distribution $\mathcal{U}$ to regularize their distribution over all the classes on the irrelevant dimension:

$$\mathcal{L}_{cross}^{A} = \sum_{s \in S} \sum_{w_i \in l_s} \mathrm{KL}\left(\mathcal{U}, P(t_a|w_i)\right), \quad (7)$$

$$\mathcal{L}_{cross}^{S} = \sum_{a \in A} \sum_{w_i \in l_a} \mathrm{KL}\left(\mathcal{U}, P(t_s|w_i)\right). \quad (8)$$

Putting the above objectives altogether, our final embedding learning objective is:

$$\mathcal{L} = \mathcal{L}_l + \lambda_g \mathcal{L}_g + \lambda_r (\mathcal{L}_{reg} + \mathcal{L}_{joint} + \mathcal{L}_{cross}), \quad (9)$$

where $\mathcal{L}_{reg} = \mathcal{L}_{reg}^{A} + \mathcal{L}_{reg}^{S}$, and the same for $\mathcal{L}_{joint}$ and $\mathcal{L}_{cross}$. For all the regularization terms, we treat them equally by using the same weight λ_r, which shows to be effective in practice.

4.2 Training CNNs for Classification

Word ordering information is crucial for sentiment analysis. For example, "Any movie is better than this one" and "this one is better than any movie" convey opposite sentiment polarities but have the exactly same words. The trained embedding space mainly captures word-level discriminative signals but is insufficient to model such sequential information. Therefore, we propose to train convolutional neural networks (CNNs) to generalize knowledge from the preliminary predictions given by the embedding space. Specifically, we first pre-train CNNs with soft predictions given by the cosine similarity between document embeddings and topic embeddings, and then adopt a self-training strategy to further refine the CNNs using their high-confident predictions on unlabeled documents.

Neural Model Pre-training. For each unlabeled review, we can (1) derive one distribution over the joint topics by calculating the cosine similarity between the document representation $\boldsymbol{d}$ and $\boldsymbol{t}_{\langle s,a \rangle}$, (2) derive separate distributions over sentiment and aspect variables using cosine similarity with marginal topics $\boldsymbol{t}_a$ and $\boldsymbol{t}_s$, or (3) combine (1) and (2) by adding the two sets of cosine scores. We find empirically that the last method achieves the best result, *i.e.*, the distribution of a test review d over the aspect and sentiment categories is computed as:

$$P(a|d) \propto \exp\left(T \cdot \left(\cos(\boldsymbol{t}_a, \boldsymbol{d}) + \frac{\sum_{s \in S} \cos(\boldsymbol{t}_{\langle s,a \rangle}, \boldsymbol{d})}{|S|}\right)\right), \quad (10)$$

$$P(s|d) \propto \exp\left(T \cdot \left(\cos(\boldsymbol{t}_s, \boldsymbol{d}) + \frac{\sum_{a \in A} \cos(\boldsymbol{t}_{\langle s,a \rangle}, \boldsymbol{d})}{|A|}\right)\right), \quad (11)$$

where $\boldsymbol{d}$ is obtained by averaging the word embeddings in d, and T is the temperature to control how greedy we want to learn from the embedding-based prediction.

We train two CNN models separately for aspect and sentiment classification by learning from the two distributions in Eqs. (10) and (11). We leverage the knowledge distillation objective (Hinton et al., 2015) to minimize the cross entropy between the embedding-based prediction p_d and the output prediction q_d of the CNNs:

$$H(p_d, q_d) = -\sum_{t} P(t|d) \log Q(t|d). \quad (12)$$

Neural Model Refinement. The pre-trained CNNs only copy the knowledge from the embedding space. To generalize their current knowledge to the unlabeled corpus, we adopt a self-training technique to bootstrap the CNNs. The idea of self-training is to use the model's high-confident predictions on unlabeled samples to refine itself. Specifically, we compute a target score (Xie et al., 2016) for each unlabeled document based on the predictions of the current model by enhancing high-confident predictions via a squaring operation:

$$\mathrm{target}(P(a|d)) = \frac{P(a|d)^2 / f_a}{\sum_{a' \in A} P(a'|d)^2 / f_{a'}},$$

where $f_a = \sum_{d \in \mathcal{D}} P(a|d)$. Since self-training updates the target scores at each epoch, the model is gradually refined by its most recent high-confident predictions. The self-training process is terminated when no more samples change label assignments after the target scores are updated. The resulting model can be used to classify any unseen reviews.

5 Evaluation

We conduct a series of quantitative and qualitative evaluation on benchmark datasets to demonstrate the effectiveness of our model.

Dataset	#Training reviews	#Test reviews
Restaurant	17,027	643
Laptop	14,683	307

Table 1: Dataset Statistics.

Dataset	Aspect	Keywords
Restaurant	Location	street block river avenue
	Drinks	beverage wines cocktail sake
	Food	spicy sushi pizza taste
	Ambience	atmosphere room seating environment
	Service	tips manager waitress servers
Laptop	Support	service warranty coverage replace
	OS	windows ios mac system
	Display	screen led monitor resolution
	Battery	life charge last power
	Company	hp toshiba dell lenovo
	Mouse	touch track button pad
	Software	programs apps itunes photoshop
	Keyboard	key space type keys

Table 2: Keywords of each aspect.

5.1 Experimental Setup

Datasets: The following two datasets are used for evaluation:

- **Restaurant**: For in-domain training corpus, we collect 17,027 unlabeled reviews from *Yelp Dataset Challenge*[2]. For evaluation, we use the benchmark dataset in the restaurant domain in SemEval-2016 (Pontiki et al., 2016) and SemEval-2015 (Pontiki et al., 2015), where each sentence is labeled with aspect and sentiment polarity. We remove sentences with multiple labels or with a *neutral* sentiment polarity to simplify the problem (otherwise a set of keywords can be added to describe it).
- **Laptop**: We leverage 14,683 unlabeled Amazon reviews under the laptop category collected by (He and McAuley, 2016) as in-domain training corpus. We also use the benchmark dataset in the laptop domain in SemEval-2016 and SemEval-2015 for evaluation. Detailed statistics of both datasets are listed in Table 1, and the aspects along with their keywords are in Table 2.

Preprocessing and Hyperparameter Setting. To preprocess the training corpus D, we use the word tokenizer provided by *NLTK*[3]. We also use a phrase mining tool, AutoPhrase (Shang et al., 2017), to extract meaningful phrases such as "great wine" and "numeric keypad" such that they can capture complicated semantics in a single text unit. We use the benchmark validation set to fine-tune the hyperparameters: embedding dimension = 100, local context window size $h = 5$, $\lambda_g = 2.5$, $\lambda_r = 1$, training epoch = 5. For neural model pre-training, we set $T = 20$. A CNN model is trained for each sub-task: aspect extraction and sentiment classification. Each model uses 20 feature maps for filters with window sizes of 2, 3, and 4. SGD is used with $1e-3$ as the learning rate in both pre-training and self-training and the batch size is set to 16.

5.2 Quantitative Evaluation

We conduct quantitative evaluation on both aspect extraction and sentiment polarity classification.

Compared Methods. Our model is compared with several previous studies. A few of them are specifically designed for aspect extraction but do not perform well on sentiment classification. So we only report their results on aspect extraction. For fair comparison, we use the same training corpus and test set for each baseline method. For weakly-supervised methods, they are fed with the same keyword list as ours.

- **CosSim**: The topic representation is averaged by the embedding of seed words trained by Word2Vec on training corpus. Cosine similarity is computed between a test sample and the topics to classify the sentence.
- **ABAE** (He et al., 2017): An attention-based model to unsupervisedly extract aspects. An autoencoder is trained to reconstruct sentences through aspect embeddings. The learned topics need to be manually mapped to aspects.
- **CAt** (Tulkens and van Cranenburgh, 2020): A recent method for unsupervised aspect extraction. A single head attention is calculated by a Radio Basis Function kernel to be the sentence summary.
- **W2VLDA** (García-Pablos et al., 2018): A state-of-the-art topic modeling based method that leverages keywords for each aspect/sentiment to jointly do aspect/sentiment classification.

labels for sentences containing keywords from a given aspect/sentiment.

- **JASen w/o joint**: An ablation of our proposed model. Neural model is pre-trained on separate topic embedding for each sentiment and aspect.
- **JASen w/o self train**: An ablation of our proposed model without self-training process.

Aspect Extraction. We report the results of aspect extraction of our model and all the baselines in Table 3. We use four metrics for evaluation: Accuracy, Precision, Recall and macro-F1 score. We observe that weakly-supervised methods tend to have a better performance than unsupervised ones, suggesting that using keywords to enrich the semantics of labels is a promising direction to increase classification performance. As shown in Table 3, our model, even without self-training, outperforms baseline methods on most of the metrics by a large margin, indicating that **JASen** obtains substantial benefits from learning the semantics of fine-grained joint topics, and self-training boosts the performance further. We observe that **JASen** can deal with cases where the target of the sentence is not explicitly mentioned. For example, **JASen** correctly labels "It's to die for!" as (good, food). Although nothing mentioned is related to food, "to die for" appears in other sentences addressing the tastiness of food, thus is captured by the joint topic of (good, food).

Sentiment Polarity Classification. We compare **JASen** against baseline methods on sentiment classification and show the results in Table 4. Since some methods are designed for aspect extraction and do not perform well on sentiment classification, we do not report their results. As shown in the table, **JASen** outperforms all the baselines on both datasets. We also observe that methods only leveraging local contexts do not perform well compared to methods that leverage both global and local contexts on **Laptop** dataset. Since "good" and "bad" are a pair of antonyms, they can have very similar collocations, so models purely capturing local contexts do not distinguish them well.

5.3 Qualitative Evaluation

To evaluate the quality of the joint topic representation, we retrieve their representative terms by ranking the embedding cosine similarity between words and each joint topic vector. For brevity, we randomly sample 3 aspects from each dataset and pair them up with the two sentiment polarity to form 12 joint topics. We list their top terms in Table 5. Results show that the representative terms form coherent and meaningful topics, and they are not restricted to be adjectives, such as "vomit" in (bad, food) and "commitment" in (good, support). Another interesting observation is that "cramped" appears in both (bad, ambience) in restaurant domain and (bad, keyboard) in laptop domain, suggesting that **JASen** captures different meanings of words based on in-domain corpus.

	Ambience	Service	Food	Support	Keyboard	Battery
Good	cozy, intimate, comfortable, loungy, great music	professional, polite, knowledgable, informative, helpful	huge portion, flavourful, super fresh, husband loves, authentic italian	accidental damage protection, accidental damage warranty, generous, guarantee, commitment	tactile feedback, tactile feel, classic, nicely spaced, chiclet style	lasts long, charges quickly, high performance, lasting, great power
Bad	cramped, unbearable, uncomfortable, dreary, chaos	inattentive, ignoring, extremely rude, condescending, inexperienced	microwaved, flavorless, vomit, frozen food, undercooked	completely useless, denied, refused, blamed, apologize	large hands, shallow, cramped, wrong key, typos	completely dead, drained, discharge, unplugged, torture

Table 5: Keywords retrieved by joint topic representations.

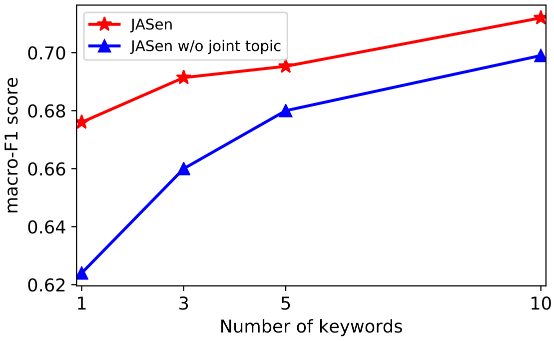

Figure 4: Macro-F1 score vs. keyword number.

5.4 Effect of Number of Keywords

We study the effect of the number of keywords. In Figure 4 we show the macro-F1 score of aspect extraction using different number of keywords for each aspect on **Laptop** dataset. The trend clearly shows the model performance increases when more keywords are provided. Moreover, when only one keyword is provided (only the label name), **JASen** still has a stable performance and a large gap over the ablation without learning joint topic embedding, implying that learning joint topic semantics is especially powerful in low resource setting.

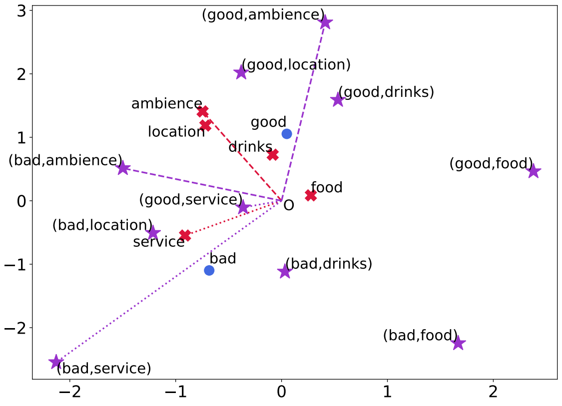

Figure 5: Visualization of joint topics (purple stars), aspect topics (red crosses) and sentiment topics (blue dots) in the embedding space.

5.5 Joint Topic Representation Visualization

To understand how the joint topics are distributed in the embedding space, along with the aspect and sentiment topics, we use PCA (Jolliffe, 2011) for dimension reduction to visualize topic embedding trained on the **Restaurant** corpus in Fig. 5. An interesting observation is that, some aspect topics (e.g., *ambience*) lie approximately in the middle of their joint topics ("*good, ambience*" and "*bad, ambience*"), showing that our embedding learning objective understands the joint topics as decomposition of their "marginal" topics, which fits with our goal to learn fine-grained topics.

5.6 Case Studies

We list several test samples along with their ground truth and model predictions in Table 6 and Table 7. Some conflicting cases between ours and the ground truth are rather ambiguous. For example, the ground truth of the second example in Table 6 is (good, location), but we still think given that the review mentions "the outdoor atmosphere" and uses terms like "sitting on the sidewalk" and "cool evening", it is more relevant to ambience than location, as is output by our full model. The gold aspect label for the second and the third reviews in Table 7 are both "company", but apparently these two sentences are talking about two different aspects: the product itself and the service of the company. Though the output of our model, "os" and "support" for these two sentences may not be the most precise prediction, at least our model treats them as two different aspects.

6 Conclusion

In this paper we propose to enhance weakly-supervised aspect-based sentiment analysis by learning the representation of ⟨sentiment, aspect⟩ joint topic in the embedding space to capture more fine-grained information. We introduce an

Review	Ground Truth	Output of Full Model	Output of Model w/o joint embedding
The wait staff is very freindly, they make it feel like you're eating in a freindly little european town.	(good, service)	(good, ambience)	(good, location)
The outdoor atmosphere of sitting on the sidewalk watching the world go by 50 feet away on 6th avenue on a cool evening was wonderful.	(good, location)	(good, ambience)	(good, ambience)
It's simply the best meal in NYC.	(good, food)	(good, food)	(good, location)
You can get a table without a reservation if you get there early I they don't make you by bottles.	(good, service)	(good, service)	(bad, service)
The sauce tasted more like Chinese fast food than decent Korean.	(bad, food)	(good, food)	(bad, food)
My wife had barely###touched that mess of a dish.	(bad, food)	(bad, food)	(good, food)
This is undoubtedly my favorite modern Japanese brasserie (that don't serve sushi), and in my opinion, one of the most romantic restaurants in the city!	(good, ambience)	(good, food)	(good, location)
We took advanatage of the half price sushi deal on saturday so it was well worth it.	(good, food)	(good, food)	(bad, food)
If you don't like it, I don't know what to tell you.	(good, food)	(bad, food)	(bad, service)

Table 6: Comparison of predictions on sample **Restaurant** reviews between our full model and model pre-trained w/o joint topic embedding.

Review	Ground Truth	Output of Full Model	Output of Model w/o joint embedding
NO junkware!!	(good, software)	(good, software)	(good, display)
I definitely will buy a Mac again if and when this computer ever fails.	(good, company)	(good, os)	(good, os)
I don't have the inclination or time to devote to a companies tech support, search functions, or hold times.....dropped the HP and never looked back.	(bad, company)	(bad, support)	(bad, company)
I find myself adjusting it regularly.	(bad, display)	(bad, display)	(bad, mouse)
I thought learning the Mac OS would be hard, but it is easily picked up if you are familiar with a PC.	(good, os)	(good, os)	(bad, os)
They told me to reprogram the computer, and I didn't need to do that, and I lost pictures of my oldests first 2 years of her life.	(bad, support)	(bad, support)	(good, support)
But, hey, it's an Apple.	(good, company)	(bad, company)	(good, company)
I'm no power###user, but I have had no learning###curve with the MAC and I don't do anything geeky enough forcing me to learn the OS.	(good, os)	(good, os)	(bad, os)
The battery lasted 12 months, then pffft.....gone.	(bad, battery)	(bad, battery)	(good, battery)

Table 7: Comparison of predictions on sample **Laptop** reviews between our full model and model pre-trained w/o joint topic embedding.

embedding learning objective that leverages user-given keywords for each aspect/sentiment and models their distribution over the joint topics. The embedding-based predictions are then used for pre-training neural models, which are further refined via self-training on unlabeled corpus. Experiments show that our method learns high-quality joint topics and outperforms previous studies substantially.

In the future, we plan to adapt our methods to more general applications that are not restricted to the field of sentiment analysis, such as doing multiple-dimension classification (e.g., topic, location) on general text corpus. Another promising direction is to leverage taxonomy construction algorithms (Huang et al., 2020) to capture more fine-grained aspects, such as "smell" and "taste" for "food".

Abstract

Peer review and rebuttal, with rich interactions and argumentative discussions in between, are naturally a good resource to mine arguments. However, few works study both of them simultaneously. In this paper, we introduce a new argument pair extraction (APE) task on peer review and rebuttal in order to study the contents, the structure and the connections between them. We prepare a challenging dataset that contains 4,764 fully annotated review-rebuttal passage pairs from an open review platform to facilitate the study of this task. To automatically detect argumentative propositions and extract argument pairs from this corpus, we cast it as the combination of a sequence labeling task and a text relation classification task. Thus, we propose a multi-task learning framework based on hierarchical LSTM networks. Extensive experiments and analysis demonstrate the effectiveness of our multi-task framework, and also show the challenges of the new task as well as motivate future research directions. [1]

Review:
[The authors introduce an extension of Continuous Ranked Probability Scores (CRPS) to the time-to-event setting termed Survival-CRPS for both right censored and interval-censored event data.]NON-ARGU ... [The claim that the proposed approach constitutes the first time a scoring rule other than maximum likelihood seems too strong, unnecessary and irrelevant to the value of the presented work.]REVIEW-1 [It is not clear how did the authors handle the irregularity (in time) of EHR encounters in the context of an RNN specification. Also, if the RNN specification considered is similar to Martinsson, 2016, why this wasn't considered as a competing model in the experiments?]REVIEW-2 ...

Rebuttal:
[Dear AnonReviewer3, we thank you for the time you spent reviewing and for the thoughtful comments.]NON-ARGU [You point out that our claim that the approach constitutes the first time a scoring rule other than maximum likelihood has been used seems too strong. ... However we have recently come across works such as adversarial time to event models, and therefore will remove the claim from the paper.]REPLY-1 [You also mention that it is unclear how irregularity (in time) of EHR encounters was handled by the RNN model. ... This approach naturally handles the irregularity of time between EHR encounters.]REPLY-2 ... [Thank you again for your time spent reviewing and constructive feedback on our work.]NON-ARGU

Table 1: An example of review-rebuttal passage pair. REVIEW-1 and REPLY-1 indicate the first argument in the review and its reply in the rebuttal.

1 Introduction

Argument mining is an important research field that attracts growing attention in recent years (Lawrence and Reed, 2019). It is applied in real-world applications such as legal documents (Mochales and Moens, 2011; Poudyal, 2015), online debates (Boltužić and Šnajder, 2015; Abbott et al., 2016), persuasive essays (Stab and Gurevych, 2014; Persing and Ng, 2016), etc. Most works in argument mining field focus on modeling arguments in monologues. Those focusing on the detection of agreement and disagreement in online interactions mainly fall in domains such as online debates and discussions (Chakrabarty et al., 2019).

Peer review is a widely-adopted evaluation process for scientific works (Kelly et al., 2014; Falkenberg and Soranno, 2018). As the number of submissions increases rapidly in recent years, how to evaluate the submissions effectively and efficiently becomes an attention-attracting challenge, and the study on peer review itself emerges as a new research topic (Xiong and Litman, 2011; Hua et al., 2019b). Nevertheless, the rebuttal part, which is often ignored, is an indispensable and interesting

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7000–7011,
November 16–20, 2020. ©2020 Association for Computational Linguistics

item in this scenario. Peer review and rebuttal, containing rich arguments, are a worth-studying domain for argument mining. In practice, a review and its rebuttal have strong interactions and relations, as a rebuttal usually contains coherent segments that argue with specific arguments in review. Compared to online debates and discussions, peer reviews and rebuttals on scientific works are a data source of rich structures and long passages for studying the argument pair extraction (APE). This study can also be applied to the study of online debates and discussions on how to respond to opponents' arguments.

Motivated by this, we aim to automatically extract the argument pairs from reviews and rebuttals by studying review-rebuttal pairs together in this work. In order to facilitate the study of this task, we introduce a newly-annotated dataset, named **R**eview-**R**ebuttal (RR) dataset. We create RR by first collecting all useful information related to the submissions from ICLR in recent years. In total, we select a corpus of 4,764 review-rebuttal passage pairs from over 22K reviews and author responses that are collected from the website. Then we annotate all these review and rebuttal passage pairs following a set of carefully defined annotation guidelines. Table 1 is an example of review-rebuttal passage pair, which shows the annotation result. The two passages of review and rebuttal are segmented into arguments and non-arguments. For arguments, indices are also labeled to show the alignment between review and rebuttal, i.e., the rebuttal argument that attacks the review argument.

With the prepared RR dataset, we focus on two subtasks in this work: (1) argument mining - detecting the arguments in each review/rebuttal by document segmentation. (2) sentence pairing - detecting if the sentences in a review argument form an argument pair with the sentences in a rebuttal argument. We cast the first subtask as a sentence-level sequence labeling task and the second subtask as a sentence-level binary classification task. As the two subtasks are mutually reinforcing each other, we then propose a multi-task learning framework based on the hierarchical bidirectional long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) networks with a conditional random field (CRF) (Lafferty et al., 2001) layer (Lample et al., 2016). Our model allows learning better sentence representations for these two subtasks simultaneously. To better understand our model's capability, we evaluate the performance for each subtask separately as well as the overall argument pair extraction performance. Extensive experiments demonstrate the effectiveness of our model and challenges of our proposed task.

To summarize, our contributions include:

- We propose a new task of argument pair extraction from peer reviews and rebuttals. Meanwhile, a large corpus that facilitates this study is created.
- We propose a multi-task learning model that learns better sentence embeddings by coordinating the two subtasks.
- Extensive experiments and analysis demonstrate the effectiveness of our model, show the challenges of the new task, and also motivate future research directions.

2 Related Work

Argument Mining. There is an increasing number of works in the computational argumentation research field in recent years, such as argument mining (Shnarch et al., 2018; Trautmann et al., 2020), argument relation detection (Rocha et al., 2018; Hou and Jochim, 2017), argument quality assessment (Wachsmuth et al., 2017; Gleize et al., 2019; Toledo et al., 2019; Gretz et al., 2019), argument generation (Hua and Wang, 2018; Hua et al., 2019a; Schiller et al., 2020), etc. Stab and Gurevych (2014) and Persing and Ng (2016) both propose pipeline approaches to identify argumentative discourse structures in persuasive essays, which mainly includes two steps: extracting argument components and identifying relations. In terms of the task and the dataset, we intend to extract argument pairs from two passages simultaneously, while they focus on a single passage. In addition, we present a multi-task framework to tackle our proposed task instead of using a pipeline approach. Swanson et al. (2015) aim to extract arguments from a large corpus of posts from online forums. They frame their problem as two separate subtasks: argument extraction and argument facet similarity. Chakrabarty et al. (2019) focus on argument mining in online persuasive discussion forums based on the CMV dataset. Compared to both of their datasets, our dataset's contents are more academic and are strongly inclined to attack the other argument. Scale-wise, our dataset consists of 156K sentences, while Chakrabarty et al. (2019)'s dataset has 2,756 sentences.

Peer Reviews Mining. Previous works focus on studying peer reviews by introducing new datasets or understanding the structure and the content of peer reviews. Kang et al. (2018) present a dataset named PeerRead collected from venues including ACL, NIPS and ICLR. It consists of 14.7K paper drafts with their corresponding accept/reject decisions and 10.7K peer reviews for a subset of papers. They also propose several tasks based on their dataset, such as predicting whether a paper is accepted. Hua et al. (2019b) then present a partially annotated dataset named AMPERE collected from ICLR, UAI, ACL and NeurIPS. They use their dataset to detect the propositions and to classify them into different types for understanding the contents of peer reviews. Compared to the two works described above, our work has two main differences. First, instead of only looking at peer reviews, we propose a task to study the reviews and rebuttals jointly. Another difference lies in dataset: ours is fully annotated with 4,764 pairs of reviews and rebuttals, while only 400 reviews are annotated in AMPERE. As mentioned, few works touch on the rebuttal part, which is the other important element of the peer review process. Gao et al. (2019) propose a task to predict after-rebuttal scores from initial reviews and author responses. They collect their dataset from ACL, which includes around 4K reviews and 1.2K author responses. However, our argument pair extraction task focuses more on the internal structure and relations between reviews and rebuttals. In addition, the size of our dataset is much larger than theirs.

3 RR Dataset

We create the **R**eview-**R**ebuttal (RR) dataset to facilitate the study of argument pair extraction. To the best of our knowledge, this is the first dataset for argument mining between paired reviews and rebuttals. We first describe the process of data collection, and then present the annotation details.

Data Collection. To prepare our dataset, we first collect all useful information for ICLR 2013 - 2020 (except for 2015 that is unavailable) from `openreview.net`. The information mainly contains two parts: (1) information about the submissions, such as title, authors, year, track, acceptance decision, original submission separated by sections, etc.; (2) information about reviews and author responses, such as review passages, rebuttal passages, review scores, reviewer confidence, etc. Only review-rebuttal pairs are used in this work, while other data are reserved for further study on relevant tasks. In total, 22,127 reviews and rebuttals are collected. After excluding those reviews receiving no reply, we extract 4,764 review-rebuttal passage pairs for data annotation. For those reviews with multiple rounds of rebuttals, only the first rebuttal is selected.

Data Annotation. In this work, we concentrate on argument pair extraction from review-rebuttal passage pairs. In total, 5 professional data annotators are hired to annotate these 4,764 passage pairs based on the unified guidelines described below.

Firstly, for the argument mining part, the annotators segment reviews and rebuttals by labeling the arguments. In reviews, only sentences expressing non-positive comments are considered as arguments, e.g., review sentences that are related to specific suggestions, questions or challenges. In rebuttals, contents that are answering or explaining the specific review arguments are considered as arguments. All annotated arguments are semantically coherent segments. Sentences such as courtesy expressions or general conclusions are labeled as non-arguments. Note that the data are annotated on sentence granularity, i.e., an argument boundary is always a sentence boundary. Given the arguments of both passages, the second step is to pair an review argument with its corresponding rebuttal argument. We first assign indices to the arguments in reviews and then label the corresponding reply arguments in rebuttals with the same index. For example, in Table 1, $\{\text{REVIEW-}1, \text{REPLY-}1\}$ and $\{\text{REVIEW-}2, \text{REPLY-}2\}$ are two argument pairs.

We label 40,831 arguments in total, with 23,150 arguments from reviews and 17,681 arguments from rebuttals. We assess the annotation quality based on random sampling from the full dataset. 5% of the original review-rebuttal passage pairs (252 pairs) are checked. 39 out of 2,417 sampled arguments' labels are missed or have marginal error. Throughout the quality assessment, the annotation accuracy of the RR dataset reaches 98.4%.

We also classify the passages into *difficult* and *easy* based on the annotation difficulty when annotating the data. *Easy* is marked when the review and rebuttal passages have well-aligned arguments with clear structure. The annotators are able to identify the argument pairs without fully understanding the contents. For example, if the author cites the review by copying part of the review argument or

		RR
	# instances (i.e., review-rebuttal pairs)	4,764
Review	# sentences	99.8K
	# arguments	23.2K
	# argument sentences	58.5K
	Avg. # sentences per passage	21.0
	Avg. # sentences per argument	2.5
Rebuttal	# sentences	94.9K
	# arguments	17.7K
	# argument sentences	67.5K
	Avg. # sentences per passage	19.9
	Avg. # sentences per argument	3.8
Vocab.	Total vocab size	165K
	Review vocab size	103K
	Rebuttal vocab size	105K
	Avg. % vocab shared in each passage pair	16.6%
	Avg. % vocab shared in each argument pair	9.9%

Table 2: Overall statistics of RR dataset.

there are clear signals (i.e., line break, index, etc.) separating the arguments, it would be considered as *easy*. In total, 65.5% of the data (3,119 pairs) are classified as *easy*. *Difficult* is marked when the review and rebuttal passages do not have clear structure. The annotators have to understand the contents to identify the argument pairs. 29% of the data (1,383 instances) are classified as *difficult*. There are also 5.5% belonging to neither of the two classes, as there is no argument pair between them. This case usually happens when the rebuttal part only contains a few sentences by a general reply, such as "Thanks for your review. We will use your suggestions to improve our work." or "Thanks, your comments were helpful and we've taken them into account in the updated paper.". Note that in our dataset, we keep the original structure information in the plain-text, such as line breaks and indents.

Data Analysis. The overall statistics are shown in Table 2. Although the rebuttal passages are generally shorter than the review passages (i.e., more sentences in each review passage on average), the rebuttal arguments are relatively longer than the review arguments. Additionally, a larger portion of sentences are arguments in rebuttals than in reviews. In the rebuttal passages, authors tend to only focus on replying reviewer's arguments by explaining their points clearly. While reviewers are more likely to provide summaries and compliments about the submissions apart from questions and suggestions, which are not considered as arguments in this work. As shown in the vocabulary part from Table 2, the average percentage of vocabulary shared between each review and rebuttal argument pair is only 9.9%, which is much lower than the ratio across entire passages (16.6%). This indicates that conducting argument pair extraction on our dataset is very challenging since there are fewer shared words in a pair.

4 Task Description

In this work, we intend to automatically detect the argument pairs from each passage pair of review and rebuttal. Specifically, we first perform argument mining on the two passages, a review passage of m sentences $R_1 = \left[s_1^1, s_1^2, \cdots, s_1^m\right]$ and a rebuttal passage of n sentences $R_2 = \left[s_2^1, s_2^2, \cdots, s_2^n\right]$. Each mined argument consists of one or more sentences from the passage with no overlapping with other arguments, such as REVIEW-1, REVIEW-2, REPLY-1, and REPLY-2 in Table 1. Then we extract the argument pairs by matching individual review arguments with the rebuttal arguments, such as $\{\text{REVIEW-1}, \text{REPLY-1}\}$ and $\{\text{REVIEW-2}, \text{REPLY-2}\}$.

Data Processing. Based on the annotation, we further process our dataset by segmentation and re-labeling in order to fit the need of downstream models. Accordingly, each segment in the passage (for both argument and non-argument) is further segmented into sentences. Each sentence is then assigned a label according to the standard IOBES tagging scheme (Ramshaw, 1995; Ratinov and Roth, 2009). For example, in Table 1, each sentence in NON-ARGU is labeled as O; REVIEW-1 is labeled as S since there is only one sentence in that argument; the two sentences in REVIEW-2 are labeled as $\{\text{B}, \text{E}\}$ in sequence. In addition, we assign a binary label for each pair of review sentence and rebuttal sentence to indicate if the two sentences in this pair are aligned. Specifically, the binary label is 1 only when: 1) both two sentences are from arguments; 2) the rebuttal sentence is replying the argument where the review sentence originates. Otherwise, 0 will be assigned.

5 Multi-task Learning based Extraction

As shown in Figure 1, we propose a multi-task learning framework with hierarchical LSTM networks, named MT-H-LSTM-CRF, to tackle the two subtasks, namely, argument mining and sentence pairing. The red dotted box on the left shows our sentence encoder which uses the pre-trained

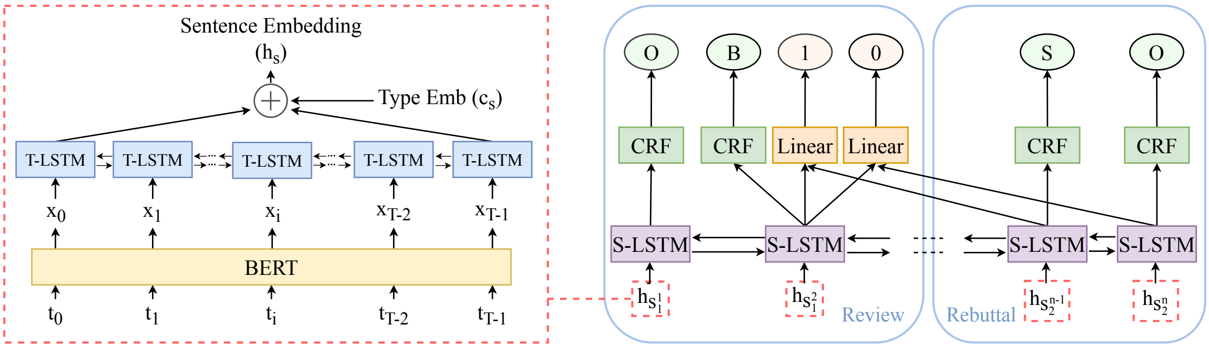

Figure 1: Overview of our MT-H-LSTM-CRF model architecture. The sentence encoder (in the red dotted box on the left) shows the process of obtaining sentence embeddings from pre-trained BERT token embeddings with T-LSTM. The multi-task learning based framework (on the right) shows the process of generating labels for both subtasks with the shared S-LSTM.

BERT (Devlin et al., 2019) token embeddings as the input of a token-level biLSTM (T-LSTM) to get sentence embeddings. Then, the encoded sentence embeddings are input to the second layer of LSTM on the sentence level (S-LSTM) to encode the sequence information of the passages. Finally, two types of labels, i.e., IOBES and 1/0, are predicted simultaneously from the shared features generated from the S-LSTM. Note that the aforementioned procedure is of multi-task training. During the inference, the trained multi-task model will be decoupled into two sub-modules to perform the two subtasks in a pipeline manner to extract the final argument pairs.

5.1 Sentence Encoder

We first introduce how to get the sentence embeddings as the input for our main model. As shown in the left part of Figure 1, the input is a sentence with a list of T tokens $s = [t_0, t_1, \cdots, t_{T-1}]$. We adopt bert-as-service (Xiao, 2018) as a tool to obtain the embeddings for all tokens $[x_0, x_1, \cdots, x_{T-1}]$ in the sentence. The token embeddings are then fed into a token-level biLSTM layer (T-LSTM), where the last hidden states from both directions are concatenated as the sentence embedding. In order to distinguish the sentence type (i.e., review or reply), we concatenate the current sentence embedding with a trainable type embedding c_s that is randomly initialized, to obtain the final sentence embedding h_s for the main model on the right.

5.2 biLSTM-CRF

After we obtain the sentence embeddings with T-LSTM as the input, we adopt a biLSTM-CRF structure to perform the sentence-level IOBES tagging for mining arguments. As shown in the right part of Figure 1, after the S-LSTM encodes the sequence information of a sentence sequence, the CRF layer takes the feature of each position to predict tags.

Given a sequence of review-rebuttal sentences $\mathbf{s} = \{s_1^1, s_1^2, \cdots, s_1^m, s_2^1, s_2^2, \cdots, s_2^n\}$, which is the concatenation of R_1 and R_2, our task is to predict a label sequence $\mathbf{y}$ where each element y_i belongs to the label set $\{\text{B}, \text{I}, \text{E}, \text{S}, \text{O}\}$. The probability of a label sequence $\mathbf{y}$ given $\mathbf{s}$ is defined as:

$$p(\mathbf{y}|\mathbf{s}) = \frac{\exp(score(\mathbf{s}, \mathbf{y}))}{\sum_{\mathbf{y}} \exp(score(\mathbf{s}, \mathbf{y}))},$$

where the $score(\mathbf{s}, \mathbf{y})$ is usually defined as a linear function in traditional CRF models. In the neural CRF model, the score can be obtained from the neural network encoders such as biLSTM networks. As shown in the following equation, it is calculated by the sum of transition scores along the label sequence $\mathbf{y}$ and the scores from the neural networks:

$$score(\mathbf{s}, \mathbf{y}) = \sum_{i=0}^{n} A_{y_i, y_{i+1}} + \sum_{i=1}^{n} F_{\theta_1}(\mathbf{s}, y_i),$$

where $A_{y_i, y_{i+1}}$ represents the transition parameters between two labels, and $F_{\theta_1}(\mathbf{s}, y_i)$ indicates the score of y_i obtained from the neural network encoder parameterized by θ_1. y_0 and y_{n+1} represent the "START" and "END" labels, respectively. We aim to minimize the negative log-likelihood for our dataset $\mathcal{D}_1$:

$$\mathcal{L}_1(A, \theta_1|\mathcal{D}_1) = -\sum_{(\mathbf{s},\mathbf{y}) \in \mathcal{D}_1} \log p(\mathbf{y}|\mathbf{s}).$$

The gradients with respect to the parameters can be calculated efficiently through the forward-backward algorithm in the CRF layer and back propagation in the neural networks.

During decoding, we retrieve the label sequence through Viterbi algorithm over all the possible label sequences:

$$\mathbf{y}^* = \arg\max_{\mathbf{y}\in\mathcal{Y}} p(\mathbf{y}|\mathbf{s}).$$

5.3 biLSTM-linear

In order to predict the pairing relation among arguments, our framework incorporates a sentence-level binary classification task. The classifier predicts that if two sentences belong to the same pair of argument, we then utilize the predictions to infer the pairing information between two augments.

Specifically, we sum up the S-LSTM outputs of the review sentence and the rebuttal sentence in a pair as the pair feature:

$$h_{pair}^{i,j} = h_{s_1^i} + h_{s_2^j}, \forall s_1^i \in R_1, s_2^j \in R_2.$$

Then $h_{pair}^{i,j}$ is fed into linear layers to predict the binary label $z_{pair}^{i,j} \in \{0, 1\}$. The negative log-likelihood for our dataset $\mathcal{D}_2$ parameterized by θ_2 is minimized as follows:

$$\mathcal{L}_2(\theta_2|\mathcal{D}_2) = -\sum_{(h_{pair},z)\in\mathcal{D}_2} \Big(z \log p(z = 1|h_{pair}) + (1 - z)\log p(z = 0|h_{pair})\Big).$$

During decoding, as shown in Figure 1, each binary tag is predicted as:

$$z^* = \arg\max_{z\in\{0,1\}} p(z|h_{pair}).$$

Here the sentence representations from S-LSTM are shared by biLSTM-linear and biLSTM-CRF, which coordinate the two subtasks to achieve the best performance on argument pair extraction.

Negative Sampling. Obviously, according to the data processing step in Section 4, the classification dataset with binary labels is unbalanced. To ease the problem, we adopt negative sampling techniques (Mikolov et al., 2013). During training, for each review argument sentence, we randomly select k non-aligned rebuttal argument sentences as negative samples. These k negative samples together with all positive pairs form our dataset $\mathcal{D}_2$.

5.4 Multi-task Training

To conduct the multi-task learning, we simply sum up the losses of the two subtasks:

$$\mathcal{L} = w_1\mathcal{L}_1(A, \theta_1|\mathcal{D}_1) + w_2\mathcal{L}_2(\theta_2|\mathcal{D}_2),$$

where w_1 and w_2 are weights for each loss accordingly. Note that in the training phase, we do not check the performance of individual subtasks, as we select the best model according to the overall argument pair extraction result on the development set. During the inference, we first mine the arguments with the sequence labeling module and then feed the labeled results of argument mining into the binary classifier to conduct sentence pairing.

6 Experiments

6.1 Data Preparation

We first split our RR dataset on review-rebuttal passage-pair level randomly by a ratio of 8:1:1 for training, development and testing, namely **RR-passage**. In RR-passage dataset, all argument pairs from the same passage pair are put into only one of the training, development and testing sets. However, different review-rebuttal passage pairs of the same submission could be put into different sets.

Since different reviewers may discuss similar issues for one submission, different review-rebuttal passage pairs of the same submission may share similar context information. To alleviate this effect, we also prepare another dataset version split on the submission level, namely **RR-submission**. It also follows the ratio of 8:1:1 for training, development and testing tests. In RR-submission, multiple review-rebuttal passage pairs of the same submission are in the same set.

6.2 Experimental Settings

We implement our multi-task framework in PyTorch. All models are run with V100 GPU. The dimension of pre-trained BERT sentence embeddings is 768 by default. The dimension of type embedding is set as 20. Number of T-LSTM layers is set as 1. Number of S-LSTM layers is set as 2. Number of linear layers for binary classification task is 3. We randomly select 5 negative samples for the classification task during training in main experiments. We use Adam (Kingma and Ba, 2014) with an initial learning rate of 0.01 and update parameters with a batch size of 10. The weights shared between two losses w_1 and w_2 are both set as 0.5. The training phase is stopped when detecting the convergence on the validation set. More details of parameter setting, such as the number of LSTM/linear layers, the weights of losses, and the comparison between sum and concatenation for sentence pair representation, can be found in Appendix A. Note that in this paper, the parameters are mainly tuned based on RR-passage.

Models	Argument Mining			Sentence Pairing			Argument Pair Extraction		
	Precision	Recall	F1	Precision	Recall	F1	Precision	Recall	F1
PL-H-LSTM-CRF	**73.10**	67.65	70.27	62.52	**75.32**	**68.32**	21.24	19.30	20.23

Table 3: Main results on **RR-passage** dataset.

6.3 Results on RR-passage Dataset

6.3.1 Results of Argument Pair Extraction

In the testing stage, our trained multi-task framework is applied as two modules to conduct the subtasks of argument mining and sentence pairing sequentially. Thus, we evaluate our model in three aspects: argument mining, sentence pairing, and argument pair extraction. After the argument mining step, we evaluate the mining result by checking the correctness of each argument span consisting of one or a few sentences labeled with IOBES. The sentence pairing step takes the mining results to predict the pairing relation of two predicted argument spans. This step first conducts prediction on sentence pairs, and then applies the sentence pairing results to infer the argument pairing relation. More details on how to determine the argument pairing relation can be found in Appendix B. After this step, we obtain the final results of argument pair extraction and check their correctness against the gold labeled argument pairs. We also evaluate the performance of binary classification for the sentence pairing step on the sentence pair data, as described in the data processing step in Section 4.

Main Results. Table 3 shows the performance on both subtasks as well as the overall extraction performance on RR-passage dataset, where we compare our proposed multi-task model (**MT-H-LSTM-CRF**) with several strong baselines. The first model is a pipeline approach, and the others are all multi-task learning based. As mentioned before, for the multi-task learning models, we select the best model according to the final argument pair extraction performance on the development set.

First, **PL-H-LSTM-CRF** is a pipeline approach that trains argument mining and sentence pairing modules independently and then pipes them together to extract argument pairs. Although **PL-H-LSTM-CRF** achieves competitive performance on argument mining task and the highest F1 score on sentence pairing task, its overall extraction performance is much worse than our multi-task model **MT-H-LSTM-CRF**. The main reason is that the sentence embeddings in the pipeline approach are not shared. Thus, although these two subtasks can be well learned separately, they are not trained to collaborate with each other. Its lower overall performance shows the necessity of multi-task training for precise argument pair extraction.

In contrast, our multi-task model shares sentence embeddings by the hierarchical LSTM design. **MT-LSTM-CRF** is a baseline without the hierarchical LSTM design. Specifically, T-LSTM is removed from our framework. Compared with **MT-H-LSTM-CRF**, **MT-LSTM-CRF** achieves much worse performance on argument mining task and overall extraction evaluation, but competitive performance on sentence pairing task. It shows the importance of the hierarchical design on the argument mining task because T-LSTM learns the semantics of individual sentences on token granularity, which is important for predicting if a sentence is argumentative. Compared with the pipeline method, i.e., **PL-H-LSTM-CRF**, **MT-LSTM-CRF** still achieves slightly better overall extraction performance, which shows the shared S-LSTM layer in the multi-task learning can help to coordinate the training of two subtasks.

To further verify the effectiveness of our multi-task learning through the hierarchical LSTM design, we investigate another baseline, namely, **Hybrid-MT-H-LSTM-CRF**, which uses the sentence embeddings from T-LSTM as the features for the sentence pairing classification and uses the embeddings from S-LSTM for labeling argument sentences. Here, the performance of the sentence pairing task is sacrificed for better overall extraction result, as the best model is selected based on the F1 score of argument pair extraction. With no incorporation of the context information captured by S-LSTM, the sentence pairing task performance drops significantly, which leads to poorer overall extraction performance compared to **MT-H-**

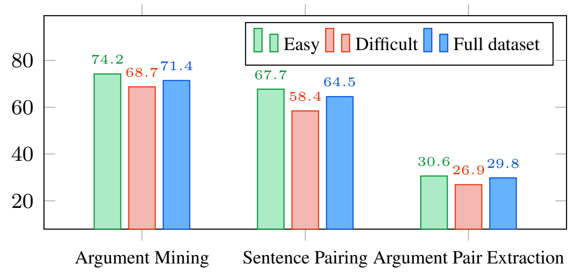

Figure 2: Breakdown F1 results by difficulty.

Models	Precision	Recall	F1
LSTM-CNN	51.42	41.01	47.29
LSTM-CRF	55.74	43.20	50.33
LSTM-CRF-type	62.98	56.24	59.42
H-LSTM-CRF (Ours)	**73.10**	**67.65**	**70.27**

Table 4: Performance on argument mining task.

LSTM-CRF. This observation again verifies the importance of sharing ample information between two subtasks with the hierarchical LSTMs design.

Comparison among different difficulty levels. We further evaluate the performance of different difficulty levels. As mentioned earlier, difficulty levels are annotated based on whether the annotators are able to extract the argument pairs by looking at the structure but without fully understanding the specific contents. It is clear to see from Figure 2 that the performance for *easy* instances is obviously better on overall argument pair extraction as well as two individual subtasks. This indicates that the structure information of review-rebuttal passages plays an important role in both argument mining and sentence pairing.

6.3.2 Argument Mining Subtask Evaluation

Here we examine the performance of different models on the argument mining task. The results are shown in Table 4. For MT-H-LSTM-CRF, we downgrade it to **H-LSTM-CRF** by only training the argument mining module, which is the same as the first step of **PL-H-LSTM-CRF**. The first two, i.e., **LSTM-CNN** (Chiu and Nichols, 2016) and **LSTM-CRF**, are classical sequential labeling models, which take the sentence embeddings from BERT as input of the LSTM layer. **LSTM-CRF-type** takes the concatenation of sentence embeddings and type (i.e., review or rebuttal) embeddings as input, which is the same as the first step of **MT-LSTM-CRF**. **LSTM-CRF-type** performs much better than **LSTM-CRF**. This indicates the usefulness of type embeddings. **H-LSTM-CRF** achieves much better results, which is consistent with our conclusion on the importance of our hierarchical LSTM design in the previous subsection. Note that as shown in Table 3, the results of **MT-LSTM-CRF** for the first subtask are a bit lower than those of **LSTM-CRF-type** here, which is mainly because the multi-task training negatively affects the former's performance. However, when we compare the results of **MT-H-LSTM-CRF** for the first subtask in Table 3 with the performance here of **H-LSTM-CRF**, the former even performs better, which shows that after adding the T-LSTM layer, our multi-task model's capability for argument mining is indeed benefited.

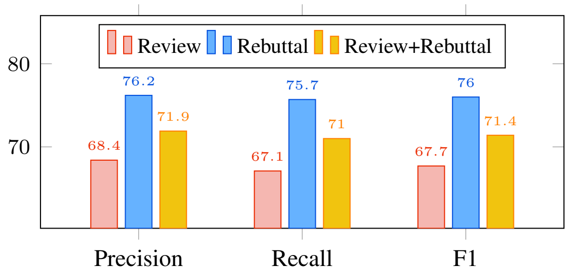

Figure 3: Comparison of argument mining results between review and rebuttal.

# NS	P:N	Precision	Recall	F1
4Argu	1:1.2	29.87	28.35	29.09
5Argu	1:1.4	30.08	**29.55**	**29.81**
6Argu	1:1.6	**30.59**	28.80	29.67
No sampling	1:15.1	29.34	27.40	28.34

Table 5: Argument pair extraction results under different negative samples (NS).

Figure 3 shows the argument mining results on reviews and rebuttals respectively. It is clear that the model performs significantly better on the rebuttal passages than on the review passages. This suggests that rebuttals have more organized and clearer structure than reviews. Indeed, in the rebuttal phase, authors reply reviewer's suggestions and questions very carefully to make the points clear, sometimes by citing the review arguments. Thus, the structure and the format of rebuttals are relatively fixed, while reviewers have more flexibility in the style and the structure when writing reviews.

6.3.3 Data Sampling Strategies

For training the sentence pairing classifier, we investigate the effect of data sampling on the matching performance. Specifically, we compare the

Models	Argument Mining			Sentence Pairing			Argument Pair Extraction		
	Precision	Recall	F1	Precision	Recall	F1	Precision	Recall	F1
PL-H-LSTM-CRF	67.63	68.51	68.06	61.01	55.49	58.12	19.86	19.94	19.90
MT-LSTM-CRF	62.38	54.29	58.05	**72.63**	**59.79**	**65.59**	23.28	18.80	20.80
Hybrid-MT-H-LSTM-CRF	69.39	69.95	69.67	49.60	13.64	21.40	21.95	22.12	22.04
MT-H-LSTM-CRF (Ours)	**70.09**	**70.14**	**70.12**	71.47	52.61	60.61	**26.69**	**26.24**	**26.46**

Table 6: Main results on **RR-submission** dataset.

performance of using different numbers (i.e., k) of negative samples for each review argument sentence. Table 5 shows the results for argument pair extraction, as well as the ratio of positive samples to negative samples (P:N). When training with all non-aligned sentence pairs as negative samples, i.e., **No sampling**, the ratio of aligned pairs to non-aligned pairs is 1:15.1, which is obviously unbalanced leading to the poor results. We then select only 4/5/6 non-aligned rebuttal argument sentences randomly as negative samples for each review argument sentence, i.e., **4Argu**, **5Argu** and **6Argu**. Generally speaking, the ratio is more balanced, and the overall extraction performance improves, and of course, the training is more efficient. Especially, when 5 non-aligned argument pairs are selected (**5Argu**), our model achieves the best F1 score (29.81) for argument pair extraction.

6.4 Results on RR-submission Dataset

We also conduct the major experiments on RR-submission dataset with the same settings as used on RR-passage. The results on argument mining, sentence pairing and argument pair extraction are shown in Table 6. We observe that our proposed **MT-H-LSTM-CRF** consistently outperforms the baseline models. However, it performs slightly worse on RR-submission than on RR-passage, plausibly because there is no context information (i.e., background knowledge from original submissions) shared between different passage pairs.

7 Conclusions and Future Work

In this paper, we introduce a new task of extracting argument pairs from review and rebuttal passages, which explores a new domain for the argument mining research field. A new large-scale and challenging dataset RR is collected and fully annotated to facilitate the study of the proposed task. We then propose a multi-task learning approach based on hierarchical LSTM networks to work towards this problem. In the future, we will explore the latent information between peer reviews and author responses to improve argument pair extraction. We will also explore related useful research tasks using extra collected information related to scientific work submissions in RR.

A Additional Experiments

Effect of Number of T-LSTM Layers. We compare the performance of argument pair extraction and two subtasks when using different numbers of T-LSTM layers (i.e., L_T). L_S denotes the number of S-LSTM layers. In Table 7, **MT-LSTM-CRF** is the model when T-LSTM is not adopted (i.e., the number of T-LSTM layers is 0). With the incorporation of the T-LSTM, **MT-H-LSTM-CRF** outperforms **MT-LSTM-CRF**. As we can see, **MT-H-LSTM-CRF**(L_T**=1,**L_S**=1**) performs better than **MT-H-LSTM-CRF**(L_T**=2,**L_S**=1**). This suggests that long-distance dependency among tokens does not help for sentence embedding learning.

Effect of Number of S-LSTM Layers. We compare the performance when using different numbers of S-LSTM layers (i.e., L_S). As we can see from Table 8, **MT-H-LSTM-CRF**(L_T**=1,**L_S**=2**) outperforms the other two models for argument mining subtask and argument pair extraction task. This again shows the importance of context information in the review and rebuttal passages. However, increasing the number of layers (e.g., L_S=3) does not gain further performance improvements for **MT-H-LSTM-CRF**. This implies that the third-order context information in the passages does not play an important role in extracting argument pairs.

Effect of Number of Linear Layers. We also evaluate the performance when using various numbers of linear layers for sentence pairing task. The results are shown in Table 9. Here, we fix the number of S-LSTM layers and the number of T-LSTM layers both at 1. When the number of linear layers is 2, **MT-H-LSTM-CRF**(L_T**=1,**L_S**=1**) performs the best on sentence pairing task. However, the performance reaches the peak when we increase the number of linear layers to 3 and drops significantly when we further increase the number of linear layers to 4. This suggests too few or too many parameters may harm the model performance.

Effect of Weight Ratio between two Losses. In order to evaluate the effect of the weights for two subtasks in our proposed multi-task model, we compare the performance when assigning different weights for both two subtasks. The results are shown in Table 10. For the argument pair extraction, **MT-H-LSTM-CRF** performs the best when equal weight is assigned across two subtasks. The performance of both argument mining subtask and argument pair extraction task drops consistently when more weights are assigned for sentence pairing subtask. This suggests that maintaining a competitive performance for argument mining task is critical for the multi-task training.

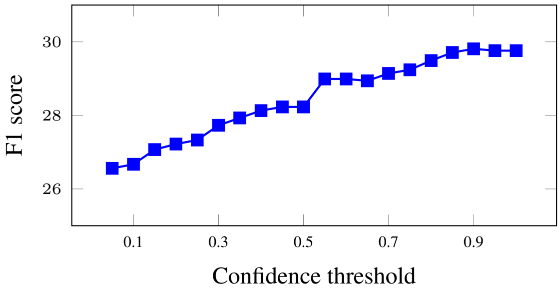

Figure 4: Effect of using different values of the confidence threshold during evaluation.

Comparison of Methods to Obtain Pair Representation. In Section 5.3, we sum up the S-LSTM outputs of each review sentence and rebuttal sentence as the pair representation. We also evaluate the performance when we use concatenation operation to obtain pair representation. It is clear to see from Table 11 that the sum operation significantly outperforms the concatenation operation for the argument pair extraction task as well as two individual subtasks. This suggests that using sum operation here is beneficial to learn better sentence pair representation for argument pair extraction.

B Details on Determining the Argument Pairing Relation

During the evaluation of the argument pair extraction performance, we determine the argument pairing relation on span level with the sentence pairing results. Specifically, we perform binary classification on all sentence pairs enumerated from a candidate argument pair. If more than $p\%$ of sentence pairs are predicted as 1, we say these two arguments form a pair. Here, $p\%$ is a confidence threshold in the range of 0.05 to 1. In the main experiments, $p\%$ is set as 0.9. Take the argument pair {REVIEW-2, REPLY-2} in Table 1 as an example, REVIEW-2 has 2 sentences, and REPLY-2 has 4 sentences. Thus, we have 8 review-rebuttal sentence pairs. If more than 7.2 (i.e., 0.9×8) sentences are predicted as 1, {REVIEW-2, REPLY-2} would be identified as an argument pair.

Effect of Confidence Threshold for Argument Pair Extraction. We compare the performance

sum	**71.85**	**71.01**	**71.43**	**72.64**	**58.05**	**64.53**	**30.08**	**29.55**	**29.81**

Table 11: Performance of **MT-H-LSTM-CRF** when using different operations to obtain pair representations.

of **MT-H-LSTM-CRF** when using different threshold values. Intuitively, a larger confidence threshold means a stricter criterion for sentence-level alignment for argument pairs. In other words, the confidence of the argument pair prediction is controlled by $p\%$. According to Figure 4, the argument pair extraction performance improves as the threshold value increases. The F1 score reaches the peak when the threshold value is set as 0.9, and drops slightly when the value is closer to 1, as it has an extremely strict requirement for the model to select the correct argument pairs. This suggests that the model is trained to select more accurate argument pairs when the threshold value is larger, while it tends to select more confusing error pair options when the threshold value is smaller.

Diversified Multiple Instance Learning for Document-Level Multi-Aspect Sentiment Classification

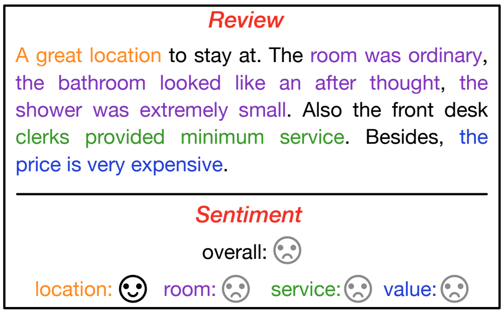
Abstract

Neural Document-level Multi-aspect Sentiment Classification (DMSC) usually requires a lot of manual aspect-level sentiment annotations, which is time-consuming and laborious. As document-level sentiment labeled data are widely available from online service, it is valuable to perform DMSC with such free document-level annotations. To this end, we propose a novel Diversified Multiple Instance Learning Network (D-MILN), which is able to achieve aspect-level sentiment classification with only document-level weak supervision. Specifically, we connect aspect-level and document-level sentiment by formulating this problem as multiple instance learning, providing a way to learn aspect-level classifier from the back propagation of document-level supervision. Two diversified regularizations are further introduced in order to avoid the overfitting on document-level signals during training. Diversified textual regularization encourages the classifier to select aspect-relevant snippets, and diversified sentimental regularization prevents the aspect-level sentiments from being overly consistent with document-level sentiment. Experimental results on TripAdvisor and BeerAdvocate datasets show that D-MILN remarkably outperforms recent weakly-supervised baselines, and is also comparable to the supervised method.

1 Introduction

Document-level multi-aspect sentiment classification (DMSC) is a fine-grained sentiment analysis task, aiming to predict the sentiments of aspects in a document consisting of several sentences. In previous studies, neural models have shown to be effective for improving DMSC with the help of large amounts of aspect-level annotations (Chen et al., 2017; Xue and Li, 2018; Chen and Qian, 2019; Wang et al., 2020). Despite the advantages, the acquisition of aspect-level sentiment annotations remains a laborious and expensive endeavor. Fortunately, the overall document-level sentiment annotations are relatively easy to obtain thanks to the widespread online reviews with overall star ratings. Therefore, it is practically meaningful to perform DMSC by weak supervision from document-level sentiment signals.



Review

A great location to stay at. The room was ordinary, the bathroom looked like an after thought, the shower was extremely small. Also the front desk clerks provided minimum service. Besides, the price is very expensive.

Sentiment

overall: ☹

location: ☺ room: ☹ service: ☹ value: ☹

Figure 1: A review example with sentiment labels.

However, this problem is far from solved. To the best of our knowledge, there is no neural model that is able to achieve DMSC with only document-level signals. There are mainly two challenges need to be settled. First, the granularity between aspect-level sentiment and document-level sentiment is quite different. It is unclear how to properly model the relation between them, in order to transfer knowledge from document-level to aspect-level. Second, the relevant text of aspect-level is unobserved. Without any constraint, a vanilla weakly supervised model would be easy to overfit to document-level signals in terms of both sentiment and attended text, despite each aspect often has its unique relevant text and different sentiment (as shown in Figure 1). However in this case, no matter the given aspect is *location*, *room*, *service*, or *value*, a vanilla model would pay more attention to the words "great", "ordinary", "small", "minimum" and "expensive",

November 16–20, 2020.

and transfer the negative sentiment from document-level to all aspects. As a result, the sentiment towards *location* is wrongly learned as negative, which should be positive instead.

Accordingly, we propose a *diversified multiple instance learning network* (D-MILN) to achieve DMSC with only document-level sentiment supervision. We novelly formularize this problem as *multiple instance learning* (MIL; Keeler and Rumelhart 1991) to model document-level sentiment as a combination of aspect-level sentiments. The aspects are regarded as instances and their sentiment distributions are predicted by an attention-based classifier, while the document is regarded as a bag and its sentiment distribution is computed as a combination of the aspect-level sentiment distributions. Thus, we provide a framework for learning aspect-level classifier by optimizing the document-level predictions. Meanwhile, in order to avoid the overfiting to document-level signals, we further propose two kinds of *diversified regularization*. Diversified textual regularization is applied to guide the aspect-level sentiment classifier to select aspect-relevant snippets. Diversified sentimental regularization is leveraged to control the variance among aspect-level sentiments. Overall, our contributions are summarized as follows:

- We propose a novel diversified multiple instance learning neural network, which properly models the relation between aspect-level and document-level sentiment, and thus achieves DMSC with merely document-level supervision.

- Two kinds of diversified regularization are introduced to alleviate the key challenge of overfitting document-level signals and to improve the aspect-level sentiment classification performance.

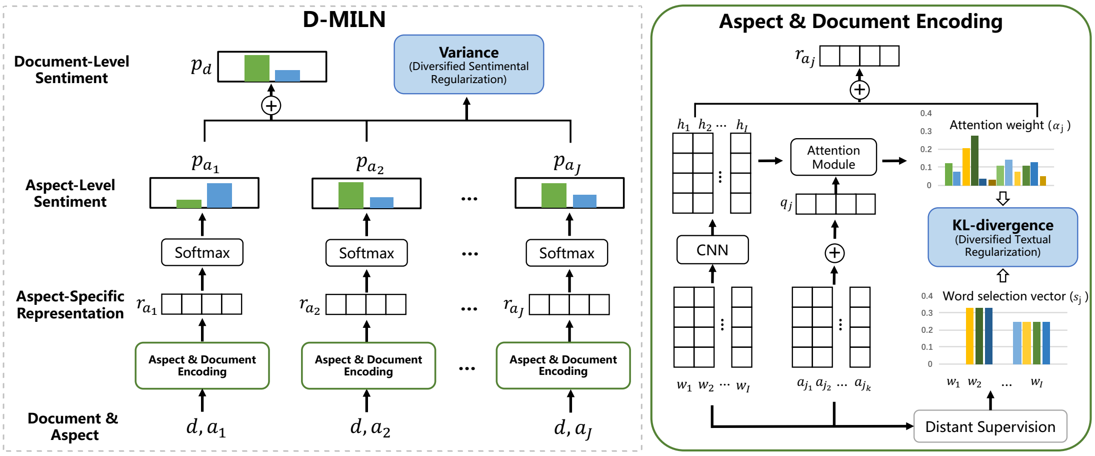
- Comprehensive experiments are conducted on the BeerAdvocate and TripAdvisor benchmark datasets. The results verify the necessity and advantages of both our framework and diversified regularizations. Meanwhile, our D-MILN outperforms previous weakly supervised methods significantly and is also comparable to the supervised method with thousands of labeled instances per aspect.

2 Related Work

Document-level multi-aspect sentiment classification In previous studies, DMSC is usually done by supervised learning methods (Lei et al., 2016; Yin et al., 2017; Li et al., 2018; Wang et al., 2019), where aspect-level annotations should be provided. However, human annotation of aspect-level sentiment is laborious and expensive, therefore, some researches focus on weakly supervised DMSC. This approach can be further categorized into knowledge-supervised and document-level supervised methods. As for knowledge-supervised methods, Zeng et al. (2019) propose to use aspect-opinion word pairs as knowledge for supervision. The aspect-level sentiment classification is achieved by accomplishing another relevant objective: to predict an opinion word when given an aspect. However, their model heavily depends on the performance of dependency parsing and manually designed rules. As for document-level supervised methods, Wang et al. (2010, 2011) propose to use the document-level sentiment as supervision which is similar to ours. Specifically, they propose a probabilistic graphical model for the task, which assumes the overall rating is generated based on a weighted sum of the latent aspect ratings. However, this non-neural network model adopts bag-of-words representations which are insufficient at capturing the order of words and complex semantics. Furthermore, their model fails to consider the problem of overfitting to document-level signals.

Multiple Instance Learning Multiple instance learning is a form of weakly supervised learning where instances are arranged in bags and a label is provided for the entire bag (Keeler and Rumelhart, 1991). Most MIL methods (Zhou et al., 2009; Wei et al., 2014; Pappas and Popescu-Belis, 2017; Haußmann et al., 2017; Tu et al., 2019; Ilse et al., 2018; Wang et al., 2018; Wang and Wan, 2018) focus on the bag-level performance and there are also a few methods focusing on the instance-level performance. Apart from the loss defined on the bag level, Kotzias et al. (2015) also introduces a regularization based on the instance similarities into the objective function. Peng and Zhang (2019) assigns the bag-level label to instances under the i.i.d assumption and directly define the loss function on the instance-level label prediction.

Some works propose to apply MIL to sentence-level sentiment classification task. Kotzias et al. (2015); Angelidis and Lapata (2018a); Wang and



(a) The main architecture of D-MILN

(b) The aspect & document encoding module

Figure 2: Architecture of our Diversified Multiple Instance Learning Network (D-MILN).

Wan (2018) and Angelidis and Lapata (2018b) propose to train the sentence-level sentiment classifier with document-level annotations. For these works, the content for each instance (i.e. words in the sentence) is already given. However, for DMSC task, the relevant text snippets for a given aspect, which are crucial for determining the sentiment, are not provided in advance. This makes the DMSC task much different and challenging to apply MIL. Besides, these works never consider the overfitting to bag-level supervision. To the best of our knowledge, this is the first work to apply MIL to DMSC task.

3 Methodology

We first briefly introduce the problem we work on. Given a review, our task is to predict the sentiments of aspects in the review. Formally, we denote the review document as d which contains I words $\{w_1, w_2, \cdots, w_I\}$, the sentiment label for the document as l_d, and the set of J aspects mentioned in the document as $\{a_1, a_2, \cdots, a_J\}$. Same as Yin et al. (2017), each aspect a_j is represented by K aspect-related keywords, $\{a_{j1}, a_{j2}, \cdots, a_{jK}\}$, in order to cover most of the semantic meanings of the aspect[1].

Figure 2 shows the architecture of D-MILN, where Figure 2(a) is the entire workflow and Figure 2(b) is the detailed network of aspect and document encoding. First, the aspect-level attention-based classifier predicts sentiment distributions for every mentioned aspect which are denoted as $p_{a_1}, p_{a_2}, \cdots, p_{a_J}$. Then, the document-level sentiment distribution p_d is computed as a weighted sum of aspect-level sentiment distributions. The diversified sentimental regularization as shown in Figure 2(a) is applied on the aspect-level sentiment distributions to alleviate the overfitting to document-level sentiment. The diversified textual regularization as shown in Figure 2(b) is applied on the attention weights to encourage the aspect-level classifier to select aspect-relevant snippets.

3.1 Aspect-level Sentiment Distribution

In this section, we introduce our aspect-level attention-based sentiment classifier.

Aspect encoding We first apply a one-layer MLP on the top of word embedding of each aspect-related keyword a_{j_k}:

$$\mathbf{q}_{j_k} = tanh(\mathbf{W}_q \mathbf{e}_{j_k} + \mathbf{b}_q) \tag{1}$$

where $\mathbf{e}_{j_k}$ is the word embedding of a_{j_k}, $\mathbf{W}_q$ and $\mathbf{b}_q$ are parameters of the one-layer MLP. Then the final representation of aspect a_j is calculated as $\mathbf{q}_j = \sum_k c_k \mathbf{q}_{j_k}$, where c_k encodes the importance of each keyword for the given aspect:

$$c_k = \frac{\exp(\mathbf{w}_c \cdot \mathbf{q}_{j_k})}{\sum_{k'} \exp(\mathbf{w}_c \cdot \mathbf{q}_{j_{k'}})} \tag{2}$$

and $\mathbf{w}_c$ is the parameter to learn.

Document encoding We first convert the words in the given document into a sequence of embedding vectors $\mathbf{E} = [\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_I]$. Usually, the sentiments are expressed through phrases in the document (Fei et al., 2004). For example, “a lovely room” expresses a positive sentiment towards the aspect *room*. Since one-dimension convolutional

---

[1] See Appendix A.1 for the keywords.

layers can serve as linguistic feature detectors to extract specific patterns of n-grams (Kalchbrenner et al., 2014), we apply several one-dimension convolutional layers on top of the word embeddings and obtain the final contextual features for the input words: $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_I]$.

Aspect-specific representations We obtain the aspect-specific representation by a weighted sum of contextual features:

$$\mathbf{r}_{a_j} = \sum_{i=1}^{I} \alpha_j^i \mathbf{h}_i \tag{3}$$

where α_j^i encodes the importance of word w_i to determine the sentiment towards aspect a_j. α_j^i is calculated through attention mechanism:

$$\alpha_j^i = \frac{\exp(\mathbf{q}_j{}^T \mathbf{W}_a \mathbf{h}_i)}{\sum_{i'} \exp(\mathbf{q}_j{}^T \mathbf{W}_a \mathbf{h}_{i'})} \tag{4}$$

where $\mathbf{W}_a$ is a bilinear term to capture the relevance between $\mathbf{q}_j$ and $\mathbf{h}_i$.

Prediction The aspect-specific representation is then used to predict the aspect-level sentiment distribution p_{a_j} by:

$$p_{a_j} = softmax(\mathbf{W}_p \mathbf{r}_{a_j} + \mathbf{b}_p) \tag{5}$$

where $\mathbf{W}_p$ and $\mathbf{b}_p$ are parameters of the softmax layer.

3.2 Document-level Sentiment Distribution

Since only document-level supervision is provided, we could not directly use the aspect-level sentiment distribution p_{a_j} for optimization. In order to connect aspect-level sentiment with document-level sentiment, we compute document-level sentiment distribution as a weighted sum of aspect-level distributions. Thus, by optimizing the document-level predictions, the parameters of the aspect-level sentiment classifier are learned through back propagation. Specifically, the document-level distribution is as following:

$$p_d = \sum_{j=1}^{J} \beta_j p_{a_j} \tag{6}$$

where β_j encodes the importance of aspect a_j for determining the sentiment of the overall document. To obtain β_j, we first average the aspect representations:

$$\mathbf{r}_d = \frac{1}{J} \sum_{j=1}^{J} \mathbf{r}_{a_j} \tag{7}$$

then we use attention mechanism to derive β_j:

$$\beta_j = \frac{\exp(\mathbf{v}_r^T tanh(\mathbf{W}_r[\mathbf{r}_{a_j}; \mathbf{r}_d] + \mathbf{b}_r))}{\sum_{j'} \exp(\mathbf{v}_r^T tanh(\mathbf{W}_r[\mathbf{r}_{a_{j'}}; \mathbf{r}_d] + \mathbf{b}_r))} \tag{8}$$

where $[\mathbf{r}_{a_j}; \mathbf{r}_d]$ is the concatenation of $\mathbf{r}_{a_j}$ and $\mathbf{r}_d$, $\mathbf{W}_r$, $\mathbf{b}_r$ and $\mathbf{v}_r$ are parameters of the attention mechanism. .

After obtaining document-level sentiment distributions, we train the model with respect to document-level sentiment labels and introspectively, the aspect-level sentiment classifier is learned through back propagation.

3.3 Diversified Regularizations

The aspect-level sentiment classifier simply learned in such a way suffers from the overfitting to document-level supervision signals. Firstly, given different aspects, the aspect-level sentiment classifier tends to focus on the same snippets, which actually express the document-level sentiment. Secondly, the predicted aspect-level sentiments tend to be overly consistent with the document-level sentiment.

Diversified Textual Regularization To alleviate the first problem, diversified textual regularization is proposed to encourage the sentiment classifier to select aspect-relevant snippets with distant supervision. The main idea is that the aspect-level classifier should pay more attention to the words which co-occur with the given aspect in a same sentence. Specifically, given an aspect a_j, a distantly-labeled word selection vector $\mathbf{s}_j$ is leveraged to guide the attention weight vector $\boldsymbol{\alpha}_j$ in Equation 4. To obtain $\mathbf{s}_j$, we first initialize the weights of all words in the document to be 0. Secondly, we find the sentences which contain any keywords of the given aspect[2]. Then we set the weights of words in these sentences to be 1. Finally, we normalize the weight vector. The diversified textual regularization is defined as the KL-divergence betweens $\boldsymbol{\alpha}_j$ and $\mathbf{s}_j$:

$$L_{d-text} = KL(\mathbf{s}_j || \boldsymbol{\alpha}_j) = \sum_i \mathbf{s}_j^i \log \frac{\mathbf{s}_j^i}{\boldsymbol{\alpha}_j^i} \tag{9}$$

Furthermore, there exist sentences which describe multiple aspects. As in most of these sentences, the parts related to different aspects are

---

[2] We experiment with different levels of snippets (sentence-level and clause-level). Experimental results show that sentence-level snippets achieve more promising results. We guess that is because the clause-level snippets may be incomplete or biased for expressing sentiments.

Dataset	*#docs*	*#words/doc*	*#aspects*	*#mentioned-aspects*	*#one-aspect-docs*	*#aspect-labels*
TripAdvisor	17,792	251.7	7	4.7	20/0.07%	11,915
BeerAdvocate	15,338	144.5	4	3.3	877/3.18%	12,686

Table 1: Statistics of two datasets. *#docs* denotes the number of training documents. *#words/doc* is the average number of words in each document. *#aspects* denotes the number of predefined aspects, while *#mentioned-aspects* is the average number of aspects mentioned in each document. *#one-aspect-docs* denotes the number/percentage of documents in which only one aspect is mentioned. *#aspect-labels* denotes the average number of labeled instances for each aspect.

non-overlapping, we also apply orthogonal regularization (Lin et al., 2017; Hu et al., 2018) to guide the attention weights in a fine granularity:

$$L_{ortho} = \sum_{j} \sum_{j' \neq j} \boldsymbol{\alpha}_j \cdot \boldsymbol{\alpha}_{j'} \tag{10}$$

Minimizing the dot product between two attention weight vectors will force orthogonality between them, so that different aspects attend on different parts of the sentence with less overlap.

Diversified Sentimental Regularization Given a document, some of its aspects often have different sentiments from the document-level sentiment. But simply fitting the document-level supervision leads the sentiments of all aspects to be same with the document-level sentiment. To tackle this problem, we propose diversified sentimental regularization to control the variance among aspect-level sentiment distributions. The variance is computed as follows:

$$\begin{aligned} L_{d-senti} &= \frac{1}{J}\sum_{j=1}^{J}(p_{a_j}(l_d) - p_u(l_d))^2 \\ p_u(l_d) &= \frac{1}{J}\sum_{j=1}^{J} p_{a_j}(l_d) \end{aligned} \tag{11}$$

where $p_{a_j}(l_d)$ is the probability of class l_d for aspect a_j. By maximizing $L_{d-senti}$, the model allows the aspect-level sentiment distributions to be different, so that for some aspects, their sentiments could be different from the document-level sentiment l_d. Furthermore, instead of using cross-entropy loss, we propose to leverage hinge loss to control the fitting degree of the document-level sentiment distribution p_d to the ground truth label l_d. The hinge loss is defined as follows:

$$L_{doc} = max(t - p_d(l_d), 0) \tag{12}$$

where $p_d(l_d)$ is the probability of the ground-truth label l_d, $t \in (0.5, 1.0]$ is the probabilistic margin, which gives the tolerance to diverse aspect-level sentiment distributions.

3.4 Final Objective Function

The final objective function of D-MILN is a combination of document-level loss and diversified regularizations. To minimize clutter, we describe the objective function for a single document:

$$L = L_{doc} + \alpha^m L_{d-text} + \beta L_{ortho} + \gamma L_{d-senti} \tag{13}$$

where α, β, γ are the hyper-parameters, m is the number of training steps. In diversified textual regularization, the distant supervision is relatively “hard” on the attention weights, which may hurt the generalization of D-MILN, so we further introduce a decay factor $\alpha \in (0, 1)$. With the increase of training steps (m), the weight of textual diversified regularization will decrease to zero such that the model will be allowed to achieve better generalization. γ controls the sentimental diversity among aspects. For $\gamma < 0$, the sentimental diversity is encouraged. For $\gamma > 0$, the sentimental diversity is discouraged.

4 Experiments

4.1 Datasets

We evaluate our model on TripAdvisor (Wang et al., 2010) and BeerAdvocate (McAuley et al., 2012) benchmark datasets, which contain seven predefined aspects (*value*, *room*, *location*, *cleanliness*, *check in/front desk*, *service*, and *business*) and four predefined aspects (*feel*, *look*, *smell*, and *taste*) respectively. We run the same preprocessing steps as Zeng et al. (2019). The original ratings of TripAdvisor and BeerAdvocate datasets are converted to binary scales, namely, positive or negative. The exploration on fine-grained sentiment classification remains for future work. The number of reviews with negative overall sentiment and that with positive overall sentiment are balanced. Table 1 shows the statistics of the two datasets. Both datasets are split into train/development/test sets with proportions 8:1:1. The development set is used to tune the hyper-parameters for all methods. We use accuracy as the evaluation metric. Note that both aspect-level and document-level sentiment annotations are provided in the datasets, but our D-MILN only uses document-level annotations for training.

4.2 Implementation Details

We adopt the pre-trained uncased GloVe 300-dimensional word embeddings (Pennington et al., 2014), which are set to be trainable during the training process[3]. In document encoding, we apply three one-dimension convolutional layers with kernel widths of 3, 5, and 7 respectively[4]. The number of filters is 200 for each convolutional layer. Batch normalization is applied on the output of the convolutional layers. The dimension of all hidden layers is 200. Dropout is applied on the embedding layer and the final representations of aspects and document words with dropout rate being 0.4. The values of α, β, γ in Equation 13 are 0.999, 0.1 and -0.1 respectively. The probabilistic margin t is 0.7. The batch size is set to be 64. Parameter optimization is performed using Adam (Kingma and Ba, 2014) with learning rate being 0.001. We run experiments on one Tesla V100 16GB GPU and each epoch takes several minutes. Our model has 438K parameters, not including word embeddings.

4.3 Compared Methods

Here, we compare our method with a variety of baselines, which can be divided into three categories. (1) Weakly supervised baselines. We use these baselines to show the advancement of D-MILN in terms of weak supervision. (2) MIL baselines. We novelly formulate weakly supervised DMSC as MIL for the first time. By comparing with several simple MIL methods, we also hope to see the necessity of D-MILN. (3) Supervised baseline. Finally, we compare D-MILN with supervised baselines to analyse the performance gap with supervised methods.

4.3.1 Weakly Supervised Baselines

Assign-O, which directly uses the overall sentiment of a review in the test set as the prediction for its aspects.

LRR (Wang et al., 2010), which is a probabilistic graphical model (non-neural model) that regards the aspect-level sentiments as latent variables and assumes the document-level sentiment is generated based on a weighted sum of the latent aspect sentiments. LRR only requires document-level annotations.

VWS-DMSC (Zeng et al., 2019), which is previous state-of-the-art weakly supervised approach for DMSC. VWS-DMS uses aspect-opinion word pairs as supervision. The sentiment of an aspect is treated as a latent variable and is used to predict the opinion word of the given aspect. VWS-DMSC also uses document-level sentiment labels to train a document encoder.

4.3.2 MIL Baselines

Vanilla-MILN, which is derived by removing key components from D-MILN. Specifically, in Vanilla-MILN, the loss function is cross-entropy loss and the diversified regularizations are not applied.

Identity-MILN, which sets the aspect-level sentiment of training data to be identical with document-level labels, and directly trains the aspect-level attention-based sentiment classifier introduced in Section 3.1.

Explicit-MILN, of which the relevant snippets for each aspect are firstly extracted by an iterative method adopted in Wang et al. (2010), then a CNN-based text classifier is applied on the extracted snippets to predict the aspect-level sentiment under the MIL framework.

4.3.3 Supervised Baselines

AB-DMSC, which is the attention-based aspect-level sentiment classifier introduced in Section 3.1. We directly train this classifier with entire aspect-level sentiment annotations. AB-DMSC serves as an upper bound to our model.

AB-DMSC-{500, 1000, 2000, 5000}, which is the AB-DMSC model trained with {500, 1000, 2000, 5000} labeled instances **per aspect**. Since the sampled labeled data may vary for different trials, we perform five trials of random sampling and report both mean and standard deviation of the results.

N-DMSC (Yin et al., 2017), which is the state-of-the-art supervised neural model. N-DMSC is also trained with entire aspect-level sentiment annotations.

---

[3] We use pre-trained word embeddings rather than BERT, because we find that BERT is easy to be overfitting in this problem and produces worse results. See Appendix A.2 for more details.

[4] We test a lot of combinations and find that the performance is better with bigger kernel widths. For most documents, especially of BeerAdvocate, there is almost no single word directly expressing the sentiment towards an aspect, so the model should focus on the pattern of a wide range of words to determine the sentiment.

4.4 Results and Analysis

Table 2 shows the main results. It contains three blocks, corresponding to the three categories of systems.We compare D-MILN with them as follows.

(1) Weakly Supervised Baselines. Our model achieves the best performance comparing with previous weakly supervised baselines. From Assign-O, we can see that directly transferring the document-level sentiment to aspects gives a poor result, showing the difficulty and necessity of finding a way to properly model the relation between document-level sentiment and aspect-level sentiment. Our model outperforms the traditional probabilistic graphical model LRR with a substantial margin, which demonstrates the necessity of utilizing neural networks to capture deep semantic features. Our model also outperforms previous SOTA VWS-DMSC significantly. VWS-DMSC relies on the extracted aspect-opinion word pairs, but we find that there are no typical opinion words for some aspects in the corpus (e.g. *look* in BeerAdvocate). Besides, in VWS-DMSC, the document-level supervision is only used to train a document encoder, which ignores the relationship between aspects and documents. As our D-MILN only relies on document-level signals, this further confirms that D-MILN properly models the relation between aspect-level and document-level sentiment.

(2) MIL Baselines. D-MILN significantly outperforms all MIL baselines with a substantial margin. Meanwhile, we find simple MIL baselines often fail to improve performance against previous work (LRR and VWS-DMSC), showing the difficulty of achieving weakly-supervised DMSC by MIL. Furthermore, from Vanilla-MILN, we can conclude that locating aspect-relevant snippets and overcoming the overfitting to document-level supervision are two challenges to improve the performance of MIL on DMSC. Compared with Identity-MILN, it suggests that our method could reduce the noises brought from the document-level supervision signals. Compared with Explicit-MILN, it suggests that our method could effectively select aspect relevant snippets.

Model	TripAdvisor	BeerAdvocate
D-MILN	0.7952	0.7986
– keywords	0.7866	0.7878
– orthogonal	0.7842	0.7955
– hinge loss	0.7795	0.7881
– d-senti	0.7631	0.7702
– d-text	0.7172	0.6742

Table 3: Accuracies on the two datasets in the ablation study.

(3) Supervised Baselines. we first find that AB-DMSC is comparable with N-DMSC, which demonstrates that our aspect-level sentiment classifier could serve as a strong supervised baseline model. Our D-MILN is comparable with AB-DMSC-2000. To analyse the performance gap between D-MILN and AB-DMSC, we conduct a case study, which is contained in Appendix A.3, to qualitatively evaluate the aspect-level attention-based sentiment classifiers.

4.5 Ablation Study

To demonstrate the effectiveness of each component of D-MILN, we conduct an ablation study and list the results in Table 3. "– keywords" means simply using the aspect term rather than its keywords to interact with the document. "– hinge loss" means replacing the hinge loss in Equation 12 by cross-entropy loss. "– d-senti" means removing diversified sentimental regularization. "– d-text" means removing diversified textual regularization. We can see that extending a single aspect term with a list of aspect relevant keywords can improve the classification performance on both datasets. The orthogonal regularization is much more useful in the TripAdvisor dataset, which indicates there are more sentences containing multiple aspects. By employing the diversified sentimental regularization, the overfitting problem of document-level signals can be alleviated and thus improves the classification performance. When removing the diversified

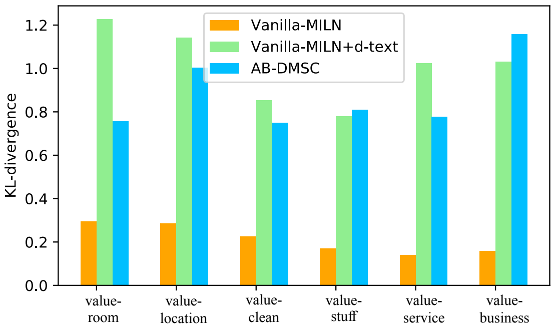

Figure 3: The KL-divergences between attention weight distributions of different aspect pairs.

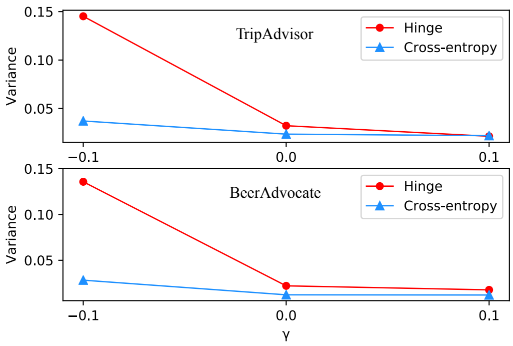

Figure 4: The variances among aspect-level sentiment distributions with different loss functions.

textual regularization, the results are much worse than removing other components, demonstrating locating the aspect-relevant snippets is crucial for correctly predicting the aspect-level sentiments.

4.6 Effectiveness of Diversified Textual Regularization

To further demonstrate the effectiveness of diversified textual regularization, we display the KL-divergence between attention weight distributions of different aspect pairs in Figure 3. The attention weight distribution, which is calculated by Equation 4, indicates the importances of document words to the given aspect. Large KL-divergences indicate that the aspect-level classifier selects distinct snippets for different aspects. For Vanilla-MILN, the KL-divergences are relatively small, which indicates that the model focuses on similar snippets for different aspects. For Vanilla-MILN+d-text, on which the diversified textual regularization is applied, the KL-divergences become larger and are similar with that of AB-DMSC, which is trained with aspect-level annotations and produces the most proper attention weights among the three models. Such results indicate that diversified textual regularization encourages the aspect-level sentiment classifier to select aspect-relevant snippets.

4.7 Hinge Loss for Diversified Sentimental Regularization

We further demonstrate that hinge loss is more compatible than cross-entropy loss with diversified sentimental regularization. In Figure 4, we display the variances, which is calculated by Equation 11, among aspect-level sentiment distributions when different loss functions are adopted. The horizontal axis γ denotes the weight of the diversified sentimental regularization. When γ turns to 0.0, which means the diversified sentimental regularization is not applied, we find that the variance is relatively small for both hinge loss and cross entropy loss, which indicates that the predicted aspect-level sentiments are over consistent with document-level ones. When γ turns to -0.1, which means the diversity of sentiments is encouraged, the variance under hinge loss grows significantly than cross-entropy loss, which verifies that by applying hinge loss, the diversity among aspect-level sentiments could be controlled more effectively.

5 Conclusion

In this paper, we propose a *diversified multiple instance learning network* to achieve DMSC with only document-level supervision. We formulate this problem as multiple instance learning, so as to model the relation between aspect-level sentiment and document-level sentiment. In order to guarantee the proper transfer from document-level supervision to aspect-level prediction, we further propose diversified textual regularization and diversified sentimental regularization. Through experiments on two benchmark datasets, we verify that our D-MILN can properly capture the interaction between aspect-level and document-level, and achieve new SOTA on weakly supervised DMSC. Detailed comparisons also show the necessity and effectiveness of our diversified regularizations. In the future, we plan to further improve D-MILN with aspect-level annotations and find appropriate way to combine D-MILN with pre-training methods (Tian et al., 2020).

A Appendices

A.1 Aspect-related keywords

The aspect-related keywords are listed in Table 4. For TripAdvisor, 10 keywords are provided for each aspect. For BeerAdvocate, 5 keywords are provided for each aspect.

A.2 Pre-trained Model in MIL

We are also curious about the application of pretrained models (e.g. BERT (Devlin et al., 2018)) in MIL, since they have achieved a great success in many NLP tasks (Raffel et al., 2019; Yang et al., 2019; Lan et al., 2019). However, we find that BERT finetuned with document-level supervision is more likely to overfit the document-level sentiment supervision and thus the performance on aspect-level sentiment prediction degrades. We propose four ways to apply BERT in MIL:

BERT-asp: We first fine tune BERT with the aspect-level annotations to demonstrate the superiority of it in supervised aspect-level sentiment classification task. Specifically, the list of keywords of the given aspect is regarded as“text A”, the given document is regarded as “text B”, and the sentiment distribution of the aspect is calculated on the final representation of token [CLS].

BERT-doc: To adapt BERT to MIL, we combine aspects’ sentiment distributions which are obtained in the same way as BERT-asp to form the document-level sentiment distribution. Then we train the model only with respect to the document-level annotations.

BERT-enc-fix: We replace the CNN encoder of D-MILN with BERT (i.e. treat BERT as a feature extractor) and set the parameters of BERT to be fixed during training.

BERT-enc-train: We replace the CNN encoder of D-MILN with BERT and set the parameters of BERT to be trainable during training.

From table 5, We can see that BERT-asp outperforms N-DMSC significantly, producing new state-of-the-art results. By comparing BERT-asp and

BERT-enc-train	0.7540	0.7613

Table 5: Averaged accuracies of BERT-based models

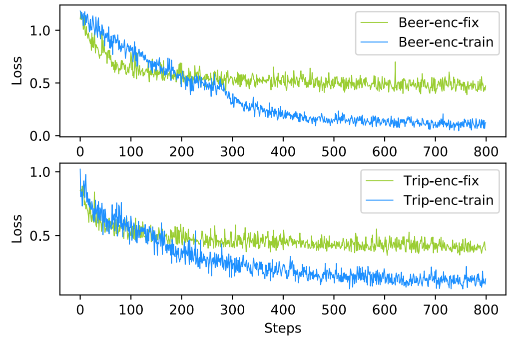

Figure 6: The change of training loss when the training step increases.

BERT-doc, we find that the accuracy declines more than 10% on both datasets when the aspect-level sentiment classifier is trained with document-level annotations with MIL even though the classifier is BERT-based. BERT-enc-fix doesn't outperform D-MILN, we believe this is because the parameters of BERT haven't been fine-tuned for DMSC task. However, when the parameters of BERT are trainable, the performance degrades. By analysing the changes of training loss of BERT-enc-fix and BERT-enc-train, as depicted in Figure 6, we find that the loss of BERT-enc-train declines rapidly to a very low level, showing that it has overfitted the document-level supervision even though the diversified regularizations are applied. In summary, fine-tuning the parameters of BERT with the document-level annotations in MIL will lead to overfitting the document-level sentiment and degrading the performance on aspect-level sentiment prediction. The experiment results also point out a direction for our future work which is to find a way to effectively utilize pre-trained models with weak supervision.

A.3 Case study

To further analyse the performance gap between AB-DMSC and D-MILN, we conduct a qualitative case study on the learned attention mechanism of the aspect-level sentiment classifier. In Figure 5, the gold sentiment labels for *room* and *stuff* are positive and negative respectively. AB-DMSC predicts correctly on both aspects while D-MILN predicts correctly only on *stuff*. For *room*, D-MILN not only picks the words describing it, but also selects the words describing *stuff*. Unfortunately, the words describing *stuff* express an opposite sentiment.

In this case, the description of *room* is much shorter than that of *stuff* and the only words describing *room* are surrounded by the words describing *stuff*. Such unbalanced and mixed descriptions remain a challenge for D-MILN.

Identifying Exaggerated Language

Abstract

While exaggeration is one of the most prevalent rhetorical devices, it is arguably one of the least studied in the figurative language processing community. We contribute to the computational study of exaggeration by (1) creating the first Chinese corpus focusing on sentence-level hyperbole detection, with the goal of facilitating a cross-lingual study on this phenomenon, (2) performing a statistical and manual analysis of our corpus, with the goal of gaining insights into the strategies humans employ when creating hyperboles, and (3) addressing the automatic hyperbole detection task with deep learning techniques.

1 Introduction

Recent years have seen a surge of interest in the automatic processing of figurative language in the NLP community, as evidenced by the successful organization of the NAACL 2018 Workshop on Figurative Language Processing. Much of the work on figurative language processing conducted so far, however, has focused on metaphor and metonymy (Tsvetkov et al., 2014), and more recently, sarcasm (Hazarika et al., 2018), idioms (Liu and Hwa, 2018), and puns (He et al., 2019). In particular, hyperbole, also known as exaggeration, is a relatively under-studied phenomenon in the community. This is somewhat surprising, especially given that the prevalence of hyperbole as a rhetorical device is only second to metaphor (Kreuz et al., 1996). Humans exaggerate in different situations for various purposes, such as creating amusement, expressing emotion and drawing attention (Li, 2013).

The vast amount of work on metaphor detection in the past few years was stimulated in large part by the availability of standard evaluation corpora. Progress on the computational study of exaggeration, on the other hand, is hindered by the lack of annotated resources. To our knowledge, HYPO, the first dataset that focuses on exaggeration, was only released in late 2018 (Troiano et al., 2018). HYPO consists of 709 hyperbolic sentences, each of which has a non-hyperbolic version created by manually paraphrasing its hyperbolic counterpart. Given the dataset, Troiano et al. introduced the task of automatic hyperbole detection, where the goal is to determine whether a sentence is a hyperbole.

Given the status quo, our goal is to further the computational study of exaggeration. Specifically, our contributions in this work are three-fold. First, we create HYPO-cn, the first Chinese dataset on exaggeration. HYPO-cn consists of 4762 sentences, of which 2680 are hyperbolic and 2082 are non-hyperbolic. To stimulate research on the computational study of exaggeration, we make HYPO-cn publicly available. We believe that this dataset can complement Troiano et al.'s English dataset and facilitate a cross-lingual study of exaggeration.

Our second contribution involves conducting an empirical analysis of HYPO-cn. We perform two kinds of analysis. First, we conduct a statistical analysis in an attempt to answer various questions involving exaggeration, such as: (1) are there strong lexical indicators of hyperbole; (2) how lexically diverse are the non-hyperbolic versions of a given hyperbolic sentence; and (3) how lexically diverse are the hyperbolic versions of a given non-hyperbolic sentence? Second, we conduct a manual analysis to identify the major strategies used by humans to overstate. We believe our analysis can advance the computational study of exaggeration and allow us to shed light on a number of interesting questions involving exaggeration.

Finally, we perform preliminary experiments on the automatic hyperbole detection task using HYPO-cn. Unlike Troiano et al., who employed only traditional (i.e., non-neural) learners for hyperbole detection, we examine the use of deep learning for model training, with the goal of understanding

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7024–7034,
November 16–20, 2020. ©2020 Association for Computational Linguistics

whether state-of-the-art learning techniques can offer better results. We show that the best deep learner outperforms the best traditional learner by 11.0% points in accuracy. These results provide suggestive evidence that hyperbole detection is indeed a task that requires a deep understanding of text semantics, as this is what primarily distinguishes a deep learner from a traditional learner.

2 Related Work

2.1 Figurative Language Processing

We begin with an overview of recent work on figurative language processing. For metaphor processing, Rivera et al. (2020) build a neural network to detect the metaphoricity of adjective-noun pairs using pre-trained word embeddings and word similarity; Zhang et al. (2019) use an attention network based on subject–predicate and verb–object relations to identify Chinese verb metaphors; and Chen et al. (2019) detect Chinese metaphors using various kinds of cultural background information such as radicals representing body parts, instruments, materials, and movements. For sarcasm detection, Hazarika et al. (2018) extract contextual information together with user embeddings in online social media discussions. For idiom processing, Liu and Hwa (2018) identify the intended usage of an idiom in an unsupervised manner, treating possible usages as a latent variable in probabilistic models and training them in a linguistically motivated feature space. Homographic pun detection is addressed by Diao et al. (2019) using a contextualized representation with a gated attention.

The recognition of metaphors and idioms is related to hyperbole detection. Humans sometimes use metaphors and idioms to create hyperbolic sentences (Carston and Wearing, 2011; Zhou and Jiang, 2014). For example, the idiom "Time is money" is a metaphor in which "time" is the noumenon and "money" is the metaphoric object. It is also a hyperbole that overstates the value of time. However, there are differences between metaphor/idiom recognition and hyperbole detection, as many metaphors and idioms are not hyperbolic, such as "The rainbow looks like a bridge".

2.2 Studies on Hyperbole

Compared with other rhetorical devices, hyperbole is less studied. The vast majority of the studies on hyperbole to date have been linguistic rather than computational in nature. Cano Mora (2009), for instance, constructs a taxonomy in which English hyperboles are categorized along two dimensions, quantitative (which involves inflating a quantitative/objective property such as time) and qualitative (which involves inflating a qualitative/subjective property such as emotion). These two dimensions are subcategorized into six semantic fields and 22 subfields. Ferré (2014) shows that at the textual level, a hyperbole can be present in a word or in the interpretation of a certain context.

There are also linguistic studies on exaggeration in Chinese. For instance, Liao and Ge (2014) explore how hyperboles are expressed in the novel "Er Ma". They conclude that hyperboles can be expressed via (1) an upsurge on a semantic scale, which can be qualitative or quantitative, corroborating Cano Mora's findings, or (2) other rhetorical devices, including personification and metaphor. Studying Mo Yan's novel "Sandalwood Punishment", Zhang (2016) points out that exaggeration may involve (1) an upsurge on a semantic scale or (2) presenting two events out of their typical temporal order, and concludes that that exaggeration can be expressed using one of eight strategies: Direct Hyperbole (which occurs when other rhetorics are not involved), Extreme Quantity (semantic upsurge on a quantitative scale), Extreme Quality (semantic upsurge on a qualitative scale), Double Negation, Metaphor, Personification, Comparison, and Other (i.e., hyperboles not included in the first seven categories). As we will see, some of these strategies are also used to generate sentences in HYPO-cn.

On the computational side, Troiano et al. (2018) create the first annotated English dataset in which every hyperbole has a non-hyperbolic counterpart. They propose the automatic hyperbole detection task, in which they train classifiers to distinguish hyperbolic sentences from non-hyperbolic sentences using traditional machine learners in conjunction with various types of features.

3 Dataset Creation

In this section, we describe the steps involved in the creation of our Chinese dataset, HYPO-cn.

Step 1: Hyperbole Collection

We begin by collecting hyperbolic sentences from two sources: webpages in professional educational websites[1] and linguistics research papers on hy-

---

[1] `www.unjs.com/h/b/148469.html`, `www.docin.com/p-2191914159.html`, `www.wnzmb.com/k/kuazhangjudaquan/`

perbole in Chinese (Huang, 2010; Zhao and Lu, 2013; Liao and Ge, 2014; Zhou and Jiang, 2014; Zhang, 2016). Specifically, we select 700 sentences from these two sources that have been discussed and determined to be hyperbolic by experts on exaggeration. As a sanity check, we manually go through each of these sentences and verify that all of them are indeed hyperbolic according to the three language-independent criteria of exaggeration summarized by Troiano et al. (2018), namely, the non-literal meaning, the upsurge on a semantic scale, and a connotative trait. We henceforth refer to this set of 700 hyperbolic sentences as S_{hyp}.

Step 2: Non-hyperbole Generation

Next, we hire three native speakers of Chinese to manually produce non-hyperbolic versions of each sentence in S_{hyp}. These annotators are graduate students in NLP (none of them are the authors) and have received a one-hour tutorial on exaggeration from us in which we presented the language-independent criteria of exaggeration described above as well as examples of hyperbolic and non-hyperbolic sentences. After that, each annotator is asked to independently produce a non-hyperbolic version of each (hyperbolic) sentence in S_{hyp} without changing its meaning. By using three annotators, we can examine the extent to which the non-hyperbolic sentences created from the same hyperbole exhibit lexical diversity, and also reduce the possibility that the sentences are biased towards a particular person's style. We henceforth refer to the resulting set of non-hyperboles as S_{common}.

Step 3: Quality Assessment

In order to ensure the quality of the annotations obtained in the previous step, we hire another two annotators to judge if each sentence in S_{common} is a non-hyperbole after giving them the same one-hour tutorial on exaggeration as the other annotators. We delete a sentence if at least one of them thinks that it is hyperbolic or that it does not truly reflect the meaning of its hyperbolic counterpart. After this verification step, 13 non-hyperboles in S_{common} are deleted. For example, the sentence 你嘴里没有实话 (There is no truth in your mouth) is deleted. Although this sentence is often mentioned in daily life, it is overstated as nobody lies all the time. In addition, if two sentences are identical, we delete one of them. Because of this, two sentences are deleted. After this step, every hyperbole in S_{hyp} still has at least one non-hyperbolic counterpart.

Step 4: Hyperbole Generation

Next, we seek to generate more hyperbolic sentences from the non-hyperboles in S_{common}. To avoid the situation where an annotator is being influenced by the original hyperboles (i.e., the sentences in S_{hyp}), we employ another three human annotators who have not seen the sentences in S_{hyp} to manually generate hyperboles after training them in the same one-hour tutorial mentioned above. The sentences in S_{common} that are presented to them are selected as follows: for each sentence s in S_{hyp}, we choose the non-hyperbole version of s from S_{common} that we determine is lexically and syntactically most similar to s. The annotators are required to overstate each non-hyperbole from their own point of view without changing its meaning.

Step 5: Reliability Assessment

Finally, we ask the two annotators involved in Step 3 to judge whether each hyperbolic sentence obtained in the previous step is indeed hyperbolic. Specifically, if at least one of them thinks a sentence is not hyperbolic or does not truly reflect the meaning of its non-hyperbolic counterpart, we will delete it. After this check, 117 sentences are disqualified. For instance, the sentence 一朵朵鲜花红得像血 (Flowers are as red as blood), which is metaphoric, is deleted since many flowers are actually scarlet. As in Step 3, if two sentences are identical, we will only keep one of them. Six sentences are removed because of this.

Overall, more sentences are being deleted in this step than in Step 3. This suggests that writing a qualified non-hyperbole is easier than writing a hyperbole. Although there seems to be more ways to express hyperbole than non-hyperbole, humans often use common expressions (e.g., the same idiom) to overstate, resulting in more repetitive hyperboles than non-hyperboles in our annotation process.

At the end of this process, 700 sentence *sets* are produced, where a sentence belongs to the same set as another sentence if one is a hyperbolic/non-hyperbolic version of the other. In total there are 4762 annotated sentences in HYPO-cn, of which 2680 are hyperbolic and 2082 are non-hyperbolic.

Table 1 shows a sample set of sentences taken from HYPO-cn, where the sentences labeled as 1 are hyperbolic and those labeled as 0 are not. Recall that two sentences in HYPO-cn are in the same set if and only if one is a hyperbolic or non-hyperbolic version of the other. Despite having the same meaning, the sentences within a set exhibit

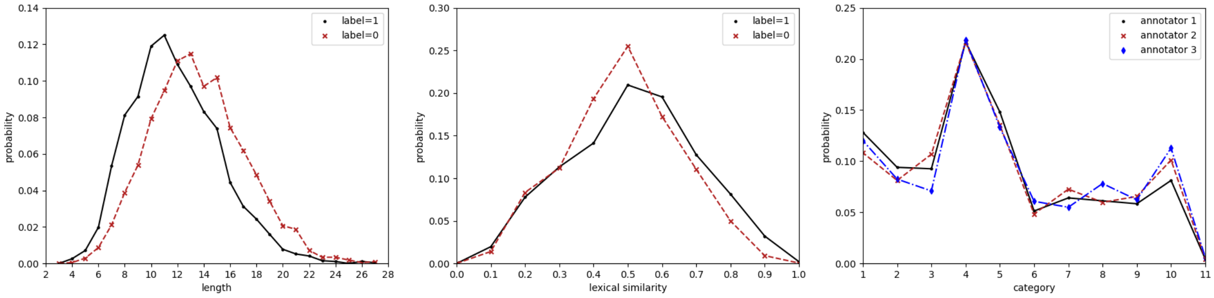

Figure 1: Experiments based on a statistical analysis of HYPO-cn.

Label	Sentence
0	她的腿很长。 Her legs are very long.
	她可以一下子迈上两层台阶。 She can step up two steps once.
	[1] 她的腿一步是我的两步。 Her one step equals my two steps.
1	[2] 她的腿很长，仿佛有两米。 Her legs may be two meters long.
	[3] 她迈开腿，一步就能跨上二楼。 She makes a step and can reach the second floor.
	她的腿比梯子还长。 Her legs are longer than the ladders.

Table 1: An example sentence set in HYPO-cn.

lexical diversity. In fact, even the sentences within the same class can be lexically very different. For instance, there is minimal lexical overlap between the first and second sentences in each class.

4 Corpus Analysis

4.1 Statistical Analysis

We conduct a statistical analysis of HYPO-cn in an attempt to answer several interesting questions about exaggeration.

First, given that hyperbolic sentences may be more descriptive (e.g., compare the first sentence in each class in Table 1), are hyperbolic sentences longer than non-hyperbolic sentences on average? To answer this question, we show in Figure 1(a) the probability distribution of the sentences in HYPO-cn over sentence lengths (as measured by the number of characters). Contrary to our expectation, non-hyperbolic sentences are 2.4 characters longer than hyperbolic sentences on average.

Second, given a random pair of semantically equivalent hyperbolic sentences and a random pair of semantically equivalent non-hyperbolic sentences, which pair is likely to be lexically more diverse? Intuitively there are more ways to express exaggeration, so one would expect the hyperbolic pair to be lexically more diverse than the non-hyperbolic pair. To answer this question, we first compute the cosine similarity of each pair of hyperbolic sentences in the same set as well as the cosine similarity of each pair of non-hyperbolic sentences in the same set, where cosine similarity is computed based on their one-hot word vectors. In other words, the more word overlaps there are between two sentences, the higher their similarity is. We then plot the probability distribution of these sentence pairs over cosine similarity, where cosine similarity is discretized into 10 equal-sized intervals. As we can see in Figure 1(b), both semantically equivalent hyperbolic sentence pairs and semantically equivalent non-hyperbolic sentence pairs are lexically quite diverse: for instance, approximately 20% of the sentence pairs in both categories have a cosine similarity of 0.3 or below, On average, hyperbolic sentence pairs (avg. cosine similarity = 0.46) are lexically less diverse than their non-hyperbolic counterparts (avg. cosine similarity = 0.43). While these results are somewhat contrary to our expectation, the example set in Table 1 may provide hints on why this happened. Specifically, while both the hyperbolic sentences and the non-hyperbolic sentences in Table 1 are lexically quite diverse, a closer inspection should reveal that the average cosine similarity computed over the hyperbolic sentences is higher than that over the non-hyperbolic ones: the topic word 腿 (leg) appears in every hyperbolic sentence but is missing in one non-hyperbolic sentence, and the word 长 (long) appears in two hyperbolic sentences but only one non-hyperbolic sentence. While “two steps” appears in two non-hyperbolic sentences, the two occurrences correspond to different Chinese words and therefore are not considered an overlap.

Third, are there strong lexical indicators of hyperbole? To answer this question, we rank the

Word	WLLR	Word	WLLR
死 (die)	.0486	每个 (each)	.0192
天 (sky)	.0425	瞎 (blind)	.0192
地球 (earth)	.0395	像 (be like)	.0167
般的 (-like)	.0220	一分钱 (a penny)	.0165
命 (life)	.0220	神仙 (immortal)	.0165

Table 2: Ten highest-ranked words computed over the hyperbolic sentences according to WLLR.

words in the hyperbole class by their weighted log-likelihood ratio (WLLR):

$$P(w_t \mid c_j) \log \frac{P(w_t \mid c_j)}{P(w_t \mid \neg c_j)},$$

where w_t and c_j denote the tth word in the vocabulary and the jth class, respectively. Informally, a word w will have a high rank with respect to a class c if it appears frequently in c and infrequently in $\neg c$ (the other class). This correlates reasonably well with what we think an informative word should be.

Table 2 shows the 10 words for the hyperbole class with the highest WLLRs. Looking at each of these words without its context, one may not be able to immediately conclude that the corresponding sentence is hyperbolic. However, one should be able to easily come up with contexts in which these words appear in hyperboles, as some of them are concerned with life and death (死,命) as well as nature and the universe (天,地球), while others indicate the presence of metaphors (般的,像).

4.2 Manual Analysis

The highest-ranked words shown in Table 2 lead us to another question: are there words, phrases, concepts, or even linguistic devices that humans tend to think of and possibly use when they exaggerate?

To answer this question, we ask two native speakers of Chinese who are not involved in any of the previous annotation experiments to perform a manual analysis of the hyperbolic sentences in HYPO-cn. After being trained in the aforementioned one-hour tutorial on exaggeration, they are asked to go over the hyperbolic sentences in HYPO-cn and come up with a way to categorize them, where the categories should shed some light on the strategies humans commonly employ to produce hyperboles. Here, a strategy is broadly construed to include, for example, the use of certain categories of words or phrases, concepts, or linguistic devices. Note that the annotators are *not* asked to go over the non-hyperbolic sentences, as our goal is to identify strategies that are commonly used in a hyperbolic context, rather than those that are used predominantly or even exclusively in hyperbolic sentences.

The annotators come up with 11 categories. Through discussion, they agree on the placement of each sentence into at least one of these 11 categories, which are described below:

1) Quantity concepts. They include (a) expressions with a number or a numeral-measure word combination, such as 两米 (two meters) in sentence [2] and 成千上万 (thousands of), as well as (b) expressions without numbers, such as 无数 (numerous) and 眨眼间 (in the twinkling of an eye). As noted before, the presence of these words/phrases alone is not a sufficient indication of hyperbole: the corresponding sentence is overstated when these expressions are used to quantify an object in a disproportionate, unusual fashion. Nevertheless, quantity concepts are commonly used in hyperboles.

2) Extreme cases. They include (a) completeness and non-exceptionality, such as 全部 (all) and 每 (every), (b) non-existence, such as 一点也不 (not at all), (c) uniqueness, such as 至高无上 (paramount) and 最 (most), as well as (d) boundlessness, such as 无边无际 (boundless) and 无尽 (endless). For example, the use of 所有 (everything) in sentence [4] makes it a hyperbole:

[4] 他是个天才，知道所有的事。
(He is a genius. He knows everything.)

3) Common sayings, including idioms and poems. For example, when describing a stingy person, two annotators use the folk adage 铁公鸡 (iron cock). Unlike the words/phrases in other categories, the idioms used in hyperboles must itself be hyperbolic regardless of the context in which they appear. For example, the idiom 多一事不如少一事 (The less trouble, the better) is not hyperbolic and cannot be employed for exaggeration.

4) Rhetorics. The rhetorical devices that are commonly used in hyperboles include metaphor (sentence [5]), personification (sentence [6]) and synesthesia (sentence [7]):

[5] 那位老先生简直料事如神。
(The old gentleman foretells like a prophet.)

[6] 天气热得连树上的叶子也在喘气。
(It was so hot that the leaves had to gasp for breath.)

[7] 树叶绿得要滴下来了。
(The green color of the leaves is dripping.)

5) Comparison. Hyperbolic sentences that involve a comparison use a reference to highlight

Id	Category	Number	%
1	Quantity concepts	380	14.2
2	Extreme cases	243	9.1
3	Common sayings	268	10.0
4	Rhetorics	686	25.6
5	Comparison	449	16.8
6	Supernatural concepts	160	6.0
7	Desc. about life	176	6.8
8	Desc. of the state of body	234	8.7
9	Desc. about nature	201	7.5
10	Fictitious scene	298	11.1
11	Impossible ordering	17	0.6

Table 3: Eleven categories of strategies employed by humans when creating hyperboles.

the characteristic of an object. Sentence [8] is an example that makes a comparison between "mind" and "sky".

[8] 他的心胸比天空宽阔。
(His mind is wider than the sky.)

Sky is commonly known to be boundless, so the contrast in the sentence underlines his generosity.

6) Description about supernatural concepts. Sentence [5] stresses how clever the old gentleman is. As we know, prophets, gods, and immortals are among the most powerful and intelligent beings, so drawing a connection between a human being and a supernatural being is a way to overstate.

7) Description about life. This semantic field includes (a) the concept of bringing/destroying life, such as 生命 (life), 重生 (reborn), and 要命 (fatal), (b) physical health, such as 病 (sick), as well as (c) mental state, such as 发疯 (crazy) and 精神病 (psychosis). Sentence [9] is hyperbolic because while the urge is annoying, it can never kill you.

[9] 他们的催促要索命。
(Their urge is killing.)

8) Description about the state of the human body. This category involves sentences that express exaggeration via describing an unusual state of the human body or organ. For example, in sentence [10], when overstating the word 看着 (stare at), the depiction of the person's eyes is used to highlight the great deal of concentration.

[10] 他看着那位小姐，大眼珠险得突破眼眶。
(He stares at the young lady. His big eyes are breaking through the orbit.)

9) Description about nature. This semantic field includes entities in nature and natural phenomena with distinctive features, such 闪电 (lightning), 地球 (earth), and 南极 (Antarctica). For example, sentence [9] uses 天空 (sky) to describe "wide" as the sky is known to be extremely vast.

10) Fictitious scene. Sometimes a human employs an imaginary scene to overstate his/her point. Sentence [3], for instance, describes a scene where "she" reaches the second floor in one step in order to highlight how long her legs are.

11) Impossible ordering. This category of sentences describes a situation in which the sequence of events involved did not take place in a possible order, as in sentence [11]:

[11]在娘肚子里我就会抽烟了。
(I learned to smoke before I was born.)

Table 3 shows the number and percentage of sentences in HYPO-cn that involve each strategy. As mentioned earlier, these categories are not disjoint. As we can see, Rhetorics is the largest category, whereas Impossible Ordering is the smallest.

An interesting question is: do humans employ the same strategy for exaggeration when trying to rewrite a non-hyperbolic sentence? Recall from Section 3 that in Step 4 of our corpus creation procedure, three hyperbolic sentences are created by having three annotators rewrite a non-hyperbolic sentence. To answer the above question, we compute statistics on how often our three annotators employ the same strategy when writing hyperboles using these non-hyperbolic sentences.[2] At the outset, we do not expect high agreement, as more than one strategy can be assigned to a given sentence.

There are 53 sets (8.9%) in which all three annotators employ the exact same strategy. Excluding these 53 sets, we have 41 sets (6.9%) in which all three annotators have at least one strategy in common (e.g., two of them employ strategy 1 while the third employs strategies 1&2). Among the remaining sets, there are 233 (39.0%) in which two annotators employ the exact same strategy and another 93 (15.6%) in which two annotators have at least one strategy in common. Finally, there are 178 sets (29.8%) in which the three annotators all employ different strategies.

It is somewhat surprising that in as many as 30% of the sets the annotators use different strategies. To gain insights into the reason, we show in Table 4 a set that belongs to this category, where the original (non-hyperbolic) sentence is in the first row. As we can see, the three annotators employ three different strategies: 5 (comparison), 1 (quantity concepts), and 2 (extreme cases).

---

[2] Recall that some hyperbolic sentences are discarded in Step 5. We compile our statistics based on only the 598 sets where none of the three hyperbolic sentences are discarded.

Sentence	Id
凭你的本事，我没有办法可以瞒住你。 Given your ability, I have no way to fool you.	–
凭你的本事，瞒住你比造火箭还难。 Given your ability, fooling you is more difficult than making the rocket.	5
凭你的本事，我使出十八般武艺都瞒不住你。 Given your ability, I cannot fool you even if I employ eighteen skills.	1
凭你的本事，瞒住谁也不可能瞒住你。 Given your ability, no one can fool you.	2

Table 4: Example set in which all three annotators employed different exaggeration strategies.

Recall that the reason for our employing multiple annotators in Section 3 is to ensure that the resulting corpus reflects diverse ways of expressing hyperbole. A relevant question is: how different are the annotators in terms of the strategies they choose to express hyperboles? To answer this question, we show in Figure 1(c) the probability distribution of the sentences produced by each annotator over the 11 strategies. While the annotators differ in terms of how often they employ a particular strategy, the three plots exhibit similar patterns. These results seem to suggest that the corpus would not have been severely biased in terms of the way the hyperboles were expressed even if it had been annotated by just one person.

5 Automatic Hyperbole Detection

Next, we present preliminary results on the automatic hyperbole detection task. We cast it as a supervised binary classification problem where we predict whether a sentence is hyperbolic or not.

5.1 Traditional Learning Algorithms

As baseline systems, we employ those used by Troiano et al. (2018), who adopt a set of traditional machine learning algorithms encapsulated in the Sklearn library (Pedregosa et al., 2011) using the default learning setting, including logistic regression (LR), k-nearest neighbor algorithms (KNN), Naïve Bayes (NB), decision tree learners (DT), support vector machines (SVM), and Latent Dirichlet Allocation (LDA), to train classifiers for determining if a sentence is a hyperbole or not.

We employ the aforementioned learners for model training in conjunction with two types of features, hand-crafted features and embedding features, as described below.

The *hand-crafted features* are taken from those described in Troiano et al. (2018). More specifically, we reimplement four of the five hand-crafted features used by Troiano et al., namely Unexpectedness (how coherent a word is with the rest of the discourse), Polarity (the sentiment of the sentence), Subjectivity (whether the sentence is objective or not), and Emotional Intensity (the sentiment strength of the sentence). To be specific, we compute Unexpectedness with the pretrained Skip-gram vectors provided by Google (Mikolov et al., 2013) and the Directional Skip-gram embeddings provided by Song et al. (2018), and Polarity with the SnowNLP library[3] and HowNet[4]. However, we are unable to implement the Imageability feature, which encodes the degree to which a word evokes a mental image. The reason is that Troiano et al. computed this feature based on the imageability ratings of the MRC psycholinguistic database, but such a resource is absent for Chinese. According to Troiano et al., the quantitative criteria for hyperboles are encoded partially by Unexpectedness, whereas the qualitative criteria are encoded by Polarity, Subjectivity, and Emotional Intensity. We will henceforth refer to this feature set as TF.

Embedding features are features derived from word embeddings. These features have recently been used extensively in various NLP tasks. We experiment with three types of pre-trained word embeddings: (1) the 300-dimensional Skip-gram representations, (2) the 200-dimensional Directional Skip-gram embeddings, and (3) the 768-dimensional contextualized embeddings trained based on BERT (Devlin et al., 2019), which we obtain by feeding the input sentence into Cui et al.'s (2019) implementation of BERT for Chinese. We generate the embedding features for a given sentence by averaging the embeddings of its constituent words. We will refer to the resulting feature sets produced via Skip-gram, Directional Skip-gram, and BERT as SG, DS, and BE, respectively.

5.2 Neural Network Setting

Troiano et al. (2018) employ only traditional learners in their experiments. A natural question is: will deep learners offer better performance on the hyperbole detection task? To answer this question, we employ the two commonly used deep learners in NLP, namely CNN and LSTM, as realized in the Keras API (Chollet et al., 2015).

For CNN, we use one convolutional layer and

Table 5: Ten-fold cross-validation accuracies on automatic hyperbole detection.

max-pooling. For both CNN and LSTM, we experiment with the three types of word embeddings described in the previous subsection to represent the words in the input sentence and employ ReLU as the activation function with a mini-batch size of 32. The dropout rate and the number of epochs are tuned to maximize accuracy on held-out development data using grid search.[5] We use negative cross-entropy as the loss function and SGD as the optimizer with an initial learning rate of 0.001.

For comparison purposes, we fine-tune a BERT model pre-trained on Chinese (Cui et al., 2019) for our task as follows. If the input is only composed of the sentence to be classified, then we pass it to the encoder, feed the embedding of [CLS] token (in the last layer) to a task-specific classification layer, and jointly fine-tune the model parameters of BERT and the classifier. If the hand-crafted features described above are additionally used as input, we simply concatenate the corresponding feature vector with the embedding of the [CLS] token and use the resulting vector for fine-tuning. We tune the dropout rate and the number of epochs in the same way as we did for CNN and LSTM.

5.3 Experimental Setup and Results

Since Chinese has no space between words, we use the Jieba library[6] for word segmentation. We remove the stopwords from each sentence and report 10-fold cross-validation results in all experiments. In each fold experiment, we use eight folds for model training, one fold for parameter tuning, and one fold for testing. Each fold contains exactly 70 sentence sets.[7] We report performance in terms of accuracy. Note that the majority baseline, which classifies every test instance as hyperbolic, has an accuracy of 56.2%.

Experimental results are shown in Table 5. In addition to using the two types of features (hand-crafted features and embedding features) in isolation, we also use them in combination. For the traditional learners, we simply concatenate the two sets of features. For the deep learners, the hand-crafted features are concatenated with the output of the encoder in the dense layer.

Several points deserve mention. First, using only the hand-crafted features, we obtain mixed results. DT, the worst-performing learner on this task, underperforms the majority baseline. While NB yields the best performance, it only achieves an accuracy of 59.3.

Second, using only the embedding features always yields better results than using only the hand-crafted features, regardless of which traditional learner and which type of embedding are used. Nevertheless, LR, SVM and LDA seem to make more effective use of the embedding features than the remaining learners, and among the three types of embeddings, DS generally offers the best results while SG generally offers the worst results.

Third, using both the hand-crafted features and the embedding features is not necessarily better than using only the embedding features. Overall, the results are rather mixed: in the presence of the embedding features, the hand-crafted features only offer slightly improved performance in the majority of the cases.

Fourth, the two deep learners, CNN and LSTM, achieve substantially better results than the traditional learners: the worst deep learning-based system outperforms the best traditional learning-based system by at least 3.9% points, and the best deep learning-based system outperforms the best traditional learning-based system by 11.0% points. The best result, 85.4%, is achieved by using LSTM in

[6] `https://github.com/fxsjy/jieba`

[7] All the sentences in the same set will appear in the same fold. This setup could minimize the lexical similarity across different folds, as the sentences in the same set are likely to be lexically more similar than those that appear in different sets.

Features	CNN		LSTM	
	NH	H	NH	H
SG	71.5	80.8	76.3	82.9
SG+TF	74.2	81.4	76.1	82.2
DS	78.1	82.8	79.2	84.2
DS+TF	79.1	83.9	79.6	84.5
BE	75.8	81.6	77.8	82.6
BE+TF	74.3	81.1	78.0	82.5

Table 6: F-scores achieved by different models on the hyperbolic (H) and non-hyperbolic (NH) classes.

conjunction with DS+TF.

Finally, as seen in the last two columns of Table 5, whether or not hand-crafted features are used, fine-tuning BERT yields results that are better than those produced by the traditional learners but not as strong as those produced by the deep learners.

To better understand how well the models identify the hyperbolic sentences and the non-hyperbolic sentences, we show in Table 6 the F-scores achieved on the hyperbolic (H) class and the non-hyperbolic (NH) class by two of the best learners, CNN and LSTM. Two points deserve mention. First, the F-scores on H are better than those on NH. This is perhaps not surprising, since there are more hyperbolic sentences than non-hyperbolic sentences in the corpus. Second, the DS results are better than the SG results and the BE results because of better identification of sentences in both classes, even though the improvements on the non-hyperbolic sentences are generally more pronounced than those on their hyperbolic counterparts.

5.4 Error Analysis

We perform an error analysis on the best-performing model, namely LSTM with DS+TF, and observe the following major error categories:

Failure to understand context. A word like 最 (most) is sometimes used in hyperboles, but not in the context in sentence [12]. Without understanding the context in which indicators like this appear, the model got confused and misclassified the corresponding sentence as hyperbolic.

[12] 她是家里孩子中最聪明的。
(She is the most intelligent child in the family.)

Lack of background knowledge. To properly understand sentence [13], one should have the background knowledge that Four Books and Five Classics are masterworks in China. Without such information, the model failed to understand the sentence and misclassified it as non-hyperbolic.

[13] 老太太的经验就是我们的四书五经。
(The old lady's experience is our Four Books and Five Classics.)

Lack of commonsense knowledge. Sentence [1] is non-hyperbolic because the fact that "her one step equals my two steps" is not anything that would be surprising to anyone. However, if one changes the number from "two" to "100", then the resulting sentence becomes hyperbolic because in reality it is not possible that one person's step would equal another person's 100 steps. Hence, the determination of whether a sentence is hyperbolic or not often requires the commonsense knowledge of whether the word/phrase used to describe an object is out of normal range or not. This kind of knowledge is currently missing in our system.

6 Conclusion

We presented an empirical study of exaggeration, which is one of the most prevalent and yet one of the least studied rhetorical devices from a computational perspective. Our contributions lie in (1) creating a Chinese corpus focused on exaggeration, (2) identifying different strategies used by humans for exaggeration and (3) showing that deep learners substantially outperform traditional learners on automatic hyperbole detection. The statistical and manual analyses of our corpus, which is absent from other computational studies on exaggeration, have shed light on various interesting questions about this rhetorical device. To stimulate research on this topic, we make HYPO-cn publicly available.[8] In future work, we plan to use HYPO and HYPO-cn to conduct a cross-lingual study on whether there are differences in the way exaggeration is expressed in English and Chinese.

Abstract

The supervised models for aspect-based sentiment analysis (ABSA) rely heavily on labeled data. However, fine-grained labeled data are scarce for the ABSA task. To alleviate the dependence on labeled data, prior works mainly focused on feature-based adaptation, which used the domain-shared knowledge to construct auxiliary tasks or domain adversarial learning to bridge the gap between domains, while ignored the attribute of instance-based adaptation. To resolve this limitation, we propose an end-to-end framework to jointly perform feature and instance based adaptation for the ABSA task in this paper. Based on BERT, we learn domain-invariant feature representations by using part-of-speech features and syntactic dependency relations to construct auxiliary tasks, and jointly perform word-level instance weighting in the framework of sequence labeling. Experiment results on four benchmarks show that the proposed method can achieve significant improvements in comparison with the state-of-the-arts in both tasks of cross-domain End2End ABSA and cross-domain aspect extraction.

1 Introduction

Aspect extraction and aspect sentiment classification are two important sub-tasks in Aspect Based Sentiment Analysis (ABSA) (Liu, 2012; Pontiki et al., 2016), which aim to extract aspect terms and predict the sentiment polarities of the given aspect terms, respectively. Since these two sub-tasks have been well studied in the literature, a number of recent studies focus on the End2End ABSA task by employing a unified tagging scheme to tackle the two sub-tasks in an end-to-end manner (Mitchell et al., 2013; Zhang et al., 2015; Li et al., 2019a). The unified tagging scheme fuses aspect boundary tags {B, I, O} and sentiment polarities {POS, NEG, NEU} together, and formulates End2End ABSA as a sequence labeling problem. For example, given a sentence *"The price is reasonable, although the service is poor."*, the End2End ABSA task aims to jointly extract aspect terms and detect sentiment polarities over them. The extracted pairs in this example are {"price": Positive; "service": Negative}. However, these existing studies heavily rely on supervised learning over a large amount of labeled data, which is usually hard to obtain for ABSA due to the intensive nature of human annotation. Therefore, it will be very attractive to explore the End2End ABSA task in a cross-domain setting, which allows us to train a robust ABSA model for a resource-poor target domain based on enough annotated data in a resource-rich source domain.

Traditional domain adaptation methods primarily focus on coarse-grained sentiment classification (Blitzer et al., 2007; Pan et al., 2010; Glorot et al., 2011; Bollegala et al., 2012; Xia et al., 2013; Yu and Jiang, 2016; Ganin et al., 2016; Li et al., 2018b). Most of these methods can be grouped into two categories: feature-based domain adaptation and instance-based domain adaptation. Feature-based methods focus on finding a new feature representation which could reduce domain discrepancy. Instance-based methods aim to re-weight training samples in source domain which essentially attempts to assign higher weights to instances similar to the target domain, and lower weights to instances different from the target domain.

In contrast, due to the difficulty in fine-grained domain adaptation, only a few approaches have been proposed for cross-domain ABSA. Most of them explored cross-domain ABSA from the feature-based adaptation perspective, aiming to induce domain-invariant representations for each word. Specifically, Ding et al. (2017) and Wang and Pan (2018) proposed to use domain-shared

November 16–20, 2020.

syntactic knowledge to construct auxiliary tasks to reduce domain disparity. More recently, Li et al. (2019b) used the memory network to model the syntactic relations between words and designed a selective adversarial learning strategy to achieve word-level adaptation. However, all these methods are still based on traditional neural network architectures. As we all know, with the recent trend of pre-training in NLP (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018), many pre-trained text encoders such as BERT have demonstrated their strong capability for domain-invariant representation learning, which poses new challenges for domain adaptation. Based on our preliminary experiments, we find that simply using BERT without domain adaptation has already obtained indistinguishable performance compared with previous domain adaptation methods. Therefore, it will be more attractive to extend these feature-based adaptation approaches to pre-trained models and further improve the domain adaptation performance.

Apart from the feature-based domain adaptation methods, Jiang and Zhai (2007) pointed out the importance of performing instance-based adaptation for different NLP tasks. As revealed by the theoretical analysis in Jiang and Zhai (2007), the domain discrepancy mainly comes from feature mismatches and instance mismatches, and needs to be jointly modeled from two attributes. However, previous studies only demonstrated the importance of instance-based domain adaptation in coarse-grained sentiment classification (Xia et al., 2014), and it is still unclear how to perform instance adaptation for the ABSA task.

To address the two challenges mentioned above, we first utilize BERT to learn domain-invariant features for the ABSA task, followed by proposing an instance weighting method for cross-domain ABSA. Finally, we integrate them into an end-to-end framework to jointly perform feature and instance adaptation. Specifically, for feature-based adaptation, we use the domain-shared part-of-speech information and dependency relations as self-supervised signals to enhance BERT to learn domain-invariant representation for cross-domain ABSA. For instance-based adaptation, since ABSA is typically modeled as a word-level prediction task, we propose to leverage a domain classier to dynamically learn an importance weight for each word and re-weight different words from the source domain during supervised training. Finally, we propose a unified framework to jointly perform feature and instance-based adaptation via sequential learning and joint learning, respectively. Experimental results on four benchmark datasets show that our method can significantly improve the performance of cross-domain End2End ABSA and cross-domain aspect extraction, and we further carry out ablation studies to quantitatively measure the effectiveness of each component in our unified framework.

The main contributions of this paper can be summarized as follows:

- To the best of our knowledge, we are the first to address both tasks of cross-domain End2End ABSA and cross-domain aspect extraction based on BERT.
- We propose a Unified Domain Adaptation (UDA) framework encompassing both feature-based adaptation and instance-based adaptation, which can significantly improve the performance of the fine-tuned BERT model without domain adaptation.
- Compared with the state-of-the-art domain adaptation method, our UDA approach gains an average improvement of 6.92% on Micro-F1 for cross-domain End2End ABSA.

2 Problem Statement

Following Li et al. (2019b), we model both the End2End ABSA task and the aspect extraction task as sequence labeling problems. The input is a sequence of tokens $w = \{w_1, w_2, ..., w_T\}$, and the output is a sequence of labels $y = \{y_1, y_2, ..., y_T\}$. For the End2End ABSA task, $y_i \in$ {B-POS, I-POS, B-NEG, I-NEG, B-NEU, I-NEU, O}; for the aspect extraction task, $y_i \in$ {B, I, O}. In this paper, we focus on unsupervised domain adaptation, where labeled data are not available in the target domain. Given a set of labeled tokens from a source domain $D_S = \{(w_s^i, y_s^i)\}_{i=1}^{N_S}$, and a set of unlabeled instances from a target domain $D_U = \{w_u^i\}_{i=1}^{N_U}$, our goal is to predict token labels for target test instances: $y_i^T = f_t(w_t^i)$, $D_T = \{w_t^i\}_{i=1}^{N_T}$.

The essential cause of domain adaptation is that the data distribution of the source domain and that of the target domain are different, i.e., $P_s(w, y) \neq P_t(w, y)$. The optimal model f_t^* for the target domain could be obtained by minimizing the following expected loss:

$$f_t^* = \arg\min_{f \in H} \int_{(w,y)} P_t(w, y) L(w, y, f) \quad (1)$$

In unsupervised domain adaptation, since labeled data are not available in the target domain. We therefore minimize the empirical loss of data drawn from the source domain instead:

$$\begin{aligned} f_t^* &= \arg\min_{f\in H} \int_{(w,y)} P_t(w,y)L(w,y;f) \\ &= \arg\min_{f\in H} \int_{(w,y)} \frac{P_t(w,y)}{P_s(w,y)} P_s(w,y)L(w,y;f) \\ &\approx \arg\min_{f\in H} \frac{1}{N_s}\sum_{i=1}^{N_s} \frac{P_t(w_i^s,y_i^s)}{P_s(w_i^s,y_i^s)} L(w_i^s,y_i^s;f) \\ &= \arg\min_{f\in H} \sum_{i=1}^{N_s} \frac{P_t(y_i^s|w_i^s)P_t(w_i^s)}{P_s(y_i^s|w_i^s)P_s(w_i^s)} L(w_i^s,y_i^s;f) \end{aligned} \tag{2}$$

According to the last line in Equation 2, as $P(w, y)$ can be factored into $P(y|w)P(w)$, an ideal domain adaptation model consider the following two attributes:

- feature-based adaptation, which needs to find a general feature representation w under which $\frac{P_t(y|w)}{P_s(y|w)} \rightarrow 1$;
- instance-based adaptation, which uses $r(w) = \frac{P_t(w)}{P_s(w)}$ as weights for sampling the instances in the source domain.

However, most previous domain adaptation methods in ABSA only presume feature-based adaptation which leverage auxiliary tasks or domain adversarial networks to learn domain-invariant feature representations while ignore instance-based adaptation. In this work, we take both attributes into consideration within a joint framework based on BERT for domain adaptation of the ABSA task.

3 Approach

Overview: As discussed above, the domain differences mainly come from two attributes, namely feature discrepancy and instance discrepancy. Therefore, we approach cross-domain End2End ABSA and cross-domain aspect extraction with a Unified Domain Adaptation (UDA) framework encompassing two components, named feature-based and instance-based domain adaptation components, which are showed in Figure 1. To reduce the feature discrepancy, we introduce two auxiliary tasks based on the domain-shared knowledge. To reduce the instance discrepancy, we perform word-level instance weighting to focus more on important words for the target domain. Finally, we unified the two components in a sequential and joint manner.

3.1 Feature-Based Domain Adaptation

Structural correspondence learning (Ando and Zhang, 2005; Blitzer et al., 2007) is the core idea of feature-based domain adaptation, whose goal is to use the structural correspondence to narrow the gap between domains. As a self-supervised learning mechanism based on large-scale corpus, the mask language model task of BERT is essentially a structural correspondence learning method. However, it does not use pivot words as masked objects, but randomly selects words to mask and predict. Based on our preliminary observations, in both tasks of End2End ABSA and aspect extraction, although aspect words vary a lot across domains, there are still some universal language structure correspondence between domains such as part-of-speech tags and dependency relations, which can serve as pivots to connect the domains. Nevertheless, this information has not been explicitly captured by BERT.

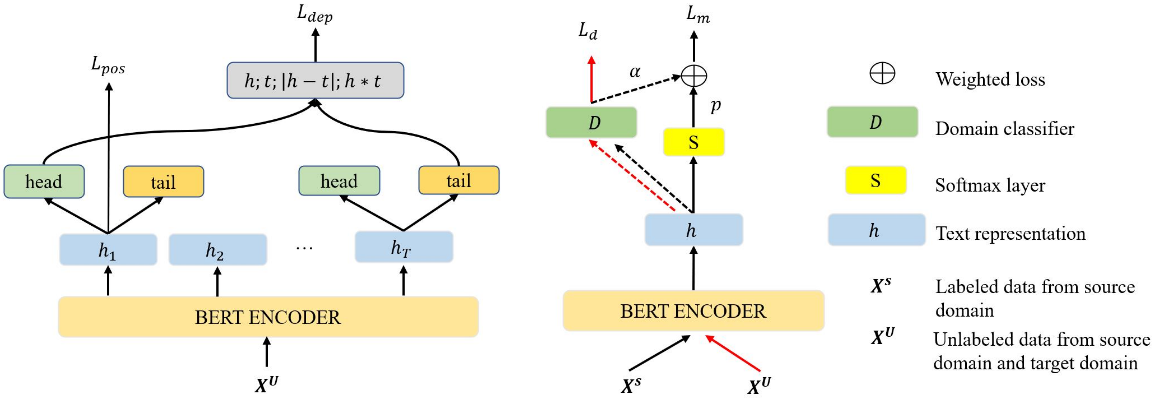
Motivated by this, we propose to use part-of-speech information and dependency relations as self-supervised signals to fine-tune BERT to learn the structural correspondence between domains for cross-domain ABSA. The overall architecture for our feature-based domain adaptation component is shown in Figure 1(a).

3.1.1 Masked POS Tag Prediction

We first convert the word sequences $w = \{w_1, w_2, ..., w_T\}$ into continuous embedding $e = \{e_1, e_2, ..., e_T\}$. The embedding of each word is the sum of four type embeddings $e_i = [t_i, s_i, p_i, tag_i]$. $t_i \in R^d$ is the word embedding of w_i. $s_i \in R^d$ is the segment embedding, which is used as a segmentation mark between sentences. $p_i \in R^d$ is the embedding for the absolute position of a word. $tag_i \in R^d$ is the POS tag embedding.

The first three kinds of embedding are the same as those defined in Devlin et al. (2018), and are initialized using the pre-trained BERT embedding. The POS tag embedding matrix is randomly initialized and trained with unlabeled data from the source and target domains. Since BERT uses sub-word tokenizer, we assume that sub-words share the same POS tags. The word embedding sequences $e = \{e_1, e_2, ..., e_T\}$ were converted into a context-aware representation $H = \{h_1, h_2, ..., h_T\}$ through a multi-layer transformer as follows:

$$H = \text{transformer}(E)$$



(a) Feature-Based Domain Adaptation Component (b) Instance-Based Domain Adaptation Component

Figure 1: Two components in our Unified Domain Adaptation (UDA) approach. Figure 1(a) shows two auxiliary tasks we proposed to learn a domain invariant representation for cross-domain ABSA. Figure 1(b) shows an illustration of our word-level instance weight method. The black line represents the flow of training data from the source domain to optimize L_m (Equation 10). The red line represents the unlabeled data from the source and target domain, which is used to optimize L_d (Equation 8). The dotted line indicates that there is no back propagation during training.

To prepare the input for masked POS tag prediction task, we randomly select about 25% of tokens and replaced the original tokens and POS tags with [MASK]. After being encoded by transformer, the masked feature in H is fed into the softmax layer, and converted to the probability over POS tag types p_i^{pos} as follows:

$$p_i^{pos} = \text{softmax}(W_p h_i + b_p)$$

where $p_i^{pos} \in R^{n\_tags}$, n_tags is the number of POS tag type, W_p and b_p are the weight matrix and bias vector of the softmax layer. We only use the masked features for prediction and we use cross-entropy loss for optimization:

$$L_{pos} = \sum_{D_U} \sum_{i}^{T} I(i) l(p_i^{pos}, y_i^{pos}) \tag{3}$$

where $I(i)$ is an indicator function, which is equal to 1 if masked, otherwise 0, and y_i^{pos} is the real POS tag type of the i-th token.

3.1.2 Dependency Relation Prediction

To reconstruct the syntactic relation in H that is useful for ABSA, we feed the context-aware representation H to two non-linear transformation functions to obtain $H^{head} = \{h_1^{head}, h_2^{head}, ..., h_T^{head}\}$ and $H_{tail} = \{h_1^{tail}, h_2^{tail}, ..., h_T^{tail}\}$ as:

$$h_i^{head} = \tanh(W_1 h_i + b_1), \tag{4}$$

$$h_i^{tail} = \tanh(W_2 h_i + b_2), \tag{5}$$

where $h_i^{head} \in R^{\frac{d}{4}}$ and $h_i^{tail} \in R^{\frac{d}{4}}$, and W_1 and W_2 are learnable parameters. h_i^{head} and h_i^{tail} can be viewed as the representations of the head token and child token in the dependency tree, respectively. Suppose the i-th and j-th words in the input sequence are connected in the dependency tree and represent the head node and the child node, respectively. We use o_{ij} to predict their dependency relation:

$$o_{ij} = [h_i^{head}; h_j^{tail}; h_i^{head} - h_j^{tail}; h_i^{head} \odot h_j^{tail}]$$

where $[;]$ indicates concatenation operation, $-$ and $\odot$ indicate element-wise subtraction and multiplication, respectively. The o_{ij} was converted into p_{ij}^{dep} by a softmax layer.

$$p_{ij}^{dep} = \text{softmax}(W_d o_{ij} + b_d)$$

where $W_d \in R^{d \times n_{arc}}$ is the weight matrix for relation classification, and n_{arc} is the number of relation classes. We use token pairs that are directly connected in the dependency tree to construct training examples. $I(ij)$ indicates whether token pairs (i, j) have a direct edge in dependency tree or not. If they are connected in the dependency tree, we predict their dependency relation. The optimization objective is as follows:

$$L_{dep} = \sum_{D_U} \sum_{i}^{T} \sum_{j}^{T} I(ij) l(p_{ij}^{dep}, y_{ij}^{dep}) \tag{6}$$

We perform feature-based domain adaptation through two auxiliary tasks, and optimize the following objective function for feature-based domain adaptation:

$$L_{feature} = L_{pos} + \lambda L_{dep} \tag{7}$$

where λ is a trade-off hyper-parameter to control the contributions of two tasks, and L_{pos} and L_{dep} are defined in Equation 3 and Equation 6 respectively.

3.2 Instance-Based Domain Adaptation

As analyzed above, instances-based domain adaptation aims to use $\frac{p_t}{p_s}$ to re-weight instances in the source domain to reduce the gap across domains. However, unlike the coarse-grained domain adaptation, our fine-grained ABSA tasks are modeled as sequence labeling tasks, which are essentially word-level classification problems. Since each sentence has domain-invariant words and domain-specific words, we need to obtain the domain distribution of each word and re-weight it at the word level.

Specifically, while training the main task, we also train a word-level domain classifier based on unlabeled data, whose goal is to identify whether each word is from the source domain or the target domain. The output of transformer H was then send to a softmax layer to get the domain distribution probability of the i-th word w_i as follows:

$$p_i^D = \text{softmax}(W_d h_i + b_d)$$

where $p_i^D \in R^{|y^{n\text{-}d}|}$ is the domain distribution probability and $y^{n\text{-}d} = \{source, target\}$. The domain classifier D is trained by the cross entropy loss between p_i^D and the ground-truth y_i^D as follows:

$$L_d = \sum_{D_U} \sum_{i=1}^{T} l(p_i^D, y_i^D) \tag{8}$$

Through the domain classifier D, we can get the domain distribution of each word, and we use the ratio of its target-domain probability to its source-domain probability, i.e., $\frac{p_{i,t}^D}{p_{i,s}^D}$, as the weight of each word during training the main task. Since the training of domain classifiers will make it difficult to generalize across domains, we cut off the gradient back pass, so that L_d only optimizes the parameters W_d and b_d in the softmax layer. As shown in Figure 1(b), when training D, the red dashed line represents the feed-forward calculation, but there is no gradient return. The main task is optimized with the weighted cross entropy loss as follows:

$$p_i^m = \text{softmax}(W_m h_i + b_m) \tag{9}$$

$$L_m = \sum_{D_S} \sum_{i}^{T} \alpha_i * l(p_i^m, y_i^m) \tag{10}$$

where α_i (i.e., the weight of each word) is computed based on the re-normalization over $\frac{p_{i,t}^D}{p_{i,s}^D}$ of all the T tokens, and the probability $p_{i,t}^D$ and $p_{i,s}^D$ are obtained by the domain classifier D.

Although AD-SAL (Li et al., 2019b) also learns an importance weight for each word, our method is significantly different. First of all, AD-SAL still essentially belongs to feature-based domain adaptation, and our method belongs to instance-based domain adaptation. For AD-SAL, the goal is to learn domain-invariant representations for each word through domain adversarial learning. As aspect words are the core of ABSA (this is also consistent with our motivation), AD-SAL introduces aspect attention weights in domain adversarial learning to learn domain-invariant representations for aspect words. In contrast, our method uses domain classifier to automatically learn the importance of each word for the target domain, so that it pays more attention to words (including aspect words and opinion words) that are closer to the target domain during the main task training process. Secondly, the training process of SAL is independent of the main task. In contrast, in our method, the weight of each word is learned through the domain classifier, and the learning process is combined with the main task, which will make the model automatically learn which words are more important for the target domain and the main task.

3.3 Training Mechanism

As analyzed before, our work mainly contains two components: feature-based and instance-based component, which was corresponding to the two attributes of domain adaptation respectively. To dynamically learn a weight for the instance-based component, L_d (Equation 8) and L_m (Equation 10) update jointly. The training objective of instance-based domain adaptation is as follows:

$$L = L_m + L_d \tag{11}$$

The feature-based domain adaptation aims to learn a shared feature space for the target domain, which could be trained separately from the main task. Thus, we can merge the instance-based component and the feature-based component in a sequential or joint training way.

Sequential Training: In the sequential training, we first train the auxiliary tasks to learn a shared feature space, and the training objective is given in Equation 7. Based on the learned shared feature space, we then perform instance-based domain adaptation, and the training objective is given in Equation 11.

Joint Training: We can also merge the two components in a joint way, i.e., training auxiliary tasks and the main task in a multi-task manner. The training objective is:

$$L = L_m + L_d + L_{pos} + \lambda L_{dep} \tag{12}$$

As revealed by Ando and Zhang (2005) and Blitzer et al. (2007), the success of the target task comes from multiple related tasks to help discover common structures between domains. As they are trained jointly, the information from auxiliary tasks could be propagated to the main task.

4 Experiment

4.1 Data & Experiment Setup

Datasets: We conduct experiments on four benchmark datasets: Laptop (L), Restaurant(R), Device (D), and Service (S). L contains reviews from the laptop domain in SemEval-2014 ABSA challenge (Pontiki et al., 2014). Following the setup in Li et al. (2019a), R is the union set of the restaurant datasets from SemEval ABSA challenge 2014, 2015, and 2016 (Pontiki et al., 2014, 2015, 2016). D is a combination of device reviews from Toprak et al. (2010) and S is introduced by Hu and Liu (2004) containing reviews from web services. Detailed statistics are shown in Table 1.

Dataset	Domain	Sentences	Training	Testing
L	Laptop	3845	3045	800
R	Restaurant	6035	3877	2158
D	Device	3836	2557	1279
S	Service	2239	1492	747

Table 1: Statistics of the datasets.

Settings & Implementation Details: We conduct experiments on 10 source→target pairs using the four domains above. Following the setup in (Li et al., 2019b), we removed D→L and L→D, as D and L are similar. For each source→target pair, the training data consists of the training data in the source domain and the unlabeled training data in the target domain. The evaluation results are obtained based on the test data from the target domain. We use Spacy to extract part-of-speech tags and dependency relations, and finally used 54 types of part-of-speech tags and 47 types of dependency relation.

For our proposed UDA approach, since it is a general DA framework, we can potentially use any pre-trained BERT model or their variants as our base model. In this work, we adopt two kinds of base models: $\mathrm{BERT_B}$ and $\mathrm{BERT_E}$. For $\mathrm{BERT_B}$, it refers to the uncased $\mathrm{BERT_{base}}$ model pre-trained by Devlin et al. (2018)[1]. For $\mathrm{BERT_E}$, it refers to an extended version of $\mathrm{BERT_B}$, which further incorporates the domain knowledge (Xu et al., 2019) by fine-tuning the pre-trained $\mathrm{BERT_B}$ model with the BERT language model on product reviews from a combination of Yelp Challenge Datasets[2] and the Electronics dataset from Amazon[3] (He and McAuley, 2016). Note that for the BERT language model fine-tuning, we use 32 bit floating point computations using the Adam optimizer (Kingma and Ba, 2014). The batch size is set to 32, and the learning rate is set to $3 \cdot 10^{-5}$. For training downstream tasks, we set λ to 0.1, and use the Adam optimizer. We perform grid search over a learning rate of $2 \cdot 10^{-5}$, $3 \cdot 10^{-5}$, $5 \cdot 10^{-5}$ and a batch size of 16, 32, 64. We tune all these parameters on the validation set, which is composed by 10% samples from the training set [4].

Evaluation Metric: The evaluation metric we used is Micro-F1. Following the setting in existing work, only exact match could be counted as correct. All experiments are repeated 5 times and we report the average results over 5 runs.

4.2 Baselines & Main Results

We compare our Unified Domain Adaptation (UDA) approach with several highly competitive DA methods as follows:

---

[1] We make use of the uncased $\mathrm{BERT_{base}}$ model as part of the pytorch-transformers library: `https://github.com/huggingface/pytorch-transformers`

Table 2: Comparison results for cross-domain End2End ABSA based on Micro-F1. The results marked by † are extracted from Li et al. (2019b). It is worth noting that different from Li et al. (2019b), we did not remove training/test samples where all the tokens are labeled as 'O' in our experiments, because a moderate amount of product reviews only contain implicit aspects in real scenarios. If we remove these samples, we can get an extra improvement of around 5% on Micro-F1 for all the BERT-based methods in our preliminary experiments.

Table 3: Comparison results for cross-domain Aspect Extraction (AE) based on Micro-F1.

- Hier-Joint (Ding et al., 2017): A recurrent neural network (RNN) with manually designed rule-based auxiliary tasks.
- RNSCN (Wang and Pan, 2018): A recursive neural structural correspondence network that incorporates syntactic structures.
- AD-SAL (Li et al., 2019b): A recent deep model that achieves state-of-the-art performance on End2End ABSA across domains.
- BERT$_\text{B}$ (Devlin et al., 2018) and BERT$_\text{E}$ (Xu et al., 2019): directly fine-tuning the two kinds of pre-trained models on the down-stream task.
- BERT$_\text{B}$-DANN and BERT$_\text{E}$-DANN: We respectively use BERT$_\text{B}$ and BERT$_\text{E}$ as the base models, and simultaneously perform adversarial training on each word, which can be viewed as the BERT version of the widely used DANN approach proposed by Ganin et al. (2016).

The overall comparison results on cross-domain End2End ABSA are shown in Table 2. On the one hand, we can observe that BERT$_\text{B}$-UDA generally performs better than the state-of-the-art DA approach (i.e., AD-SAL) on most transfer pairs for cross-domain End2End ABSA. Moreover, with BERT$_\text{E}$ as the base model, our BERT$_\text{E}$-UDA approach can significantly boost the average performance of BERT$_\text{B}$-UDA from 35.75% to 40.63%, which outperforms AD-SAL by 6.92% on average. On the other hand, by comparing BERT-based approaches, we can clearly see that simply performing adversarial training (i.e., DANN) for each word does not give satisfactory improvements over BERT$_\text{B}$ and BERT$_\text{E}$, whereas our UDA approach can significantly outperform all the BERT-based baselines and consistently achieve the best performance on all the transfer pairs. All these observations demonstrate the effectiveness of our UDA framework.

We also report the results on cross-domain AE in Table 3. Clearly, we can find that the overall trend of the performance of each approach is similar to their performance in cross-domain End2End ABSA. But the results of End2End ABSA are much lower than those of AE, which is reasonable as AE is one of its sub-tasks. Compared with AD-SAL, our BERT$_\text{E}$-UDA approach is 1.62% higher in terms of the average performance of all transfer pairs for the task of cross-domain AE. Compared with cross-domain End2End ABSA, the improve-

Table 4: Ablation study of our UDA approach based on $\mathrm{BERT}_{\mathrm{E}}$ for cross-domain End2End ABSA.

ment of our approach is not that huge, probably due to the inherent difficulty of cross-domain AE, where most aspect words in different domains do not intersect.

4.3 Ablation Study

Since our UDA framework includes two components, i.e., feature-based and instance-based domain adaptation, we further conduct experiments over different variants of the proposed model in Table 4 to show the effect of each component. Only Feature and Only Instance represent the feature-based domain adaptation and the instance-based domain adaptation on basis of $\mathrm{BERT}_{\mathrm{E}}$, respectively. Compared with $\mathrm{BERT}_{\mathrm{E}}$, both components have achieved much better F1 scores on most transfer pairs. This indicates that our proposed two components have effectively reduced the domain discrepancy. Besides, we also merge the two components in a sequential and joint way, denoted by Sequential and Joint respectively. It is easy to see that Joint performs slightly better than Sequential, which shows the advantages of joint optimization.

To qualitatively show the effect of our word-level instance weighting method, we show the most important words for the target domain on three transfer pairs in Table 5. The results show that the common opinion words (e.g., *beauty*, *amazement* and *satisfactory*) or aspect words (e.g., *employee*, *desk* and *kitchen*) gain more weight in the word-level instance weighting.

5 Related Work

Aspect extraction and aspect-level sentiment classification are two important subtasks in Aspect-Based Sentiment Analysis (ABSA), which aim to extract aspect terms and identify the sentiment orientations towards them, respectively (Liu, 2012). As two fundamental tasks, aspect extraction (Qiu et al., 2011; Liu et al., 2015; Poria et al., 2016; Wang et al., 2016a, 2017; Li et al., 2018a; Xu et al., 2018) and aspect-level sentiment classification (Dong et al., 2014; Tang et al., 2016; Wang et al., 2016b; Ma et al., 2017; Wang et al., 2018; Li et al., 2019c) have been extensively studied in the literature.

S→R	contentious, bearing, hated, beauty, ##mi, amazement, ##ant, canned, mistake, madden, accused, nicely, employee, proud, difficulty, impressive, likely, catalogue, ##working
L→R	enjoying, lesson, strongly, reality, comfortably, artwork, food, loving, dissatisfaction, spice, ##kind, fork, appears, weary, desk, projects, monster, covering, recipients, purchases
D→R	displayed, desk, robust, lightly, capable, waking, satisfactory, birthday, releasing, kitchen, noises, appearing, experiences, sophisticated, extreme, providing, nuts, interaction, recommendations

Table 5: Words with higher instance weights in the instance-based adaptation component of our UDA approach.

Since these two tasks are strongly related with each other, a number of previous studies propose to tackle them together in an end-to-end manner (Mitchell et al., 2013; Zhang et al., 2015). Some recent studies have further demonstrated that a unified tagging scheme can effectively eliminate the error propagation issue of traditional pipeline methods, and thus achieve the state-of-the-art performance. However, since annotating each word with fine-grained label is time-consuming, it is next to impossible to obtain enough annotated data for the ABSA task in every new domain. Therefore, in this work, we resort to transfer learning, and focus on proposing an effective domain adaptation approach for the ABSA task.

Existing domain adaptation studies in sentiment analysis primarily focus on coarse-grained domain adaptation problem. Most of them can be grouped into two categories: feature-based methods (Blitzer et al., 2007; Pan et al., 2010; Chen et al., 2012; Zhuang et al., 2015; Yu and Jiang, 2017; Ganin et al., 2016; Li et al., 2018b) and instance-based methods (Jiang and Zhai, 2007; Bickel et al., 2007; Xia et al., 2013, 2014). The former one attempts to learn a domain-invariant representation with auxiliary tasks or domain adversarial learning, while the latter one tries to re-weight source instances in order to assign higher weights to instances similar to the target domain and lower weights to instances different from the target domain.

Due to the challenges in fine-grained domain adaptation, only a few studies have explored the ABSA task in cross-domain settings. Ding et al. (2017) and Wang and Pan (2018) used domain general syntactic relations to construct auxiliary task to bridge the domains. Li et al. (2019b) proposed a selective adversarial learning method to learn domain-invariant representations for aspect words. However, these methods are still based on traditional networks such as LSTM, but fail to resort to recent pre-trained text encoders such as BERT. Moreover, all these methods only perform feature-based adaptation, but ignore instance-based adaptation. In contrast, our work aims to propose a unified feature and instance-based method based on BERT for cross-domain ABSA. Besides, it is worth noting that Rietzler et al. (2019) explored BERT for cross-domain aspect sentiment classification, where the aspect terms or categories are provided for both source and target domains. Different from their work, we primarily focus on the cross-domain End2End ABSA task in this work, which aims to first extract aspect terms followed by identifying the sentiment towards each detected aspect term.

6 Conclusion

In this paper, we explored the potential of BERT to domain adaptation, and proposed a unified feature and instance-based adaptation approach for both tasks of cross-domain End2End ABSA and cross-domain aspect extraction. In feature-based domain adaptation, we use domain-shared syntactic relations and POS tags to construct auxiliary tasks, which can help learn domain-invariant representations for domain adaptation. In instance-based domain adaptation, we employ a domain classifier to learn to assign appropriate weights for each word. Extensive experiments on four benchmark datasets demonstrate the superiority of our Unified Domain Adaptation (UDA) approach over existing methods in both cross-domain End2End ABSA and cross-domain aspect extraction.

Compositional and Lexical Semantics in RoBERTa, BERT and DistilBERT: A Case Study on CoQA

Ieva Staliūnaitė and **Ignacio Iacobacci**
Huawei Noah's Ark Lab, London, United Kingdom
{ieva.staliunaite,ignacio.iacobacci}@huawei.com

Abstract

Many NLP tasks have benefited from transferring knowledge from contextualized word embeddings, however the picture of what type of knowledge is transferred is incomplete. This paper studies the types of linguistic phenomena accounted for by language models in the context of a Conversational Question Answering (CoQA) task. We identify the problematic areas for the finetuned RoBERTa, BERT and DistilBERT models through systematic error analysis - basic arithmetic (counting phrases), compositional semantics (negation and Semantic Role Labeling), and lexical semantics (surprisal and antonymy). When enhanced with the relevant linguistic knowledge through multitask learning, the models improve in performance. Ensembles of the enhanced models yield a boost between 2.2 and 2.7 points in F1 score overall, and up to 42.1 points in F1 on the hardest question classes. The results show differences in ability to represent compositional and lexical information between RoBERTa, BERT and DistilBERT.

1 Introduction

It has recently been recognized in the research community that neural network models generally do not exploit the compositionality of language, often relying on superficial features[1]. Compositionality refers to the fact that linguistic constituents combine into phrases hierarchically to compose meaning. Contextualized word embeddings (BERT, Devlin et al., 2018; RoBERTa, Liu et al., 2018; DistilBERT, Sanh et al., 2019; etc.) can be expected to be limited in their ability to learn such complex aspects of language, since the models are usually trained with cloze filling and next sentence prediction objectives, and are not directly exposed to semantic relations between phrases.

While larger models yield higher performance, they still lack generalization ability (Talmor et al., 2019) and are computationally expensive, which has led to an increasing interest in reducing model size. For instance, DistilBERT is built using the knowledge distillation technique (Bucilă et al., 2006; Hinton et al., 2015) on BERT, which leads to a lighter and faster model that does not lose much in performance on the majority of the tested tasks. On the other hand, state-of-the-art models use vast amounts of training data - 16GB for BERT, 10 times more for RoBERTa.

This study tackles the question of what type of linguistic knowledge is missing from contextualized word embeddings, comparing models on the basis of their training set size (BERT vs. RoBERTa) as well as their model size (BERT vs. DistilBERT).

The tasks of machine reading comprehension (MRC) and dialogue are particularly fitting for this purpose, due to the fact that they require a system to interpret language within a context and perform semantic and pragmatic inference between sentences. The task in the **Co**nversational **Q**uestion **A**nswering dataset (Reddy et al., 2019, CoQA) is MRC combined with dialogue - the input to the system is a context document and a dialogue of questions and answers about that text, which lead up to the question that the system is required to answer. An example from CoQA follows.

Background: [...] At the time, the name did <u>not</u> *describe* a single political entity <u>or</u> *a distinct population of people* [...]
Question n-1: Did the name describe a political body?
Answer n-1: No
Question n: Did it *describe a people group*?
Answer n: No

In order to answer question n without relying on superficial features, one needs to be able to interpret the logical operators "*and*" and "*or*" (underlined), and their scopes, as well as determine that the italicized phrases are synonymous. This study tackles such cases with linguistically enhanced models. Our assumption in this paper is that if a model performs poorly on the classes of question-answer (QA) pairs that require certain linguistic knowledge X (e.g. negation, disjunction and synonymy in the example above) for their solutions, and if its performance boosts when it explicitly learns X (e.g. through a multitask setting with an auxiliary linguistic task), it can be considered evidence for the original model's lack of linguistic representations of X. The main contributions of this paper can be summarized as:

1. A qualitative error analysis of the models in the BERT family on a conversational question answering task;
2. An automatic feature extraction method for quantitative evaluation of the lexical and compositional semantics learnt by the models;
3. An improvement of the model performance by injecting linguistic knowledge into the pre-trained models through a multi-task approach.

2 Related Work

There has recently been much interest in diagnostic analysis of BERT, studying what type of linguistic representations it learns. Rogers et al. (2020) provide an overview of such papers under the name of BERTology, showing what types of linguistic phenomena cause difficulty for BERT.

Some such studies focus on compositional semantics in the form of negation, Negative Polarity Items (NPIs) and Semantic Role Labeling (SRL). In testing NPI licensing, Warstadt et al. (2019) perform a cloze task and compare whether BERT predicts a higher probability for an NPI in a licensed context or outside of such a span. They show that while BERT is capable of detecting NPI licensors (e.g. "*don't*") and NPIs themselves (e.g. "*ever*"), it only does so successfully in cases where the span of the NPI appears in the canonical position with regard to its licensor. This suggests that the model relies on word order instead of parsing the syntactic dependencies.

When it comes to interpreting negation, Ettinger (2020) analyzes whether BERT predicts a higher probability for sentences such as "*Robin is not a tree*" and "*Robin is a bird*" than "*Robin is a tree*" and "*Robin is not a bird*", and conclude that BERT is not very sensitive to negation. This test, however, relies strongly on BERT's ability to represent lexical semantics of the nouns and the lack of intersection of their typical meanings. It could be argued that it therefore is not a reliable test to tell whether BERT can make logical deductions based on negation. Instead, we argue that it should be tested in a context where "*Robin*" can be anything, including a name of a tree, so that it can be determined whether BERT can infer that in such a case "*Robin*" would not be a bird.

Similarly, Ettinger (2020) has also addressed the question of whether BERT has the knowledge required to infer semantic roles from a text. For example, she tests BERT's ability to assign a higher probability to the word "*served*" in a statement such as "*the restaurant owner forgot which customer the waitress had served*" than in "*the restaurant owner forgot which waitress the customer had served*". This test is analogous to the previous example with a Robin, in the sense that it tests the model's ability to learn biases of common semantic roles that certain nouns manifest. The model can simply rely on the fact that one of these two word orders is more likely than the other, however this does not provide evidence that BERT can make inferences about semantic roles. Thus, it remains to be verified whether BERT can abstract the semantic roles from any range of naturally occurring sentences, some of which exhibit uncommon semantic role occurrences (e.g. customers serving waiters).

In a similar vein, previous research has shown that the embeddings of antonyms in models such as BERT are not clearly distinguishable (Talmor et al., 2019). This, similarly to issues with negation, shows that BERT is not good at representing non-intersecting denotations.

What is more, Richardson et al. (2019) show that BERT performs poorly on artificially constructed diagnostic items which test the model's ability to perform logical inference. Nonetheless, they demonstrate that it is possible for BERT to extrapolate the relevant linguistic phenomena quickly by finetuning the model on the same artificial data.

Pragmatics also plays a role in determining relations between sentences, however this field has been less explored with regard to contextualized word embeddings. Some research has probed

BERT on its capabilities to infer pragmatic phenomena related to negation, such as factives, conditionals and questions (Jiang and de Marneffe, 2019). For instance, one has to make the pragmatic inference that a speaker would only utter "*not a one of them realized I was not human*" if their lack of humanity was already established as common knowledge. Jiang and de Marneffe (2019) show that BERT takes longer to learn such complex reasoning than negation.

In contrast, some studies research what common sense knowledge and abstract reasoning that BERT and other language models learn. Talmor et al. (2019) show that there is a large gap between BERT and RoBERTa with regard to their inference abilities. For instance, since RoBERTa is trained on significantly more data, it can determine which person is older based on their ages or dates of birth, while BERT cannot. Interestingly, however, even RoBERTa is shown to rely on the range of examples seen at training time, as it is not able to generalize to the ages of people who are not born between 1920s and 2000s. This suggests that there is a need for a more abstract reasoning ability in models such as BERT, which does not seem to be solved by an increased size of the training set. Finally, Ju et al. (2019) show that even for the RoBERTa-based abstractive model, which reached state-of-the-art results on CoQA at the time, questions with numerical answers account for a disproportionately large fraction of errors.

Based on the studies conducted so far, one general trend appears to be pertinent. That is, while many studies have explored the linguistic knowledge of BERT, it is still not clear whether BERT is able to infer compositional structures from text as opposed to relying on biases. In addition, to the best of our knowledge, no probing tasks have been performed on BERT in the conversational question domain, which is fitting for analyzing BERT's behaviour in complex reasoning and inference. Finally, while larger models such as RoBERTa yield gains in performance, they still lack in generalization ability. Thus, this paper aims to shed light on the less scrutinized aspects of BERT's linguistic capabilities.

3 Dataset

The CoQA dataset[2] is used as a case study in this paper. It covers several domains and amounts to 127,000+ samples including a story, a QA pair and the dialogue history. The answers to the questions are based on the context document, however they can be paraphrases. The training data also contains *rationales*, which are the spans of the background text containing both the answer and the context required to determine the answer. The test set is composed of the Reddit and Science domains, while the rest of the domains are split between train, development and test (see Table 1). Covering various domains makes CoQA diverse with regard to style and content of the dataset, whereas the addition of the dialogue history makes the dataset interesting in that it combines different language modes - a written paragraph and a conversation. Such diversity allows for a robust analysis of linguistic relations since it gives access to negation in questions as well as statements, fictional settings of unusually flipped semantic roles, counting of any abstract or concrete objects, etc. The state-of-the-art models on this dataset (Ju et al., 2019) use RoBERTa, while the dataset has not received much attention with smaller or distilled models such as DistilBERT.

Domain	#Passages	#QA pairs	Passage Length	#Turns per passage
Childrens Stories	750	10.5k	211	14.0
Literature	1,815	25.5k	284	15.6
School exams	1,911	28.6k	306	15.0
News	1,902	28.7k	268	15.1
Wikipedia	1,821	28.0k	245	15.4
Reddit	100	1.7k	361	16.6
Science	100	1.5k	251	15.3
Total	8,399	127k	271	15.2

Table 1: CoQA dataset details (Reddy et al., 2019).

4 Baseline Models

The input to the model is a concatenation of the background story, the latest dialogue history of 64 tokens, and the current question. The length of the input is limited to 512 tokens. We build the baseline RoBERTa, BERT and DistilBERT base models for CoQA as extractive models, within the framework of Wolf et al. (2019) and following Wu et al. (2019), who produce the highest results with a BERT-based extractive model on CoQA. An extractive model does not generate the answer as an abstractive model would, but selects the span in the document that best matches the gold answer. In order to train our extractive models, the substrings

---

[2] `https://stanfordnlp.github.io/coqa/`

of the rationales which are most similar to the gold answers (as measured by F1) are selected as the training labels.

Following a standard procedure, a linear classifier head is added on top of BERT with ReLU activation which classifies every token in the input sequence as start or end of the answer span. Another linear classifier predicts whether each token in the input span falls within the rationale span or outside of it. Finally, one more classifier predicts whether the example is FREEFORM, has a YES/NO answer or is UNANSWERABLE. YES/NO/UNANSWERABLE answers are used instead of the predicted span if the model predicts the latter classes with higher confidence than the start and end tokens of the answer. Models are trained for 4 epochs (taking a few hours on a single GeForce GTX 1080 Ti GPU) with a learning rate of $3\mathrm{e}{-5}$ and AdamW optimizer (Loshchilov and Hutter, 2017). The same hyperparameters are used for all models trained in this work.

5 Baseline Results and Error Analysis

On the development set[3], the RoBERTa model gets 81.2 points F1 [4], BERT scores 76.9 F1 and falls two points short of the Wu et al. (2019) implementation, and DistilBERT scores 66.6 F1, which establishes a baseline as this is the first work using DistilBERT on CoQA (see Table 2).

To resolve what types of linguistic inference are the hardest for the baseline models, several potentially difficult QA classes are analyzed. They are defined based on the findings of previous research as well as the observations of a qualitative evaluation of the errors made by the BERT model. Then, a quantitative evaluation of how the baseline models perform on each class is performed. There is ample variation in how the models score on various example classes (see Table 2). Nonetheless, a noticeable trend appears across the three models which are failing in similar classes, with DistilBERT lagging behind BERT in most of the classes, by up to 15 points in F1 in some, and RoBERTa beating BERT by a smaller margin.

The first expected source of error for the baseline models is the inability to count listed phrases. Since the models are extractive, counting cannot fall within their capabilities. For example, the rationale below lists the characters in the background story:

Rationale: a poor man Ti, his son Dicky and their alien dog CJ7
Question: How many characters were there?
Answer: Three

In the current setting the models cannot chunk the text into noun phrases and then count the chunks to answer the question, as they are limited to extracting the answer from the background text. While the model performance is satisfactory on a wide range of questions with numerical answers (NUM), they fail consistently on questions with answers in the integer set between 1 and 5 (1-5). The NUM class is defined using a state-of-the-art rule-based question classification system from Madabushi and Lee (2016), which evaluates each QA based on the question alone. The contrast between the scores on the two classes can be explained by the fact that while extracting numerical answers such as dates is easy for the models, they struggle on the task of counting linguistic objects, which are usually manifested in low value integers.

The second expected problematic area is negation. Negation cues are words (“*not*”, “*without*”) or morphemes (“*dis-*”, “*un-*”, “*ab-*”), which negate the context that they span over. The example below illustrates two ways that the model can fail in face of negation cues.

Rationale: Something looked like a bird’s belly [...] it was not a bird’s belly [...] a bottle floated there
Question: What looked like a bird’s belly?
Answer: A bottle
Wrong answer 1: A bird’s belly
Wrong answer 2: Not a bird’s belly

The most general type of error is neglecting the negation cue altogether and answering the question with **Wrong answer 1**. This reflects on the model’s inability to determine that the noun phrase “*a bird’s belly*” falls under the scope of the negation cue “*not*”. **Wrong answer 1** would be the correct answer if the phrase was not negated. The second and more rarely observed type of error reflects a lack of pragmatic knowledge as opposed to semantic or syntactic. In **Wrong answer 2** the model could be argued to have answered correctly as it

---

[3] Due to a limitation of at most 2 submissions per week for official evaluation on CoQA, the experiments on the test set are not included.

[4] The results do not compare to the 89.5 F1 score of the extractive model of Ju et al. (2019), who do not report which RoBERTa model they use. The difference would be accounted for if they use RoBERTa large.

class Model	overall	NUM	1-5	NEG	YES	NO	SENT	ANT	ORD	SRL-	SRL+	HUM	LOC	ENT	SURP
size	7983	972	128	436	790	682	2443	185	6817	3175	1242	1418	624	1089	433
RoBERTa	81.2	76.4	40.1	72.9	89.5	85.9	83.0	82.3	81.8	80.7	83.5	83.2	83.6	83.1	78.6
BERT	76.9	77.2	41.9	68.9	85.3	77.3	79.0	74.8	77.2	76.4	78.5	77.4	80.8	79.4	74.1
DistilBERT	66.6	69.6	36.8	56.7	82.1	71.4	69.0	71.3	67.2	65.8	70.0	64.2	65.4	70.0	58.9

Table 2: The results of the baseline models on the CoQA development set (F1 scores). The grayscale colors reflect the variation within models between QA classes.

is technically true that what looked like a bird's belly was not a bird's belly. However assuming Grice's maxim of quantity, which states that one should be as informative as required (Grice, 1989), the answer is not satisfactory. **Wrong answer 2** is not informative at all as it has already been implied by the question. We define the NEG QA class as containing answers that are embedded under negation. For recognizing such answers, negation cues and their spans are detected with a BERT-based model following Khandelwal and Sawant (2020) and trained on the Sherlock dataset (Morante and Blanco, 2012). We reproduce the results on that dataset before using the model for detecting the negated spans in the background documents in the CoQA dataset to find the NEG type answers. Our baseline models perform worse on the NEG QA class than overall, and score much higher on questions with YES answers than NO answers, which suggests that the models do not interpret negation correctly. The effect of negation on performance is particularly stark in the case of DistilBERT.

Furthermore, the ANT class is composed of examples in which the rationale contains antonyms of the words in the question, using WordNet (Fellbaum, 1998). Here explicit negation is not necessarily involved, however the model's ability to reason over semantic polarity is tested in this QA class. Our baseline results on class ANT are in line with previous conclusions stating that BERT is not good at representing antonymy, as it scores lower on this class than overall. Yet interestingly, DistilBERT as well as RoBERTa perform better on this subclass of questions than overall. We conjecture that lexical semantics is the strongest feat of BERT, therefore it is likely that DistilBERT retains most of the lexical information such as antonymy through the process of distillation. On the other hand, RoBERTa learns more about lexical features such as antonymy from the huge size of the training set.

In addition, SENT is a QA class in which the sentiment of the sentence containing the rationale is different from the sentiment of the question. The class items are determined by sentence splitting (Honnibal and Montani, 2017) and sentence-level sentiment classification (Wolf et al., 2019). This class is intended to capture examples where the polarity between the question and the answer can be expressed not only by negation or antonymy but also any other means, for example pragmatics. However, a qualitative analysis of the examples of the SENT class shows that the examples which contain contradictory sentiments between the question and the answer mostly do not require one to determine the sentiment in order to answer the question correctly. For instance, the question below has a slightly negative connotation about a long job hunt:

Rationale: Nearly four years later, as Obama seeks reelection, Casillas has finally landed his first full-time job, emerging out of the group known as the long-term unemployed.

Question: How much later did he get his next job?

Answer: Nearly four years later

In contrast, the rationale takes a more positive outlook. Nonetheless, the answer is "*four years*", regardless of whether that is considered too long or not. There generally does not appear to be a relation between the sentiment values of the rationale and question and the model predictions. Accordingly, neither of the baseline models struggle to answer SENT questions.

Moreover, as stated in Reddy et al. (2019), the order of questions on the CoQA dataset follows the natural order of text. That is, later questions refer, generally, to information presented towards the end of the background story. Hence, the one answering the questions ought to make inferences about what has already been discussed and where in the story they are when a given question is posed. In some cases this knowledge can be crucial for reaching the correct answer. For instance, in the example below, one has to determine what time within the story the question refers to.

Background: [...] The hospital had been bombed and Hans had made his way back into Western Germany on foot. [...]
Question: Was he in the Eastern or Western part?
Answer: East Germany

That is, the answer differs depending whether the question refers to Hans's location prior or post his journey, which is also reflected in the different answers that the human annotators provide to this question. In this case the answer is "*East Germany*" even though that part of the country is never mentioned in the text, which makes the example very challenging with regard to pragmatic inference. In order to evaluate how our models perform with regard to following the dialogue flow, they are evaluated on items which do in fact follow the order of the document, so that the answer to question n in the text is subsequent to the answer to question $n-1$ (ORD). It appears that all baseline models are able to infer this order to some extent and perform better on such questions than those that jump to previous passages in the text.

Furthermore, examples are classified with regard to whether the order of the semantic roles mentioned in the question is the same (SRL+) or different (SRL-) to the semantic role order in the sentence containing the rationale. SRL is performed employing an AllenNLP (Shi and Lin, 2019) model. To illustrate, Figure 1 shows an example where the roles of agent (Arg0) and patient (Arg1) are reversed in the question by means of a passive voice. All three models fail more on such examples with different word order between the question and the rationale, scoring lower on the SRL- class than overall or SRL+. The results of the experiments show that the models find the correct answer more frequently when they can rely on the word order, avoiding the need to reason over semantic roles.

Finally, some of the observed issues are induced by the model choosing prominent entities as answers regardless of their actual relation to the question at hand. For instance, a document tells a fictional children's story wherein foods and utensils are anthropomorphised, as in the example below:

Rationale: cereal is winning the race in a bowl of milk
Question: Who is a good swimmer?
Answer: cereal

The baseline BERT model chooses a human entity that is mentioned by name at the beginning of the text instead of the inanimate entity that takes up the agent position in the rationale. In contrast, if "*cereal*" is substituted with a common name such as "*Mark*" in the background document, the model correctly chooses it as the answer. This suggests that the model relies on lexical semantics and biases about types of entities denoted by nouns more than analyze the semantic relations in the relevant sentence. Therefore, we define a QA class where the rationale contains entities that have high entropy and are thus surprising given the rest of the sentence (Hale, 2001; Levy, 2008; Smith and Levy, 2008), like "*cereal*" in the above example. In order to detect such entities, proper nouns (as tagged by spaCy, from Honnibal and Montani, 2017) are masked and BERT is used to evaluate the likelihood of the original word being the filler for that mask. Words that fall below the likelihood threshold of $5\text{e}{-5}$ are then deemed to be surprising entities[5]. All three models perform worse on questions about surprising entities (SURP) than overall, with DistilBERT exhibiting the largest margin.

Moreover, the classes of human (HUM), location (LOC) or general entities (ENT), as classified by Madabushi and Lee (2016), test the models' ability to answer questions about entity roles. RoBERTa and BERT's performance on these classes is higher than their overall performance. On the other hand, DistilBERT fails on HUM and LOC entity questions more than other QA types. For many HUM and LOC questions there are multiple entities in the text that fit the entity type. Together with the results on the SURP class, this is an indication that DistilBERT relies on entity type more than the larger models.

The baseline results on the various classes corroborate most of the results of previous research on BERT's shortcomings. Moreover, the results show that DistilBERT mostly repeats the same mistakes and often more gravely, except for some cases of lexical semantics. DistilBERT appears to lose more of BERT's already limited representations of the formal aspects of language and have stronger biases. Finally, RoBERTa also exhibits a lack of ability to perform compositional reasoning and reaches the highest scores on the more lexical QA types.

---

[5] The threshold is selected after finetuning the model augmented with surprising word substitution, as discussed in Section 6.

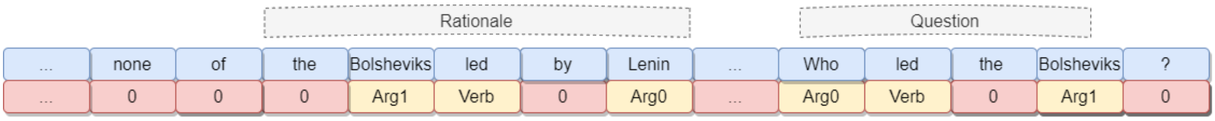

Figure 1: Illustration of the order of semantic roles in a CoQA example.

6 Model Enhancement

6.1 Auxiliary tasks

The methods for defining QA classes are also used as sources of linguistic knowledge which are incorporated in the baseline models to enhance their performance with regard to the respective classes. Firstly, besides the existing FREEFORM, YES/NO and UNKNOWN, five additional classifiers of integer answers between 1 and 5 are defined within the model, as it would be impossible for the models to answer counting questions extractively. This results in the *base#* model[6]. Then, four additional enhanced multitask models are built in order to tackle the issues observed in the previous section.

For every enhanced model (*negation#*, *order#*, *sentiment#*, *srl#*), the training data is tagged with annotations of the relevant linguistic information that was also used for defining the problematic classes. For *negation#*, tokens are labelled as under the scope of negation (1) or not (0); for *order#* they are labelled as occurring after the answer to question $n-1$ (1) or not (0); for *sentiment#* they are labelled as part of a sentence with a negative sentiment (1) or not (0); while for *srl#* a multi-label setup is used where every token is labelled as either taking a particular semantic role (1) or not (0). Each of these sets of labels are then used as an additional training goal for the model. The loss of a given additional goal is added to the main loss in a weighted sum. Namely, the sum is calculated as:

$$\begin{aligned} loss = {} & start\_of\_answer\_loss \;/\; 2 + \\ & end\_of\_answer\_loss \;/\; 2 + \\ & rationale\_loss + \\ & alpha * additional\_goal\_loss \end{aligned}$$

with *alpha* values from $[0.01, 0.1, 0.2]$.

In addition to the multitask approach, other architectures were explored for adjoining the information from the four knowledge sources. These approaches include supplying the information as an additional input feature added or concatenated to the BERT model at the level of BERT inputs themselves or the BERT model outputs. However, experiments with the latter methods showed no considerable increase in the model performance. Thus, the multitask approach was finally adopted for enhancing models. The multitask approach is also beneficial as the model can be applied to other test sets without the overhead of extracting the linguistic knowledge from the new set.

6.2 Surprising Word Substitution

One more enhanced model is produced by augmenting the training data by means of surprising word substitution (*surprisal#*). Supplementary data samples are produced by substituting surprising entities in the CoQA training set with entities that would be very likely to take their place, according to BERT. In order to ensure that the sentence structure is not affected and an entity is substituted with another entity, the substituting word was only selected if the new word was also tagged as a proper noun in the newly produced sentence. This procedure leads to 5880 additional samples for training. The reason behind adding these items on top of the training set instead of substituting the surprising examples is the intention to provide rare entities with better context instead of ignoring them. Many models in NLP suffer from strong social biases and therefore this approach attempts to level the playing field for rare entities by introducing them in the same contexts as the common entities. Such a method could potentially also be applied to larger datasets and more early stages such as pretraining.

Finally, the enhanced models are combined into an *ensemble* in order to combine the strongest points of each model. In order to use the specialized knowledge from each model where it is relevant, the ensemble is created by selecting the model with the highest confidence for each prediction from all the models, including *base#*.

7 Enhanced Model Results

The results of all the enhanced models on all QA classes on the development set are presented in Table 3. BERT and RoBERTa gain most in terms of

---

[6] The # sign next to the model name marks that the model includes a classifier for low-valued integer answers.

class	overall	NUM	1-5	NEG	YES	NO	SENT	ANT	ORD	SRL-	SRL+	HUM	LOC	ENT	SURP

Table 3: The results of the baseline and enhanced models on the CoQA development set (F1 scores). The heatmap colors reflect the variation within QA classes between models. The results of the *base#* models should be compared to the *base* results in gray to see the effect of adding the numerical answer classifier, whereas the remaining models should be compared to the *base#* results in gray in order to see the effects of the additional linguistic knowledge.

F1 with the counting model on counting questions (*base#* on 1-5), while DistilBERT only improves on these questions remarkably with the *ensemble* model, requiring more auxiliary resources than the larger models for this level of abstraction.

Moreover, BERT appears to learn formal aspects of semantics in the multitask setting. The *srl#* model improves on the QA class with semantic roles in a different order in the question and the answer (SRL-), while the *negation#* model improves the results on the answers that require interpreting negation (NEG and NO). To illustrate, while the *base#* model fails to take into account the negative morpheme "*dis-*" and answers "*yes*" to the question below, the *negation#* model avoids such errors.

Rationale: Some refer to Tolstoy's disagreement with state-backed religion.
Question: Did he agree with the states view on Religion?
Answer: No

This shows that the *negation#* model has learnt to recognize the negation spanning over the "*agree*" root, which plays a deciding role for determining the correct answer to the question.

In the meantime, RoBERTa does not improve on the QAs in the negation or Semantic Role classes. One might say that RoBERTa has learnt the abstract linguistic representations already, however its *base* results show that it makes many of the same mistakes as BERT and DistilBERT on NEG and SRL-. In fact, BERT outperforms RoBERTa on the NEG class when enhanced with the explicit information about negation (the *negation#* model). This, combined with the fact that RoBERTa gets a big improvement on NEG only when various linguistic features are combined into an *ensemble*, suggests that RoBERTa mostly relies on better lexical representations for its higher scores, which is only outweighed when many compositional semantic cues are provided. Similarly, DistilBERT only gains a small boost over the baseline on NEG and

NO QA classes with *negation#* and also requires an *ensemble* to improve on SRL-.

On the other hand, BERT and DistilBERT improve on the HUM and LOC classes with the *ensemble* models, demonstrating an ability to improve its lexical representations. RoBERTa does not yield an improvement in this case, however even its *base* model performs relatively well on these classes.

Furthermore, BERT and DistilBERT do not get a boost in the cases of pragmatics, namely *sentiment#* and *order#*. In contrast, RoBERTa gets a boost over the ANT class from the *sentiment#*, and gains the largest increases across almost all classes from *order#*. It appears that RoBERTa can improve on its already high score on items containing antonymy relying on more pragmatic aspects of lexical semantics, and also is the most receptive to the pragmatic aspects of dialogue in CoQA.

Moreover, the model trained on the dataset which was augmented through surprising word substitution (*surprisal#*) improves over *base#* on the class with surprising entities (SURP) with BERT and DistilBERT. This shows that the method helps the models generalize better to cover new examples with surprising entities and get rid of some of the biases about entities. For example, while the *base#* BERT model answers the question below incorrectly, the model enhanced with *surprisal#* selects the name of the relevant character.

Background: [...] When Link Merwell went down again Dave looked at Nat Poole, thinking that lad might possibly attack him. [...] Merwell brought this on himself–you know that as well as I do. He's pretty badly hurt, I fear. [...]
Question: Who is badly injured?
***base#* Answer:** Nat Poole
***surprisal#* Answer:** Link Merwell

The *base#* model simply selects the name that is more common. In contrast, the enhanced model detects the correct name of the person who is performing the role in the question. Substituting the name in the original background document with a mask token shows that BERT assigns a larger probability to the name "*Nat Poole*" than "*Link Merwell*". Such examples stand to show that a BERT model is biased towards more common entity names. Nonetheless, the models are able to learn to abstract away from the biases of the connotations and lexical semantics of entity names and find the entities with the right semantic roles even for rare entities, given that the model has been exposed to both rare and common entities in the same contexts during training.

Interestingly, in the case of BERT the largest boosts in the SURP class are produced by the *negation#* and *srl#* models, showing that focusing on compositional information such as semantic roles and negation helps the model to be less biased towards very prominent lexical information of stereotypical entities as discussed in Section 5. In contrast, in the case of RoBERTa, *surprisal#* does not yield an improvement on the SURP class. RoBERTa requires all of the enhanced models to be combined into an *ensemble* in order to get rid of the biases, suggesting that its focus on (biased) lexical representations is even stronger than BERT or DistilBERT's.

Finally, the *ensemble* models perform better on virtually all classes and provide a better overall score. This is to be expected as the enhanced models, while performing at a similar level, make different errors and complement each other with their respective specializations.

8 Conclusion

By and large, this paper provides additional evidence that models like BERT lack linguistic abstraction abilities, often relying on superficial features such as entity name biases or word order to answer questions in the conversational question answering task. More precisely, we show that BERT, RoBERTa and DistilBERT models mostly fail on questions that require inference over the compositional aspects of language, such as semantic roles and negation. Furthermore, we find that while RoBERTa improves over BERT's performance, a large portion of its gain comes from better lexical representations and it appears to fall short of solving the compositional semantic problems. What is more, we provide the first evaluation and analysis of DistilBERT on CoQA, showing that DistilBERT, more so than BERT, relies on lexical information most and lacks capacity to learn compositional representations. Finally, we show that all the BERT-like models tested can be enhanced to a varying extent by feeding them linguistic knowledge through a multitask approach. Even a small amount of training data for linguistic information such as negation can provide a very large boost to the model performance on the QA classes which rely on that information.

Abstract

Attention is a key component of Transformers, which have recently achieved considerable success in natural language processing. Hence, attention is being extensively studied to investigate various linguistic capabilities of Transformers, focusing on analyzing the parallels between *attention weights* and specific linguistic phenomena. This paper shows that attention weights alone are only one of the two factors that determine the output of attention and proposes a norm-based analysis that incorporates the second factor, the norm of the transformed input vectors. The findings of our norm-based analyses of BERT and a Transformer-based neural machine translation system include the following: (i) contrary to previous studies, BERT pays poor attention to special tokens, and (ii) reasonable word alignment can be extracted from attention mechanisms of Transformer. These findings provide insights into the inner workings of Transformers.

1 Introduction

Transformers (Vaswani et al., 2017; Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019; Lan et al., 2020) have improved the state-of-the-art in a wide range of natural language processing tasks. The success of the models has not yet been sufficiently explained; hence, substantial research has focused on assessing the linguistic capabilities of these models (Rogers et al., 2020; Clark et al., 2019).

One of the main features of Transformers is that they utilize an attention mechanism without the use of recurrent or convolutional layers. The attention mechanism computes an output vector by accumulating relevant information from a sequence of input vectors. Specifically, it assigns attention weights (i.e., relevance) to each input, and sums up input vectors based on their weights. The analysis of correlations between attention weights and various linguistic phenomena (i.e., *weight-based analysis*) is a prominent research area (Clark et al., 2019; Kovaleva et al., 2019; Reif et al., 2019; Lin et al., 2019; Mareček and Rosa, 2019; Htut et al., 2019; Raganato and Tiedemann, 2018; Tang et al., 2018).

This paper first shows that weight-based analysis is insufficient to analyze the attention mechanism. Weight-based analysis is a common approach to analyze the attention mechanism by simply tracking attention weights. The attention mechanism can be expressed as a *weighted* sum of *linearly transformed vectors* (Section 2.2); however, the effect of transformed vectors in weight-based analysis is ignored. We propose a *norm-based analysis* that considers the previously ignored factors (Section 3). In this analysis, we measure the norms (lengths) of the vectors that were summed to compute the output vector of the attention mechanism.

Using the norm-based analysis of BERT (Section 4), we interpreted the internal workings of the model in more detail than when weight-based analysis was used. For example, the weight-based analysis (Clark et al., 2019; Kovaleva et al., 2019) reports that specific tokens, such as periods, commas, and special tokens (e.g., separator token; `[SEP]`), tend to have high attention weights. However, our norm-based analysis found that the information collected from vectors corresponding to special tokens was considerably lesser than that reported in the weight-based analysis, and the large attention weights of these vectors were canceled by other factors. Additionally, we found that BERT controlled the levels of contribution from frequent, less informative words by controlling the norms of their vectors.

In the analysis of a Transformer-based NMT system (Section 5), we reinvestigated how accurate word alignment can be extracted from the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7057–7075,
November 16–20, 2020.

source-target attention. The weight-based results of Li et al. (2019), Ding et al. (2019), and Zenkel et al. (2019) have empirically shown that word alignments induced by the source-target attention of the Transformer-based NMT systems are noisy. Our experiments show that more accurate alignments can be extracted by focusing on the vector norms.

The contributions of this study are as follows:

- We propose a novel method of analyzing an attention mechanism based on vector norms (norm-based analysis). The method considers attention weights and previously ignored factors, i.e., the norm of the transformed vector.
- Our norm-based analysis of BERT reveals that (i) the attention mechanisms pay considerably lesser attention to special tokens than to observations that are solely based on attention weights (weight-based analysis), and (ii) the attention mechanisms tend to discount frequent words.
- Our norm-based analysis of a Transformer-based NMT system reveals that reasonable word alignment can be extracted from source-target attention, in contrast to the previous results of the weight-based analysis.

The codes of our experiments are publicly available.[1]

2 Background

2.1 Attention mechanism

Attention is a core component of Transformers, which consist of several layers, each containing multiple attentions ("heads"). We focused on analyzing the inner workings of these heads.

As illustrated in Figure 1, each attention head gathers relevant information from the input vectors. A vector is updated by vector transformations, attention weights, and a summation of vectors. Mathematically, attention computes each output vector $\boldsymbol{y}_i \in \mathbb{R}^d$ from the corresponding pre-update vector $\widetilde{\boldsymbol{y}}_i \in \mathbb{R}^d$ and a sequence of input vectors $\mathcal{X} = \{\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n\} \subseteq \mathbb{R}^d$:

$$\boldsymbol{y}_i = \left(\sum_{j=1}^{n} \alpha_{i,j} \boldsymbol{v}(\boldsymbol{x}_j)\right) \boldsymbol{W}^O \tag{1}$$

$$\alpha_{i,j} := \operatorname*{softmax}_{\boldsymbol{x}_j \in \mathcal{X}} \left(\frac{\boldsymbol{q}(\widetilde{\boldsymbol{y}}_i) \boldsymbol{k}(\boldsymbol{x}_j)^\top}{\sqrt{d'}} \right) \in \mathbb{R}, \tag{2}$$

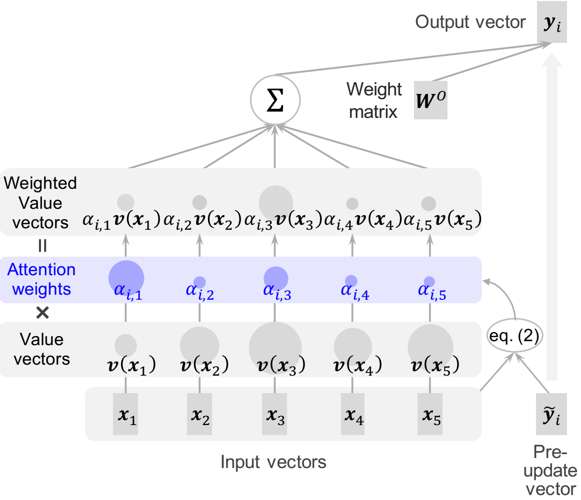

Figure 1: Overview of attention mechanism in Transformers. Sizes of the colored circles illustrate the value of the scalar or the norm of the corresponding vector.

where $\alpha_{i,j}$ is the attention weight assigned to the token x_j for computing y_i, and $\boldsymbol{q}(\cdot)$, $\boldsymbol{k}(\cdot)$, and $\boldsymbol{v}(\cdot)$ are the query, key, and value transformations, respectively.

$$\boldsymbol{q}(\widetilde{\boldsymbol{y}}_i) := \widetilde{\boldsymbol{y}}_i \boldsymbol{W}^Q + \boldsymbol{b}^Q \quad \left(\boldsymbol{W}^Q \in \mathbb{R}^{d \times d'}, \boldsymbol{b}^Q \in \mathbb{R}^{d'}\right)$$
$$\boldsymbol{k}(\boldsymbol{x}_j) := \boldsymbol{x}_j \boldsymbol{W}^K + \boldsymbol{b}^K \quad \left(\boldsymbol{W}^K \in \mathbb{R}^{d \times d'}, \boldsymbol{b}^K \in \mathbb{R}^{d'}\right)$$
$$\boldsymbol{v}(\boldsymbol{x}_j) := \boldsymbol{x}_j \boldsymbol{W}^V + \boldsymbol{b}^V \quad \left(\boldsymbol{W}^V \in \mathbb{R}^{d \times d'}, \boldsymbol{b}^V \in \mathbb{R}^{d'}\right).$$

Attention gathers value vectors $\boldsymbol{v}(\boldsymbol{x}_j)$ based on attention weights and then, applies matrix multiplication $\boldsymbol{W}^O \in \mathbb{R}^{d' \times d}$ (Figure 1).[2] Boldface letters such as $\boldsymbol{x}$ denote row (not column) vectors, following the notations in Vaswani et al. (2017).

In self-attention, the input vectors $\mathcal{X}$ and the pre-update vector $\widetilde{\boldsymbol{y}}_i$ are previous layer's output representations. In source-target attention, $\mathcal{X}$ corresponds to the representations of the encoder, and vector $\widetilde{\boldsymbol{y}}_i$ (and updated vector $\boldsymbol{y}_i$) corresponds to the vector of the i-th input token of the decoder.

2.2 Attention is a weighted sum of vectors

With a simple reformulation, one can observe that the attention mechanism computes the weighted sum of the transformed input vectors. Because of the linearity of the matrix product, we can rewrite Equation 1 as

$$\boldsymbol{y}_i = \sum_{j=1}^{n} \boxed{\boxed{\alpha_{i,j}} \, \boxed{f(\boldsymbol{x}_j)}} \tag{3}$$

---

[1] `https://github.com/gorokoba560/norm-analysis-of-transformer`

[2] Whether bias $\boldsymbol{b}$ is added to calculate query, key, and value vectors depends on the implementation. $\boldsymbol{W}^O \in \mathbb{R}^{d' \times d}$ in Equation 1 corresponds to the part of $\boldsymbol{W}^O \in \mathbb{R}^{hd' \times d}$ that was introduced in Vaswani et al. (2017) which is applied to each head; where h is the number of heads, and $hd' = d$ holds.

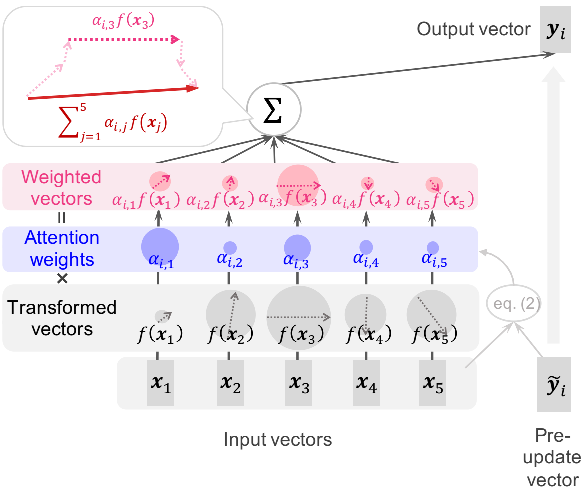

Figure 2: Overview of attention mechanism based on Equation 3. It computes the output vector by summing the weighted vectors; vectors with larger norms have higher contributions. Sizes of the colored circles illustrate the value of the scalar or the norm of the corresponding vector.

$$f(\boldsymbol{x}) := \left(\boldsymbol{x}\boldsymbol{W}^{V} + \boldsymbol{b}^{V}\right)\boldsymbol{W}^{O}. \tag{4}$$

Equation 3 shows that the attention mechanism first transforms each input vector $\boldsymbol{x}$ to generate $f(\boldsymbol{x})$; computes attention weights α; and then compute the *sum* $\alpha f(\boldsymbol{x})$ (see Figure 2).

2.3 Problems encountered in weight-based analysis

The attention mechanism has been designed to update representations by gathering relevant information from the input vectors. Prior studies have analyzed attention, focusing on attention weights, to ascertain which input vectors contribute (weight-based analysis) (Clark et al., 2019; Kovaleva et al., 2019; Reif et al., 2019; Lin et al., 2019; Mareček and Rosa, 2019; Htut et al., 2019; Raganato and Tiedemann, 2018; Tang et al., 2018).

Analyses solely based on attention weight are based on the assumption that the larger the attention weight of an input vector, the higher its contribution to the output. However, this assumption disregards the magnitudes of the transformed vectors. The problem encountered when neglecting the effect of $f(\boldsymbol{x}_j)$ is illustrated in Figure 2. The transformed vector $f(\boldsymbol{x}_1)$ for input $\boldsymbol{x}_1$ is assumed to be very small ($\|f(\boldsymbol{x}_1)\| \approx 0$), while its attention weight $\alpha_{i,1}$ is considerably large. Note that the small $\alpha_{i,1}f(\boldsymbol{x}_1)$ contributes a little to the output vector $\boldsymbol{y}_i$ because $\boldsymbol{y}_i$ is the sum of $\alpha f(\boldsymbol{x})$, where a larger vector contributes more to the output. Conversely, the large $\alpha_{i,3}f(\boldsymbol{x}_3)$ dominates the output $\boldsymbol{y}_i$. Therefore, in this case, only considering the attention weight may lead to a wrong interpretation of the high contribution of input vector $\boldsymbol{x}_1$ to output $\boldsymbol{y}_i$. Nevertheless, $\boldsymbol{x}_1$ hardly has any effect on $\boldsymbol{y}_i$.

Analyses based on attention weights have not provided clear results in some cases. For example, Clark et al. (2019) reported that input vectors for separator tokens `[SEP]` tend to receive remarkably large attention weights in BERT, while changing the magnitudes of these weights does not affect the masked-token prediction of BERT. Such results can be attributed to the aforementioned issue of focusing only on attention weights.

3 Proposal: norm as a degree of attention

As described in Section 2.3, analyzing the attention mechanism with only attention weights neglects the effect of the transformed vector $f(\boldsymbol{x}_j)$, which has a significant impact as we discussed later.

Herein, we propose the measurement of the *norm of the weighted transformed vector* $\|\alpha f(\boldsymbol{x})\|$, given by Equation 3, to analyze the attention mechanism behavior.[3] Unlike in previous studies, we analyzed the behaviors of the norms, $\|\alpha f(\boldsymbol{x})\|$ and $\|f(\boldsymbol{x})\|$, and α to gain more in-depth insights into the functioning of attention. The proposed method of analyzing the attention mechanism is called **norm-based analysis** and the method that solely analyzes the attention weights is called **weight-based analysis**.

In Sections 4 and 5, we provide insights into the working of Transformers using norm-based analysis. Appendix A explains that our norm-based analysis can also be effectively applied to an entire multi-head attention mechanism.

4 Experiments: BERT

First, we show that the previously ignored transformed-vector norm affects the analysis of attention in BERT (Section 4.1). Applying our norm-based analysis, we re-examine the previous reports on BERT obtained by weight-based analysis (Section 4.2). Next, we demonstrate the previously overlooked properties of BERT (Section 4.3).

---

[3] We use the standard Euclidean norm.

Head	μ	σ	CV	Max	Min
Layer 2–Head 4 (max CV)	4.26	1.59	**0.37**	12.66	0.96
Layer 2–Head 7 (min CV)	4.00	0.50	**0.12**	6.15	1.35
Average	5.15	1.17	**0.22**	-	-

Table 1: Mean (μ), standard deviation (σ), coefficient of variance (CV), and maximum and minimum values of $\|f(\boldsymbol{x})\|$. In the last row, the former three are averaged over all the heads.

General settings: Following the previous studies (Clark et al., 2019; Kovaleva et al., 2019; Reif et al., 2019; Lin et al., 2019; Htut et al., 2019), we used the pre-trained BERT-base[4], with 12 layers, each containing 12 attention heads. We used the data provided by Clark et al. (2019) for the analysis.[5] The data contains 992 sequences extracted from Wikipedia, where each sequence consists of two consecutive paragraphs, in the form of: `[CLS] paragraph1 [SEP] paragraph2 [SEP]`. Each sequence consists of up to 128 tokens, with an average of 122 tokens.

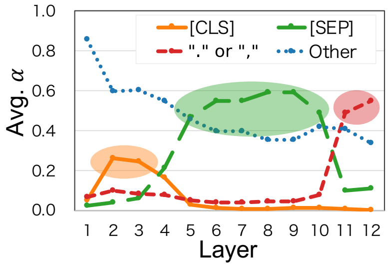
4.1 Does $f(\boldsymbol{x})$ have an impact?

We analyzed the coefficient of variation (CV)[6] of previously ignored effect—$\|f(\boldsymbol{x})\|$—to first demonstrate the degree to which $\|\alpha f(\boldsymbol{x})\|$ differs from weight α. We computed the CV of $\|f(\boldsymbol{x})\|$ of all the example data for each head. Table 1 shows that the average CV is 0.22. Typically, the value of the norm $\|f(\boldsymbol{x})\|$ varies from 0.78 to 1.22 times the average value of the $\|f(\boldsymbol{x})\|$. Thus, there is a difference between the weight α and $\|\alpha f(\boldsymbol{x})\|$ due to the dispersion of $\|f(\boldsymbol{x})\|$, which motivated us to consider $\|f(\boldsymbol{x})\|$ in the attention analysis. Appendix B presents the detailed results.

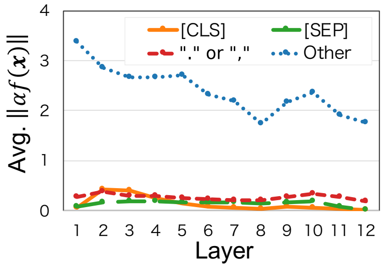
4.2 Re-examining previous observation

In this section, with the application of our norm-based analysis, we reinvestigate the previous observation of Clark et al. (2019); they analyzed BERT using the weight-based analysis.

Settings: First, all the data were fed into BERT. Then, the weight α and $\|\alpha f(\boldsymbol{x})\|$ were collected from each head. Following Clark et al. (2019), we report the results of the following categories: (i) `[CLS]`, (ii) `[SEP]`, (iii) periods and commas, and (iv) the other tokens. More specific descriptions of the experiments are provided in Appendix D.



(a) Weight-based analysis.



(b) Norm-based analysis.

Figure 3: Each point corresponds to averaged α or $\|\alpha f(\boldsymbol{x})\|$ on a word category in a given layer. Note that, in each layer, the sum of α among all the categories is 1. The x-axis denotes the index of the layers.

Token category	Number of vectors	Spearman's ρ
[CLS]	17,443,296	-0.34
[SEP]	34,886,592	-0.69
comma & period	182,838,528	-0.25
Others	1,944,928,224	-0.06

Table 2: Spearman rank correlation coefficient between α and $\|f(\boldsymbol{x})\|$ in each token category.

Results: The weight-based and norm-based analyses exhibited entirely different trends (Figure 3). The vectors for specific tokens—`[CLS]`, `[SEP]`, and punctuations—have remarkably large attention weights, which is consistent with the report of Clark et al. (2019). In contrast, our norm-based analysis demonstrated that the contributions of vectors corresponding to these tokens were generally small (Figure 3b). The result demonstrates that the size of the transformed vector $f(\boldsymbol{x})$ plays a considerable role in controlling the amount of information obtained from the specific tokens.

Clark et al. (2019) hypothesized that if the necessary information is not present in the input vectors, BERT assigns large weights to `[SEP]`, which appears in every input sequence, to avoid the incorporation of any additional information via at-

---

[4] We used PyTorch implementation of BERT-base (uncased) released at `https://github.com/huggingface/transformers`.

[5] `https://github.com/clarkkev/attention-analysis`

[6] *Coefficient of variation* (CV) is a standardized (scale-invariant) measure of dispersion, which is defined by the ratio of the standard deviation σ to the mean μ; CV $:= \sigma/\mu$.

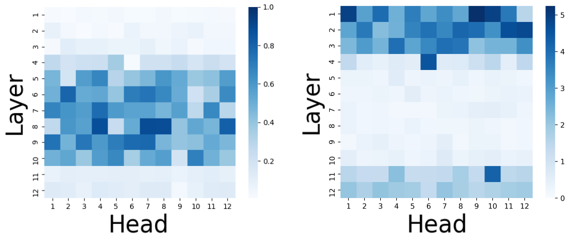
tention.[7] Clark et al. (2019) called this operation no-operation (no-op). However, it is unclear whether assigning large attention weights to `[SEP]` realizes the operation of collecting little information from the input sequence.

Our norm-based analysis demonstrates that the amount of information from the vectors corresponding to `[SEP]` is small (Figure 3b). This result supports the interpretation that BERT conducts "no-op," in which attention to `[SEP]` is considered a signal that does not collect anything. Additionally, we hope that our norm-based analysis can provide a better interpretation of other existing findings.

Analysis—The relationship between α and $\|f(\boldsymbol{x})\|$: It remains unclear how attention *collects only a little information* while assigning a high attention weight to a specific token, `[SEP]`. Here, we demonstrate an interesting trend of α and $\|f(\boldsymbol{x})\|$ cancelling each other out on the tokens.[8] Table 2 shows the Spearman rank correlation coefficient between α and $\|f(\boldsymbol{x})\|$, corresponding to the vectors in each category. The weight α and the norm $\|f(\boldsymbol{x})\|$ have a negative correlation in terms of `[CLS]`, `[SEP]`, periods, and commas. This cancellation manages to *collect a little information* even with large weights.

Figure 4 illustrates the contrast between α and $\|f(\boldsymbol{x})\|$ corresponding to `[SEP]` in each head. For most of the heads, α and $\|f(\boldsymbol{x})\|$ clearly negate the magnitudes of each other. A similar trend was observed in `[CLS]`, periods, and commas. Conversely, no significant trend was observed in the other tokens (see Appendix D.3).

Figure 5 shows 1% randomly selected pairs of α and $\|f(\boldsymbol{x})\|$ in each word category. Even when the same weight α is assigned, $\|f(\boldsymbol{x})\|$ can vary, suggesting that α and $\|f(\boldsymbol{x})\|$ play a different roles in attention.



(a) α. (b) $\|f(\boldsymbol{x})\|$.

Figure 4: The higher value of averaged α or $\|f(\boldsymbol{x})\|$ for `[SEP]` tokens in a given head, the darker its cell.

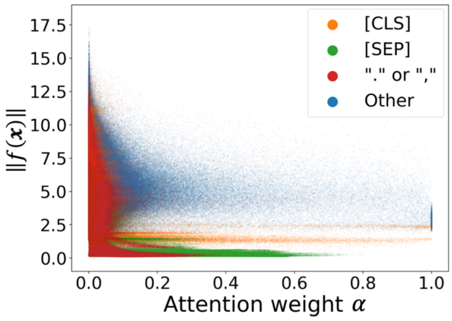


Figure 5: Relationship between α and $\|f(\boldsymbol{x})\|$. Each plot corresponds to a pair of $\alpha_{i,j}$ and $\|f(\boldsymbol{x}_j)\|$ in one of the attention heads. Each plot is colored by the word category corresponding to $\boldsymbol{x}_j$. Visualizations by category are shown in Appendix D.3.

4.3 Relation between frequency and $\|f(\boldsymbol{x})\|$

In the previous section, we demonstrated that $\|f(\boldsymbol{x})\|$ corresponding to the specific tokens (e.g., `[SEP]`) is small. Based on the high frequencies[9] of these word types[10], we hypothesized that BERT controlled contributions of highly frequent, less informative words by adjusting the norm of $f(\boldsymbol{x})$.

Settings: First, all the data were fed into the model. Then, for each input token t, we collected the weight α and $\|f(\boldsymbol{x})\|$. We averaged α and $\|f(\boldsymbol{x})\|$ for all the heads for each t to analyze the trend of the entire model. Let $r(\cdot)$ be a function that returns the frequency rank of a given word.[11] We analyzed the relationship of $r(t)$ with α and $\|f(\boldsymbol{x})\|$.

Results: The Spearman rank correlation coefficient between the frequency rank $r(t)$ and $\|f(\boldsymbol{x})\|$ was 0.75, indicating a strong positive correlation. In contrast, the Spearman rank correlation coefficient did not show any correlation ($\rho = 0.06$) between $r(t)$ and α.[12] The visualizations of their relationships are shown in Appendix D.4.

These results demonstrate that the self-

---

[7] Note that the attention mechanism has the constraint that the sum of the attention weights becomes 1.0 (see Equation 2).

[8] Note that for any positive scalar $\lambda \in \mathbb{R}$ and vector $\boldsymbol{x} \in \mathbb{R}^d$, $\|\lambda\boldsymbol{x}\| = \lambda\|\boldsymbol{x}\|$.

[9] The frequency ranks of the words `[CLS]`, `[SEP]`, period, and comma, out of approximately 30,000 words, are 50, 28, 2, and 3, respectively.

[10] We call word type as "word." Each instance of a word is called "token."

[11] We counted the frequency for each word type by reproducing the training data of BERT.

[12] The Spearman rank correlation coefficient without special tokens, periods, and commas was 0.28 for the attention weights and 0.69 for the norms.

attentions in BERT reduce the information from highly frequent words by adjusting $\|f(\boldsymbol{x})\|$ and not α. This frequency-based effect is consistent with the intuition that highly frequent words, such as stop words, are unlikely to play an important role in solving the pre-training tasks (masked-token prediction and next-sentence prediction).

5 Experiments: Transformer for NMT

Additionally, we analyzed the source-target attention in a Transformer-based NMT system. One major research topic in the NMT field is whether NMT systems internally capture word alignment between source and target texts, and if so, how word alignment can be extracted from black-box NMT systems. Li et al. (2019), Ding et al. (2019), and Zenkel et al. (2019) empirically showed, using the weight-based method, that word alignment induced by the attention of the Transformer is noisy. In this section, we show the analysis of source-target attention using vector norms $\|\alpha f(\boldsymbol{x})\|$ and demonstrate that clean alignments can be extracted from the source-target attention. Word alignment can be used to provide rich information for the users of NMT systems (Ding et al., 2019).

Experimental procedure: Following Zenkel et al. (2019) and Ding et al. (2019), we trained a Transformer-based NMT system for German-to-English translation on the Europarl v7 corpus[13]. Next, we extracted word alignments from α and $\|\alpha f(\boldsymbol{x})\|$ under the force decoding setup. Finally, we evaluated the derived alignment using the alignment error rate (AER) (Och and Ney, 2000). A low AER score indicates that the extracted word alignments are close to the reference. We used the gold alignment dataset provided by Vilar et al. (2006)[14]. Experiments were performed on five random seeds, and the average AER scores were reported. The experimental settings are detailed in Appendix E.

5.1 Alignment extraction from attention

Weights or norms: A typical alignment extraction method uses attention weights (Li et al., 2019; Ding et al., 2019; Zenkel et al., 2019). Specifically, given a source-target sentence pair, $\{s_1, \ldots, s_J\}$ and $\{t_1, \ldots, t_I\}$, word alignment is estimated by calculating a source word s_j that has the highest weight when generating a target word t_i. We call this method the *weight-based alignment extraction*. In contrast, we propose a *norm-based alignment extraction* method that extracts word alignments based on $\|\alpha f(\boldsymbol{x})\|$ instead of α. Formally, in these methods, the source word s_j with the highest attention weight or norm during the generating of target word t_i is extracted as the word that is aligned with t_i:

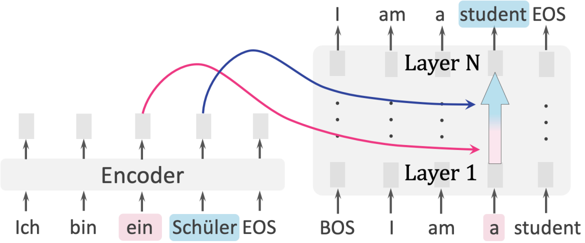

Figure 6: An example of behavior of the source-target attentions in an NMT system (German-to-English). Attentions in the earlier layers focus the source word "ein" aligned with the input word "a," while those in the latter layers focus the source word "Schüler" aligned with the output word "student."

$$\underset{s_j}{\operatorname{argmax}}\, \alpha_{i,j} \quad \text{or} \quad \underset{s_j}{\operatorname{argmax}}\, \|\alpha_{i,j} f(\boldsymbol{x}_j)\|. \qquad (5)$$

In Section 5.2, following Li et al. (2019), we analyze the word alignments that we obtained from each layer by integrating H heads within the same layer:

$$\underset{s_j}{\operatorname{argmax}} \sum_{h=1}^{H} \alpha_{i,j}^h \quad \text{or} \quad \underset{s_j}{\operatorname{argmax}} \Big\| \sum_{h=1}^{H} \alpha_{i,j}^h f^h(\boldsymbol{x}_j) \Big\|,$$

where $f^h(\boldsymbol{x}_j)$ and $\alpha_{i,j}^h$ are the transformed vector and the attention weight at the h-th head, respectively.

Alignment with input or output word: In our preliminary experiments (Appendix E.3), we observed that the behavior of the source-target attention of the decoder differs between the earlier and later layers. As shown in Figure 6, at the time decoding the word t_{i+1} with the input t_i, attention heads in the earlier layers assign large weights or norms to s_j corresponding to the input t_i "a," whereas those in the latter layers assign large values to s_j corresponding to the output word t_{i+1} "student."

---

[13] `http://www.statmt.org/europarl/v7`

[14] `https://www-i6.informatik.rwth-aachen.de/goldAlignment/`

Based on this observation, we explored two settings for investigating alignment extraction methods: *alignment with output* (AWO) and *alignment with input* (AWI). The AWO setting refers to the approach introduced in Equation 5. Specifically, alignments (s_j, t_i) were extracted by considering a source word s_j that gained the highest weight (norm) when *outputting* a particular target word t_i.

In the AWI setting, alignments (s_j, t_i) were extracted by considering a source word s_j that gained the highest weight (norm) when *inputting* the word t_i (i.e., predicting a word t_{i+1}). Formally, alignment with the AWI setting is calculated as follows:

$$\operatorname*{argmax}_{s_j} \alpha_{i+1,j} \quad \text{or} \quad \operatorname*{argmax}_{s_j} \|\alpha_{i+1,j} f(\boldsymbol{x}_j)\|. \tag{6}$$

5.2 Comparative experiments

We compared the quality of the alignments that were obtained by the following six methods:

- norm-based extraction with the AWO/AWI settings
- weight-based extraction with the AWO/AWI settings (Li et al., 2019; Zenkel et al., 2019; Ding et al., 2019)
- gradient-based extraction (Ding et al., 2019)
- existing word aligners (Och and Ney, 2003; Dyer et al., 2013)

We report the best and averaged AER scores across the layers. In addition, we report on the AER score at the head and the layer with the highest average $\|\alpha f(\boldsymbol{x})\|$ in the norm-based extraction.[15] The settings are detailed in Appendix E.2.

The AER scores of each method are listed in Table 3. The results show that word alignments extracted using the proposed norm-based approach are more reasonable than those extracted using the weight-based approach. Additionally, better word alignments were extracted in the AWI setting than in the AWO setting. The alignment extracted using the layer with the highest average $\|\alpha f(\boldsymbol{x})\|$ in the AWI setting is better than the gradient-based method, and competitive with one of the existing word aligners—fast_align.[16] These results show that much clearer word alignments can be extracted from a Transformer-based NMT system than the results reported by existing research.

Methods	AER	±SD
Transformer – Attention-based Approach		
— *Alignment with output* setting —		
Weight-based		
layer mean	68.4	1.0
best layer (layer 4 or 5)	47.7	1.7
Norm-based (ours)		
layer mean	62.9	0.7
best layer (layer 5)	41.4	1.4
layer with the highest average $\|\alpha f(\boldsymbol{x})\|$	83.0	1.1
head with the highest average $\|\alpha f(\boldsymbol{x})\|$	87.1	2.3
— *Alignment with input* setting —		
Weight-based		
layer mean	68.5	1.9
best layer (layer 2)	29.8	3.7
Norm-based (ours)		
layer mean	60.4	1.3
best layer (layer 2)	25.0	1.5
layer with the highest average $\|\alpha f(\boldsymbol{x})\|$	25.0	1.5
head with the highest average $\|\alpha f(\boldsymbol{x})\|$	35.5	21.0
Transformer – Gradient-based Approach		
SmoothGrad from Ding et al. (2019)	36.4	-
Word Aligner		
fast_align from Zenkel et al. (2019)	28.4	-
GIZA++ from Zenkel et al. (2019)	21.0	-

Table 3: AER scores with different methods for German-to-English translation. The closer the extracted word alignment is to the reference, the lower the AER score. The "layer mean" denotes the average of AER scores across all layers. Each value is the average of five random seeds.

The primary reason behind the differences between the results of the weight- and norm-based methods was analogous to the finding discussed in Section 4.2, while some specific tokens, such as ⟨/s⟩, the special token for the end of the sentence, tended to obtain heavy attention weights; their transformed vectors were adjusted to be smaller, as shown in Figure 7.

5.3 Relationship between norms and alignment quality

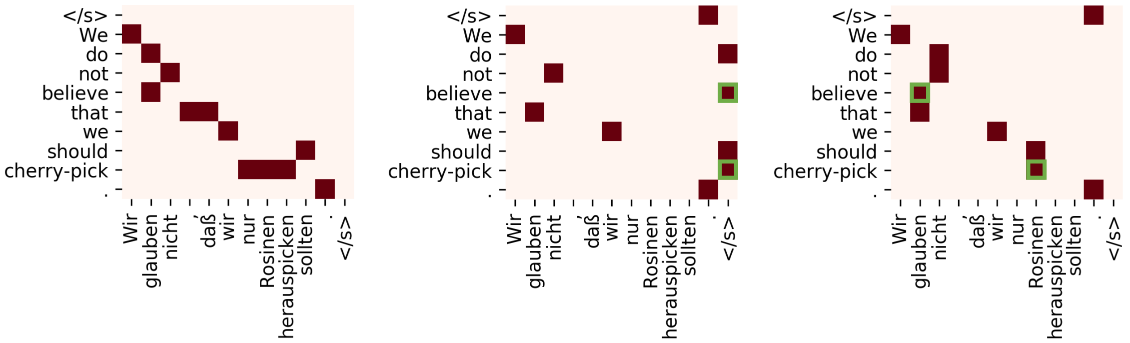
We further analyze the relationship between $\|\alpha f(\boldsymbol{x})\|$ and AER scores in the head-level. Figures 8a and 8b show the AER scores of the alignments obtained by the norm based extraction at each head in the AWO and AWI settings. Figure 8c shows the average of $\|\alpha f(\boldsymbol{x})\|$ at each head. The small $\|\alpha f(\boldsymbol{x})\|$ implies that α and $\|f(\boldsymbol{x})\|$ tend to cancel out in the head.

Comparing Figures 8a and 8c, the average $\|\alpha f(\boldsymbol{x})\|$ and AER scores in the AWI setting

---

[15] The average $\|\alpha f(\boldsymbol{x})\|$ of the layer was determined by the sum of the average $\|\alpha f(\boldsymbol{x})\|$ at each head in the layer.

[16] Even at the head with the highest average $\|\alpha f(\boldsymbol{x})\|$. Although the average score of five seeds in the AWI setting was 35.5, four seeds out of them achieved great score range from 23.6-to 25.7. The score was 77.5 for a remaining seed.



(a) Reference. (b) α. (c) $\|\alpha f(\boldsymbol{x})\|$.

Figure 7: Examples of the reference and extracted alignments using each method in layer 2 (best layer) in the AWI setting on one out of five seeds. Two misalignments in the weight-based extraction were resolved in the norm-based analysis—alignments with the green frame. Examples of the extracted alignments in all the layers are shown in Appendix E.4.

are inversely correlated (the Spearman rank and Pearson correlation coefficients are -0.44 and -0.52, respectively). This result is consistent with Table 3, where the head or the layer with the highest average $\|\alpha f(\boldsymbol{x})\|$ provides clean alignments in the AWI setting. This result suggests that Transformer-based NMT systems may rely on specific heads that align source and target tokens. This result is also consistent with the exiting reports that pruning some attention heads in Transformers does not change its performance; on the contrary, it improves the performance (Michel et al., 2019; Kovaleva et al., 2019).

In contrast, in the AWO setting (Figures 8b and 8c), such a negative correlation is not observed; rather, a positive correlation is observed (Spearman's ρ is 0.56, and the Pearson's r is 0.55). Actually, in the AWO setting, the alignments extracted from the head/layer with the highest $\|\alpha f(\boldsymbol{x})\|$ is considerably worse than those from the other settings in Table 3. Investigating the reason for these contrasting results would be our future work. In Appendix F, we also present the results of a model with a different number of heads.

6 Related work

6.1 Probing of Transformers

Transformers are used for many NLP tasks. Many studies have probed their inner workings to understand the mechanisms underlying their success (Rogers et al., 2020; Clark et al., 2019).

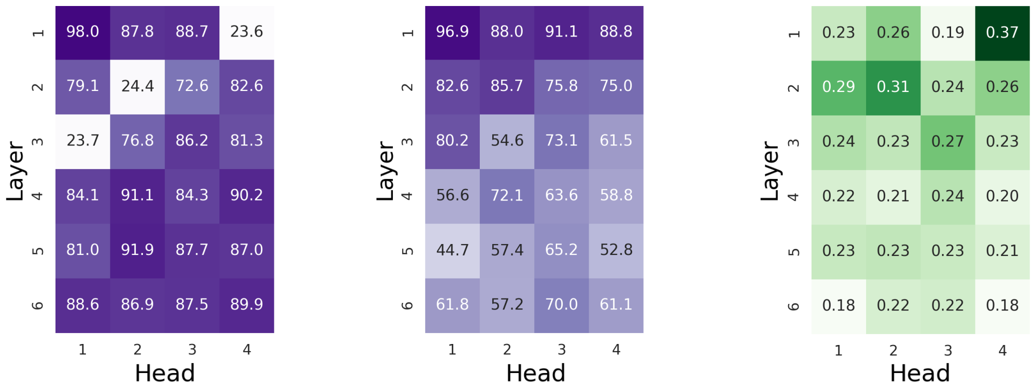
There are mainly two probing perspectives to investigate these models; they differ based on whether the target of the analysis is per-token level or it considers token-to-token interactions. The first category assesses a single word or phrase-level linguistic capabilities of BERT, such as its performance on part-of-speech tagging and word sense disambiguation performance (Tenney et al., 2019; Jawahar et al., 2019; Reif et al., 2019; Lin et al., 2019; Wallace et al., 2019).

The latter category explores the ability of Transformers to capture token-to-token interactions, such as syntactic relations and word alignment in the translation (Clark et al., 2019; Kovaleva et al., 2019; Htut et al., 2019; Reif et al., 2019; Lin et al., 2019; Goldberg, 2019; Ding et al., 2019; Zenkel et al., 2019; Li et al., 2019; Raganato and Tiedemann, 2018). The present study is closely related to the latter group; we have provided insights into the token-to-token attention in Transformer-based systems.

6.2 Analyzing the token-to-token interaction

Two types of methods are mainly considered to analyze the token-to-token interactions in Transformers. One is to track the attention weights, and the other is to check the gradient of the output with respect to the input of attention mechanisms.

Weight-based analysis: Many studies have analyzed the linguistic capabilities of Transformers by tracking attention weights. This type of analysis has covered a wide range of subjects, including syntactic and semantic relationships (Tang et al., 2018; Raganato and Tiedemann, 2018; Clark et al., 2019; Reif et al., 2019; Jawahar et al., 2019; Htut et al., 2019; Kovaleva et al., 2019; Mareček and Rosa, 2019). However, as outlined in Section 2.3, these studies have ignored the effect of $f(\boldsymbol{x})$. It has been actively discussed so far whether the attention weights can be interpreted to explain



Layer	Head 1	Head 2	Head 3	Head 4

(c) Averaged $\|\alpha f(\boldsymbol{x})\|$.

Figure 8: AER scores and averaged $\|\alpha f(\boldsymbol{x})\|$ in each head on one out of five seeds. The closer the extracted word alignment is to the reference, the lower the AER score—the lighter the color. The larger the averaged $\|\alpha f(\boldsymbol{x})\|$, the darker the color.

the models (Jain and Wallace, 2019; Serrano and Smith, 2019; Wiegreffe and Pinter, 2019; Pruthi et al., 2020; Vashishth et al., 2019).

Brunner et al. (2020) have introduced "effective attention," which has upgraded the weight-based analysis. Their proposal is similar to ours; they exclude attention weights that do not affect the output owing to the application of transformation f and input $\boldsymbol{x}$ in the analysis. However, our proposal differs from theirs in some aspects. Specifically, we aim to analyze the behavior of the whole attention mechanism more accurately, whereas they aim to make the attention weights more accurate. Furthermore, the effectiveness of their approach depends on the length of an input sequence; however, ours approach does not have such a limitation (see Appendix G). Additionally, we incorporate the scaling effects of f and $\boldsymbol{x}$, whereas Brunner et al. (2020) have considered only the binary effect—either the weight is canceled or not.

Gradient-based analysis: In the gradient analysis, the contribution of the input with respect to the output of the attention mechanism is calculated using the norm of a gradient matrix between the input and the output vector (Pascual et al., 2020). Intuitively, such gradient-based methods measure the change in the output vector with respect to the perturbations in the input vector. Estimating the contribution of $\boldsymbol{a}$ to $\boldsymbol{b} = \sum k\boldsymbol{a}$ by computing the gradient $\partial\boldsymbol{b}/\partial\boldsymbol{a}$ $(= k)$ is analogous to estimating the contribution of $\boldsymbol{x}$ to $\boldsymbol{y} = \sum \alpha f(\boldsymbol{x})$ by observing only an attention weight α.[17] The two approaches have the same kind of problems; that is, both ignore the magnitude of the input, $\boldsymbol{a}$ or $f(\boldsymbol{x})$.

7 Conclusions and future work

This paper showed that attention weights alone are only one of two factors that determine the output of attention. We proposed the incorporation of another factor, the transformed input vectors. Using our norm-based method, we provided a more detailed interpretation of the inner workings of Transformers, compared to the studies using the weight-based analysis. We hope that this paper will inspire researchers to have a broader view of the possible methodological choices for analyzing the behavior of Transformer-based models.

We believe that these findings can provide insights not only into the interpretation of the behaviors of Blackbox NLP systems but also into developing a more sophisticated Transformer-based system. One possible direction is to design an attention mechanism that can collect almost no information from an input sequence as the current systems achieve it by exploiting the `[SEP]` token.

In future work, we plan to apply our norm-based analysis to attention in other models, such as fine-tuned BERT, RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020). Furthermore, we expect to extend the scope of analysis from the attention to an entire Transformer architecture to better understand the inner workings and linguistic capabilities of the current powerful systems in NLP.

---

[17] For simplicity, we consider a linear example: $\boldsymbol{b} = \sum k\boldsymbol{a}$. We are aware that there is a gap between the two examples in terms of linearity. Further exploration of the connection to the gradient-based method is needed.

A Multi-head attention and the norm-based analysis

Our norm-based analysis is applicable to the analysis of the multi-head attention mechanism implemented in Transformers. The i-th output of the multi-head attention mechanism $\boldsymbol{y}_i^{\text{integrated}}$ is calculated as follows:

$$\boldsymbol{y}_i^{\text{integrated}} = \sum_h \boldsymbol{y}_i^h \tag{7}$$

$$\boldsymbol{y}_i^h = \sum_{j=1}^{n} \alpha_{i,j}^h f^h(\boldsymbol{x}_j) \tag{8}$$

$$f^h(\boldsymbol{x}) := \left(\boldsymbol{x}\boldsymbol{W}^{V,h} + \boldsymbol{b}^{V,h}\right)\boldsymbol{W}^{O,h}, \tag{9}$$

where $\alpha_{i,j}^h$, $\boldsymbol{W}^{V,h}$, $\boldsymbol{b}^{V,h}$, and $\boldsymbol{W}^{O,h}$ are the same as $\alpha_{i,j}$, $\boldsymbol{W}^V$, $\boldsymbol{b}^V$, and $\boldsymbol{W}^O$ in Equations 3 and 4 for each head h, respectively. n is the number of tokens in the input vectors. Equation 7 can be rewritten as follows:

$$\boldsymbol{y}_i^{\text{integrated}} = \sum_{j=1}^{n} \boxed{\textstyle\sum_h \boxed{\alpha_{i,j}^h} \boxed{f^h(\boldsymbol{x}_j)}} \tag{10}$$

As shown in Equation 10, the multi-head attention mechanism is also linearly decomposable, and one can analyze the flaw of the information from the j-th vector to the i-th vector by measuring $\|\sum_h \alpha_{i,j}^h f^h(\boldsymbol{x}_j)\|$. In Section 5, we actually used $\|\sum_h \alpha_{i,j}^h f^h(\boldsymbol{x}_j)\|$ to extract the alignment from each layer's multi-head attention.

The output of the multi-head attention mechanism is calculated via the sum of the outputs of all the heads and a bias $\boldsymbol{b}^O \in \mathbb{R}^d$. Because adding a fixed vector is irrelevant to the token-to-token interaction that we aim to investigate, we omitted $\boldsymbol{b}^O$ in our analysis.

B The source of the dispersion of $\|f(\boldsymbol{x})\|$

As described in Section 4.1, $\|f(\boldsymbol{x})\|$ exhibits dispersion; however, it remains unclear whether this dispersion is attributed to $\|\boldsymbol{x}\|$ or f. Hence, we checked the dispersion of $\|\boldsymbol{x}\|$ and the scaling effects of the transformation f.

Dispersion of $\|\boldsymbol{x}\|$: First, we checked the coefficient of variation (CV) of $\|\boldsymbol{x}\|$. Table 4 shows that the average CV is 0.12, which is less than that of $\|f(\boldsymbol{x})\|$ (0.22). The value of $\|\boldsymbol{x}\|$ typically varies between 0.88 and 1.12 times the average value of $\|\boldsymbol{x}\|$. The layer normalization (Ba et al., 2016) that applied at the end of the previous layer should have a large impact on the variance of $\|\boldsymbol{x}\|$.

Scaling effects of f: Second, we investigated the scaling effect of the transformation f on the norm of the input. Because the affine transformation $f\colon \mathbb{R}^d \to \mathbb{R}^d$ can be considered a linear transformation $\mathbb{R}^{d+1} \to \mathbb{R}^{d+1}$ (Appendix C), the singular values of f can be regarded as its scaling effect. Figure 9 shows the singular values of f in randomly selected heads in BERT. The singular values are displayed in descending order from left to right. In each head, there is a difference of at least 1.8 times between the maximum and minimum singular values. This difference is larger than that of $\|\boldsymbol{x}\|$, where $\|\boldsymbol{x}\|$ typically varies between 0.88 and 1.12 times the average value. These results suggest that the dispersion of $\|f(\boldsymbol{x})\|$ is primarily attributed to the scaling effect of f.

C Affine transformation as linear transformation

The affine transformation $f\colon \mathbb{R}^d \to \mathbb{R}^d$ in Equation 4 can be viewed as a linear transformation $\widetilde{f}\colon \mathbb{R}^{d+1} \to \mathbb{R}^{d+1}$. Given $\widetilde{\boldsymbol{x}} := \begin{bmatrix} \boldsymbol{x} & 1 \end{bmatrix} \in \mathbb{R}^{d+1}$, where 1 is concatenated to the end of each input vector $\boldsymbol{x} \in \mathbb{R}^d$, the affine transformation f can be viewed as:

$$\widetilde{f}(\widetilde{\boldsymbol{x}}) = \widetilde{\boldsymbol{x}}\widetilde{\boldsymbol{W}}^V\widetilde{\boldsymbol{W}}^O \tag{11}$$

$$\widetilde{\boldsymbol{W}}^V := \begin{bmatrix} & 0 \\ \boldsymbol{W}^V & \vdots \\ & 0 \\ \boldsymbol{b}^V & 1 \end{bmatrix} \in \mathbb{R}^{(d+1)\times(d'+1)} \tag{12}$$

$$\widetilde{\boldsymbol{W}}^O := \begin{bmatrix} & & & 0 \\ & \boldsymbol{W}^O & & \vdots \\ & & & 0 \\ 0 & \cdots & 0 & 1 \end{bmatrix} \in \mathbb{R}^{(d'+1)\times(d+1)}. \tag{13}$$

D Details on Sections 4.2 and 4.3

We describe the detailed experimental setup presented in Sections 4.2 and 4.3.

D.1 Notations

The dataset consists of several sequences; Data $= (s_1, \cdots, s_{|Data|})$. Each sequence consists of sev-

Layer	μ	σ	CV	Max	Min
12 (max CV)	20.49	4.62	**0.23**	32.84	4.13
7 (min CV)	21.64	1.40	**0.06**	23.03	11.87
Average	19.93	2.39	**0.12**	-	-

Table 4: Mean (μ), standard deviation (σ), coefficient of variance (CV), and maximum and minimum values of $\|\mathbf{x}\|$; the former three are averaged on all the layers.

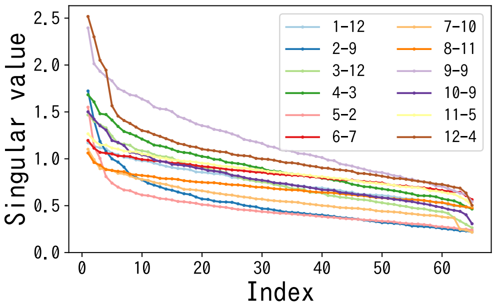

Figure 9: Singular values of f at randomly selected heads in each layer. We use ⟨layer⟩-⟨head number⟩ to denote a particular attention head. The singular values are

eral tokens, $s_p = (t_1^p, \cdots, t_{|s_p|}^p)$, where t_q^p is the q-th token in the p-th sequence. For simplicity, we define the following functions:

$$\mathrm{Weight}(p,q,\ell,h) = \frac{1}{|s_p|}\sum_{i=1}^{|s_p|} \alpha_{p,i,q}^{\ell,h}$$

$$\mathrm{Norm}(p,q,\ell,h) = \|f^{\ell,h}(\boldsymbol{x}_{p,q}^{\ell})\|$$

$$\mathrm{WNorm}(p,q,\ell,h) = \frac{1}{|s_p|}\sum_{i=1}^{|s_p|} \|\alpha_{p,i,q}^{\ell,h} f^{\ell,h}(\boldsymbol{x}_{p,q}^{\ell})\|,$$

where $\alpha_{p,i,q}^{\ell,h}$ is the attention weight assigned from the i-th pre-update vector to the q-th input vector in the p-th sequence. h and ℓ denote that the score is obtained from the h-th head of the ℓ-th layer. $\boldsymbol{x}_{p,q}^{\ell}$ denotes the input vector for token t_q^p in the ℓ-th layer. $f^{\ell,h}(\boldsymbol{x}_{p,q}^{\ell})$ is the transformed vector for $\boldsymbol{x}_{p,q}^{\ell}$ in the h-th head of the ℓ-th layer.

Next, the vocabulary $\mathcal{V}$ of BERT is divided into the following four categories:

$$\begin{aligned} A &= \{\texttt{[CLS]}\} \\ B &= \{\texttt{[SEP]}\} \\ C &= \{\text{“.”}, \text{“,”}\} \\ D &= \mathcal{V} \setminus (A \cup B \cup C). \end{aligned} \tag{14}$$

Let $T(p, Z)$ be a function that returns all tokens t_q^p belonging to the category Z in the p-th sequence. To formally describe our experiments, several functions are defined as follows. Note that we analyzed a model with 12 heads in each layer.

$$\mathrm{MeanN}(Z,\ell,h,p) = \frac{1}{|T(Z,p)|}\sum_{t_q^p \in T(Z,p)} \mathrm{Norm}(p,q,\ell,h)$$

$$\mathrm{SumW}(Z,\ell,h,p) = \sum_{t_q^p \in T(Z,p)} \mathrm{Weight}(p,q,\ell,h)$$

$$\mathrm{SumWN}(Z,\ell,h,p) = \sum_{t_q^p \in T(Z,p)} \mathrm{WNorm}(p,q,\ell,h)$$

$$\mathrm{HeadN}(Z,\ell,h) = \frac{1}{|\mathrm{Data}|}\sum_{s_p \in \mathrm{Data}} \mathrm{MeanN}(Z,\ell,h,p)$$

$$\mathrm{HeadW}(Z,\ell,h) = \frac{1}{|\mathrm{Data}|}\sum_{s_p \in \mathrm{Data}} \mathrm{SumW}(Z,\ell,h,p)$$

$$\mathrm{HeadWN}(Z,\ell,h) = \frac{1}{|\mathrm{Data}|}\sum_{s_p \in \mathrm{Data}} \mathrm{SumWN}(Z,\ell,h,p)$$

$$\mathrm{LayerW}(Z,\ell) = \frac{1}{12}\sum_{h=1}^{12} \mathrm{HeadW}(Z,\ell,h)$$

$$\mathrm{LayerWN}(Z,\ell) = \frac{1}{12}\sum_{h=1}^{12} \mathrm{HeadWN}(Z,\ell,h).$$

The $\mathrm{LayerW}(\cdot)$ and $\mathrm{LayerWN}(\cdot)$ functions are used to analyze the average behavior of the heads in a layer.

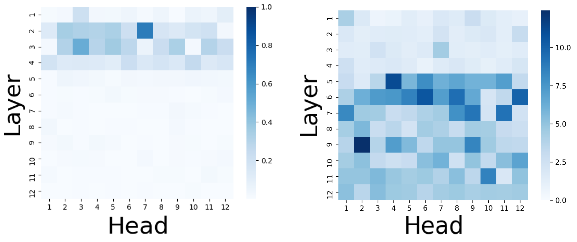
D.2 Experimental setup for Section 4.2

In Figure 3, the results of each layer are reported for each category. In Figures 3a and 3b, the values for each category Z were calculated using $\mathrm{LayerW}(Z,\ell)$ and $\mathrm{LayerWN}(Z,\ell)$, respectively.

In Figure 4, α and $\|f(\boldsymbol{x})\|$ in the h-th head of the ℓ-th layer were calculated using $\mathrm{HeadW}(Z,\ell,h)$ and $\mathrm{HeadN}(Z,\ell,h)$, respectively. The scores reported in Table 2 are the Spearman rank correlation coefficient r between $\mathrm{Weight}(p,q,\ell,h)$ and $\mathrm{WNorm}(p,q,\ell,h)$. We calculated the r using all the pairs of $\mathrm{Weight}(p,q,\ell,h)$ and $\mathrm{WNorm}(p,q,\ell,h)$ for the possible values of p, q, ℓ, and h. In Figure 5, each plot corresponds to the pair of $\mathrm{Weight}(p,q,\ell,h)$ and $\mathrm{WNorm}(p,q,\ell,h)$, where the combination of (p,q,ℓ,h) was randomly determined.

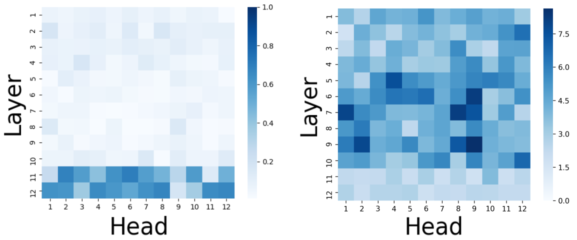
D.3 Visualizations of α and $\|f(\boldsymbol{x})\|$ for each word category

As described in Section 4.2, α and $\|f(\boldsymbol{x})\|$ for the `[SEP]` token were canceled out in almost all heads (Figure 4). Here, we show the trends for the other categories—B, C, and D in Equation 14. Figures 10, 11, and 12 show the trends of α and $\|f(\boldsymbol{x})\|$ for category B (the `[CLS]` token), C (periods and commas), and D (other tokens), respec-



(a) α. (b) $\|f(\boldsymbol{x})\|$.

Figure 10: α and $\|f(\boldsymbol{x})\|$ corresponding to `[CLS]` token, averaged on all the input text.



(a) α. (b) $\|f(\boldsymbol{x})\|$.

Figure 11: α and $\|f(\boldsymbol{x})\|$ corresponding to periods and commas, averaged on all the input text.

tively. The values in these figures were calculated as described in Appendix D.2. Figures 10 and 11 show that the trends for categories B and C were analogous to those for the `[SEP]` token; the large α was canceled by the small $\|f(\boldsymbol{x})\|$. However, the trends for category D do not exhibit the trends of the negative correlation between α and $\|f(\boldsymbol{x})\|$. In each heatmap of $\|f(\boldsymbol{x})\|$, the color scale is determined by the maximum value of $\|f(\boldsymbol{x})\|$ in each category.

We also reported the relationship between α and $\|f(\boldsymbol{x})\|$ in Section 4.2 (Figure 5). Figure 13 shows the results for each word category to provide a clearer display of the results.

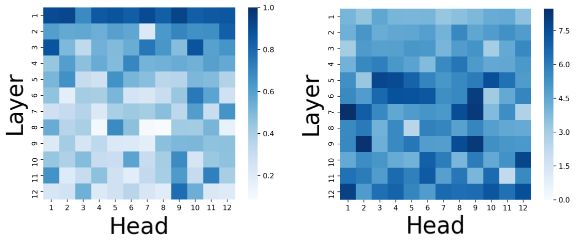
D.4 Experimental setup and visualizations for Section 4.3

In Section 4.3, we analyzed the relationship between the word frequency and $\|f(\boldsymbol{x})\|$. To formally describe our experiments, we further define the functions as follows:

$$\mathrm{AvgW}(p,q) = \frac{1}{12 \cdot 12} \sum_{\ell=1}^{12} \sum_{h=1}^{12} \mathrm{Weight}(p,q,\ell,h)$$

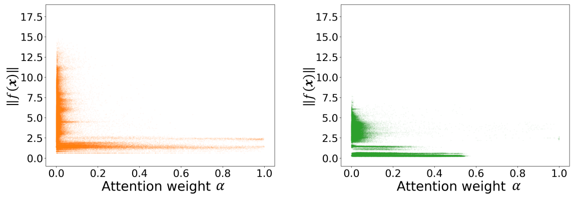
$$\mathrm{AvgN}(p,q) = \frac{1}{12 \cdot 12} \sum_{\ell=1}^{12} \sum_{h=1}^{12} \mathrm{Norm}(p,q,\ell,h).$$

Note that we analyzed a model comprising 12 layers; each layer has 12 attention heads. Let

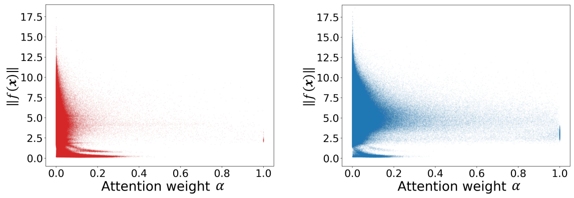


(a) α. (b) $\|f(\boldsymbol{x})\|$.

Figure 12: α and $\|f(\boldsymbol{x})\|$ corresponding to other tokens, averaged on all the input text.



(a) `[CLS]`. (b) `[SEP]`.



(c) Periods and commas. (d) Other tokens.

Figure 13: Relationship between α and $\|f(\boldsymbol{x})\|$ for each category.

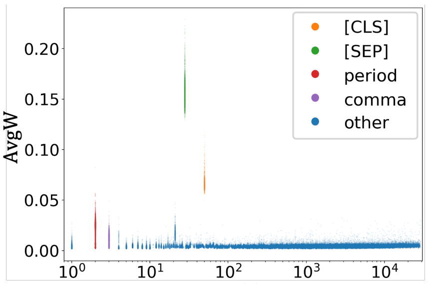
$r(\cdot)$ be a function that returns the frequency rank of a given word. We first calculated the Spearman rank correlation coefficient between $r(t^p_q)$ and $\mathrm{AvgW}(p,q)$. The score was 0.06, which suggests that there is no relationship between α and the frequency rank of the word. Then, we calculated the Spearman rank correlation coefficient between $r(t^p_q)$ and $\mathrm{AvgN}(p,q)$. The score was 0.75, which suggests a strong correlation between $\|f(\boldsymbol{x})\|$ and the frequency rank of the word; Figure 14 shows these results.

In addition, the results for the word frequency, instead of the frequency rank, are shown in Figure 15. $c(\cdot)$ denotes a function that returns the frequency of a given word in the training dataset of BERT. We reproduced the dataset because it is not released.

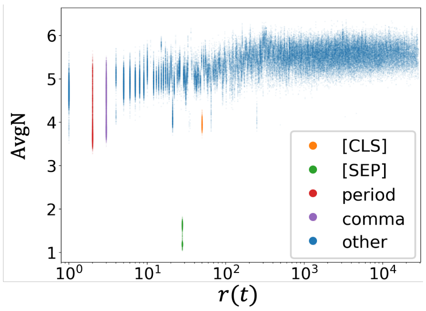
E Details on Section 5

E.1 Hyperparameters and training settings

We used the Transformer (Vaswani et al., 2017) NMT model implemented in fairseq (Ott et al., 2019) for the experiments. Table 5 shows the hyperparameters of the model, which were the same



(a) Relationship between $r(t)$ and AvgW.



(b) Relationship between $r(t)$ and AvgN.

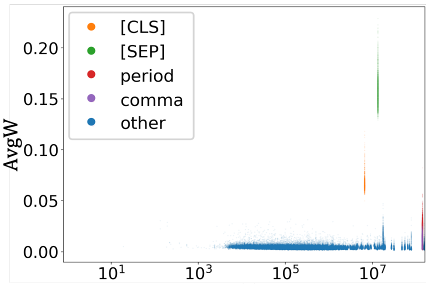
Figure 14: Relationship between frequency rank $r(t_q^p)$ and AvgW(p, q), and that between $r(t_q^p)$ and AvgN(p, q).

as those used by Ding et al. (2019). We used the model with the highest BLEU score in the development set for our experiments.

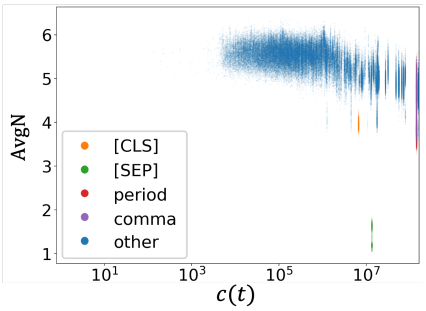
We conducted the data preprocessing[18] following the method by Zenkel et al. (2019) and Ding et al. (2019). All the words in the training data of the NMT systems were split into subword units using byte-pair encoding (BPE, Sennrich et al. (2016)) with 10k merge operations. Following Ding et al. (2019), the last 1000 instances of the training data were used as the development data.

E.2 Settings of the word alignment extraction

First, we applied BPE, which was used to split the training data of the NMT systems to create the evaluation data used for calculating the AER scores. Next, we extracted the scores of α and $\|\alpha f(\boldsymbol{x})\|$ for each subword in the evaluation data for the force decoding setup. The gold alignments are annotated at the word-level, not the subword-level. To calculate the word-level alignment scores, α and $\|\alpha f(\boldsymbol{x})\|$ for the subwords were merged along with the target token in the gold data by averaging, then merged along with the source tokens in the gold data by summation. These operations were the same as Li et al. (2019).



(a) Relationship between $c(t)$ and AvgW.



(b) Relationship between $c(t)$ and AvgN.

Figure 15: Relationship between frequency count $c(t_q^p)$ and AvgW(p, q), and that between $c(t_q^p)$ and AvgN(p, q).

In existing studies, ⟨`/s`⟩, the special token for the end of the sentence, was probably removed in calculating word alignments. We included ⟨`/s`⟩ as the alignment targets and we considered the alignments to ⟨`/s`⟩ as no alignment. In other words, if the model aligns a certain word with ⟨`/s`⟩, we assume that the model decides that the word is not aligned to any word.

E.3 Layer-wise analysis

We preliminarily investigated how the source-target attentions in a Transformer-based NMT system behave depending on the layer. Tang et al. (2018) have reported that they behave differently depending on the layer. The AER scores in the AWI and AWO settings were calculated for each layer (Figure 16). In the AWO setting, AER scores tend to be better in the latter layers than in the earlier layers (Figure 16a). In contrast, the AER scores tend to be better in the earlier layers than in the latter layers in the AWI setting (Figure 16b).

These results suggest that the earlier and latter layers focus on the source word that is aligned with the input and output target word, respectively (as shown in Figure 6). Furthermore, we believe that it is a convincing result to extract cleaner word alignments from the AWI setting than the AWO setting (Figure 16), because the AWI setting is

more advantageous. The main advantage is that while the decoder may fail to predict the correct output words, the input words are perfectly accurate owing to the teacher forcing.

E.4 Alignments in different layers

Figures 17 to 22 show additional examples of the extracted alignments from the different layers of the NMT system. Note that the color scale in each heatmap is determined by the maximum value in each figure. One can observe that while the attention weights α are biased towards $\langle$`/s`$\rangle$, the norms $\|\alpha f(\boldsymbol{x})\|$ corresponding to the token are small.

F Word alignment experiments on different settings

To verify whether the results obtained in the Section 5 are reproducible in different settings, we conducted an additional experiment using the model with a different number of attention heads. Specifically, we used a model with eight attention heads in both the encoder and decoder. Table 6 shows the AER scores of the 8-head model. As with the results obtained by the 4-head model, word alignments extracted using the proposed norm-based approach were more reasonable than those extracted using the weight-based approach, and better word alignments are extracted in the AWI setting than in the AWO setting. Furthermore, the alignments extracted using the head or the layer with the highest average $\|\alpha f(\boldsymbol{x})\|$ in the AWI setting are competitive with one of the existing word aligners—fast_align. With respect to the weight-based extraction, the scores obtained using

Figure 21: Examples of the reference alignment and the extracted patterns by each method in layer 5.

the 8-head model were worse than those obtained using the 4-head model. This may be owing to the increase in the number of heads that do not capture reasonable alignments.

Figures 23a and 23b show the AER scores of the alignments obtained by the norm-based extraction at each head on one out of five seeds. Figure 23c shows the average of $\|\alpha f(\boldsymbol{x})\|$ at each head. As with the results obtained by the 4-head model, the heads with the low (i.e., better) AER score in the AWI setting tended to have the high $\|\alpha f(\boldsymbol{x})\|$ (the Spearman rank and Pearson correlation coefficients between the AER scores and averaged $\|\alpha f(\boldsymbol{x})\|$ among the $6{\times}8$ heads are -0.26 and -0.50). In contrast, in the AWO setting, such a negative correlation is not observed; rather, a positive correlation is observed (the Spearman's ρ is 0.40 and the Pearson's r is 0.40).

Additionally, following Appendix E.3, the AER scores for both the AWI and AWO settings for each layer were calculated (Figure 24). As with the 4-head model (Appendix E.3), the latter layers correspond to the AWO setting and the earlier layers corresponds to the AWI setting in the 8-head

G Comparison with effective attention (Brunner et al., 2020)

In this section, we discuss the difference between our approach and “effective attention” (Brunner et al., 2020), which is an enhanced version of the weight-based analysis. The effective attention exclude the components that do not affect the output owing to the application of transformation f and input $\boldsymbol{x}$ from the attention weight matrix $\boldsymbol{A}$. The output-irrelevant components are derived from the null space of the matrix $\boldsymbol{T}$, which is the stack of $f(\boldsymbol{x})$. Figure 25a shows the Pearson correlation coefficient between the raw attention weight and the effective attention. Since the dimension of the null space of the matrix $\boldsymbol{T}$ depends on the length of the input sequence, as shown in Figure 25a, the effective attention and raw attention weight are identical for short input sequences. Figure 25b shows the Pearson correlation coefficient between the raw attention weight and our norm-based method. Since we incorporate the scaling effects of f and $\boldsymbol{x}$, which contain canceling, our proposed method $\|\alpha f(\boldsymbol{x})\|$ differs from the raw attention weight, whether the input sequence is long or short.

Abstract

Explainable question answering systems predict an answer together with an explanation showing why the answer has been selected. The goal is to enable users to assess the correctness of the system and understand its reasoning process. However, we show that current models and evaluation settings have shortcomings regarding the coupling of answer and explanation which might cause serious issues in user experience. As a remedy, we propose a hierarchical model and a new regularization term to strengthen the answer-explanation coupling as well as two evaluation scores to quantify the coupling. We conduct experiments on the HotpotQA benchmark data set and perform a user study. The user study shows that our models increase the ability of the users to judge the correctness of the system and that scores like F_1 are not enough to estimate the usefulness of a model in a practical setting with human users. Our scores are better aligned with user experience, making them promising candidates for model selection.

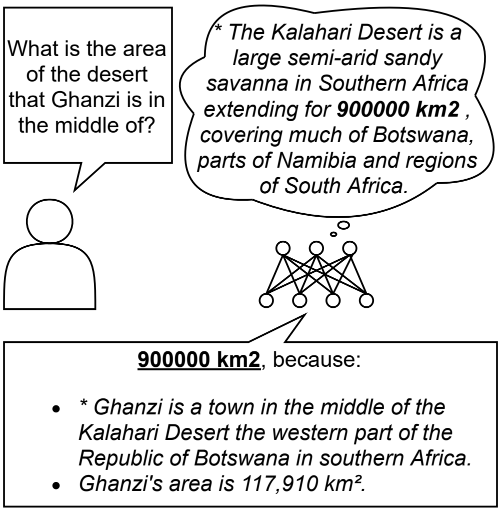

Figure 1: Example output of a representative XQA system (Yang et al., 2018) that would receive an answer-F_1 of 1 and an explanation-F_1 of 0.5 although the explanation provides no value to the user since the actual answer evidence (shown in cloud) is not included in the explanation (asterisks mark ground truth explanation).

1 Introduction

Understanding the decisions of deep learning models is of utmost importance, especially when they are deployed in critical domains, such as medicine or finance (Ribeiro et al., 2016). In natural language processing (NLP), a variety of tasks have been addressed regarding explainability of neural networks, such as textual entailment (Camburu et al., 2018), sentiment classification (Clos et al., 2017), machine translation (Stahlberg et al., 2018) and question answering (Yang et al., 2018). In this paper, we address question answering (QA) due to its proximity to users in real-life settings, for instance, in the context of personal assistants.

Explainable question answering (XQA) is the task of (i) answering a question and (ii) providing an explanation that enables the user to understand *why* the answer was selected, e.g., by pointing to the facts that are needed for answering the question. Compared to approaches that output importance weights or analyze gradients (Simonyan et al., 2014; Ribeiro et al., 2016; Lundberg and Lee, 2017; Sundararajan et al., 2017), this has the advantage that the explanations are intuitively assessible even by lay users without machine learning background.

A *good explanation* (i.e., one that is helpful for the user) should therefore satisfy the following requirements: (i) It should contain all information that the model used to predict the answer for the question. This is necessary so that the user can reconstruct the model's reasoning process. (ii) It should not include additional information that it did not use for predicting the answer. Otherwise, the explanation will confuse the users rather than help them. Note that these requirements do not

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7076–7095,
November 16–20, 2020.

only hold for correct model decisions but are also valid for explaining wrong model answers so that the user can assess the correctness of the answers. Previous work on XQA mostly focuses on developing models that predict the correct answer and, independent of this, the correct explanation (Yang et al., 2018; Qi et al., 2019; Shao et al., 2020). This can lead to model outputs in which the explanations do not sufficiently relate to the answers. Consider the example provided in Figure 1. The model gives the correct answer to the question and provides an explanation consisting of one out of two relevant facts. However, the most important relevant fact (in which the answer actually appears) is not part of the explanation. As a result, the user cannot assess whether the model answer is correct or not and, thus, cannot trust the system. To strengthen the *coupling of answer and explanation prediction* in the model architecture and during training, we propose two novel approaches in this paper: (i) a hierarchical neural network architecture for XQA that ensures that only information included in the explanation is used to predict the answer to the question, and (ii) a regularization term for the loss function that explicitly couples answer and explanation prediction during training.

A *good evaluation measure* should score explanations by satisfying the following requirements: (i) It should reward explanations that are coupled to the answers of the model. (ii) It should punish explanations that are unrelated to the answers of the model. (iii) It should be correlated to user experience. Since explanations cannot only empower the user to assess the correctness of a system (Biran and McKeown, 2017; Kim et al., 2016) but also improve user satisfaction and confidence (Sinha and Swearingen, 2002; Biran and McKeown, 2017) and, thus, increase the acceptance of automatic systems (Herlocker et al., 2000; Cramer et al., 2008), this aspect is very important when evaluating models that should be applied in real-life scenarios. In most recent works, evaluation of XQA models focuses on optimizing F_1-scores of answers and explanations (a collection of so-called supporting or relevant facts) (Yang et al., 2018). However, F_1-scores only assess model outputs with respect to ground-truth annotations which only contain explanations for the correct answer. Thus, they fail to quantify the coherence between answer and explanation, especially when the predicted model answer is wrong. The example model output in Figure 1 leads to an answer-F_1-score of 1 and an explanation-F_1-score of 0.5 although the explanation is useless for the user as described before. To *quantify the model's answer-explanation coupling*, we propose two novel evaluation scores: (i) FARM which tracks prediction changes when removing facts, and (ii) LOCA which assesses whether the answer is contained in the explanation or not. Both scores do not require ground-truth annotations.

To summarize, we make contributions in two directions in this paper: For *modeling*, (i) we propose a hierarchical neural network architecture as well as (ii) a regularization term for the loss function of XQA systems. For *evaluation*, (iii) we propose two scores that are able to quantify a model's answer-explanation coupling without relying on ground-truth annotations. (iv) To investigate the relation between different evaluation scores and user experience, we conduct a *user study*. The results show that our proposed models increase the ability of the user to judge the correctness of an answer and that our scores are stronger predictors of human behavior than standard scores like F_1. (v) For reproducibility and future research, we will release code for our methods and for computing the evaluation scores as well as the user study data.[1]

2 Related Work

In the context of XQA, Yang et al. (2018) present the HOTPOTQA data set which we also use for the experiments in this paper. In addition to questions and answers, it contains explanations in the form of relevant sentences from Wikipedia articles.

Most state-of-the-art models for HOTPOTQA extend the BiDaf++ architecture (Clark and Gardner, 2018; Seo et al., 2017), e.g., (Yang et al., 2018; Qi et al., 2019; Nishida et al., 2019; Ye et al., 2019; Qiu et al., 2019; Shao et al., 2020). Other approaches are based on question decomposition (Min et al., 2019; Perez et al., 2020), graph/hierarchical structures (Tu et al., 2019; Fang et al., 2019; Asai et al., 2020), virtual knowledge bases (Dhingra et al., 2020) or transformer models (Zhao et al., 2020).

So far, all of the research work on HOTPOTQA focuses on reaching higher F_1-scores. In contrast, we question whether this actually aligns with user experience. To the best of our knowledge, only Chen et al. (2019) additionally conduct a human

---

[1] `https://github.com/boschresearch/f1-is-not-enough`

evaluation. This confirms the observation of Adadi and Berrada (2018) that only very few papers related to explainable AI address (human) evaluation of explainability. Despite the large body of research in the field of human computer interaction, Abdul et al. (2018) show that there is a lack of collaboration and transfer of results to machine learning communities.

Another line of research our work relates to is the criticism of automatic evaluation scores. One frequently questioned score is BLEU (Papineni et al., 2002), which was shown to only correlate weakly with human judgements in tasks like machine translation (Callison-Burch et al., 2006), storytelling (Wang et al., 2018) and dialogue response generation (Liu et al., 2016). F_1 has been criticized from various perspectives including theoretical considerations and concrete applications (Hand and Christen, 2018; Chicco and Jurman, 2020; Sokolova et al., 2006). Qian et al. (2016) show that modifying F_1-scores based on insights from psychometrics improves their correlation with human evaluations. In this paper we criticize the usage of F_1 as a measure of explainability in XQA and show in a user study that it is not related to user experience.

3 Methods for XQA

We built upon the model by Qi et al. (2019) as it is an improved version of the BiDaf++ model, which is used in numerous state-of-the-art XQA models (Yang et al., 2018; Qi et al., 2019; Nishida et al., 2019; Ye et al., 2019; Qiu et al., 2019) including the best-scoring publication (Shao et al., 2020). It consists of a question and context encoding part with self-attention, followed by two prediction heads: a prediction of relevant facts (i.e., the explanation) and a prediction of the answer to the question. The two heads are trained in a multi-task fashion based on the sum of their respective losses. First, we analyze the outputs of the model, revealing severe weaknesses in answer-explanation coupling. To address those weaknesses, we then propose (i) a novel neural network architecture that *selects* and *forgets* facts, and (ii) a novel answer-explanation coupling regularization term for the loss function.

3.1 Limitations of Current Models

We manually analyze outputs of the models by Qi et al. (2019) and Yang et al. (2018) and identify the following two problems.

Silent Facts. The models make use of facts without including them into their explanations (cf., Figure 1). As a result, the predicted answer does not occur in the explanation, leaving the user uninformed about where it came from.

Unused Facts. The models predict facts to be relevant without any relation to the predicted answer. The second fact of the explanation in Figure 1 is an example for this. We also found examples where the facts predicted to be relevant do not even contain the entities from the question.

3.2 Select & Forget Architecture

To explicitly ensure that the model only uses information from facts it predicts to be relevant for the answer selection, we propose a hierarchical model that first *selects* facts which are relevant to answer the question and then *forgets* about all other facts (see Figure 2). We use recurrent and self-attention layers to create encodings of the question and the context. In particular, we create two different encodings: one that will be used for predicting the relevance of the facts (fact-specific encoding) and one that will be used for predicting the answer to the question (QA-specific encoding). Based on the fact-specific encoding, the model first predicts which facts are relevant to answer the question. Next, we reduce the QA-specific encoding of the context based on the relevance predictions. In particular, we mask all facts that were not predicted to be relevant by zeroing out their encodings. The reduced context representation is concatenated with the QA-specific question encoding and passed on to the answer prediction, which we implement in the same way as Qi et al. (2019). Thus, the answer prediction now only receives encodings of facts that the model has predicted to be relevant. It predicts the type of the answer (yes/no/text span), as well as the start and end positions of the answer span within the context.

3.3 Answer-Fact Coupling Regularizer

Our second method addresses the coupling of answer and explanation prediction by modifying the loss function. The loss function used by Qi et al. (2019) is the sum of four cross entropy losses concerning (i) the answer type (yes/no/span) distribution, (ii) the answer start token distribution, (iii) the answer end token distribution, and (iv) the fact relevance distributions. All terms are optimized to be close to their respective ground truth annota-

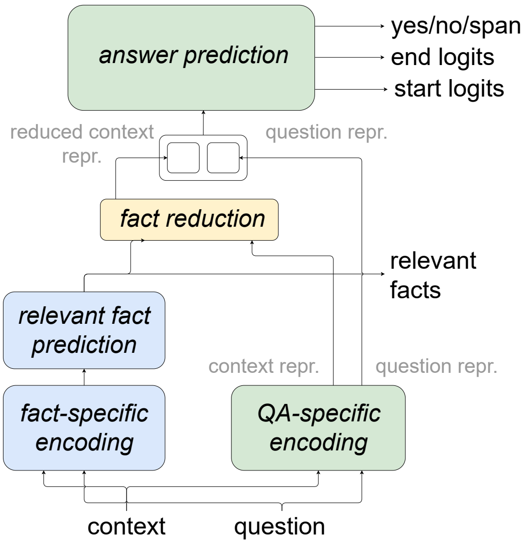

Figure 2: "Select and Forget" architecture with task-specific encodings and fact reduction.

tions. This is the desired effect in many, but, as our examples in Section 3.1 show, not in all situations. The loss function especially encourages the model to predict the ground truth explanation rather than an explanation that explains the predicted answer.

In order to reward a coupling between answer and explanation, we propose to add the following regularization term to the loss function:

$$J_{\text{reg}} = \underbrace{p_{\text{a}} \cdot (\overbrace{p_{\text{e}} \cdot 0}^{\text{GT expl.}} + \overbrace{(1 - p_{\text{e}}) \cdot c_1}^{\text{non-GT expl.}})}_{\text{correct answer}} + \underbrace{(1 - p_{\text{a}}) \cdot (\overbrace{p_{\text{e}} \cdot c_2}^{\text{GT expl.}} + \overbrace{(1 - p_{\text{e}}) \cdot c_3}^{\text{non-GT expl.}})}_{\text{wrong answer}} \quad (1)$$

with p_{a} corresponding to the probability of the model for the correct answer span and p_{e} denoting the probability of the model for the ground truth relevant facts. The term can be broken down into four cases: (i) correct answer and ground truth explanation, (ii) correct answer but non-ground truth explanation, (iii) incorrect answer but ground truth explanation and (iv) incorrect answer and non-ground truth explanation. Each case corresponds to a constant cost of 0, c_1, c_2 and c_3, respectively, with c_1, c_2, c_3 being hyperparameters. The resulting cost J_{reg} is the sum of the four individual costs weighted with their respective probabilities.

In particular, p_{a} is defined as the product of the probabilities assigned to start and end token positions of the answer span. For a data set instance with a context containing N facts, we define $\mathbf{s_t} \in \{0, 1\}^N$ as the ground truth annotations for the relevant facts. Accordingly, we denote the model's relevance probability estimates with $\mathbf{s_p} \in [0, 1]^N$. Based on this, we define p_{e} as $p_{\text{e}}^* = \prod_{i \in F} \mathbf{s_p}_i$ with $F = \{i \in \{1, ..., N\} : \mathbf{s_t}_i = 1\}$ denoting the indices that correspond to ground truth facts. This corresponds to the joint probability of selecting the ground truth facts assuming the single selection probabilities to be independent. For our experiments, we adapt this definition to a numerically more stable term p_{e}^+ by replacing the product with a sum as this led to slightly better results on the development set.

4 New Evaluation Scores for XQA

In this section, we motivate that standard scores like F_1 are not enough to score XQA systems by presenting their limitations in those settings. To be able to quantify the degree to which a model is affected by those limitations, we propose two scores that go beyond standard scores: the *fact-removal score* and the *answer-location score*. Both scores can be calculated without any assumptions on model architecture and no need for ground truth annotations for answers or supporting facts.

4.1 Limitations of Current Evaluation Scores

Current evaluation of XQA is focused on three scores: (i) answer-F_1, which is based on the token overlap between the predicted and the ground truth answer, (ii) SP-F_1, which calculates F_1 based on the overlap of predicted and ground truth relevant ("supporting") facts and (iii) joint-F_1, which is based on the definitions of joint precision and joint recall as the products of answer and SP precision and recall as described in Yang et al. (2018). For HOTPOTQA, models are ranked based on joint-F_1. We argue that this creates a false incentive that potentially hinders the development of truly usable models for the following reasons.

No Empirical Evidence. There is no empirical evidence that joint-F_1 is related to user performance or experience regarding XQA.

Rewarding Poor Explanations. Figure 1 shows an example prediction that is rewarded with a joint-F_1 of 0.5 although its explanation provides no value to the user. The reward stems from the overlap of the explanation with the ground truth but does not consider that the predicted answer is not contained in any of the predicted relevant facts.

Punishing Good Explanations. Consider a model output in which the predicted answer is wrong but the explanation perfectly explains this wrong answer, showing to the user why the model has selected it. Standard F_1-scores compare the model output to the ground truth annotations and will, therefore, score both the answer and the explanation with an F_1 of 0. However, we argue that an explanation should be evaluated with a score higher than 0 if it is able to explain the reasoning process of the model to the user and, thus, lets the user identify the failure of the model.

4.2 Fact-Removal Score (FARM)

Ideally, the explanations of the model include all facts that the model uses within its reasoning chain but no additional facts beyond that. Note that even for a wrong model answer, this assumption should hold so that the relevant facts provide explanations for the (wrongly) predicted answer. To quantify the degree of answer-explanation coupling, we propose to iteratively remove parts (individual facts) of the explanation, re-evaluate the model using the reduced context and track how many of the model's answers change. For a model with perfect coupling of answer and explanation, the answer will change with the first fact being removed (assuming no redundancy) but will not change when removing irrelevant facts not belonging to the explanation. We remove facts in order of decreasing predicted relevance as more relevant facts should influence the model's reasoning process the strongest.

In the following, we denote an instance of the data set by $e \in E$ with its corresponding question e_{ques} and context e_{con}. We use $\text{answer}(\cdot, \cdot)$ to denote the answer that a model predicts for a given question and context. The functions $\text{reduce}_{\text{rel}}(\cdot, k)$ ($\text{reduce}_{\text{irr}}(\cdot, k)$) return a context from which up to k facts the model predicts to be relevant (irrelevant) have been removed.[2] We re-evaluate the model on this reduced context and calculate the fraction of changed answers $c_{\text{rel}}(k)$ and $c_{\text{irr}}(k)$, respectively.

$$a(e) = \text{answer}(e_{\text{ques}}, e_{\text{con}}) \quad (2)$$

$$\hat{a}_{\text{rel},k}(e) = \text{answer}(e_{\text{ques}}, \text{reduce}_{\text{rel}}(e_{\text{con}}, k)) \quad (3)$$

$$\hat{a}_{\text{irr},k}(e) = \text{answer}(e_{\text{ques}}, \text{reduce}_{\text{irr}}(e_{\text{con}}, k)) \quad (4)$$

$$c_{\text{rel}}(k) = \frac{|\{e \in E : a(e) \neq \hat{a}_{\text{rel},k}(e)\}|}{|E|} \quad (5)$$

$$c_{\text{irr}}(k) = \frac{|\{e \in E : a(e) \neq \hat{a}_{\text{irr},k}(e)\}|}{|E|} \quad (6)$$

Finally, we condense $c_{\text{rel}}(k)$ and $c_{\text{irr}}(k)$ into a single fact-removal score:

$$\text{FARM}(k) = \frac{c_{\text{rel}}(k)}{1 + c_{\text{irr}}(k)} \in [0, 1] \quad (7)$$

$\text{FARM}(k)$ ranges between zero and one and a higher score corresponds to a better explanation.

4.3 Answer-Location Score (LOCA)

A second important indicator for the degree of a model's answer-explanation coupling is the location of the answer span: As shown in Figure 1, the models can predict answers that are located outside the facts they predict to be relevant, i.e., outside the explanation. This is confusing for a user. Therefore, we consider the fractions of answer spans that are inside the explanation of the model and the fraction of answer spans that are outside. For an ideal model, all answer spans would be located inside the explanation. We use I and O to denote the number of answers inside/outside of the set of facts predicted as relevant. A denotes the total number of answers.[3] Based on these counts, we propose the answer-location score that we define as

$$\text{LOCA} = \frac{\frac{I}{A}}{1 + \frac{O}{A}} = \frac{I}{A + O} \in [0, 1]. \quad (8)$$

The LOCA score ranges between zero and one, with larger values indicating better answer-explanation coupling.

5 Experiments and Results

In this section, we describe the dataset we used in our experiments as well as our results. More details for reproducibility, including hyperparameters, are provided in the appendix.

5.1 Dataset

The HOTPOTQA data set is a multi-hop open-domain explainable question answering data set containing 113k questions with crowd-sourced annotations. Each instance of the training data contains a question, a context consisting of the first paragraph of ten Wikipedia articles, the annotated answer and an explanation in the form of a selection of relevant sentences from the context. As HOTPOTQA was designed as a multi-hop data set,

---

[2] If the number of facts predicted as (ir)relevant is less or equal to k, we remove all (ir)relevant facts from the context.

[3] In HOTPOTQA, answers can stem from article titles although titles are never used as relevant facts. Thus, $A > I + O$ is possible. Our score is still applicable in this case.

	Score	Qi-2019	S&F	reg.	S&F+reg.

Table 1: Comparison of our methods to Qi et al. (2019) regarding evaluation scores from related work and our proposed scores on the distractor dev set (SP: supporting facts). All values in %.

finding the answer to a question requires combining information from two different articles. The eight other articles are *distracting* the system.[4]

5.2 Experimental Results

In our experiments, we assess the effects of our Select & Forget architecture (S&F) and the regularization term (reg.). Table 1 shows our approaches in comparison to the model by Qi et al. (2019).[5] While our S&F architecture performs comparable in standard scores like answer-exact-match (Answer-EM), answer-F_1, joint-EM and joint-F_1 (for some of them slightly better, for some of them slightly lower), the regularization term increases the recall of the relevant fact prediction considerably.

In terms of our proposed scores for measuring answer-explanation-coupling, all our three models clearly outperform the baseline model (lower part of Table 1). In the first three rows, we report the models' FARM scores and the fractions of changed answers for $k = 4$, i.e., when a maximum of four facts are removed. We choose $k = 4$ as this is the highest number of facts within an explanation in the ground truth annotations of the HOTPOTQA data. The last three rows show the LOCA scores and the respective fractions of answers inside and outside facts predicted as relevant.

The different behavior of models regarding joint-F_1 vs. FARM and LOCA raises the question which scores are better suited to quantify explainability in a real-life setting with human users. To answer this, we conduct a user study in Section 6.

6 Human Evaluation

We conduct a user study to investigate whether standard scores like F_1 or our proposed scores are better suited to predict user behavior and performance. Moreover, the study provides another way to compare our proposed methods to the model by Qi et al. (2019) and the ground truth explanations. In contrast to the human evaluation from Chen et al. (2019), we evaluate explanations in the context of the model answer, ask participants to rate the predictions along multiple dimensions and collect responses from 40 instead of 3 subjects.

6.1 Choice of Models

We choose to compare the model proposed by Qi et al. (2019) (called "Qi-2019" in the following) as a representative of the commonly used BiDaf++ architecture (Clark and Gardner, 2018) in XQA, our proposed Select & Forget architecture (S&F) and our proposed regularization term (reg.). In addition, we include the ground truth (GT) annotations to set an upper bound. Although the combination of regularization and the S&F architecture reaches promising performance in Table 1, we assess the effects of our methods in isolation here and leave the evaluation of the combination to future work.

6.2 Study Design

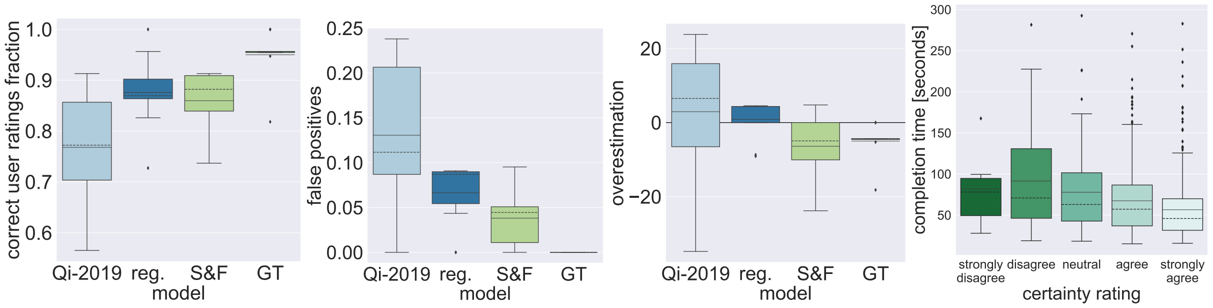
We make use of a unifactorial between-subject design in which each model constitutes one condition. We randomly sample a set of 25 questions from the HOTPOTQA dev set and collect the model answer and explanation predictions (or annotations for GT) for each condition. For each answer prediction, we manually assess whether it is equivalent to the ground truth answer.[6] Each participant sees the 25 questions and the answers and explanations

---

[4] The data set also contains a *full wiki* test set in which the context spans all collected Wikipedia articles. We focus on the distractor setting in this paper. The data set can be downloaded from `https://hotpotqa.github.io/`.

[5] We retrain their model using the implementation and preprocessing provided at `https://github.com/qipeng/golden-retriever`.

[6] For example, we consider the answer prediction "Firth of Clyde, Scotland" to be equivalent to the ground truth answer "Firth of Clyde".



(a) Correct user ratings. (b) False positive ratio. (c) Overestimation in percent. (d) Completion time∼certainty.

Figure 3: Boxplots showing results from the user study. Boxes mark quartiles, whiskers mark 1.5 inter-quartile ranges, outliers are plotted separately. Horizontal solid/dashed lines within boxes mark means and medians, resp.

of one model in a random permutation. For each question, we ask the participants to rate whether the model answer is correct. In addition, we ask for multiple self-reports to assess, e.g., the trust of the user in the system. In particular, we track the variables discussed in the following subsection.

6.3 Dependent Variables

We derive multiple dependent variables from the participants' ratings, namely completion time (Lim et al., 2009; Lage et al., 2019), several performance variables indicating how well they judged the correctness of the model (fraction of correct ratings, false positive ratio (FP), false negative ratio (FN), true positive ratio (TP), true negative ratio (TN), precision (P), recall (R) and F_1 values), agreement (fraction of model predictions that the users rate as correct (Bussone et al., 2015)), and overestimation (difference between agreement and true model accuracy (Nourani et al., 2019)).

Furthermore, we collect the following variables in self-reports with five-point Likert scales: certainty of the participants (Greis et al., 2017a), completeness and helpfulness of the explanations (Nourani et al., 2019), trust of the participants in the model (Bussone et al., 2015), and satisfaction (Kulesza et al., 2012; Greis et al., 2017b).

All the questions and screenshots of our study are given in the appendix.

6.4 Participants and Data Cleaning

We collect the ratings of 40 participants (16 female, 24 male) with a mean age of 26.6 years ($SD = 3.4$). We filter out all responses with a completion time smaller than 15 seconds or larger than 5 minutes as this indicates that the participant did not read the whole explanation or was interrupted during the study. We further asked them whether they knew the answer before and exclude the responses to those questions from our evaluation. In total, we discard 12.10% of the responses.

6.5 Results

In this section, we summarize the main results of the user study. For better overview, we do not include evaluations on every variable from Section 6.3 but show them in the appendix.

Figure 3a shows the fraction of correct user ratings of model correctness. The correctness of our proposed models can be better judged than the Qi-2019 model: The regularized model and the S&F model increase the fraction by 10.79% and 9.17%, respectively, compared to Qi-2019. The GT comparison shows an upper bound.

Among the performance variables, the false positive ratio deserves particular attention as a false positive corresponds to a user thinking the model answer is correct while it is not. Such an error can be dangerous in safety-critical domains. Figure 3b shows that the fraction of FPs is decreased by 6.43% by the regularized model and by 9.25% by the S&F model compared to Qi-2019. The ground truth has zero false positives by definition.

A similar effect can be seen when evaluating overestimation: Both our models alleviate overestimation as shown in Figure 3c. While participants overestimate the model accuracy of Qi-2019 by 2.93% on average, the regularized model only leads to 0.87% overestimation. The S&F model is even underestimated by 6.40% on average. While an ideal model would lead to neither over- nor underestimation, underestimation can be preferable to overestimation if the model is deployed into high-risk environments, such as medical contexts. In general, a reduction in overestimation can — besides enhanced fact selection — also be linked to

	Standard Scores												Proposed Scores						
	Answer				Supporting Facts				Joint				Answer Changes		FARM		%-in-fact		LOCA
Human eval.	EM	F_1	P	R	EM	F_1	P	R	EM	F_1	P	R	rel.	irrel.	FARM(1)	FARM(4)	rel.	irrel.	LOCA
correct decision								⊕		-	-			⊕	⊕		⊕		
overestimation		+		+									⊖			⊖		⊖	⊖
completion time	+		+		⊖	⊖	⊖		⊖			+							
human-FP		+		+									⊖			⊖		⊖	⊖
human-TP								⊕		-	-			⊕	⊕		⊕		
human-FN	⊖		⊖		+	+	+		+			⊖							
human-TN								⊕		-	-			⊕	⊕		⊕		
human-P		-		-									⊕			⊕		⊕	⊕
human-R								⊕		-	-			⊕	⊕		⊕		
human-F_1								⊕		-	-			⊕	⊕		⊕		

Table 2: The table shows whether sorting the conditions by a human score (rows) and an automatized score (columns) results in the same order (+), the inverse order (-) or a different order (blank cell). Green (🟩) cells with circles mark desirable relations, red (🟥) cells without circles mark undesirable relations.

an improved answer accuracy as better-performing models naturally leave more room for underestimation.

Finally, we consider relations within the variables from Section 6.3. Figure 3d shows that mean completion time monotonously decreases with increasing user certainty (with the exception of "strongly disagree").[7] This confirms the findings of Greis et al. (2017a) who investigate the effect of user uncertainty on behavioral measurements.

6.6 Correlation with Evaluation Scores

Finally, we investigate the correlation of human ratings with model evaluation scores. We rank the models by (i) human measures obtained in the user study and (ii) model evaluation scores. In Table 2, a cell is marked with a "+" if the ranking with respect to the human measure and the model score is identical (e.g., the ranks regarding human-FPs and answer-F_1 are identical). If the ranks are exactly reversed, we mark the cell with a "-". All other cells are left empty. "+" and "-" both indicate a perfect correlation and do not imply one being preferable over the other. Next, we consider whether selecting a model based on the different model scores would result in a desired change in human evaluation scores or not. This depends on whether a high score (e.g., F_1) or a low score (e.g., the fraction of answers outside the predicted relevant facts) is aimed for. We indicate desired model selection with green circled cells and undesired model selection with red cells (e.g., choosing a model with a higher answer-F_1 would result in a model with more human-FPs. This is not desired.) All F_1-scores show at least one undesirable rank relation. Notably, joint-F_1 is among the least aligned scores. In contrast, our scores have only desirable relations. In particular, FARM(4) and LOCA lead to a model ranking that is inverse to the ranking by human-overestimation and human-FPs. This is also confirmed in Figure 4, which shows how the human-FP ratio varies in comparison to the three F_1 scores (upper plot: no correlation) and to our pro-

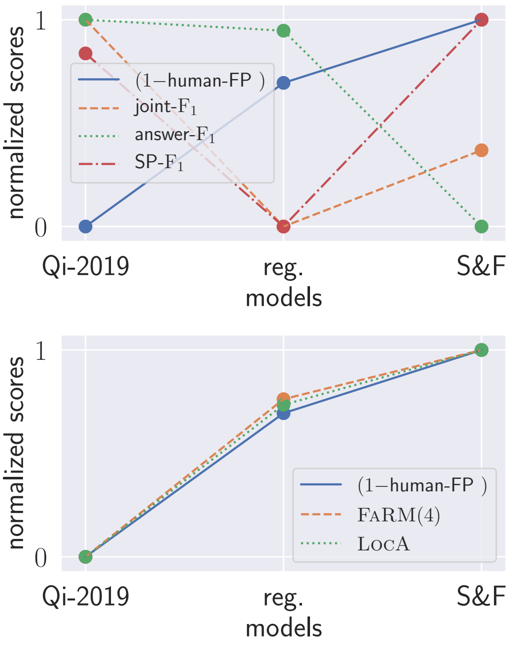


Figure 4: Model score comparisons between human-false positives and model scores. All scores are normalized to $[0, 1]$. We show $(1-\text{human-FP})$ as less FPs are better. The upper figure shows that F_1 poorly correlates to human performance. The lower figure shows a much stronger correlation for our proposed scores.

---

[7] The low completion time for "strongly disagree" could indicate that the users could not find any relation at all between answer and explanation.

posed scores (lower plot: correlated). See appendix for other dependent variables.

To sum up, our results indicate that (i) F_1 is not suited to quantify the explanatory power of a model and (ii) our proposed scores predict user behavior better than standard scores, opening the possibility of using them for model selection.

7 Conclusion

In this paper, we investigated explainable question answering, revealing that existing models lack an explicit coupling of answers and explanations and that evaluation scores used in related work fail to quantify that. This highly impairs their applicability in real-life scenarios with human users. As a remedy, we addressed both modeling and evaluation, proposing a hierarchical neural architecture, a regularization term, as well as two new evaluation scores. Our user study showed that our models help the users assess their correctness and that our proposed evaluation scores are better correlated with user experience than standard measures like F_1.

Appendix

A HOTPOTQA Data Set

We conduct our analysis and experiments on the explainable multi-hop reasoning question answering data set HOTPOTQA (Yang et al., 2018). The data set contains 113k questions with crowd-sourced annotations for answers and explanations. Explanations correspond to a selection of supporting facts (i.e., sentences) from Wikipedia articles. The data set contains 90,564 training instances as well as 7405 development instances. The test set is split into two separate test sets with 7405 instances each: the full-wiki test set and the distractor test set. Models evaluated on the full-wiki test data need to retrieve relevant articles from a given set of Wikipedia articles (therefore *full wiki*) while the distractor test set provides models with ten articles of which two contain the supporting facts and the other eight articles are *distracting* the system. Both test sets are not publicly available. F_1 values on the test sets can be obtained by submitting a model to the leaderboard. As our proposed FARM and LOCA scores need to access context information, we evaluate all tested models on the distractor development set while training them on the provided training data. The training and development data as well as the leaderboard can be found online.[8]

---

[8] `https://hotpotqa.github.io/`

B S&F Workflow Example

Figure 5 shows an exemplary workflow of the S&F architecture. First, relevant facts are selected. Second, all other facts are masked and third, the answer is predicted based on the masked context.

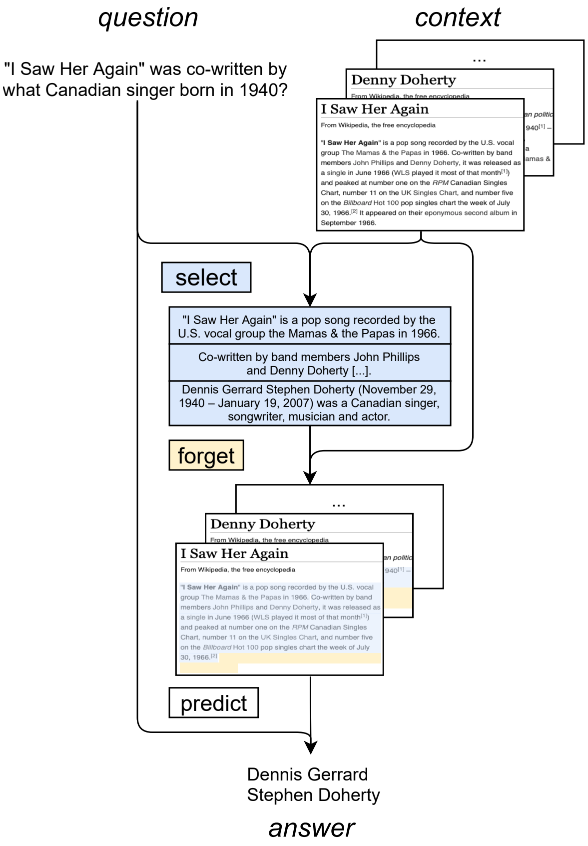

Figure 5: Exemplary workflow of the S&F model.

C Training Details and Hyperparameters

We use the same preprocessing, hyperparameters and early stopping procedure as Qi et al. (2019) to train our models.[9] The Qi-2019 model as well as our regularized adaption contain 99M parameters, our S&F model and its regularized version contain 100M parameters each. The additional hyperparameters of our regularization term are optimized with random search using 100 runs. In particular, we sample $c_i \sim U([0.0, 5.0]), i \in \{1, 2, 3\}$ and select p^*_e and p^+_e with equal probability. We select the best model based on the percentage of answer spans inside facts predicted as relevant to ensure decent answer-explanation coupling while not directly optimizing on the LocA. Based on our hyperparameter search, the best regularization parameters for the model proposed by Qi et al. (2019) are $c_1 = 4.96$, $c_2 = 2.02$ and $c_1 = 3.10$. The best parameters for the regularized S&F model are $c_1 = 1.18$, $c_2 = 0.24$ and $c_1 = 1.61$. We trained all models on Nvidia Tesla V100 GPUs.

	Metric	Yang-2018	Qi-2019
Standard Scores	Answer-EM	43.74	**49.48**
	Answer-F_1	57.29	**63.76**
	Answer-P	59.76	**66.26**
	Answer-R	58.74	**65.52**
	SP-EM	24.54	**39.81**
	SP-F_1	68.02	**79.34**
	SP-P	69.86	**78.01**
	SP-R	72.90	**85.26**
	Joint-EM	12.83	**22.28**
	Joint-F_1	41.12	**52.51**
	Joint-P	43.43	**53.33**
	Joint-R	45.44	**57.92**
Proposed Scores	FaRM(4)	50.08	**66.20**
	↳ $c_{\text{rel}}(4)$	62.50	**77.06**
	↳ $c_{\text{irrel}}(4)$	24.81	**16.39**
	LocA	44.78	**60.49**
	↳ I	54.90	**67.48**
	↳ O	22.60	**11.55**

Table 3: Comparison of the HotpotQA baseline model by Yang et al. (2018) and the modified model by Qi et al. (2019). The modified model outperforms the baseline on all scores. All values in %.

D Comparison of BiDaf++ Versions

We compare the BiDaf++ model used as the official HopotQA baseline of Yang et al. (2018) to the modified model by Qi et al. (2019) in Table 3. As the modified model outperforms the Yang-2018 model on all metrics, we use the model proposed by Qi et al. (2019) throughout our experiments as well as the user study.

E Hierarchical Error Propagation

As the S&F model first selects the supporting facts and then predicts the answer based on the selected subset, we evaluate how errors in the fact selection effect the answer prediction and compare it to the Qi-2019 model. For both models, we compare the fraction of predictions with correct (exact match) answers among predictions that (i) contain all ground truth facts or (ii) contain no ground truth facts. We observe that for Qi-2019 the fraction of correct answers drops from 51.5% for predictions with all ground truth facts to 25.8% for predictions with no ground truth facts. For the S&F model, we observe a drop from 50.4% to 20.6% respectively.

---

[9] `https://github.com/qipeng/golden-retriever`

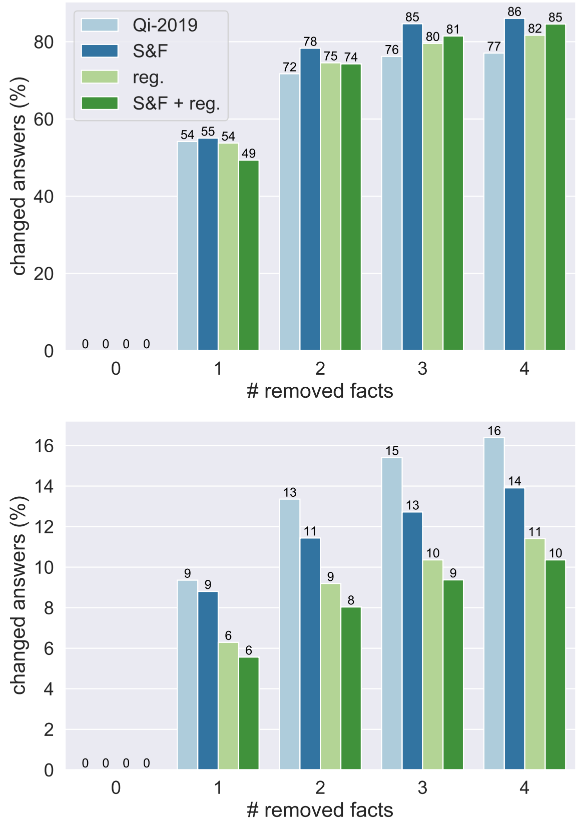

Figure 6: Answer changes $c_{\text{rel}}(k)$ and $c_{\text{irr}}(k)$ when removing facts predicted as relevant (top) and irrelevant (bottom).

This confirms our expectations of an increased error propagation in the S&F model. However, only 1.8% of the S&F fact predictions contain no ground truth fact at all, whereas for Qi-2019 this case occurs for 2.1% of the predictions.

F Answer Changes per Removal Step

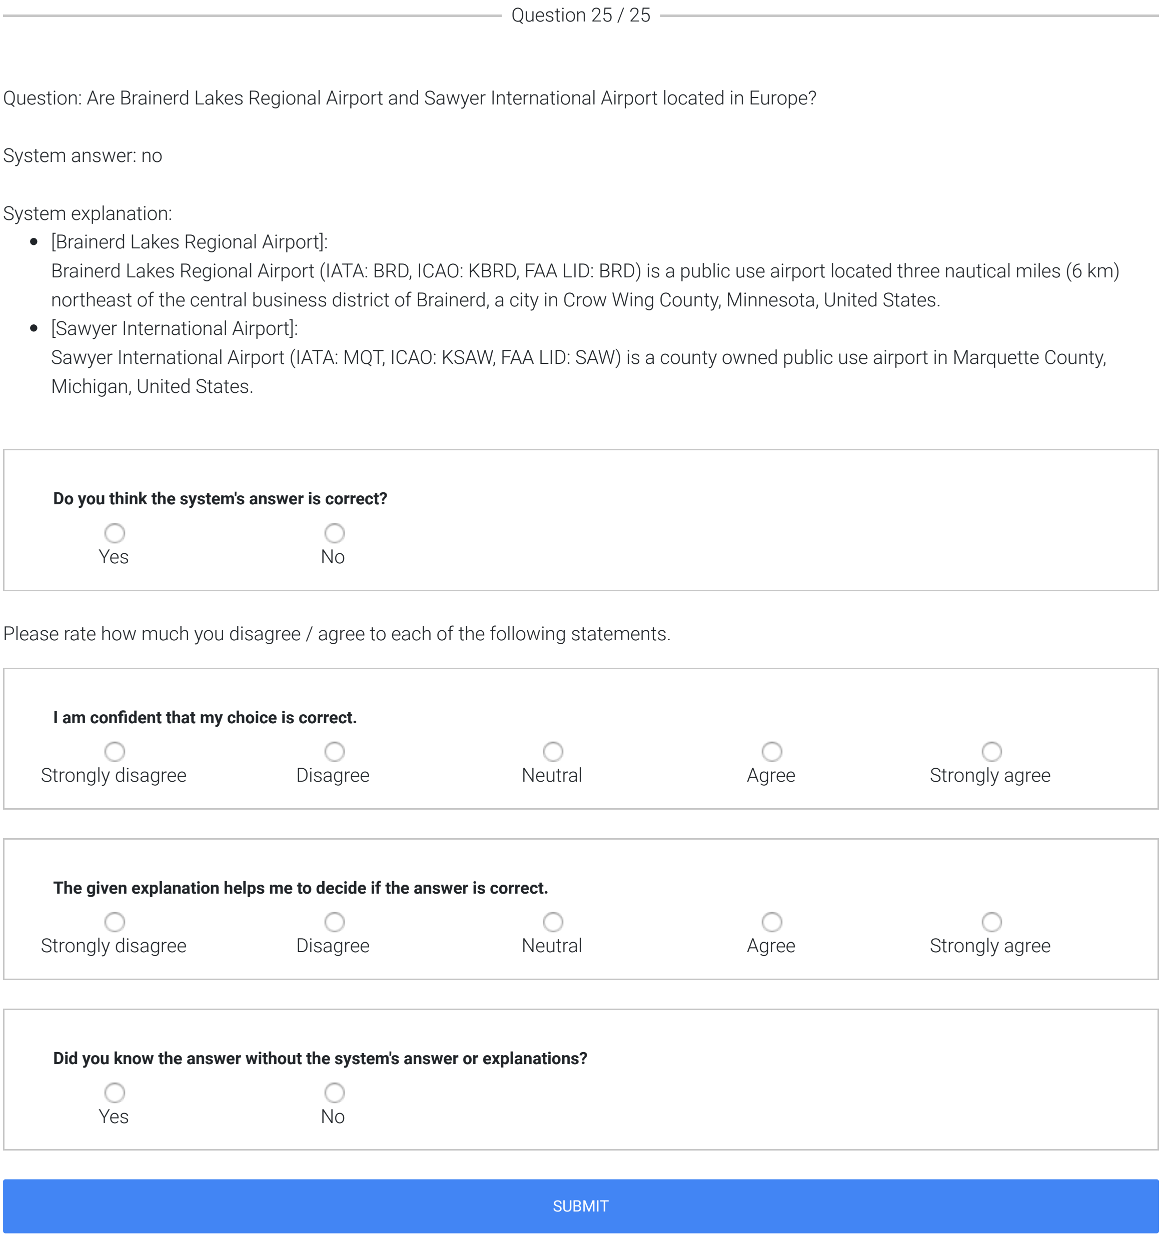
Figure 6 shows the values of $c_{\text{rel}}(k)$ (top), i.e., the fraction of changed answers when removing k facts predicted as relevant, and $c_{\text{irr}}(k)$ (bottom), i.e., the fraction of changed answers when removing k facts predicted as irrelevant, for $k \in \{0, \ldots, 4\}$.

G User Study Design Details

All questions and statements that we ask participants to answer/rate are listed in Table 4. Figure 7 and Figure 8 show screenshots of the study interface for the question rating and the post-questionnaire.

H Detailed User Study Results

Figure 9 shows boxplots per condition for all continuous dependent variables. Figure 10 shows rating distributions per condition for all ordinal dependent variables. Figures 11 and 12 compare model scores and human measures grouped into F_1-scores and our proposed FaRM(4) and LocA scores. Rows alternate between F_1-scores and our scores. Table 5 shows pairwise Pearson correlation coefficients between human and automatized scores.



Question 25 / 25

Question: Are Brainerd Lakes Regional Airport and Sawyer International Airport located in Europe?

System answer: no

System explanation:

- [Brainerd Lakes Regional Airport]:
  Brainerd Lakes Regional Airport (IATA: BRD, ICAO: KBRD, FAA LID: BRD) is a public use airport located three nautical miles (6 km) northeast of the central business district of Brainerd, a city in Crow Wing County, Minnesota, United States.
- [Sawyer International Airport]:
  Sawyer International Airport (IATA: MQT, ICAO: KSAW, FAA LID: SAW) is a county owned public use airport in Marquette County, Michigan, United States.

Do you think the system's answer is correct?

○ Yes ○ No

Please rate how much you disagree / agree to each of the following statements.

I am confident that my choice is correct.

○ Strongly disagree ○ Disagree ○ Neutral ○ Agree ○ Strongly agree

The given explanation helps me to decide if the answer is correct.

○ Strongly disagree ○ Disagree ○ Neutral ○ Agree ○ Strongly agree

Did you know the answer without the system's answer or explanations?

○ Yes ○ No

Figure 7: Screenshot of the question rating interface.

Context	Question/Statement	Answer Range
Each Question	Do you think the system's answer is correct?	yes/no
	Did you know the answer without the system's answer or explanations?	yes/no

Abstract

Transformers have supplanted recurrent models in a large number of NLP tasks. However, the differences in their abilities to model different syntactic properties remain largely unknown. Past works suggest that LSTMs generalize very well on regular languages and have close connections with counter languages. In this work, we systematically study the ability of Transformers to model such languages as well as the role of its individual components in doing so. We first provide a construction of Transformers for a subclass of counter languages, including well-studied languages such as n-ary Boolean Expressions, Dyck-1, and its generalizations. In experiments, we find that Transformers do well on this subclass, and their learned mechanism strongly correlates with our construction. Perhaps surprisingly, in contrast to LSTMs, Transformers do well only on a subset of regular languages with degrading performance as we make languages more complex according to a well-known measure of complexity. Our analysis also provides insights on the role of self-attention mechanism in modeling certain behaviors and the influence of positional encoding schemes on the learning and generalization abilities of the model.

1 Introduction

Transformer (Vaswani et al., 2017) is a self-attention based architecture which has led to state-of-the-art results across various NLP tasks (Devlin et al., 2019; Liu et al., 2019; Radford et al., 2018). Much effort has been devoted to understand the inner workings and intermediate representations of pre-trained models; Rogers et al. (2020) is a recent survey. However, our understanding of their practical ability to model different behaviors relevant to sequence modeling is still nascent.

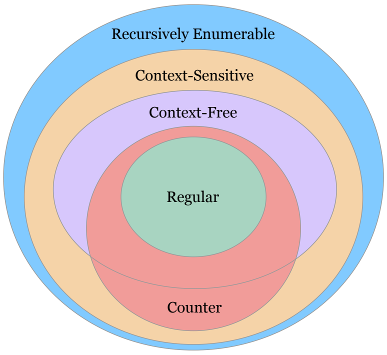

Figure 1: Counter languages form a strict superset of regular languages, and are a strict subset of context-sensitive languages. Counter and context-free languages have a nonempty intersection and neither set is contained in the other.

On the other hand, a long line of research has sought to understand the capabilities of recurrent neural models such as the LSTMs (Hochreiter and Schmidhuber, 1997) . Recently, Weiss et al. (2018), Suzgun et al. (2019a) showed that LSTMs are capable of recognizing counter languages such as Dyck-1 and $a^n b^n$ by learning to perform counting like behavior. Suzgun et al. (2019a) showed that LSTMs can recognize shuffles of multiple Dyck-1 languages, also known as Shuffle-Dyck. Since Transformer based models (e.g., GPT-2 and BERT) are not equipped with recurrence and start computation from scratch at each step, they are incapable of directly maintaining a counter. Moreover, it is known that theoretically RNNs can recognize any regular language in finite precision, and LSTMs work well for this task in practical settings. However, Transformer's ability to model such properties in practical settings remains an open question.

Prior to the current dominance of Transformers for NLP tasks, recurrent models like RNN-based models such as LSTMs were the most common choice, and their computational capabilities have

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7096–7116,
November 16–20, 2020.

been studied for decades, e.g., (Kolen and Kremer, 2001). In this work, we investigate the ability of Transformers to express, learn, and generalize on certain counter and regular languages. Formal languages provide us a controlled setting to study a network's ability to model different syntactic properties in isolation and the role of its individual components in doing so.

Recent work has demonstrated close connections between LSTMs and counter automata. Hence, we seek to understand the capabilities of Transformers to model languages for which the abilities of LSTMs are well understood. We first show that Transformers are expressive enough to recognize certain counter languages like Shuffle-Dyck and n-ary Boolean Expressions by using self-attention mechanism to implement the relevant counter operations in an indirect manner. We then extensively evaluate the model's learning and generalization abilities on such counter languages and find that models generalize well on such languages. Visualizing the intermediate representations of these models shows strong correlations with our proposed construction. Although Transformers can generalize well on some popularly used counter languages, we observe that they are limited in their ability to recognize others. We find a clear contrast between the performance of Transformers and LSTMs on regular languages (a subclass of counter languages). Our results indicate that, in contrast to LSTMs, Transformers achieve limited performance on languages that involve modeling periodicity, modular counting, and even simpler star-free variants of Dyck-1, which they were able to recognize effortlessly. Our analysis provides insights about the significance of different components, namely self-attention, positional encoding, and the number of layers. Our results also show that positional masking and positional encoding can both aid in generalization and training, but in different ways. We conduct extensive experiments on over 25 carefully chosen formal languages. Our results are perhaps the first indication of the limitations of Transformers for practical-sized problems that are, in a precise sense, very simple, and in particular, easy for recurrent models.

2 Related Work

Numerous works, e.g., Suzgun et al. (2019b); Sennhauser and Berwick (2018); Skachkova et al. (2018), have attempted to understand the capabilities and inner workings of recurrent models by empirically analyzing them on formal languages. Weiss et al. (2018) showed that LSTMs are capable of simulating counter operations and explored their practical ability to recognize languages like a^nb^n and $a^nb^nc^n$. Suzgun et al. (2019a) further showed that LSTMs can learn to recognize Dyck-1 and Shuffle-Dyck and can simulate the behavior of k-counter machines. Theoretical connections of recurrent models have been established with counter languages (Merrill, 2019; Merrill et al., 2020; Merrill, 2020). It has also been shown that RNN based models can recognize regular languages (Kolen and Kremer, 2001; Korsky and Berwick, 2019) and efforts have been made to extract DFAs from RNNs trained to recognize regular languages (Weiss et al., 2019; Wang et al., 2018b; Michalenko et al., 2019). We are not aware of such studies for Transformers.

Recently, researchers have sought to empirically analyze different aspects of the Transformer trained on practical NLP tasks such as the information contained in intermediate layers (Rogers et al., 2020; Reif et al., 2019; Warstadt et al., 2019). Voita et al. (2019) studied the role of different types of attention heads. Yang et al. (2019); Tsai et al. (2019) examined the ability of the model to learn order information via different positional encoding schemes. Complementary to these, our work is focused on analyzing Transformer's ability to model particular behaviors that could be relevant to modeling linguistic structure. Recently, it has been shown that Transformers are Turing-complete (Pérez et al., 2019; Bhattamishra et al., 2020) and are universal approximators of sequence-to-sequence functions given arbitrary precision (Yun et al., 2020). Hahn (2020) shows that Transformers cannot recognize languages Parity and Dyck-2. However, these results only apply to very long words, and their applicability to practical-sized inputs is not clear (indeed, we will see different behavior for practical-sized input). Moreover, these results concern the expressive power of Transformers and do not apply to learning and generalization abilities. Thus Transformers' ability to model formal languages requires further investigation.

3 Definitions

We consider the Transformer as used in popular pre-trained LM models such as BERT and GPT, which is the encoder-only model of the original seq-to-seq architecture (Vaswani et al., 2017). The encoder consists of multiple layers with two blocks each: (1) self-attention block, (2) a feed-forward network (FFN). For $1 \leq i \leq n$, at the i-th step, the model takes as input the sequence $s_1, s_2, \ldots, s_i$ where $s \in \Sigma$ and generates the output vector $\boldsymbol{y}_i$. Each input s_i is first converted into an embedding vector using the function $f_e : \Sigma \rightarrow \mathbb{R}^{d_{\text{model}}}$ and usually some form of positional encoding is added to yield the final input vector $\boldsymbol{x}_i$. The embedding dimension d_{model} is also the dimension of intermediate vectors of the network. Let $\boldsymbol{X}_i := (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_i)$ for $i \geq 1$.

In the self-attention block, the input vectors undergo linear transformations $Q(\cdot), K(\cdot)$, and $V(\cdot)$ yielding the corresponding query, key and value vectors, respectively. The self-attention mechanism takes as input a *query* vector $Q(\boldsymbol{x}_i)$, *key* vectors $K(\boldsymbol{X}_i)$, and *value* vectors $V(\boldsymbol{X}_i)$. An attention-head denoted by $\text{Att}(Q(\boldsymbol{x}_i), K(\boldsymbol{X}_i), V(\boldsymbol{X}_i))$, is a vector $\boldsymbol{a}_i = \sum_{j=1}^{i} \alpha_j \boldsymbol{v}_j$, where $(\alpha_1, \ldots, \alpha_i) = \mathsf{softmax}(\langle Q(\boldsymbol{x}_i), K(\boldsymbol{x}_1)\rangle, \ldots, \langle Q(\boldsymbol{x}_i), K(\boldsymbol{x}_i)\rangle)$.

The output of a layer denoted by $\boldsymbol{z}_i$ is computed by $\boldsymbol{z}_i = O(\boldsymbol{a}_i)$ where $1 \leq i \leq n$ and $O(\cdot)$ typically denotes an FFN with ReLU activation. The complete L-layer model is a repeated application of the single-layer model described above, which produces a vector $\boldsymbol{z}_i^L$ at its final layer where L denotes the last layer. The final output is obtained by applying a projection layer with some normalization or an FFN over the vectors $\boldsymbol{z}_i^L$'s and is denoted by $\boldsymbol{y}_i = F(\boldsymbol{z}_i^L)$. Residual connections and layer normalization are also applied to aid the learning process of the network.

In an LM setting, when the Transformer processes the input sequentially, each input symbol can only attend over itself and the previous inputs, masking is applied over the inputs following it. Note that, providing positional information in this form via masked self-attention is also referred to as positional masking (Vaswani et al., 2017; Shen et al., 2018). A Transformer model without positional encoding and positional masking is order-insensitive.

3.1 Formal Languages

Formal languages are abstract models of the syntax of programming and natural languages; they also relate to cognitive linguistics, e.g., Jäger and Rogers (2012); Hahn (2020) and references therein.

Counter Languages. These are languages recognized by a deterministic counter automaton (DCA), that is, a DFA with a finite number of unbounded counters (Fischer et al., 1968). The counters can be incremented/decremented by constant values and can be reset to 0 (details in App. B.1). The commonly used counter languages to study sequence models are Dyck-1, $a^n b^n$, and $a^n b^n c^n$. Several works have explored the ability of recurrent models to recognize these languages as well as their underlying mechanism to do so. We include them in our analysis as well as some general form of counter languages such as Shuffle-Dyck (as used in Suzgun et al. (2019a)) and n-ary Boolean Expressions. The language Dyck-1 over alphabet $\Sigma = \{[,]\}$ consists of balanced parentheses defined by derivation rules $S \rightarrow [\ S\ ] \mid SS \mid \epsilon$. Shuffle-Dyck is a family of languages containing shuffles of Dyck-1 languages. Shuffle-k denotes the shuffle of k Dyck-1 languages: it contains k different types of brackets, where each type of bracket is required to be well-balanced, but their relative order is unconstrained. For instance, a Shuffle-2 language over alphabet $\Sigma = \{[,],(,)\}$ contains the words $([)]$ and $[((]))$ but not $])[($. We also consider n-ary Boolean Expressions (hereby BoolExp-n), which are a family of languages of valid Boolean expressions (in the prefix notation) parameterized by the number of operators and their individual arities. For instance, an expression with unary operator $\sim$ and binary operator $\wedge$ contains the word '$\wedge \sim 01$' but not '~ 10' (formal definitions in App. B).

Note that, although languages such as Dyck-1 and $a^n b^n$ are context-free, a DCA with a single counter is sufficient to recognize Dyck-1 and $a^n b^n$. Similarly, a DCA with two single-turn counters can recognize $a^n b^n c^n$. On the other hand, recognizing Shuffle-Dyck requires multiple multi-turn counters, where for a given type of bracket, its corresponding counter is incremented or decremented by 1. Hence, it represents a more general form of counter languages. Similarly, recognizing BoolExp requires a 1-counter DCA with the counter updates depending on the operator: a ternary operator will increment the counter by 2 $(= \text{arity} - 1)$ whereas a unary operator will increment it by 0. Figure 1 shows the relationship between counter languages and other classes of formal languages.

Regular Languages. Regular languages, perhaps the best studied class of formal languages, form a subclass of counter languages[1]. They neatly divide

---

[1] For simplicity, from now on, we will refer to a particular language as a counter language if a DCA with a nonzero number of counters is necessary to recognize it, else we will refer to it as a regular language.

into two subclasses: *star-free* and *non-star-free*. Star-free languages can be described by regular expressions formed by union, intersection, complementation, and concatenation operators but not the Kleene star ($*$). Like regular languages, star-free languages are surprisingly rich with algebraic, logical, and multiple other characterizations and continue to be actively researched, e.g., (McNaughton and Papert, 1971; Jäger and Rogers, 2012). They form a simpler subclass of regular languages where the notion of simplicity can be made precise in various ways, e.g. they are first-order logic definable and cannot represent languages that require modular counting.

We first consider Tomita grammars containing 7 regular languages representable by DFAs of small sizes, a popular benchmark for evaluating recurrent models and extracting DFA from trained recurrent models (see, e.g., Wang et al. (2018a)). Tomita grammars contain both star-free and non-star-free languages. We further investigate some non-star-free languages such as $(aa)^*$, Parity and $(abab)^*$. Parity contains words over $\{0, 1\}$ with an even number of 1's. Similarly $(aa)^*$ and $(abab)^*$ require modeling periodicity.

On the other hand, the seemingly similar looking language $(ab)^*$ is star-free: $(ab)^* = (b\emptyset^c + \emptyset^c a + \emptyset^c aa\emptyset^c + \emptyset^c bb\emptyset^c)^c$, where $\cdot^c$ denotes set complementation, and thus $\emptyset^c = \Sigma^*$. The dot-depth of a star-free language is a measure of nested concatenation or sequentiality required in a star-free regular expression (formal definition in App. B.2). We define a family $\mathcal{D}_0, \mathcal{D}_1, \ldots$ of star-free languages. For $n \geq 0$, the language $\mathcal{D}_n$ over $\Sigma = \{a, b\}$ is defined inductively as follows: $\mathcal{D}_n = (a\mathcal{D}_{n-1}b)^*$ where $\mathcal{D}_0 = \epsilon$, the empty word. Thus $\mathcal{D}_1 = (ab)^*$ and $\mathcal{D}_2 = (a(ab)^*b)^*$. Language $\mathcal{D}_n$ is known to have dot-depth n.

The list of all considered languages and their definitions are provided in the App. B.

4 Expressiveness Results

Proposition 4.1. *There exists a Transformer as defined in Section 3 that can recognize the family of languages Shuffle-Dyck.*

Proof. Let $s_1, s_2, \ldots, s_n$ denote a sequence $w \in$ Shuffle-k over the alphabet $\Sigma = \{[_0, \ldots, [_{k-1},]_0, \ldots,]_{k-1}\}$. The language Shuffle-1 is equivalent to Dyck-1. For any Shuffle-k language, consider a model with $d_{model} = 2k$, where the embedding function f_e is defined as follows. For each type of open bracket $[_j$ where,$0 \leq j < k$, the vector $f_e([_j)$ has the value $+1$ and -1 at the indices $2j$ and $2j + 1$, respectively. It has the value 0 at the rest of the indices. Similarly for each closing bracket, the vector $f_e(]_j)$ has the value -1 and $+1$ at the indices $2j$ and $2j + 1$, and it has the value 0 at the rest of the indices. For Dyck-1, this would lead to $f_e([) = [+1, -1]^T$ and $f_e(]) = [-1, +1]^T$ (with $d_{model} = 2$). We use a single-layer Transformer where we set the matrix corresponding to linear transformation for key vectors to be null matrix, that is $K(\boldsymbol{x}) = \mathbf{0}$ for all $\boldsymbol{x}$. This will lead to equal attention weights for all inputs. The matrices corresponding to $Q(\cdot)$ and $V(\cdot)$ are set to Identity. Thus, $\mathrm{Att}(Q(\boldsymbol{x}_i), K(\boldsymbol{X}_i), V(\boldsymbol{X}_i)) = \frac{1}{i}\sum_{j=1}^{i} \boldsymbol{v}_j$ for $1 \leq i \leq n$. Hence, at the i-th step, the self-attention block produces a vector $\boldsymbol{a}_i$ which has the values $\frac{\sigma([_j) - \sigma(]_j)}{i}$ at indices $2j$ and the values $\frac{\sigma(]_j) - \sigma([_j)}{i}$ at indices $2j + 1$, where $\sigma(s)$ denotes the number of occurrence of the symbol s. For instance, in Dyck-1, if in the first i inputs, there are $\sigma([)$ open brackets and $\sigma(])$ closing brackets, then $\boldsymbol{a}_i = [\frac{\sigma([) - \sigma(])}{i}, \frac{\sigma(]) - \sigma([)}{i}]^T$, where $i = \sigma([) + \sigma(])$. In $\boldsymbol{a}_i$, the value $\sigma([) - \sigma(])$ represents the depth (difference between the number of open and closing brackets) of the Dyck-1 word at index i. Hence, the first coordinate is the ratio of the depth of the Dyck-1 word and its length at that index, while the other coordinate is its negative.

We then apply a simple FFN with ReLU activation over the vector $\boldsymbol{a}_i$. The vector $\boldsymbol{z}_i = \mathsf{ReLU}(\mathbf{I}\boldsymbol{a}_i)$. The even indices of the vector $\boldsymbol{z}_i$ will be nonzero if the number of open brackets of the corresponding type is greater than the number of closing brackets. A similar statement holds for the odd indices. Thus, for a given word to be in Shuffle-k, the values at odd indices of the vector $\boldsymbol{z}_i$ must never be nonzero, and the values of all coordinates must be zero at the last step to ensure the number of open and closing brackets are the same.

For an input sequence $s_1, s_2, \ldots, s_n$, the model will produce $\boldsymbol{z}_1, \ldots, \boldsymbol{z}_n$ based on the construction specified above. A word w belongs to language Shuffle-k if $\boldsymbol{z}_{i,2j+1} = 0$ for all $1 \leq i \leq n, 0 \leq j < k$ and $\boldsymbol{z}_n = \mathbf{0}$ and does not belong to the language otherwise. This can be easily implemented by an additional layer of self-attention and feedforward network to classify a given sequence.

Table 1: The performance of Transformers and LSTMs on the respective counter languages. Refer to section 6 for details. Performance on other counter languages such as Shuffle-4 and Shuffle-6 are listed in Table 8 in appendix.

tion above is the calculation of values of the form $\frac{\sigma([)-\sigma(])}{i}$ in the vector $\boldsymbol{a}_i$. Since in a finite precision setting with r bits, this can be computed up to a value exponential in r, our proof entails that Transformers can recognize languages in Shuffle-Dyck for lengths exponential in the number of bits.

Using a similar logic, one can also show that Transformers can recognize the family of languages BoolExp-n (refer to Lemma C.2). By setting the value vectors according to the arities of the operators, the model can obtain the ratio of the counter value of the underlying automata and the length of the input at each step via self-attention. Although the above construction is specific to these language families, we provide a proof for a more general but restricted subclass of Counter Languages in the appendix (refer to Lemma C.1). The above construction serves to illustrate how Transformers can recognize such languages by indirectly doing relevant computations. As we will later see, this will also help us interpret how trained models recognize such languages.

5 Experimental Setup

In our experiments, we consider 27 formal languages belonging to different parts in the hierarchy of counter and regular languages. For each language, we generate samples within a fixed-length window for our training set and generate multiple validation sets with different windows of length to evaluate the model's generalization ability.

For most of the languages, we generate 10k samples for our training sets within lengths 1 to 50 and create different validation sets containing samples with distinct but contiguous windows of length. The number of samples in each validation set is 2k, and the width of each window is about 50. For languages that have very few positive examples in a given window of length, such as $(ab)^*$ and $a^n b^n c^n$, we train on all positive examples within the training window. Similarly, each validation set contains all possible strings of the language for a particular range. Table 6 in appendix lists the dataset statistics of all 27 formal languages we consider.[2]. We have made our source code available at https://github.com/satwik77/Transformer-Formal-Languages.

5.1 Training details

We train the model on character prediction task as introduced in Gers and Schmidhuber (2001) and as used in Suzgun et al. (2019b,a). Similar to an LM setup, the model is only presented with positive samples from the given language. For an input sequence $s_1, s_2, \ldots, s_n$, the model receives the sequence $s_1, \ldots, s_i$ for $1 \leq i \leq n$ at each step i and the goal of the model is to predict the next set of legal/valid characters in the $(i+1)^{th}$ step. From here onwards, we say a model can recognize a language if it can perform the character prediction task perfectly.

The model assigns a probability to each character in the vocabulary of the language corresponding to its validity in the next time-step. The output can be represented by a k-hot vector where each coordinate corresponds to a character in the vocabulary of the language. The output is computed by applying a sigmoid activation over the scores assigned by the model for each character. Following Suzgun et al. (2019b,a), the learning objective of

---

[2] Our experimental setup closely follows the setup of Suzgun et al. (2019a,b) for RNNs

the model is to minimize the mean-squared error between the predicted probabilities and the k-hot labels.[3] During inference, we use a threshold of 0.5 to obtain the predictions of the model. For a test sample, the model's prediction is considered to be correct if and only if its output at every step is correct. Note that, this is a relatively stringent metric as a correct prediction is obtained only when the output is correct at every step. The accuracy of the model over test samples is the fraction of total samples predicted correctly[4]. Similar to Suzgun et al. (2019a) we consider models of small sizes to prevent them from memorizing the training set and make it feasible to visualize the model. In our experiments, we consider Transformers with up to 4 layers, 4 heads and the dimension of the intermediate vectors within 2 to 32. We extensively tune the model across various hyperparameter settings. We also examine the influence of providing positional information in different ways such as absolute encodings, relative encodings (Dai et al., 2019) and using only positional masking without any explicit encodings.

6 Results on Counter Languages

We evaluated the performance of the model on 9 counter languages. Table 1 shows the performance of different models described above on some representative languages. We also include the performance of LSTMs as a baseline. We found that Transformers of small size (single head and single layer) can generalize well on some general form of counter languages such as Shuffle-Dyck and BoolExp-n. Surprisingly, we observed this behavior when the network was not provided any form of explicit positional encodings, and positional information was only available in the form of masking. For models with positional encoding, the lack of the ability to generalize to higher lengths could be attributed to the fact that the model has never been trained on some of the positional encodings that it receives at test time. On the other hand, the model without any explicit form of positional encoding is less susceptible to such issues if it is capable of performing the task and was found to generalize well across various hyperparameter settings.

(b)

Figure 2: Values of different coordinates of the output of self-attention block of the models trained on Shuffle-2 and BoolExp-3. The dotted lines are the scaled depth to length ratios for Shuffle-2 and scaled counter value to length ratios for BoolExp-3. We observe a near perfect Pearson correlation coefficent of 0.99 between outputs of self attention block and the DL and CL ratios.

6.1 Role of Self-Attention

In order to check our hypothesis in Sec. 4, we visualize certain attributes of trained models that generalize well on Shuffle-2 and BoolExp-3.[5] Our construction in Sec. 4 recognizes sequences in Shuffle-Dyck by computing the depth to length ratio of the input at each step via self-attention mechanism. For BoolExp-n, the model can achieve the task similarly by computing the corresponding counter value divided by length (refer to Lemma C.2). Interestingly, upon visualizing the outputs of the self-attention block for a model trained on Shuffle-2, we found a strong correlation of its elements with the depth to length ratio. As shown in Fig. 2a, different coordinates of the output vector of the self-attention block contain computations corresponding to different counters of the Shuffle-2 language. We observe the same behavior for models trained on Shuffle-4 language (refer to Figure 5 in appendix). Similarly, upon visualizing a model trained on Boolean Expressions with 3 operators, we found strong correlation[6] between its elements and the ratio of the counter value and length of the input (refer to Figure 2b). This indicates that the model learns to recognize inputs by carrying out the required computation in an indirect manner,

---

[3] We also tried BCE loss in our initial experiments and found similar results for languages such as Parity, Tomita grammars and certain counter languages.

[4] A discussion on the choice of character prediction task and its relation to other tasks such as standard classification and LM is provided in section D.1 in the appendix.

[5] We take the model with the smallest number of parameters that generalized well making it feasible for us to visualize it.

[6] The Pearson correlation of values were ~ 0.99

Model Type	1-Layer Bin 0	1-Layer Bin 1	2-Layer Bin 0	2-Layer Bin 1
Positional Masking	45.1	38.9	100.0	99.2
Positional Encoding	55.8	37.9	100.0	99.6
LSTM	100.0	100.0	100.0	100.0

Table 2: Results on language Reset-Dyck-1 with different number of layers.

as described in our construction. Additionally, for both models, we found that the attention weights of the self-attention block were uniformly distributed (refer to Figure 4 in appendix). Further, on inspecting the embedding and value vectors of the open and closing brackets, we found that their respective coordinates were opposite in sign and similar in magnitude. As opposed to Shuffle-Dyck, for BoolExp-n, the magnitudes of the elements in the value vectors were according to their corresponding arity. For instance, the magnitude for a ternary operator was (almost) thrice the magnitude for a unary operator (refer to Figure 3 in appendix). These observations are consistent with our construction, indicating that the model uses its value vectors to determine the counter updates and then at each step, aggregates all the values to obtain a form of the final counter value in an indirect manner. This is complementary to LSTMs, which can simulate the behavior of k-counters more directly by making respective updates to its cell states upon receiving each input (Suzgun et al., 2019a).

6.2 Limitations of the Single-Layer Transformer

Although we observed that single-layer Transformers are easily able to recognize some of the popularly studied counter languages, at the same time, it is not necessarily true for counter languages that require reset operations. We define a variant of the Dyck-1 language. Let Reset-Dyck-1 be the language defined over the alphabet $\Sigma = \{[,], \#\}$, where $\#$ denotes a symbol that resets the counter. Words in Reset-Dyck-1 have the form $\Sigma^*\#v$, where the string v belongs to Dyck-1. When the machine encounters the reset symbol $\#$, it must ignore all the previous input, reset the counter to 0 and go to start state. It is easy to show that this cannot be directly implemented with a single layer self-attention network with positional masking (Lemma C.3 in Appendix). The key limitation for both with and without encodings is the fact that for a single layer network the scoring function $\langle Q(\boldsymbol{x}_n), K(\boldsymbol{x}_\#)\rangle$ and the value vector corresponding to the reset symbol is independent of the preceding inputs which it is supposed to negate (reset). The same limitation does not hold for multi-layer networks where the value vector, as well as the scoring function for the reset symbol, are dependent on its preceding inputs. On evaluating the model on data generated from such a language, we found that single-layer networks are unable to perform well in contrast to networks with two layers (Table 2)[7]. LSTMs, on the other hand, can emulate the reset operation using forget gate.

Language	Star-Free	Transformer Bin 0	Transformer Bin 1	LSTM Bin 0	LSTM Bin 1
Tomita 1	✓	100.0	100.0	100.0	100.0
Tomita 2	✓	100.0	100.0	100.0	100.0

Table 3: Results on Tomita grammar

7 Results on Regular Languages

We first examine the popular benchmark of Tomita grammars. While the LSTMs generalize perfectly on all 7 languages, Transformers are unable to generalize on 3 languages, all of which are non-star-free. Note that, all star-free languages in Tomita grammar have dot-depth 1. Recognizing non-star-free languages requires modeling properties such as periodicity and modular counting. Consequently, we evaluate the model on some of the simplest non-star-free languages such as the languages $(aa)^*$ and Parity. We find that they consistently fail to learn or generalize on such languages, whereas LSTMs of very small sizes perform flawlessly. Table 4 lists the performance on some non-star-free languages. Note that LSTMs can easily recognize such simple non-star-free languages considered here by using its internal memory and recurrence [8]. However, doing the same task via self-attention mechanism without using any internal memory could be highly non-trivial and potentially impossible. Languages such as $(aa)^*$ and Parity are among the simplest

---

[7] The results and limitations of single-layer Transformers are confined to this subsection. The rest of the results in the paper are not specific to single-layer Transformers unless explicitly mentioned.

[8] For tasks such as Parity, LSTMs can simply flip between two values in its hidden state upon receiving 1's as input and ignore when it receives 0's as input.

		Transformer		LSTM	
Language	**Property**	**Bin 0**	**Bin 1**	**Bin 0**	**Bin 1**
Parity	non-SF	68.7 (23.0)	0.0 (0.0)	100.0	100.0
$(aa)^*$	non-SF	100 (1.3)	0.0 (0.0)	100.0	100.0
$(abab)^*$	non-SF	100.0 (9.9)	5.4 (0.0)	100.0	100.0
$\mathcal{D}_1$	depth-1	100.0	100.0	100.0	100.0
$\mathcal{D}_2$	depth-2	74.6	3.1	100.0	100.0
$\mathcal{D}_4$	depth -4	90.2	3.3	100.0	100.0

Table 4: Results on non-star-free languages (non-SF) and the language $\mathcal{D}_n$. The values in parenthesis correspond to the scores obtained for a model without residual connections. This is to prevent the model from solving the task by memorizing the positional encodings and study the ability of self-attention mechanism to solve the task.

	$(aa)^*$		$(aaaa)^*$	
Encoding Scheme	**Bin 0**	**Bin 1**	**Bin 0**	**Bin 1**
Positional Masking	0.0	0.0	0.0	0.0
Absolute Encoding	1.3	0.0	6.7	0.0
Relative Encoding	0.6	0.0	1.7	0.0
$\cos(n\pi)$	100.0	100.0	0.0	0.0
Trainable Embedding	100.0	0.0	100.0	0.0

Table 5: Performance of transformer based models on $(aa)^*$ and $(aaaa)^*$, for different types of position encoding schemes. To separately study the effect of different position encodings on the self attention mechanism, we do not include residual connections in the models studied here.

non-star-free languages, and hence limitations in recognizing such languages carry over to a larger class of languages. The results above may suggest that the star-free languages are precisely the regular languages recognizable by Transformers. As we will see in the next section, this is not so.

7.1 Necessity of Positional Encodings

The architecture of Transformer imposes limitations for recognizing certain types of languages. Although Transformers seem to generalize well when they are capable of performing a task with only positional masking, they are incapable of recognizing certain types of languages without explicit positional encodings. We consider the family of star-free languages $\mathcal{D}_n$ defined in Sec. 3.1. Note that the task of recognizing $\mathcal{D}_n$ is equivalent to recognizing Dyck-1 with maximum depth n, where the symbols a and b in $\mathcal{D}_n$ are analogous to open and closing brackets in Dyck-1 respectively. The primary difference between recognizing $\mathcal{D}_n$ and Dyck-1 is that in case of $\mathcal{D}_n$, when the input reaches the maximum depth n, the model must predict a (the open bracket) as invalid for the next character, whereas in Dyck-1, open brackets are always allowed. We show that although Transformers with only positional masking can generalize well on Dyck-1, they are incapable of recognizing the language $\mathcal{D}_n$ for $n > 1$. The limitation arises from the fact that when the model receives a sequence of only a's, then due to the softmax based aggregation, the output of the self-attention block $\boldsymbol{a}_i$ will be a constant vector, implying that the output of the feed-forward will also be a constant vector, that is, $\boldsymbol{z}_1 = \boldsymbol{z}_2 = \ldots = \boldsymbol{z}_n$. In case of languages such as $\mathcal{D}_n$, if the input begins with n consecutive as, then, since the model cannot distinguish between the n-th a and the preceding a's, the model cannot recognize the language $\mathcal{D}_n$. This limitation does not exist if the model is provided explicit positional encoding. Upon evaluating Transformers with positional encodings on instances of the language $\mathcal{D}_n$, we found that the models are able to generalize to a certain extent on strings within the same lengths as seen during training but fail to generalize on higher lengths (Table 4). It is perhaps surprising that small and simpler self-attention networks can generalize very well on languages such as Dyck-1 but achieve limited performance on a language that belongs to a much simpler class such as star-free.

Similarly, since $(aa)^*$, is a unary language (alphabet size is 1), the model will always receive the same character at each step. Hence, for a model with only positional masking, the output vector will be the same at every step, making it incapable of recognizing the language $(aa)^*$. For the language Parity, when the input word contains only 1's, the task reduces to recognizing $(11)^*$ and hence a model without positional encodings is incapable of recognizing Parity even for very small lengths regardless of the size of the network (refer to Lemma C.4). We find it surprising that for Parity, which is permutation invariant, positional encodings are necessary for transformers to recognize them even for very small lengths.

7.2 Influence of Custom Positional Encodings

The capability and complexity of the network could significantly depend on the positional encoding scheme. For instance, for language $(aa)^*$, the ability of a self-attention network to recognize it depends solely on the positional encoding. Upon evaluating with standard absolute and relative encoding schemes, we observe that the model is unable to learn or generalize well. At the same time, it is easy to show that if $\cos(n\pi)$, which has a period of two is used as positional encoding, the self-attention mechanism can easily achieve the task which we also observe when we empirically evaluated with such an encoding. However, the same encoding would not work for a language such as $(aaaa)^*$, which has a periodicity of four. Table 5 shows the performance of the model with different types of encodings. When we used fixed-length trainable positional embeddings, the obtained learned embeddings were very similar to the $\cos(n\pi)$ form; however, such embeddings cannot be used for sequences of higher lengths. This also raises the need for better learnable encodings schemes that can extrapolate to variable lengths of inputs not seen during training data such as (Liu et al., 2020).

Our experiments on over 15 regular languages seem to indicate that Transformers are able to generalize on star-free languages within dot-depth 1 but have difficulty with higher dot-depths or more complex classes like non-star-free languages. Table 9 in Appendix lists results on all considered regular languages.

8 Discussion

We showed that Transformers can easily generalize on certain counter languages such as Shuffle-Dyck and Boolean Expressions in a manner similar to our proposed construction. Our visualizations imply that Transformers do so with a generalizable mechanism instead of overfitting on some statistical regularities. Similar to natural languages, Boolean Expressions consist of recursively nested hierarchical constituents. Recently, Papadimitriou and Jurafsky (2020) showed that pretraining LSTMs on formal languages like Shuffle-Dyck transfers to LM performance on natural languages. At the same time, our results show clear limitations of Transformers compared to LSTMs on a large class of regular languages. Evidently, the performance and capabilities of Transformers heavily depend on architectural constituents e.g., the positional encoding schemes and the number of layers. Recurrent models have a more automata-like structure well-suited for counter and regular languages, whereas self-attention networks' structure is very different, which seems to limit their abilities for the considered tasks.

Our work poses a number of open questions. Our results are consistent with the hypothesis that Transformers generalize well for star-free languages with dot-depth 1, but not for higher depths. Clarifying this hypothesis theoretically and empirically is an attractive challenge. What does the disparity between the performance of Transformers on natural and formal languages indicate about the complexity of natural languages and their relation to linguistic analysis? (See also Hahn (2020)). Another interesting direction would be to understand whether certain modifications or recently proposed variants of Transformers improve their performance on formal languages. Regular and counter languages model some aspects of natural language while context-free languages model other aspects such as hierarchical dependencies. Although our results have some implications on them, we leave a detailed study on context-free languages for future work.

A Roadmap

The appendix is organized as follows. In section B we first provide formal definitions of the key languages used in our investigation in the main paper. In sections B.1 and B.2, we also provide the formal definitions of automata, star-free languages and the dot-depth hierarchy. In section C, we provide the details of all our expressiveness results. Section D contains the details of our experimental setup which could be relevant for reproducibility of the results and includes a thorough discussion of the choice of character prediction task. The list of all the formal languages we have considered, their dataset statistics as well as the results are provided in section D.

B Definitions

In this section, we provide formal definitions of some of the languages used in our analysis. In counter languages, we first define the family of shuffled Dyck-1 languages. The language Dyck-1 is a simple context-free language that can also be recognized by a counter automaton with a single counter. We generate the data for Dyck-1 based on the following PCFG,

$$S \rightarrow \begin{cases} (S) & \text{with probability } p \\ SS & \text{with probability } q \\ \varepsilon & \text{with probability } 1-(p+q) \end{cases}$$

where $0 < p, q < 1$ and $(p+q) < 1$. We use 0.5 as the value of p and 0.25 as the value for q.

Shuffle-Dyck. We now define the Shuffle-Dyck language introduced and described in (Suzgun et al., 2019a). We first define the shuffling operation formally. The shuffling operation $|| : \Sigma^* \times \Sigma^* \rightarrow \mathcal{P}(\Sigma^*)$ can be inductively defined as follows:[9]

- $u||\varepsilon = \varepsilon||u = \{u\}$
- $\alpha u||\beta v = \alpha(u||\beta v) \cup \beta(\alpha u||v)$

for any $\alpha, \beta \in \Sigma$ and $u, v \in \Sigma^*$. For instance, the shuffle of ab and cd is

$$ab||cd = \{abcd, acbd, acdb, cabd, cadb, cdab\}.$$

There is a natural extension of the shuffling operation $||$ to languages. The *shuffle* of two languages $\mathcal{L}_1$ and $\mathcal{L}_2$, denoted $\mathcal{L}_1||\mathcal{L}_2$, is the set of all possible interleavings of the elements of $\mathcal{L}_1$ and $\mathcal{L}_2$, respectively, that is:

$$\mathcal{L}_1||\mathcal{L}_2 = \bigcup_{u\in\mathcal{L}_1,\, v\in\mathcal{L}_2} u||v$$

Given a language $\mathcal{L}$, we define its self-shuffling $\mathcal{L}||^2$ to be $\mathcal{L}||\sigma(\mathcal{L})$, where σ is an isomorphism on the vocabulary of $\mathcal{L}$ to a disjoint vocabulary. More generally, we define the k-self-shuffle

$$\mathcal{L}||^k = \begin{cases} \{\varepsilon\} & \text{if } k = 0 \\ \mathcal{L}||\sigma(\mathcal{L}||^{k-1}) & \text{otherwise} \end{cases} .$$

We use Shuffle-k to denote the shuffle of k Dyck-1 languages (Dyck-$1||^k$) each with its own brackets. Shuffle-1 is the same as Dyck-1. For instance the language Shuffle-2 is the shuffle of Dyck-1 over alphabet $\Sigma = \{(,)\}$ and another Dyck-1 over the alphabet $\Sigma = \{[,]\}$. Hence the resulting Shuffle-2 language is defined over alphabet $\Sigma = \{[,], (,)\}$ and contains words such as ([)] and [(()]) but not])[(. This is different from the context-free language Dyck-2 in which ([]) belongs to the language but ([)] does not. Similar to (Suzgun et al., 2019a) we generate the training data by generating sequence for Dyck-n but by providing the correct target values for the character prediction task.

n-ary Boolean Expressions. We now define the family of languages n-ary Boolean Expressions parameterized by the number and arities of its operators. An instance of the language contains operators of different arities and as shown in (Fischer et al., 1968), these languages can be recognized by counter-machines with a single counter. However as opposed to Dyck-1 the values with which the counters will be incremented or decremented will depend on the arity of its operator. A language with n operators can be defined by the following derivation rules

```
<exp> -> <VALUE>
<exp> -> <UNARY> <exp>
<exp> -> <BINARY> <exp> <exp>
..
<exp> -> <n-ARY> <exp> .. <exp>
```

Tomita Grammars Tomita Grammars are 7 regular langauges defined on the alphabet $\Sigma = \{0, 1\}$. Tomita-1 has the regular expression 1^* i.e. the strings containing only 1's and no 0s are allowed. Tomita-2 is defined by the regular expression $(10)^*$. Tomita-3 accepts the strings where odd number

---

[9] We abuse notation by allowing a string to stand for the singleton containing that string. ϵ is the empty string.

of consecutive 1s are always followed by an even number of 0s. Tomita-4 accepts the strings that do not contain 3 consecutive 0s. In Tomita-5 only the strings containing an even number of 0s and even number of 1s are allowed. In Tomita-6 the difference in the number of 1s and 0s should be divisible by 3 and finally, Tomita-7 has the regular expression $0^*1^*0^*1^*$.

We note that Tomita 2 $= \mathcal{D}_1 = (01)^*$ and that the very simple language $\{0,1,2\}^*02^*$ has dot-depth 2 (Cohen and Brzozowski, 1971).

B.1 Counter Automata

We define the general counter machine following (Fischer et al., 1968). We are concerned with real-time counter machines here in which the number of computation steps is bounded by the number of inputs similar to how we use sequence models in practice. The machine has a finite number of unbounded counters and it modifies it by adding or subtracting values or resetting the counter value to 0. For $m \in \mathbb{Z}$, let $+m$ denote the function $x \mapsto x + m$. Let $\times 0$ denote the constant zero function $x \mapsto 0$.

Definition B.1 (General counter machine (Fischer et al., 1968))**.** A k-counter machine is a tuple $\langle \Sigma, Q, q_0, u, \delta, F\rangle$ with

1. A finite alphabet Σ
2. A finite set of states Q
3. An initial state q_0
4. A counter update function

$$u : \Sigma \times Q \times \{0,1\}^k \to \\ \big(\{+m : m \in \mathbb{Z}\} \cup \{\times 0\}\big)^k$$

5. A state transition function

$$\delta : \Sigma \times Q \times \{0,1\}^k \to Q$$

6. An acceptance mask

$$F \subseteq Q \times \{0,1\}^k$$

A machine processes an input string x one token at a time. For each token, we use u to update the counters and δ to update the state according to the current input token, the current state, and a finite mask of the current counter values.

For a vector $\boldsymbol{v}$, let $z(\boldsymbol{v})$ denote the broadcasted "zero-check" function, i.e. $z(\boldsymbol{v})_i$ is 0 if $v_i = 0$ or 1 otherwise. Let $\langle q, \boldsymbol{c}\rangle \in Q \times \mathbb{Z}^k$ be a configuration of machine M. Upon reading input $x_t \in \Sigma$, we define the transition

$$\langle q, \boldsymbol{c}\rangle \to_{x_t} \langle \delta(x_t, q, z(\boldsymbol{c})), u(x_t, q, z(\boldsymbol{c}))(\boldsymbol{c})\rangle.$$

For any string $x \in \Sigma^*$ with length n, a counter machine accepts x if there exist states $q_1, .., q_n$ and counter configurations $\boldsymbol{c}_1, .., \boldsymbol{c}_n$ such that

$$\langle q_0, \mathbf{0}\rangle \to_{x_1} \langle q_1, \boldsymbol{c}_1\rangle \to_{x_2} .. \to_{x_n} \langle q_n, \boldsymbol{c}_n\rangle \in F.$$

A counter machines accepts a language L if, for each $x \in \Sigma^*$, it accepts x iff $x \in L$. Refer to (Merrill, 2020) for more details on counter machines, variants and their properties.

B.2 Star-free regular languages and the dot-depth hierarchy

Star-free regular languages (defined in the main paper) are a simpler subclass of regular languages; they have regular expressions without Kleene star (but use set complementation). The set of star-free languages is further stratified by the dot-depth hierarchy, which is a hierarchy of families of languages whose union is the family of star-free languages. Informally, the position of a language in this hierarchy is a measure of the number of nested concatenations or sequentiality required to express the language in a star-free regular expression. Both the star-free regular languages as well as the dot-depth hierarchy are well-studied with rich connections and multiple (equivalent) definitions. For more information, see e.g. (McNaughton and Papert, 1971; Cohen and Brzozowski, 1971; Straubing, 1994; Diekert and Gastin, 2008; Jäger and Rogers, 2012; Pin, 2017).

To define the dot-depth hierarchy, we first define Boolean and concatenation closures of language families. For a language family $\mathcal{L}$ over a finite alphabet $\Sigma = \{a_1, \ldots, a_k\}$, its Boolean closure $\mathcal{BL}$ is the set of languages obtained by applying Boolean operators (union, intersection and set complementation w.r.t. Σ^*) to the languages in $\mathcal{L}$. In other words, $\mathcal{BL}$ is the smallest family of languages containing $\mathcal{L}$ and closed under Boolean operations: if $L_1, L_2 \in \mathcal{L}$ then $L_1 \cap L_2 \in \mathcal{BL}$ and $L_1 \cup L_2 \in \mathcal{BL}$ and $L_1^c, L_2^c \in \mathcal{BL}$. Similarly, define the concatenation closure of $\mathcal{L}$ as the smallest family of languages containing $\mathcal{L}$ and closed under concatenation: if $L_1, L_2 \in \mathcal{L}$ then $L_1L_2 \in \mathcal{ML}$.

We begin with the class $\mathcal{E}$ of basic languages consisting of $\{a_1\}, \ldots \{a_k\}, \{\epsilon\}, \emptyset$. By alternately applying the operators $\mathcal{B}$ and $\mathcal{M}$ to $\mathcal{E}$ we can define the hierarchy

$$\mathcal{E} \subseteq \mathcal{ME} \subseteq \mathcal{BME} \subseteq \mathcal{MBME} \subseteq \ldots.$$

Let $\mathcal{B}_0 = \mathcal{BME}$. The dot-depth hierarchy is the sequence of families of languages $\mathcal{B}_0 \subseteq \mathcal{B}_1 \subseteq \ldots$ defined inductively by $\mathcal{B}_{n+1} = \mathcal{BMB}_n$ for $n \geq 0$. It is known that all the inclusions in $\mathcal{B}_0 \subseteq \mathcal{B}_1 \subseteq \ldots$ are strict and is exemplified by the languages $\mathcal{D}_n$ (see Pin (2017)). Minor variations in the definition exist in the literature; in particular, we could have applied the operator $\mathcal{B}$ first, but these have only minor effects on the overall concept and results.

C Expressiveness Results

We define a weaker version of counter automata which are restricted in a certain sense. Then, we show that Transformers are at least as powerful as such automata.

Definition C.1 (Simplified and Stateless counter machine)**.** We define a counter machine to be simplified and stateless if u and δ have the following form,

$$u : \Sigma \rightarrow \{+m : m \in \mathbb{Z}\}^k,$$

$$\delta : \Sigma \rightarrow Q$$

This implies that the machine can have k counters. The counters can be incremented or decremented by any values but it will only depend on the input symbol. Similarly, the state transition will also depend on the current input. A string $x \in \Sigma^*$ will be accepted if $\langle q_n, z(\boldsymbol{c}_n)\rangle \in F$. We use L_{RCL} to denote the class of languages recognized by such a counter machine. The above language is similar to Σ-restricted counter machine defined in (Merrill et al., 2020).

Lemma C.1. *Transformers can recognize L_{RCL}.*

Proof. Let $s_1, s_2, \ldots, s_n$ denote a sequence $w \in \Sigma^*$. If the counter machine has k counters, then let the dimension of intermediate vectors $d_{model} = 2k + |\Sigma|$. The first $2k$ dimensions will be reserved for counter related operations and then $|Q|$ dimensions will be reserved to obtain the state vector. The embedding vector $\boldsymbol{x}_i$ of each symbol will have 0s in the first $2k$ dimensions and the last $|\Sigma|$ dimensions will have the one-hot encoding representation of the symbol. For a k counter machine the value vectors would have a subvector of dimension 2 reserved for computations pertaining to each of the counter. That is, $\boldsymbol{x}_{2j:2j+1}$ will be reserved for the jth counter where $0 \leq j < k$. For any given input symbol s, if $u(s)$ has counter operation of $+m$ at the jth counter, then the value will be such that $\boldsymbol{v}$ will contain $+m$ at index $2j$ and $-m$ at index $2j+1$ upto index $2k$. The last $|\Sigma|$ dimensions will have the value 0 in the value vectors. This can be easily obtained by a linear transformation $V(.)$ over one-hot encodings. The linear transformation $K(.)$ to obtain the key vectors will lead to zero vectors and hence all inputs will have equal attention weights. The linear transformation $V(.)$ to obtain the value vectors $\boldsymbol{v}_i$ will be identity function. Hence the output of the self-attention block along with residual connection will be of the form $\boldsymbol{a}_i = \frac{1}{i}\sum_{t=1}^{i} \boldsymbol{v}_t + \boldsymbol{x}_i$.

The last $|\Sigma|$ dimensions of the vector $\boldsymbol{a}_i$ will have one-hot encoding of the input vector at i-th step. The one-hot encoding of the input can be easily mapped to the one-hot encoding for the corresponding state using a simple FFN. Additionally, this will ensure that, at the i-th step, the output of the self-attention block $\boldsymbol{a}_i$ will have the value $\frac{c_j}{i}$ at indices $2j$, where c_j denotes the counter value of the counter automata representing the language. Similarly, the odd indices $2j+1$ will have the value $-\frac{c_j}{i}$. After applying a simple feed-forward network with ReLU activation, we obtain the output vector $\boldsymbol{z}_i$. It is easy to implement the zero check function with a simple linear layer over the output vector. The network accepts an input sequence w when the values in the output vector corresponding to each counter and state at the n-th correspond to that required for the final state.

□

We next show that n-ary Boolean Expressions can be recognized by Transformers with a similar construction.

Lemma C.2. *Transformers can recognize n-ary Boolean Expressions.*

Proof. Let L_m denote a language of type n-ary Boolean Expressions with m operators defined over the alphabet Σ. Consider a single layer Transformer network with $d_{model} = 2$. Let $s_0, s_1, \ldots, s_n$ be sequence w where $w \in \Sigma^*$. Let s_0 be a special start symbol with embedding $f_e = [+1, -1]$. The embeddings of each input symbol $s \in \Sigma$ are defined as follows, $f_e(s) =$

$[+(r-1), -(r-1)]$ where r denotes the arity of the symbol. The arity of values such as 0 and 1 is taken as 0. Similar to the previous construction, the key values are null and hence attention weights are uniform leading to $\boldsymbol{a}_i = \frac{1}{i}\sum_{t=1}^{i} \boldsymbol{v}_t$. Hence the output of the self-attention block will be $\boldsymbol{a}_i = [\frac{c_j}{i}, -\frac{c_j}{i}]$, where c_j denotes the counter value of the automata representing the language. Essentially, for each operator, the value added to the counter is equal to its arity subtracted by 1. For each value such as 0 and 1, the counter value is decremented by 1. We then apply a simple FFN with ReLU activation to obtain the output vector $\boldsymbol{z}_i = \mathsf{ReLU}(\mathbf{I}\boldsymbol{a}_i)$.

An input sequence w belongs to the language L_m if the second coordinate of the output is zero at every step, that is, $\boldsymbol{z}_{i,2} = 0$ for $0 \leq i \leq n$ and $\boldsymbol{z}_n = \mathbf{0}$. □

Let Reset-Dyck-1 be a language defined over alphabet $\Sigma = \{[,], 1\}$, where 1 denotes a symbol that requires a reset operation. Words in Reset-Dyck-1 have the form $\Sigma^* 1 v$, where the string v belongs to Dyck-1. So essentially, when the machine encounters the reset symbol 1, it has to ignore all the previous inputs, reset the counter to 0 and go to start state.

Lemma C.3. *A single-layer Transformer with only positional masking cannot recognize the language Reset-Dyck-*1.

Proof. The proof is straightforward. Let $s_1, s_2, \ldots, s_n$ be an input sequence w. Let s_r denote the r-th symbol where the reset symbol occurs. It is easy to see that the scoring function $\langle \boldsymbol{q}_n, K(\boldsymbol{v}_r)\rangle$ is independent of the position as well as the inputs before the reset symbol which are relevant for the reset operation. Consider the case where the first half of the input contains a sequence of open and closing brackets such that it does not belong to Dyck-1 and the second half contains a sequence that belongs to Dyck-1. If the reset symbol occurs after the first half of the sequence, then the word belongs to Dyck-1 and if it occurs in the beginning then it does not belong to the language Dyck-1. However, by construction, the output of the model $\boldsymbol{z}_n$ will remain the same regardless of the position of the reset symbol and hence by contradiction, it cannot recognize such a language. □

The above limitation does not exist if there is a two layer network. The scoring function as well as value vector of the reset symbol will be dependent of the inputs that precede it. Hence it is not necessary that a two layer network will not be able to recognize such a language. Indeed, as shown in the main paper, the 2-layer Transformer performs well on Reset-Dyck-1.

Lemma C.4. *Transformers with only positional masking cannot recognize the language* $(aa)^*$.

Proof. Let $s_1, s_2, \ldots, s_n$ be an input sequence w where $w \in a^*$. Since it is a unary language, the input at each step will be the same symbol and hence the embedding as well as query, key and value vectors will be the same. Since all the value vectors are the same, regardless of the attention weights, the output of the self-attention vector $\boldsymbol{a}_i$ will be a constant vector at each timestep. This implies that the output vectors $\boldsymbol{z}_1 = \boldsymbol{z}_2 = \ldots = \boldsymbol{z}_n$. Inductively, it is easy to see that regardless of the number of layers this phenomenon will carry forward and hence the output vector at each timestep will be the same. Thus, the network cannot distinguish output at even steps and odd steps which is necessary to recognize the language $(aa)^*$. □

For parity, in the case where the input consists of only 1s, the problem reduces to recognizing $(11)^*$. Hence it follows from the above result that a network without positional encoding cannot recognize parity even for minimal lengths.

D Experiments

D.1 Discussion on Character Prediction Task

As described in section 5.1, we use character prediction task in our experiments to evaluate the model's ability to recognize a language. In character prediction task the model is only presented with positive samples from a given language and its goal is to predict the next set of valid characters. During inference, the model predicts the next set of legal characters at each step and a prediction is considered to be correct if and only if the model's output at every step is correct. The character prediction task is similar to predicting which of the input characters are allowed to make a transition in a given automaton such that it leads to a non-dead state. If an input character is not among the legal characters, that implies the underlying automaton will transition to a dead state and regardless of the following characters, the input word will never be accepted. When the end-of-sequence symbol is allowed as one of the next set of legal characters, it implies that the underlying automaton is in the final state and the input can be accepted.

Character prediction and classification. If a model can perform character prediction task perfectly, then it can also perform classification in the following way. For an input sequence $s_1, s_2, \ldots, s_n$, the model receives the sequence $s_1, \ldots, s_i$ for $1 \leq i \leq n$ at each step i and model predicts the set of valid characters in the $(i+1)^{th}$ position. If the next character is among the model's predicted set of valid characters at each step i and the end of symbol character is allowed at the n-th step, then the word is accepted and if any character is not within the model's predicted set of valid characters, then the word is rejected. One of the primary reason for the choice of character prediction task is that it is arguably more robust than the standard classification task. The metric for character prediction task is relatively stringent and the model is required to model the underlying mechanism as opposed to just one label in standard classification. Note that the null accuracy (accuracy when all the predictions are replaced by a single label) is 50% if the distribution of labels is balanced (higher otherwise), on the other hand the null accuracy of character prediction task is close to 0. Additionally, in case of classification, depending on how the positive or negative data are generated, the model may also be biased to predict based on some statistical regularites instead of modeling the actual mechanism. In (Weiss et al., 2019), they find that LSTMs trained to recognize Dyck-1 via classification on randomly sampled data do not learn the correct mechanism and fail on adversarially generated samples. On the other hand, Suzgun et al. (2019a) show that LSTMs trained to recognize Dyck-1 via character prediction task learn to perform the correct mechanism required to do the task.

Character prediction and language modelling. The character prediction task has clear connections with Language modelling. If a model can perform language modelling perfectly, then it can perform character prediction task in the following way. For an input sequence $s_1, s_2, \ldots, s_n$, the model receives the sequence $s_1, \ldots, s_i$, for $1 \leq i \leq n$ at each step i and predicts a distribution over the vocabulary. Mapping all the characters for which the model assigns a nonzero probability to 1 and mapping to 0 for all characters that are assigned zero probability will reduce it to character prediction task. However, there are a few issues with using language modelling in our formal language setting. Firstly, as mentioned in (Suzgun et al., 2019a), the task of recognizing a language is not inherently probabilistic. Our goal here is to understand whether a network can or cannot model a particular language. Using language modelling will require us to impose a distribution arbitrarily for the given setting. More importantly, in character prediction task, some signals are explicitly provided. In the case of language modelling, we may just have to rely on the model to pick up those nuanced signals. For instance, in the language $\mathcal{D}_n$, when the input reaches the maximum depth n, in character prediction task it is explicitly provided the target value that a is not allowed anymore whereas in language modelling the model is expected to assign zero probability to a at the maximum depth based on the fact that it will never see a word depth more than n in the training data. This phenomenon has major issues. For instance, when we consider Dyck-1 in practical setting, we can only provide it with limited data which implies there will be a sequence with a maximum finite depth. In this scenario, a language model trained on such data may learn the Dyck-1 language or the language $\mathcal{D}_n$ with that particular maximum depth. This limitation does not exist in the character prediction task where the signal is explicitly provided during training.

D.2 Experimental Details

We use 4 NVIDIA Tesla P100 GPUs each with 16 GB memory to run our experiments, and train and evaluate our models on about 9 counter languages and 18 regular languages. The important details of all of these languages like the training and test sizes and the lengths of the strings considered, have been summarized in Table 6. In all of our experiments, the first bin always has the same length range as the training set, i.e. if the training set contains strings with lengths in range $[2, 50]$, then the strings in the first test bin will also lie in the same range. Width of bin is the difference between upper and lower limits of the string lengths that lie in that bin. All the test bins are taken to be disjoint from each other. Hence, if we have 3 bins with a width of 50 and the training range is $[2, 50]$, then the length ranges for the test bins will be $[2, 50]$, $[52, 100]$ and $[102, 150]$.

Language	Training Data Size	Training Data Length Range	Test Data Size per Bin	Test Data Length Range	Test Data Number of Bins	Test Data Bin Width
Counter Languages						
Shuffle-2	10000	[2, 50]	2000	[2, 150]	3	50
Shuffle-4	10000	[2, 100]	2000	[2, 200]	3	50

$\{0,1,2\}^*02^*$	10000	[2, 50]	2000	[2, 100]	2	50
$\mathcal{D}_2$	10000	[2, 100]	2000	[2, 200]	2	100
$\mathcal{D}_3$	10000	[2, 100]	2000	[2, 200]	2	100
$\mathcal{D}_4$	10000	[2, 100]	2000	[2, 200]	2	100
$\mathcal{D}_{12}$	10000	[2, 100]	2000	[2, 200]	2	100
Parity	10000	[2,50]	2000	[2, 100]	2	50
$(aa)^*$	250	[2, 500]	50	[2, 600]	2	100
$(aaaa)^*$	125	[4, 500]	25	[4, 600]	2	100
$(abab)^*$	125	[4, 500]	25	[4, 600]	2	100
Tomita 3	10000	[2, 50]	2000	[2, 100]	2	50
Tomita 5	10000	[2, 50]	2000	[2, 100]	2	50
Tomita 6	10000	[2, 50]	2000	[2, 100]	2	50

Table 6: Statistics of different datasets used in the experiments. Note that the width of the first bin is always defined by the training set (see D), and hence can be different from the widths of other bins reported in Bin Width column. As an example, for $(aa)^*$, the first bin will have a length range of [2, 500] and [502, 600] for the second bin.

For each of these languages, we extensively tune on a bunch of different architectural and optimization related hyperparameters. Table 7 lists the hyperparameters considered in our experiments and the bounds for each of them. This corresponds to about 162 different configurations for tuning transformers (for a hidden size of 3, 4 heads are not allowed) and 40 configurations for LSTMs . Over all the languages and hyperparameters there were a minimum of 117 parameters and a maximum of 17,888 parameters for the models that we considered. We use a grid search procedure to tune the hyperparameters. While reporting the accuracy scores for a given language, we compute the mean of the top 5 accuracies, corresponding to all hyperparameter configurations. For some experiments we had to consider the hyperparameters lying outside of the values specified in Table 7. As an instance, we considered 4 layer transformers in the cases where the training accuracies obtained were low for single and two layered networks and reported the results accordingly.

For training our models we used RMSProp optimizer with the smoothing constant $\alpha = 0.99$. In our initial few experiments we also tried Stochastic Gradient Descent with learning rate decay and Adam Optimizer, but decided to go ahead with RMSProp as it outperformed SGD in majority of experiments and gave similar performance as Adam but needed fewer hyperparameters. For each language we train models corresponding to each language for 100 epochs and a batch size of 32. In case of convergence, i.e. perfect accuracies for all the bins, before completion of all epochs, we stop the training process early. The results of our experiments on counter and regular languages are provided in Tables 8 and 9 respectively.

Hyperparameter	**Bounds**
Hidden Size	[3, 32]
Heads	[1, 4]
Number of Layers	[1, 2] — [1, 4]
Learning Rate	[1e-2, 1e-3]
Position Encoding Scheme	[Absolute, Relative, Positional Masking]

Table 7: Different hyperparameters and the values considered for each of them. Note that certain parameters like Heads and Position Encoding Scheme are only relevant for Transformer based models and not for LSTMs. We considered upto 4 layers transformers in the cases where the training accuracies obtained were low for single and two layered networks and reported the results accordingly.

E Plots

We visualize different aspects of the trained models to understand how they achieve a particular task and if the learned behaviour resembles our constructions. Figure 3 shows the value vectors corresponding to the trained models on Shuffle-2 and Boolean-3 Language. We also visualize the attention weights corresponding to these two models in Figure 4. Similar to the self-attention output visualizations for Shuffle-2 and Boolean-3 in the main paper, we visualize these values for a model trained on Shuffle-4 in Figure 5 and again, find close correlations with the depth to length ratios of different types of brackets in the language. Finally, in Figure 6, we visualize a component of the learned position embeddings vectors and found a similar behaviour to $\cos(n\pi)$ agreeing with our hypothesis.

Figure 3: Plot of value vectors of transformer based models trained on Shuffle-2 3a and Boolean-3 language 3b. The Shuffle-2 model had a hidden size of 8 and boolean-3 model had a hidden size of 3. The x-axis corresponds to different components of the value vectors for both models. Shuffle-2 language consisted of square and round brackets, while for Boolean-3 we considered 3 operators namely: $\sim$ a unary operator, $+$ a binary operator and finally, $>$ which is a ternary operator..

Language	Model	Bin-1 Accuracy [1, 50]↑	Bin-2 Accuracy [51, 100]↑	Bin-3 Accuracy [101, 150]↑

Abstract

Knowledge graphs (KGs) can vary greatly from one domain to another. Therefore supervised approaches to both graph-to-text generation and text-to-graph knowledge extraction (semantic parsing) will always suffer from a shortage of domain-specific parallel graph-text data; at the same time, adapting a model trained on a different domain is often impossible due to little or no overlap in entities and relations. This situation calls for an approach that (1) does not need large amounts of annotated data and thus (2) does not need to rely on domain adaptation techniques to work well in different domains. To this end, we present the *first approach to unsupervised text generation from KGs* and show simultaneously how it can be used for *unsupervised semantic parsing*. We evaluate our approach on WebNLG v2.1 and a new benchmark leveraging scene graphs from Visual Genome. Our system outperforms strong baselines for both text↔graph conversion tasks without any manual adaptation from one dataset to the other. In additional experiments, we investigate the impact of using different unsupervised objectives.[1]

1 Introduction

Knowledge graphs (KGs) are a general-purpose approach for storing information in a structured, machine-accessible way (Van Harmelen et al., 2008). They are used in various fields and domains to model knowledge about topics as different as lexical semantics (Fellbaum, 2005; van Assem et al., 2006), common sense (Speer et al., 2017; Sap et al., 2019), biomedical research (Wishart et al., 2018) and visual relations in images (Lu et al., 2016).

This ubiquity of KGs necessitates interpretability because diverse users – both experts and non-experts – work with them. Even though, in principle, a KG is human-interpretable, non-experts may have difficulty making sense of it. Thus, there is a need for methods, such as automatic natural language generation (“graph→text”), that support them.

Semantic parsing, i.e., the conversion of a text to a formal meaning representation, such as a KG, (“text→graph”) is equally important because it makes information that only exists in text form accessible to machines, thus assisting knowledge base engineers in KG creation and completion.

As KGs are so flexible in expressing various kinds of knowledge, separately created KGs vary a lot. This unavoidably leads to a shortage of training data for both graph↔text tasks. We therefore propose an unsupervised model that (1) easily adapts to new KG domains and (2) only requires unlabeled (i.e., non-parallel) texts and graphs from the target domain, together with a few fact extraction heuristics, but no manual annotation.

To show the effectiveness of our approach, we conduct experiments on the latest release (v2.1) of the WebNLG corpus (Shimorina and Gardent, 2018) and on a new benchmark we derive from *Visual Genome* (Krishna et al., 2016). While both of these datasets contain enough annotations to train supervised models, we evaluate our unsupervised approach by ignoring these annotations. The datasets are particularly well-suited for our evaluation as both graphs and texts are completely human-generated. Thus for both our tasks, models are evaluated with natural, i.e., human-generated targets.

Concretely, we make the following contributions: (1) We present the first unsupervised non-template approach to text generation from KGs (graph→text). (2) We jointly develop a new unsupervised approach to semantic parsing that automatically adjusts to a target KG schema (text→graph). (3) In contrast to prior unsupervised graph→text and text→graph work, our model does not re-

quire manual adaptation to new domains or graph schemas. (4) We provide a thorough analysis of the impact of different unsupervised objectives, especially the ones we newly introduce for text↔graph conversion. (5) We create a new large-scale dataset for text↔graph transformation tasks in the visual domain.

2 Related Work

graph → text. Our work is the first attempt at fully unsupervised text generation from KGs. In this respect it is only comparable to traditional rule- or template-based approaches (Kukich, 1983; McRoy et al., 2000). However, in contrast to these approaches, which need to be manually adapted to new domains and KG schemas, our method is generally applicable to all kinds of data without modification.

There is a large body of literature about supervised text generation from structured data, notably about the creation of sports game summaries from statistical records (Robin, 1995; Tanaka-Ishii et al., 1998). Recent efforts make use of neural encoder-decoder mechanisms (Wiseman et al., 2017; Puduppully et al., 2019). Although text creation from relational databases is related and our unsupervised method is, in principle, also applicable to this domain, in our work we specifically address text creation from graph-like structures such as KGs.

One recent work on supervised text creation from KGs is (Bhowmik and de Melo, 2018). They generate a short description of an entity, i.e., a single KG node, based on a set of facts about the entity. We, however, generate a description of the whole KG, which involves multiple entities and their relations. Koncel-Kedziorski et al. (2019) generate texts from whole KGs. They, however, do not evaluate on human-generated KGs but automatically generated ones from the scientific information extraction tool SciIE (Luan et al., 2018). Their supervised model is based on message passing through the topology of the incidence graph of the KG input. Such graph neural networks (Kipf and Welling, 2017; Veličković et al., 2018) have been widely adopted in supervised graph-to-text tasks (Beck et al., 2018; Damonte and Cohen, 2019; Ribeiro et al., 2019, 2020).

Even though Marcheggiani and Perez-Beltrachini (2018) report that graph neural networks can make better use of graph input than RNNs for supervised learning, for our unsupervised approach we follow the line of research that uses RNN-based sequence-to-sequence models (Cho et al., 2014; Sutskever et al., 2014) operating on serialized triple sets (Gardent et al., 2017b; Trisedya et al., 2018; Gehrmann et al., 2018; Castro Ferreira et al., 2019; Fan et al., 2019). We make this choice because learning a common semantic space for both texts and graphs by means of a shared encoder and decoder is a central component of our model. It is a nontrivial, separate research question whether and how encoder-decoder parameters can effectively be shared for models working on both sequential and non-sequential data. We thus leave the adaptation of our approach to graph neural networks for future work.

text → graph. Converting a text into a KG representation, our method is an alternative to prior work on open information extraction (Niklaus et al., 2018) with the advantage that the extractions, though trained without labeled data, automatically adjust to the KGs used for training. It is therefore also related to relation extraction in the unsupervised (Yao et al., 2011; Marcheggiani and Titov, 2016; Simon et al., 2019) and distantly supervised setting (Riedel et al., 2010; Parikh et al., 2015). However, these systems merely predict a single relation between two given entities in a single sentence, while we translate a whole text into a KG with potentially multiple facts.

Our text→graph task is therefore most closely related to semantic parsing (Kamath and Das, 2019), but we convert statements into KG facts whereas semantic parsing typically converts a question into a KG or database query. Poon and Domingos (2009) proposed the first unsupervised approach. They, however, still need an additional KG alignment step, i.e., are not able to directly adjust to the target KG. Other approaches overcome this limitation but only in exchange for the inflexibility of manually created domain-specific lexicons (Popescu et al., 2004; Goldwasser et al., 2011). Poon (2013)'s approach is more flexible but still relies on preprocessing by a dependency parser, which generally means that language-specific annotations to train such a parser are needed. Our approach is end-to-end, i.e., does not need any language-specific preprocessing during inference and only depends on a POS tagger used in the rule-based text→graph system to bootstrap training.

Unsupervised sequence generation. Our unsupervised training regime for both text↔graph tasks is inspired by (Lample et al., 2018b). They used self-supervised pretraining and backtranslation for unsupervised translation from one language to another. We adapt these principles and their noise model to our tasks, and introduce two new noise functions specific to text↔graph conversion.

3 Preliminaries

3.1 Data structure

We formalize a KG as a labeled directed multigraph (V, E, s, t, l) where entities are nodes V and edges E represent relations between entities. The lookup functions $s, t : E \to V$ assign to each edge its source and target node. The labeling function l assigns labels to nodes and edges where node labels are entity names and edge labels come from a predefined set $\mathcal{R}$ of relation types.

An equivalent representation of a KG is the set of its facts. A fact is a triple consisting of an edge's source node (the subject), the edge itself (the predicate), and its target node (the object). So the set of facts $\mathcal{F}$ of a KG can be obtained from its edges:

$$\mathcal{F} := \{ (s(e), e, t(e)) \mid e \in E \} .$$

Applying l to all triple elements and writing out $\mathcal{F}$ in an arbitrary order generates a serialization that makes the KG accessible to sequence models otherwise used only for text. This has the advantage that we can train a sequence encoder to embed text and KGs in the same semantic space. Specifically, we serialize a KG by writing out its facts separated with end-of-fact symbols (`EOF`) and elements of each fact with special `SEP` symbols. We thus define our task as a sequence-to-sequence (seq2seq) task.

3.2 Scene Graphs

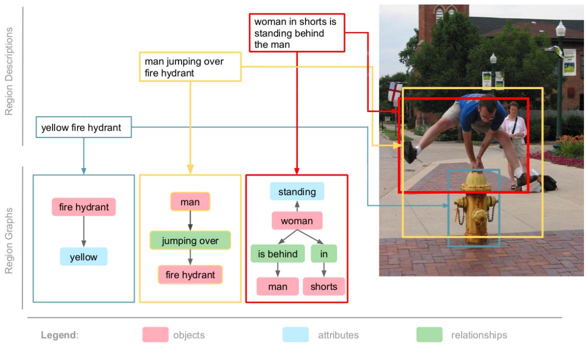

Figure 1: Region graphs and textual region descriptions in Visual Genome (VG). Image regions serve as common reference for text and graph creation but are disregarded in our work. We solely focus on the pairs of corresponding texts and graphs. Illustration adapted from (Krishna et al., 2016).

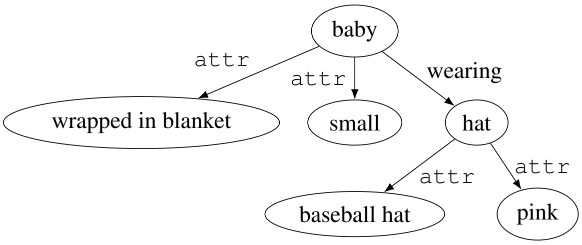

Figure 2: Example graph in our new VG benchmark.

The Visual Genome (VG) repository is a large collection of images with associated manually annotated **scene graphs**; see Fig. 1. A scene graph formally describes image objects with their attributes, e.g., (hydrant, `attr`, yellow), and their relations to other image objects, e.g., (woman, in, shorts). Each scene graph is organized into smaller subgraphs, known as **region graphs**, representing a subpart of a more complex larger picture that is interesting on its own. Each region graph is associated with an English text, the **region description**. Texts and graphs were not automatically produced from each other, but were collected from crowdworkers who were presented an image region and then generated text and graph. So although the graphs were not specifically designed to closely resemble the texts, they describe the same image region. This semantic correspondence makes scene graph↔text conversion an interesting and challenging problem because text and graph are not simple translations of each other.

Scene graphs are formalized in the same way as other KGs: V here contains image objects and their attributes, and $\mathcal{R}$ contains all types of visual relationships and the special label `attr` for edges between attribute and non-attribute nodes. Fig. 2 shows an example.

VG scene graphs have been used before for traditional KG tasks, such as KG completion (Wan et al., 2018), but we are the first to use them for a text↔graph conversion dataset.

4 Approaches

4.1 Rule-based systems

We propose a rule-based system as unsupervised baseline for each of the text↔graph tasks. Note that they both assume that the texts are in English.

R$^{\text{graph}\to\text{text}}$. From a KG serialization, we remove

noise function	behavior
`swap`	applies a random permutation σ of words or facts with $\forall i \in \{1, \ldots, n\}, \lvert\sigma(i) - i\rvert \leq k$; $k = 3$ for text, $k = +\infty$ for knowledge graphs.
`drop`	removes each fact/word with a probability of p_{drop}.
`blank`	replaces each fact/word with a probability of p_{blank} by a special symbol `blanked`.
`repeat`	inserts repetitions with a probability of p_{repeat} in a sequence of facts/words.
`rule`	generates a noisy translation by applying $\mathrm{R}^{\text{graph}\to\text{text}}$ to a graph or $\mathrm{R}^{\text{text}\to\text{graph}}$ to a text.

Table 1: Noise functions and their behavior on graphs and texts.

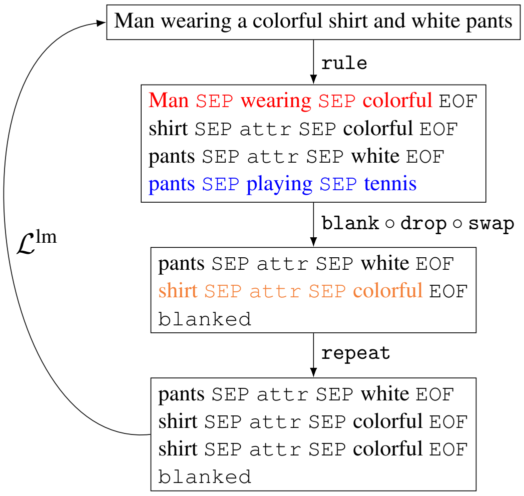

Figure 3: Example noisy training instance for the graph→text task in the composed noise setting. The fact highlighted in red is removed by `drop`, the one in blue is replaced with `blanked` by `blank`, the one in orange is repeated by `repeat`.

`SEP` symbols and replace `EOF` symbols by the word *and*. The special label `attr` is mapped to *is*. This corresponds to a template-based enumeration of all KG facts. See Table 5 for an example.

$\mathbf{R}^{\textbf{text}\to\textbf{graph}}$. After preprocessing a text with NLTK's default POS tagger (Loper and Bird, 2004) and removing stop words, we apply two simple heuristics to extract facts: (1) Each verb becomes a predicate; *is* creates facts with predicate `attr`. The content words directly before and after such a predicate word become subject and object. (2) Adjectives a form attributes, i.e., build facts of the form $(X, \texttt{attr}, a)$ where X is filled with the first noun after a. These heuristics are similar in nature to a rudimentary parser. See Table 8 for an example.

4.2 Neural seq2seq systems

Our main system is a neural seq2seq architecture. We equip the standard encoder-decoder model with attention (Bahdanau et al., 2014) and copy mechanism (Gu et al., 2016). Allowing the model to directly copy from the source to the target side is beneficial in data to text generation (Wiseman et al., 2017; Puduppully et al., 2019). The encoder (resp. decoder) is a bidirectional (resp. unidirectional) LSTM (Hochreiter and Schmidhuber, 1997). Dropout (Hinton et al., 2012) is applied at the input of both encoder and decoder (Britz et al., 2017). We combine this model with the following concepts:

Multi-task model. In unsupervised machine translation, systems are trained for both translation directions (Lample et al., 2018b). In the same way, we train our system for both conversion tasks text↔graph, sharing encoder and decoder. To tell the decoder which type of output should be produced (text or graph), we initialize the cell state of the decoder with an embedding of the desired output type. The hidden state of the decoder is initialized with the last state of the encoder as usual.

Noisy source samples. Lample et al. (2018a) introduced denoising auto-encoding as pretraining and auxiliary task to train the decoder to produce well-formed output and make the encoder robust to noisy input. The training examples for this task consist of a noisy version of a sentence as source and the original sentence as target. We adapt this idea and propose the following noise functions for the domains of graphs and texts: `swap`, `drop`, `blank`, `repeat`, `rule`. Table 1 describes their behavior. `swap`, `drop` and `blank` are adapted from (Lample et al., 2018a) with facts in graphs taking the role of words in text. As order should be irrelevant in a set of facts, we drop the locality constraint in the `swap` permutation for graphs by setting $k = +\infty$.

Denoising samples generated by `repeat` requires the model to learn to remove redundant information in a set of facts. In the case of text, `repeat` mimics a behavior often observed with insufficiently trained neural models, i.e., repeating words considered important.

Unlike the other noise functions, `rule` does not “perturb” its input, but rather noisily backtranslates it. We will see in Section 7 that bootstrapping with these noisy translations is essential.

We consider two fundamentally different noise injection regimes: (1) The **composed noise** setting is an adaptation of Lample et al. (2018a)'s noise model (`blank`$\circ$`drop`$\circ$`swap`) where our newly introduced noise functions `rule` and `repeat` are added to the start and end of the pipeline, i.e., all data samples are treated equally with the same noise function $C_{\text{comp}} := \texttt{repeat}\circ\texttt{blank}\circ\texttt{drop}\circ\texttt{swap}\circ\texttt{rule}$. Figure 3 shows an example. (2) In the **sampled noise** setting, we do not use all noise functions at once but sample a single one per data instance.

4.3 Training regimes

We denote the sets of graphs and corresponding texts by $\mathcal{G}$ and $\mathcal{T}$. The set of available supervised examples $(x, y) \in \mathcal{G} \times \mathcal{T}$ is called $\mathcal{S} \subset \mathcal{G} \times \mathcal{T}$. P_g and P_t are probabilistic models that generate, conditioned on any input, a graph (g) or a text (t).

Unsupervised training. We first obtain a language model for both graphs and text by training one epoch with the denoising auto-encoder objective:

$$\mathcal{L}^{\text{denoise}} = \underset{x\sim\mathcal{G}}{\mathbb{E}}[-\log P_g(x|C(x))] + \underset{y\sim\mathcal{T}}{\mathbb{E}}[-\log P_t(y|C(y))]$$

where $C \in \{C_{\text{comp}}\}$ for composed noise and $C \in \{\texttt{swap}, \texttt{blank}, \texttt{drop}, \texttt{repeat}, \texttt{rule}\}$ for sampled noise. In this pretraining epoch only, we use all possible noise functions individually on all available data. As sampled noise incorporates five different noise functions and composed noise only one, this results in five times more pretraining samples for sampled noise than for composed noise.

In subsequent epochs, we additionally consider $\mathcal{L}^{\text{back}}$ as training signal:

$$\mathcal{L}^{\text{back}} = \underset{x\sim\mathcal{G}}{\mathbb{E}}[-\log P_g(x|z^*(x))] + \underset{y\sim\mathcal{T}}{\mathbb{E}}[-\log P_t(y|w^*(y))]$$

$$z^*(x) = \arg\max_z P_t(z|x)$$

$$w^*(y) = \arg\max_w P_g(w|y)$$

This means that, in each iteration, we apply the current model to backtranslate a text (graph) to obtain a potentially imperfect graph (text) that we can use as noisy source with the clean original input being the target. This gives us a pseudo-parallel training instance for the next iteration – recall that we address unsupervised generation, i.e., without access to parallel data.

The total loss in these epochs is $\mathcal{L}^{\text{back}} + \mathcal{L}^{\text{denoise}}$, where now $\mathcal{L}^{\text{denoise}}$ only samples one possible type of noise independently for each data instance.

Supervised training. Our intended application is an unsupervised scenario. For our two datasets, however, we have labeled data (i.e., a "parallel corpus") and so can also compare our model to its supervised variant. Although supervised performance is generally better, it serves as a reference point and gives us an idea of the impact of supervision as opposed to factors like model architecture and hyperparameters. The supervised loss is simply defined as follows:

$$\mathcal{L}^{\text{sup}} = \underset{(x,y)\sim\mathcal{S}}{\mathbb{E}}[-\log P_t(y|x) - \log P_g(x|y)]$$

	VG	VG_{ball}	WebNLG
train split size	2,412,253	151,790	34,338
val split size	323,478	21,541	4,313
test split size	324,664	20,569	4,222
#relation types	36,506	5,167	373

avg % graph tokens in text	52.3	54.7	75.6

Table 2: Statistics of WebNLG v2.1 and our newly created benchmark VG; VG_{ball} is a subset of VG representing images from ball sports events. Data split sizes are given as number of graph-text pairs.

5 Experiments

5.1 Data

For our experiments, we randomly split the VG images 80/10/10 into train/val/test. We then remove all graphs from train that also occur in one of the images in val or test. Finally, we unify graph serialization duplicates with different texts to single instances with multiple references for graph→text and proceed analogously with text duplicates for text→graph. For WebNLG v2.1, we use the data splits as provided. Following (Gardent et al., 2017a), we resolve the camel case of relation names and remove underscores from entity names in a preprocessing step. For both datasets, the order of facts in graph serializations corresponds to the order of triples in the original dataset. Because of VG's enormous size and limited computation power, we additionally create a closed-domain ball

graph → text	Visual Genome						WebNLG					
	BLEU		METEOR		CHRF++		BLEU		METEOR		CHRF++	
	val	test	val	test	val	test	val	test	val	test	val	test
Rgraph→text	5.9	5.9	28.2	28.1	43.4	43.3	18.3	18.3	33.5	33.6	55.0	55.2

Ours w/ composed noise	**23.2**	**23.2**	**33.0**	**32.9**	**53.7**	**53.6**	30.8	30.5	30.2	30.0	53.1	52.8
Ours *supervised*	26.5	26.4	32.3	32.2	53.7	53.6	35.1	34.4	39.6	39.5	64.1	64.0

Table 3: Results for unsupervised and supervised text generation. Note that training a supervised model on millions of labeled samples is usually not an option. Best unsupervised models are identified by best BLEU on $\mathcal{V}_{100}$. BLEU and METEOR are computed with scripts from (Lin et al., 2018); the CHRF++ script is from (Popović, 2017b).

sports subset of VG, called VG$_{\text{ball}}$, which we can use to quickly conduct additional experiments (see Section 7). We identify all images where at least one region graph contains at least one fact that mentions an object ending with *ball* and take all regions from them (keeping data splits the same). In contrast to alternatives like random subsampling, we consider this domain-focused construction more realistic.

Table 2 shows relevant statistics for all datasets. While VG and WebNLG have similar statistics, VG is around 70 times larger than WebNLG, which makes it an interesting benchmark for future research, both supervised and unsupervised. Apart from size, there are two important differences: (1) The VG graph schema has been freely defined by crowd workers and thus features a large variety of different relations. (2) The percentage of graph tokens occurring in the text, a measure important for the text→graph task, is lower for VG than for WebNLG. Thus, VG graphs contain more details than their corresponding texts, which is a characteristic feature of the domain of image captions: they mainly describe the salient image parts.

5.2 Training details

We train all models with the Adam optimizer (Kingma and Ba, 2015) for maximally 30 epochs. We stop supervised models early when $\mathcal{L}^{\text{sup}}$ does not decrease on val for 10 epochs. Unsupervised models are stopped after 5 iterations on VG because of its big size and limited computational resources. All hyperparameters and more details are described in Appendices A and B. Our implementation is based on AllenNLP (Gardner et al., 2017).

In unsupervised training, input graphs and texts are the same as in supervised training – only the gold target sides are ignored. While it is an artificial setup to split paired data and treat them as unpaired, this not only makes the supervised and unsupervised settings more directly comparable, but also ensures that the text data resemble the evaluation texts in style and domain. For the purpose of experiments on a benchmark, this seems appropriate to us. For a concrete use case, it would be an important first step to find adequate texts that showcase the desired language style and that are about a similar topic as the KGs that are to be textualized. As KGs are rarely the only means of storing information, e.g., in an industrial context, such texts should not be hard to come by in practice.

Table 4: BLEU scores on VG for our unsupervised models evaluated for graph→text at different iterations. $\mathcal{U}$ is calculated on all unlabeled data used for training. $\mathcal{V}_{100}$ is a 100-size random sample from val. All results are computed with scripts from (Lin et al., 2018).

6 Results and Discussion

6.1 Text generation from graphs

Model selection. Table 4 shows how performance of our unsupervised model changes at every back-translation iteration, measured in BLEU (Papineni et al., 2002), a common metric for natural language generation. For model selection, we adopt the two methods proposed by Lample et al. (2018b), i.e., a small validation set (we take a 100-size random subset of val, called $\mathcal{V}_{100}$) and a fully unsupervised criterion ($\mathcal{U}$) where BLEU compares an unlabeled sample with its back-and-forth translation. We confirm their finding that $\mathcal{U}$ is not reliable for neural

Ours w/ composed noise	**22.1**	**21.7**	32.5	33.1
Ours *supervised*	23.5	23.0	52.8	52.8

Table 7: F1 scores of facts extracted by our unsupervised semantic parsing (text→graph) systems and our model trained with supervision.

text generation models whereas $\mathcal{V}_{100}$ correlates better with performance on the larger test sets. We use $\mathcal{V}_{100}$ for model selection in the rest of this paper.

Quantitative evaluation. Table 3 shows BLEU, METEOR (Banerjee and Lavie, 2005) and CHRF++ (Popović, 2017a) for our unsupervised models and the rule baseline $\text{R}^{\text{graph}\rightarrow\text{text}}$, which is in many cases, i.e., if parallel graph-text data are scarce, the only alternative.

First, we observe that $\text{R}^{\text{graph}\rightarrow\text{text}}$ performs much better on WebNLG than VG, indicating that our new benchmark poses a tougher challenge. Second, our unsupervised models consistently outperform this baseline on all metrics and on both datasets, showing that our method produces textual descriptions much closer to human-generated ones. Third, noise composition, the general default in unsupervised machine translation, does not always perform better than noise sampling. Thus, it is worthwhile to try different noise settings for new tasks or datasets.

Surprisingly, supervised and unsupervised models perform nearly on par. Real supervision does not seem to give much better guidance in training than our unsupervised regime, as measured by our three metrics on two different datasets. Some metric-dataset combinations even favor one of the unsupervised models. Our qualitative observations provide a possible explanation for that.

Qualitative observations. Taking a look at example generations (Table 5), we also see qualitatively how much easier it is to grasp the content of our natural language summarization than reading through a simple enumeration of KG facts. We find that the unsupervised model (c) seems to output the KG information in a more complete manner than its supervised counterpart (d). The supervision probably introduces a bias present in the training data that image captions focus on salient image parts and therefore the supervised model is encouraged to omit information. As it never sees a corresponding text-graph pair together, the unsupervised model cannot draw such a conclusion.

6.2 Graph extraction from texts

We evaluate semantic parsing (text→graph) performance by computing the micro-averaged F1 score of extracted facts. If there are multiple reference graphs (cf. Section 5.1), an extracted fact is considered correct if it occurs in at least one reference graph. For the ground truth number of facts to be extracted from a given text, we take the maximum number of facts of all its reference graphs.

Model selection. Table 6 shows that (compared to text generation quality) $\mathcal{U}$ is more reliable for text→graph performance. For sampled noise, it correctly identifies the best iteration, whereas for composed noise it chooses second best. In both noise settings, $\mathcal{V}_{100}$ perfectly chooses the best model.

Quantitative observations. Table 7 shows a comparison of our unsupervised models with two rule-based systems, our $\text{R}^{\text{text}\rightarrow\text{graph}}$ and the highly domain-specific Stanford Scene Graph Parser (SSGP) by Schuster et al. (2015).

We choose these two baselines to adequately represent the state of the art in the unsupervised setting. Recall from Section 2 that the only previous unsupervised works either cannot adapt to a target graph schema (open information extraction), which means their precision and recall of retrieved facts is always 0, or have been created for SQL query

Input sentence	Man wearing a colorful shirt and white pants playing tennis
Reference (RG)	(shirt, `attr`, colorful) (pants, `attr`, white) (man, wearing, shirt) (man, wearing, pants)
$R^{\text{text}\rightarrow\text{graph}}$	🟥 (Man, wearing, colorful) 🟩 (shirt, `attr`, colorful) 🟩 (pants, `attr`, white) 🟥 (pants, playing, tennis)
Stanford Scene Graph Parser	🟥 (shirt, play, tennis) , 🟥 (pants, play, tennis) , 🟩 (shirt, `attr`, colorful) , 🟩 (pants, `attr`, white)
Unsuperv. model w/ composed noise	🟥 (pants, `attr`, colorful) 🟩 (pants, `attr`, white) 🟩 (man, wearing, shirt) 🟨 (man, playing, tennis)
Supervised model	🟩 (shirt, `attr`, colorful) 🟩 (pants, `attr`, white) 🟩 (Man, wearing, shirt) 🟩 (Man, wearing, pants)

Table 8: Example fact extractions and evaluation wrt reference graph (RG). Green: correct ($\in$ RG). Yellow: acceptable fact, but $\notin$ RG. Red: incorrect ($\notin$ RG).

generation from natural language questions (Poon, 2013), a related task that is yet so different that an adaptation to triple set generation from natural language statements is nontrivial. While rule-based systems do not automatically adapt to new graph schemas either, $R^{\text{text}\rightarrow\text{graph}}$ and SSGP were at least designed with the scene graph domain in mind.

Although SSGP was not optimized to match the scene graphs from VG, its rules were still engineered to cover typical idiosyncrasies of textual image descriptions and corresponding scene graphs. Besides, we evaluate it with lemmatized reference graphs because it only predicts lemmata as predicates. All this gives it a major advantage over the other presented systems but it is nonetheless outperformed by our best unsupervised model – even on VG. This shows that our automatic method can beat even hand-crafted domain-specific rules.

Both $R^{\text{text}\rightarrow\text{graph}}$ and SSGP fail to predict any fact from WebNLG. The DBpedia facts from WebNLG often contain multi-token entities while $R^{\text{text}\rightarrow\text{graph}}$ only picks single tokens from the text. Likewise, SSGP models multi-token entities as two nodes with an `attr` relation. This illustrates the importance of automatic adaptation to the target KG. Although our system uses $R^{\text{text}\rightarrow\text{graph}}$ during unsupervised training and is similarly not adapted to the WebNLG dataset, it performs significantly better.

Table 9: Ablation study of our models on val of VG_{ball} and WebNLG v2.1. Models selected based on $\mathcal{V}_{100}$. Bold: best performance per column and block. Underlined: worse than corresponding rule-based system.

Supervision helps more on WebNLG than on VG. The poor performance of $R^{\text{text}\rightarrow\text{graph}}$ on WebNLG is probably a handicap for unsupervised learning.

Qualitative observations. Table 8 shows example facts extracted by different systems. $R^{\text{text}\rightarrow\text{graph}}$ and SSGP are both fooled by the proximity of the noun *pants* and the verb *play* whereas our model correctly identifies *man* as the subject. It, however, fails to identify *shirt* as an entity and associates the two attributes *colorful* and *white* to *pants*. Only the supervised model produces perfect output.

6.3 Noise and translation completeness

Sampled noise only creates training pairs that either are complete rule-based translations or reconstruction pairs from a noisy graph to a complete graph or a noisy text to a complete text. In contrast, composed noise can introduce translations from a noisy text to a complete graph or vice versa and thus encourage a system to omit input information (cf. Fig. 3). This difference is mirrored nicely in the results of our unsupervised systems for both tasks: composed noise performs better on VG where omitted information in an image caption is common and sampled noise works better on WebNLG where the texts describe their graphs completely.

7 Noise Ablation Study

Our unsupervised objectives are defined by different types of noise models. Hence, we examine their impact in a noise ablation study. Table 9 shows results for text→graph and graph→text on the validation splits of $\mathrm{VG}_{\mathrm{ball}}$ and WebNLG.

For both datasets and tasks, introducing variation via noise functions is crucial for the success of unsupervised learning. The model without noise (i.e., $C(x) = x$) fails completely as do all models lacking `rule` as type of noise, the only exception being the only-`drop` system on WebNLG. Even though `drop` seems to work equally well in this one case, the simple translations delivered by our rule-based systems clearly provide the most useful information for the unsupervised models – notably in combination with the other noise functions: removing `rule` and keeping all other types of noise (cf. "sample all but `rule`" and "comp. all but `rule`") performs much worse than leaving out `drop`.

We hypothesize that our two rule systems provide two important pieces of information: (1) $\mathrm{R}^{\mathrm{graph}\to\mathrm{text}}$ helps distinguish data format tokens from text tokens and (2) $\mathrm{R}^{\mathrm{text}\to\mathrm{graph}}$ helps find probable candidate words in a text that form facts for the data output. As opposed to machine translation, where usually every word in a sentence is translated into a fluent sentence in the target language, identifying words that probably form a fact is more important in data-to/from-text generation.

We moreover observe that our unsupervised models always improve on the rule-based systems even when `rule` is the only type of noise: graph→text BLEU increases from 6.2/18.3 to 19.5/37.4 on $\mathrm{VG}_{\mathrm{ball}}$/WebNLG and text→graph F1 from 14.4/0.0 to 18.5/31.0.

Finally, our ablation study makes clear that there is no best noise model for all datasets and tasks. We therefore recommend experimenting with both different sets of noise functions and noise injection regimes (sampled vs. composed) for new data.

8 Conclusion

We presented the first fully unsupervised approach to text generation from KGs and a novel approach to unsupervised semantic parsing that automatically adapts to a target KG. We showed the effectiveness of our approach on two datasets, WebNLG v2.1 and a new text↔graph benchmark in the visual domain, derived from Visual Genome. We quantitatively and qualitatively analyzed our method on text↔graph conversion. We explored the impact of different unsupervised objectives in an ablation study and found that our newly introduced unsupervised objective using rule-based translations is essential for the success of unsupervised learning.

A Hyperparameters

We use the following settings for all our experiments: learning rate of 10^{-4}, word embeddings of size 300, an LSTM hidden size of 250, a dropout rate of 0.2 and a batch size of 10. Following Lample et al. (2018b), we set $p_{\text{blank}} = p_{\text{repeat}} = 0.2$, $p_{\text{drop}} = 0.1$. For inference, we decode greedily with a maximum number of 40 decoding steps. To speed up unsupervised learning, we increase the batch size to 64 when creating backtranslations.

B Model details

We train with homogeneous batches of one target output type (text or graph) at a time. We use a single GeForce GTX 1080 GPU for training and inference. In this environment, pure training takes approximately 9 ms per instance and inference, which also means backtranslation, takes approximately 21 ms per instance. This means that unsupervised learning approximately needs 30 ms per instance. WebNLG models use 10.6 million parameters, VG models have 60.7 million parameters. The difference is due to a larger vocabulary size of 70,800 for VG compared to 8,171 for WebNLG.

C Results of all iterations on WebNLG

See Table 10 for all intermediate graph→text results of unsupervised training on WebNLG and Table 11 for text→graph. We find similar trends as for VG (Tables 4 and 6) except for $\mathcal{U}$ being a less reliable performance indicator for text→graph in the sampled noise setting.

Abstract

We propose DGST, a novel and simple Dual-Generator network architecture for text Style Transfer. Our model employs two generators only, and does not rely on any discriminators or parallel corpus for training. Both quantitative and qualitative experiments on the Yelp and IMDb datasets show that our model gives competitive performance compared to several strong baselines with more complicated architecture designs.

1 Introduction

Attribute style transfer is a task which seeks to change a stylistic attribute of text, while preserving its attribute-independent information. Sentiment transfer is a typical example of such kind, which focuses on controlling the sentiment polarity of the input text (Shen et al., 2017). Given a review *"the service was very poor"*, a successful sentiment transferrer should covert the negative sentiment of the input to positive (e.g., replacing the phrase *"very poor"* with *"pretty good"*), while keeping all other information unchanged (e.g., the aspect *"service"* should not being changed to *"food"*).

Without supervised signals from parallel data, a transferrer must be supervised in a way to ensure that the generated texts belongs to a certain style category (i.e., transfer intensity). There is a growing body of studies to intensify the target style by means of adversarial training (Fu et al., 2018), variational autoencoder (John et al., 2019; Li et al., 2019; Fang et al., 2019), generative adversarial nets (Shen et al., 2017; Zhao et al., 2018; Yang et al., 2018), or subspace matrix projection (Li et al., 2020)

Furthermore, in order to boost the preservation of non-attribute information during style transformation, some works explicitly focus on modifying sentiment words, which is so-called the "pivot word" (Li et al., 2018; Wu et al., 2019). There are also works which add extra components for constraining the content from being changed too much. These include models like autoencoder (Lample et al., 2019; Dai et al., 2019), part-of-speech preservation, and the content conditional language model (Tian et al., 2018). In order to achieve high-quality style transfer, existing works normally resort to adding additional inner or outer structures such as additional adversarial networks or data preprocessing steps (e.g. generating pseudo-parallel corpora). This inevitably increases the complexity of the model and raises the bar of training data requirement.

In this paper, we propose a novel and simple model architecture for text style transfer, which employs two generators only. In contrast to some of the dominant approaches to style transfer such as CycleGAN (Zhu et al., 2017), our model does not employ any discriminators and yet can be trained without requiring any parallel corpus. We achieve this by developing a novel sentence noisification approach called *neighbourhood sampling*, which can introduce noise to each input sentence dynamically. The nosified sentences are then used to train our style transferrers in the way similar to the training of denoising autoencoders (Vincent et al., 2008). Both quantitative and qualitative evaluation on the Yelp and IMDb benchmark datasets show that DGST gives competitive performance compared to several strong baselines which have more complicated model design. The code of DGST is available at: `https://xiao.ac/proj/dgst`.

2 Methodology

Suppose we have two non-parallel corpora X and Y with style S_x and S_y, the goal is training two transferrers, each of which can (i) transfer a sen-

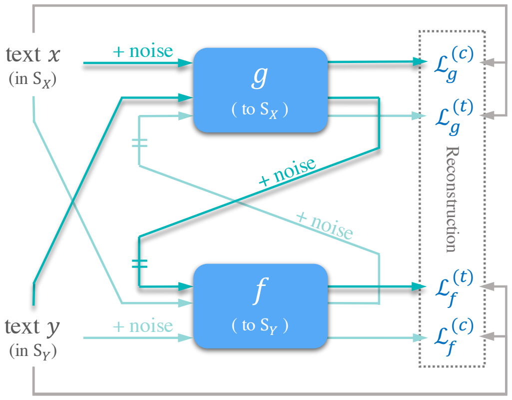

Figure 1: The general architecture of DGST, in which "=" means no back-propagation of gradients.

tence from one style (either S_x and S_y) to another (i.e., transfer intensity); and (ii) preserve the style-independent context during the transformation (i.e., preservation). Specifically, we denote the two transferrers f and g. $f : \mathcal{X} \rightarrow \mathcal{Y}$ transfers a sentence $x \in \mathcal{X}$ with style S_x to y^* with style S_y. Likewise, $g : \mathcal{Y} \rightarrow \mathcal{X}$ transfers a sentence $y \in \mathcal{Y}$ with style S_y to x^* with S_x. To obtain good style transfer performance, f and g need to achieve both a high transfer intensity and a high preservation, which can be formulated as follows:

$$\forall x, \forall x' \in \mathcal{X},\ \forall y, \forall y' \in \mathcal{Y}$$

$$y^* = f(x) \in \mathcal{Y}, x^* = g(y) \in \mathcal{X} \tag{1}$$

$$D(y^*||x) \leq D(y'||x), D(x^*||y) \leq D(x'||y) \tag{2}$$

Here $D(x||y)$ is a function that measures the abstract distance between sentences in terms of the minimum edit distance, where the editing operations Φ includes word-level replacement, insertion, and deletion (i.e., the Hamming distance or the Levenshtein distance). On the one hand, Eq. 1 requires the transferred text should fall within the target style spaces (i.e., $\mathcal{X}$ or $\mathcal{Y}$). On the other hand, Eq. 2 constrains the transferred text from changing too much, i.e., to preserve the style-independent information.

Inspired by CycleGAN (Zhu et al., 2017), our model (sketched in Figure 1) is trained by a cyclic process: for each transferrer, a text is transferred to the target style, and then back-transferred to the source style using another transferrer. In order to transfer a sentence to a target style while preserving the style-independent information, we formulate two sets of training objectives: one set ensures that the generated sentences is preserved as much as possible (detailed in §2.1) and the other set is responsible for transferring the input text to the target style (detailed in §2.2).

2.1 Preserving the Content of Input Text

This section discusses our loss function which enforces our transferrers to preserve the style-independent information of the input. A common solution to this problem is to use the reconstruction loss of the autoencoders (Dai et al., 2019), which is also known as the identity loss (Zhu et al., 2017). However, too much emphasis on preserving the content would hinder the style transferring ability of the transferrers. To balance our model's capability in content preservation and transfer intensity, we instead first train our transferrers in the way of training denoising autoencoders (DAE, Vincent et al., 2008), which has been proved to help preserving the style independent content of input text (Shen et al., 2020). More specifically, we train f (or g; we use f as an example in the rest of this section) by feeding it with a noisy sentence $\mathring{y}$ as input, where $\mathring{y}$ is noisified from $y \in \mathcal{Y}$ and f is expected to reconstruct y.

Different from previous works which use DAE in style transfer or MT (Artetxe et al., 2018; Lample et al., 2019), we propose a novel sentence noisification approach, named *neighbourhood sampling*, which introduces noise to each sentence dynamically. For a sentence y, we define $U_\alpha(y, \gamma)$ as a neighbourhood of y, which is a set of sentences consisting of y and all variations of noisified y with the same noise intensity γ (which will be explained later). The size of the neighbourhood $U_\alpha(y, \gamma)$ is determined by the proportion (denoted by m) of tokens in y that are modified using the editing operations in Φ. Here the proportion m is sampled from a Folded Normal Distribution $\mathcal{F}$. We hereby define that the average value of m (i.e., the mean of $\mathcal{F}$) is the noise intensity γ. Formally, m is defined as:

$$m \sim \mathcal{F}(m'; \gamma) = \frac{2}{\pi\gamma} e^{-\frac{m'^2}{\pi\gamma^2}} \tag{3}$$

That said, a neighbourhood $U_\alpha(y, \gamma)$ would be constructed using y and all sentences that are created by modifying $(m \times \text{length}(y))$ words in y, from which we sample $\mathring{y}$, i.e., a noisified sentence of y: $\mathring{y} \sim U_\alpha(y, \gamma)$. Analogously, we could also construct a neighbourhood $U_\beta(x, \gamma)$ for $x \in \mathcal{X}$ and sample $\mathring{x}$ from it. Using these noisified data as inputs, we then train our transferrers f and g in the way of DAE by optimising the following reconstruction objectives:

$$\begin{aligned}\mathcal{L}_f^{(c)} &= \mathbb{E}_{y\sim Y,\mathring{y}\sim U_\alpha(y,\gamma)}D(y||f(\mathring{y}))\\ \mathcal{L}_g^{(c)} &= \mathbb{E}_{x\sim X,\mathring{x}\sim U_\beta(x,\gamma)}D(x||g(\mathring{x}))\end{aligned} \tag{4}$$

With Eq. 4, we essentially encourages the generator to preserve the input as much as possible.

2.2 Transferring Text Styles

Making use of non-parallel datasets, we train f and g in an iterative process. Let $M = \{g(y)|y \in Y\}$ be the range of g when the input is all sentences in the training set Y. Similarly, we can define $N = \{f(x)|x \in X\}$. During the training cycle of f, g will be kept unchanged. We first feed each sentence y ($y \in Y$) to g, which tries to transfer y to the target style $\mathcal{X}$ (i.e. ideally $x^* = g(y) \in \mathcal{X}$). In this way, we obtain M which is composed of all x^* for each $y \in Y$. Next, we sample $\mathring{x}^*$ (a noised sentence of x^*) based on x^* via the neighbourhood sampling, i.e., $\mathring{x}^* \sim U_\alpha(x^*, \gamma) = U_\alpha(g(y), \gamma)$. We use $\mathring{M}$ to represent the collection of $\mathring{x}^*$. Similarly, we obtains N and $\mathring{N}$ using the aforementioned procedures during the training cycle for g.

Instead of directly using the sentences from X for training, we use $\mathring{M}$ to train f by forcing f to transfer each $\mathring{x}^*$ back to the corresponding original y. In parallel, $\mathring{N}$ is utilised to train g. We represent the aforementioned operation as the *transfer objective*.

$$\begin{aligned}\mathcal{L}_f^{(t)} &= \mathbb{E}_{\alpha,y\sim Y,\mathring{x}^*\sim U_\alpha(g(y),\gamma)}D(y||f(\mathring{x}^*))\\ \mathcal{L}_g^{(t)} &= \mathbb{E}_{\beta,x\sim X,\mathring{y}^*\sim U_\beta(f(x),\gamma)}D(x||g(\mathring{y}^*))\end{aligned} \tag{5}$$

The main difference between Eq. 4 and Eq. 5 is how $U_\alpha(\cdot, \gamma)$ and $U_\beta(\cdot, \gamma)$ are constructed, i.e., $U_\alpha(y, \gamma)$ and $U_\beta(x, \gamma)$ in Eq. 4 compared to $U_\alpha(g(y), \gamma)$ and $U_\beta(f(x), \gamma)$ in Eq. 5. Finally, the overall loss of DGST is the sum of the four partial losses:

$$\mathcal{L} = \mathcal{L}_f^{(c)} + \mathcal{L}_f^{(t)} + \mathcal{L}_g^{(c)} + \mathcal{L}_g^{(t)} \tag{6}$$

During optimisation, we freeze g when optimising f, and vice versa. Also with the reconstruction objective, x^* must to be sampled first, and then passed $\mathring{x}^*$ into f; in contrast, it is not necessary to sample according to y when we obtain $x^* = g(y)$.

3 Experiment

3.1 Setup

Dataset. We evaluated our model on two benchmark datasets, namely, the Yelp review dataset (Yelp), which consists of restaurants and business reviews together with their sentiment polarity (i.e., positive or negative), and the IMDb Movie Review Dataset (IMDb), which consists of online movie reviews. For Yelp, we split the dataset following Li et al. (2018), who also provided human produced reference sentences for evaluation. For IMDb, we follow the pre-processing and data splitting protocol of Dai et al. (2019). Detailed dataset statistics is given in Table 1.

Dataset	Yelp		IMDb	
	Positive	Negative	Positive	Negative
Train	266,041	177,218	178,869	187,597
Dev	2,000	2,000	2,000	2,000
Test	500	500	1,000	1,000

Table 1: Statistics of Datasets.

Evaluation Protocol. Following the standard evaluation practice, we evaluate the performance of our model on the textual style transfer task from two aspects: (1) **Transfer Intensity**: a style classifier is employed for quantifying the intensity of the transferred text. In our work, we use FastText (Joulin et al., 2017) trained on the training set of Yelp; (2) **Content Preservation**: to validate whether the style-independent context is preserved by the transferrer, we calculate *self*-BLEU, which computes a BLEU score (Papineni et al., 2002) by comparing inputs and outputs of a system. A higher *self*-BLEU score indicates more tokens from the sources are retained, henceforth, better preservation of the contents. In addition, we also use *ref*-BLEU, which compares the system outputs and the references written by human beings.

3.2 Experimental Results

In our experiment, the two transferrers (f and g) are Stacked BiLSTM-based sequence-to-sequence models, i.e., both 4-layer BiLSTM for the encoder and decoder. The noise intensity γ is set to 0.3 in the first 50 epochs and 0.03 in the following epochs.

As shown in Table 2, for the Yelp dataset our model defeats all baselines models (apart from StyleTransformer (Multi-Class)) on both *ref*-BLEU and *self*-BLEU. In addition, as shown in Table 2, our model works remarkably well on both transfer intensity and preservation without requiring adversarial training or reinforcement learning, or external offline sentiment classifiers (as in Dai et al. (2019)). Besides, the current version of our

Model	Yelp			IMDb	
	acc.	*ref*-BLEU	*self*-BLEU	acc.	*self*-BLEU
RetrieveOnly (Li et al., 2018)	92.6	0.4	0.7	n/a	n/a

Table 2: Automatic evaluation results on Yelp and IMDb corpora, most of which are from Dai et al. (2019).

Yelp	**positive → negative**
input output	this golf club is one of the best in my opinion . this golf club is one of the worst in my opinion .
input output	i definitely recommend this place to others ! i do not recommend this to anyone !
Yelp	**negative → positive**
input output	the garlic bread was bland and cold . the garlic bread was tasty and fresh .
input output	my dish was pretty salty and could barely taste the garlic crab . my dish was pretty good and could even taste the garlic crab .
IMDb	**positive → negative**
input output	a timeless classic , one of the best films of all time . a complete disaster , one of the worst films of all time .
input output	and movie is totally backed up by the excellent music both in background and in songs by monty . the movie is totally messed up by the awful music both in background and in songs by chimps .
IMDb	**negative → positive**
input output	this one is definitely one for my “ worst movies ever ” list . this one is definitely one of my “ best movies ever ” list .
input output	i found this movie puerile and silly , as well as predictable . i found this movie credible and funny , as well as tragic .

Table 3: Example results from our model for the sentiment style transfer on the Yelp and IMDb datasets.

model is built upon fundamental BiLSTM, which is a likely explanation of why we lose to the SOTA (i.e., StyleTransformer (Multi-Class)) for a small margin, which are based on the Transformer architecture (Vaswani et al., 2017) with much higher capacity. For the IMDb dataset, comparing to other systems, our model obtained moderate accuracy but competitive *self*-BLEU score (70.2), i.e., slightly lower than StyleTransformer. Table 3 lists several examples for style transfer in sentiment for both datasets. By examining the results, we can see that DGST is quite effective in transferring the sentiment polarity of the input sentence while maintaining the non-sentiment information.

3.3 Ablation Study

To confirm the validity of our model, we did an ablation study on Yelp by eliminating or modifying a certain component (e.g., objective functions, or sampling neighbourhood). We tested the following variations: 1) **full-model**: the proposed model; 2) **no-tran**: the model without the transfer objective; 3) **no-rec**: the model without the reconstruction objective; 4) **rec-no-noise**: the model adding no noise when optimising the reconstruction objective; 5) **tran-no-noise**: the model adding no noise when optimising the transfer objective; 6) **pre-noise**: the model trained by adding noise to y first and then feeding the nosified sentences $\mathring{y}$ to g (or $\mathring{x}$ to f) in Eq. 5. In this study, the transferrers are the simplest LSTM-based sequence-to-sequence models. The hidden size and γ are set to 256 and 0.3, respec-

	positive → negative	**negative → positive**
input	*it is a cool place , with lots to see and try .*	*so , that was my one and only time ordering the benedict there .*
full-model	it is a sad place , with lots to see and something .	so , that was my one and best time in the shopping there .
no-rec	no no , , _num_ .	so , that was my one and time time over the there there .
rec-no-noise	it is a cool place , with me to see and try .	service was very friendly .
no-tran	it is a loud place , with lots to try and see .	so , that was my only and first visit ordering the there) .
tran-no-noise	it is a noisy place , with lots to try and see .	so , that was my one and time time ordering the ordering there .
pre-noise	it is a cool place , with lots to see to try .	so , that 's one one and my only the the day there .
input	*it is the most authentic thai in the valley .*	*even if i was insanely drunk , i could n't force this pizza down .*
full-model	it is the most overrated thai in the valley .	even if i was n't hungry , i 'll definitely enjoy this pizza here .
no-rec	i was in the the the the food .	she was perfect .
rec-no-noise	it is the most authentic thai in the valley .	even if i was n't , , i could n't recommend this pizza . .
no-tran	it is the most authentic thai in the valley .	even if i was n't , , i could n't get this pizza down .
tran-no-noise	it is the most common thai in the valley .	even if i was hungry hungry , i could n't love this pizza shop .
pre-noise	it is the most thai thai in the valley .	even if i was n't hungry , i could n't recommend this pizza down .

Table 4: Example transferred from the ablation study.

Model Variants	*self*-BLEU	acc.
no-rec	0.0	98.9
rec-no-noise	41.9	73.1
no-tran	98.0	4.2
tran-no-noise	35.6	82.9
pre-noise	38.9	76.8
full-model	37.2	86.3

Table 5: Evaluation results for the ablation study.

tively.

Results. Table 5 depicts the results of the ablation study. As we can see, eliminating the reconstruction or transfer objectives would damage preservation and transfer intensity, respectively. As for the use of noise, the results of the rec-no-noise model shows that the noise in the reconstruction objective helps balance our model's ability in content preservation and transfer intensity. For the transfer objective, omitting noise (tran-no-sp) would reduce the transfer intensity while placing noise in the wrong position (pre-noise) reduces it yet again.

Case Study. Transferred sentences produced by each model variant in the ablation study are listed in Table 4. The model without correction objective (no-corr) collapsed and as a result it generates irrelevant sentences to the inputs most of the time. When neighbourhood sampling is dropped in either corrective or transfer objectives, the transfer intensity is reduced. These models, including rec-no-noise, tran-no-noise, and pre-noise, tend to substitute random words, and result in reduced transfer intensity (i.e., style words are either not modified or still express the same sentiment after modification) and preservation. For example, when transferring from negative to positive, rec-no-noise replace *"force"* to *"recommend"* resulting *"I couldn't recommend this pizza"*, which is still a negative review.

4 Conclusion

In this paper, we propose a novel and simple dual-generator network architecture for text style transfer, which does not rely on any discriminators or parallel corpus for training. Extensive experiments on two public datasets show that our model yields competitive performance compared to several strong baselines, despite of our simpler model architecture design.

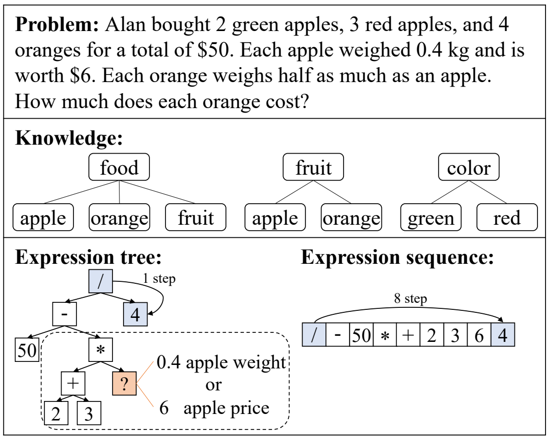
Abstract

With the advancements in natural language processing tasks, math word problem solving has received increasing attention. Previous methods have achieved promising results but ignore background common-sense knowledge not directly provided by the problem. In addition, during generation, they focus on local features while neglecting global information. To incorporate external knowledge and global expression information, we propose a novel knowledge-aware sequence-to-tree (KA-S2T) network in which the entities in the problem sequences and their categories are modeled as an entity graph. Based on this entity graph, a graph attention network is used to capture knowledge-aware problem representations. Further, we use a tree-structured decoder with a state aggregation mechanism to capture the long-distance dependency and global expression information. Experimental results on the Math23K dataset revealed that the KA-S2T model can achieve better performance than previously reported best results.

1 Introduction

Math word problem solving has attracted increasing attention, and many math word problem solving systems have been developed. Early statistical learning methods (Feigenbaum et al., 1963; Fletcher, 1985; Bakman, 2007; Roy and Roth, 2016) extracted templates or features from problems and generated corresponding math expressions based on these templates or features. These methods require a large number of manually formulated features or can only be applied to small application problems in small areas. In recent years, many methods (Wang et al., 2017, 2018b; Xie and Sun, 2019) have been developed that apply neural networks to analyze math word problems, with promising results. These methods use end-to-end models to directly generate the corresponding math expressions from the problem text.



Problem: Alan bought 2 green apples, 3 red apples, and 4 oranges for a total of $50. Each apple weighed 0.4 kg and is worth $6. Each orange weighs half as much as an apple. How much does each orange cost?

Figure 1: An example of a math word problem. With external knowledge, a model can capture the relationships between the entities in the problem. With the global information of a generated expression tree, a model can capture information between long-distance nodes.

Although previous methods have achieved promising results, several problems remain that need to be addressed: 1) Background knowledge and common sense should be incorporated. For example, as shown in Figure 1, both apples and oranges are fruit. Humans are naturally aware of this common-sense information, but it is difficult for the model to learn this information from the problem text alone. 2) When generating expressions, sequence-to-sequence (Seq2Seq) methods tend to focus on local features and ignore global information. For example, the root node "/" of the expression tree in Figure 1 is directly adjacent to its right child "4", but they are eight steps apart in the pre-order expression sequence. Xie and Sun (2019) proposed a sequence-to-tree (Seq2Tree) method for generating an expression

November 16–20, 2020.

tree in pre-order based on the parent node and the left sibling tree of each node. However, global information is still not being considered in the generated expression tree.

To overcome these problems, we propose a novel knowledge-aware sequence-to-tree (KA-S2T) method for exploring how to better utilize external knowledge and capture the global expression information. The proposed model connects related entities and categories based on external knowledge bases to capture common-sense information and obtain better interaction between words. In addition, we designed a tree-structured decoder to capture the long-distance dependency and global expression information. KA-S2T updates all nodes in the generated expression at each time step, whereby the node state is updated by a recursive aggregation of its neighboring nodes. Through multiple iterations of aggregation, the model can use global information associated with the generated expression to generate the next node and thereby achieve better predictions.

The main contributions of this paper can be summarized as follows:

- We incorporate common-sense knowledge from external knowledge bases into math word problem solving tasks.

- We propose a tree-structured decoder for generating math expressions. To incorporate global information associated with generated partial expressions, we recursively aggregate the neighbors of each node in the expression at each time step.

- We conducted experiments on the Math23k dataset to verify the effectiveness of our KA-S2T model, and the results show that our model achieved better performance than previous methods.

2 Models

In this section, we define the problem and present our proposed KA-S2T model. As shown in Figure 2, we first use a bidirectional long short-term memory (LSTM) network to encode the math word problem sequences (Section 2.2). Then, we construct an entity graph based on external knowledge to model the relationships between different entities and categories in the problem (Section 2.3), and use a two-layer graph attention network (GAT) to obtain knowledge-aware problem representations (Section 2.4). Finally, we used a tree-structured decoder with a state aggregation mechanism to generate pre-order traversal math expression trees (Section 2.5).

2.1 Problem Definition

Consider the input sequence of a math word problem $\mathrm{X} = (x_1, x_2, \ldots, x_n)$. Our goal is to train a model that can generate its math expression $\mathrm{Y} = (y_1, y_2, \ldots, y_{n'})$. The task is to estimate a probability distribution in which $\mathbf{P}(\mathrm{Y}|\mathrm{X}) = \prod_{t=1}^{n'} \mathbf{P}(y_t|y_{<t}, \mathrm{X})$. Here, words generated in the math expression Y are either drawn from the input math word problem X, or a vocabulary V. Y, the pre-order sequence of a math expression tree, is executed to produce the answer to the problem X.

2.2 Bidirectional LSTM Encoder

The encoder transforms the words in math word problems into vector representations. We used a bidirectional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) network to encode each word x_i into a vector representation $\mathbf{h_i^{seq}}$:

$$\mathbf{h_i^{seq}} = \mathrm{BiLSTM}(\mathbf{e}(x_i), \mathbf{h_{i-1}^{seq}}) \in \mathrm{R}^{n \times 2d}, \quad (1)$$

where n and d are the size of the input sequence X and the BiLSTM hidden state, respectively. $\mathbf{e}(x_i)$ is the word embedding for word x_i in the problem. $\overrightarrow{\mathbf{h_i^{seq}}}$ and $\overleftarrow{\mathbf{h_i^{seq}}}$ are the BiLSTM hidden states generated by reading X in the forward and backward order, respectively. We define the final vector representation $\mathbf{h_i^{seq}}$ as the concatenation of the forward and backward hidden states, i.e., $\mathbf{h_i^{seq}} = [\overrightarrow{\mathbf{h_i^{seq}}} : \overleftarrow{\mathbf{h_i^{seq}}}]$.

2.3 Constructing Entity Graphs with External Knowledge

Each math word problem corresponds to an entity graph $\mathrm{G} = (\mathrm{N}, \mathrm{A})$, where N is a node list and A is the adjacent matrix of these nodes. The graphs are retrieved from external knowledge bases, with the words in the math word problem as nodes. If multiple words in X belong to the same category c in the knowledge base, we set category c as a node in the graph G and connect these words with their categories. For example, both “green” and “red” belong to the category “color”.

To incorporate knowledge about phrases, if several phrases in X are combined with words belonging to the same category and the same words

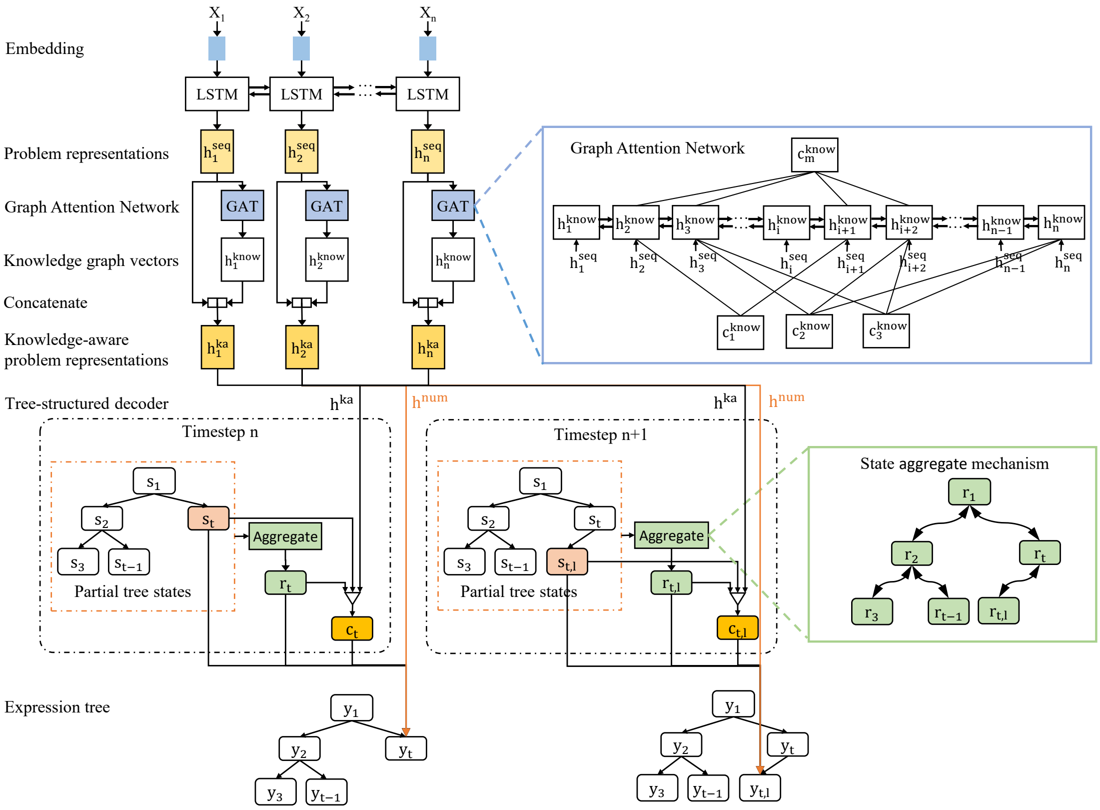

Figure 2: Main structure of our proposed KA-S2T model. At the top side of this figure shows an encoder consisting of a bidirectional LSTM network and a knowledge-aware graph attention network (see Section 2.2 and Section 2.4 for more details). The red line h_{num} indicates the representation of numbers in the problem, which are identified as $\{N1, N2, N3, \ldots\}$ according to their positions in the problem. Instead of generating these numbers directly from the output vocabulary, KA-S2T generates position identifiers that copy the numbers from the problem. The bottom of the figure shows a tree-structured decoder. At each time step, this decoder generates a current node state based on its parent node. Then, the decoder uses a state aggregation mechanism to obtain the context state r_t for each node in the partial expression tree, and generates context vector c_t based on encoder's hidden states. See Section 2.5 for more details.

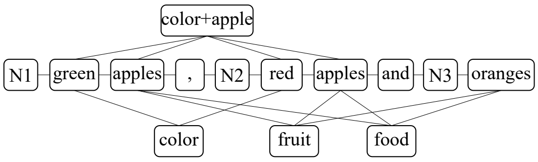

Figure 3: An example of an entity graph

in order, then we build a phrase category c' for these phrases and set c' as a node. As shown in Figure 3, "green apples" and "red apples" are combined in the same category words "green, red" and by the same word "apple". We build a phrase category "color+apple" for these two phrases. Then we connect this phrase category c' to the first and last words of its related phrase.

With n words from the problem and m categories from the knowledge base, an entity graph has a node list N $= \{x_1, x_2, \ldots, x_n, c_1, \ldots, c_m\}$ with $n + m$ nodes.

2.4 Knowledge-aware Problem Representations

For an entity graph, we initialize category c with the average of the vector representations of words adjacent to c. For example, for the category c_1 "color" adjacent to the word x_2 "green" and the word x_6 "red", we initialize c_1 as $\mathbf{c_1} = \text{avg}(\mathbf{h_2^{seq}}, \mathbf{h_6^{seq}})$. In this way, for the nodes in this entity graph, we have node initial vectors $\mathbf{h^{seq'}} = \{\mathbf{h_1^{seq}}, \ldots, \mathbf{h_n^{seq}}, \mathbf{c_1}, \ldots, \mathbf{c_m}\}$. Then, we use a two-layer GAT (Veličković et al., 2017) to obtain the hidden vectors $\mathbf{h^{know'}}$ of these nodes. The GAT functions are given as follows:

$$\mathbf{h_i^{know'}} = \underset{k=1,\ldots,K}{\Vert} \sigma\Big(\sum_{\mathrm{A_{ij}}=1} \alpha_{ij} W_k \mathbf{h_j^{seq'}}\Big), \qquad (2)$$

$$\alpha_{ij} = \frac{\exp(\mathrm{LRelu}(\mathrm{w_s^T}[\mathrm{W_h}\mathbf{h_i^{seq'}}||\mathrm{W_h}\mathbf{h_j^{seq'}}]))}{\sum\limits_{\mathrm{A_{ij}}=1}\exp(\mathrm{LRelu}(\mathrm{w_s^T}[\mathrm{W_h}\mathbf{h_i^{seq'}}||\mathrm{W_h}\mathbf{h_j^{seq'}}]))},$$

where w_s^T, $\mathrm{W_h}$, $\mathrm{W_k}$ are trainable weight vector and matrices. $||$ is concatenation operation and LRelu is a LeakyRelu activation function (Xu et al., 2015). K is the number of heads in GAT and $\mathrm{A_{ij}} = 1$ means there are edge between the i-th and j-th node.

To represent n words in problem X, we simply select the first n vectors of $\mathbf{h^{know'}} \in \mathbf{R}^{(n+m)\times 2d}$ as the knowledge graph vectors.

$$\mathbf{h^{know}} = \mathbf{h^{know'}}[0:n]. \tag{3}$$

After concatenating the word vector $\mathbf{h^{seq}}$ and the knowledge graph vectors $\mathbf{h^{know}}$, the knowledge-aware problem representation $\mathbf{h^{ka}}$ is obtained and fed to the tree-structured decoder.

$$\mathbf{h^{ka}} = [\mathbf{h^{seq}} : \mathbf{h^{know}}]. \tag{4}$$

If there are n_{num} numbers in X, we may want to copy them directly from problem X rather than generating them from the vocabulary. We extract $\mathbf{h^{num}} \in \mathrm{R}^{n_{num}\times 2d}$ from $\mathbf{h^{ka}}$ based on the position of these numbers. $\mathbf{h_i^{num}}$ is the representation of the i-th number in the problem. We use $\mathbf{h^{num}}$ to compute the distribution score of these numbers in Equation 6.

2.5 Tree-structured Decoder

In the KA-S2T tree-structured decoder, we generate pre-order expressions Y from top to bottom. At time step t, if the y_t we generate is an operator, this means it is an internal node and its left child $y_{t,l}$ and right child $y_{t,r}$ must still be generated. If y_t is a number, it is a leaf node. Once the children of all the internal nodes are generated, then the output expression sequence Y can be transformed into a complete executable expression tree.

The tree-structured decoder has three roles: 1) it attentively reads the knowledge-aware problem representation to obtain a context vector, and uses this vector to update the decoder's state; 2) it recursively aggregates the neighbors of each node in the generated partial expression to capture global information; and 3) it adaptively chooses a word from the vocabulary or copies a number from the math word problem for generation.

The decoder updates its state as follows:

$$\begin{aligned}\mathbf{s_{t,l}} &= \sigma(\mathrm{W_{left}}[\mathbf{s_t} : \mathbf{c_t} : \mathbf{r_t} : (\mathbf{e}(y_t))]),\\ \mathbf{s_{t,r}} &= \sigma(\mathrm{W_{right}}[\mathbf{s_t} : \mathbf{c_t} : \mathbf{r_t} : (\mathbf{e}(y_t))]),\end{aligned} \tag{5}$$

where $\mathrm{W_{left}}$ and $\mathrm{W_{right}}$ are the weight matrices and σ is a sigmoid function. $\mathbf{e}(y_t)$ is the embedding of t-th generated word y_t. $\mathbf{s_{t,l}}$ and $\mathbf{s_{t,r}}$ is the left child state and right child state of $\mathbf{s_t}$, respectively. For the root node y_1, it initializes $\mathbf{s_1}$ with the max pooling of $\mathbf{h^{ka}}$. $\mathbf{c_t}$ is the context vector for the hidden states of the encoder. $\mathbf{r_t}$ is the context state for the partial expression generated at previous time steps.

Finally, the tree-structured decoder generates a word from vocabulary V or copies a number from the math word problem X with the following distributions:

$$\begin{aligned}\mathbf{P}_{\mathrm{gen}}(y_t) &= \mathrm{softmax}(\mathrm{W_g}[\mathbf{s_t}:\mathbf{c_t}:\mathbf{r_t}])\\ \mathbf{P}_{\mathrm{copy}}(y_t) &= \mathrm{softmax}(\mathrm{W_p}[\mathbf{s_t}:\mathbf{c_t}:\mathbf{r_t}:\mathbf{h^{num}}])\\ \beta_t &= \sigma(\mathrm{W_z}[\mathbf{s_t}:\mathbf{c_t}:\mathbf{r_t}:\mathbf{h^{num}}]),\\ \mathbf{P}(y_t|y_{<t},\mathrm{X}) &= \begin{cases}(1-\beta_t)\mathbf{P}_{\mathrm{gen}}(y_t)\\ \quad\beta_t\,\mathbf{P}_{\mathrm{copy}}(y_t)\end{cases},\end{aligned} \tag{6}$$

where $\mathrm{W_g}$, $\mathrm{W_p}$ are weight matrices. $\beta_t \in [0,1]$ is a gate value to determine whether generate a word from vocabulary or copy a number from math word problem. $y_{<t}$ represents the words generated at earlier timesteps. The final distribution $\mathbf{P}(y_t|y_{<t},\mathrm{X})$ is a concatenation of generate distribution $\mathbf{P}_{\mathrm{gen}}(y_t)$ and copy distribution $\mathbf{P}_{\mathrm{copy}}(y_t)$.

Attention. We use attention mechanism (Bahdanau et al., 2014) to compute the context vector $\mathbf{c_t}$. Given the decoder state $\mathbf{s_t}$ and the expression context state $\mathbf{r_t}$, it first attends on the encoder's problem representation $\mathbf{h^{ka}}$ to obtain $\mathbf{c_t}$, which is defined as below:

$$\begin{aligned}\alpha_{ti} &= \frac{\exp(\mathrm{W_e}\tanh(\mathrm{W_m}\mathbf{h_i^{ka}}+\mathrm{W_s}\mathbf{s_t}+\mathrm{W_r}\mathbf{r_t}))}{\sum_{j=1}^{n}\exp(\mathrm{W_e}\tanh(\mathrm{W_m}\mathbf{h_j^{ka}}+\mathrm{W_s}\mathbf{s_t}+\mathrm{W_r}\mathbf{r_t}))},\\ \mathbf{c_t} &= \sum_{i=1}^{n}\alpha_{ti}\mathbf{h_i^{ka}},\end{aligned} \tag{7}$$

where $\mathrm{W_e}$, $\mathrm{W_m}$ and $\mathrm{W_s}$ are the weight matrices. α_{ti} denotes the attention distribution on the knowledge-aware problem representations $\mathbf{h^{ka}}$.

State Aggregation Mechanism: To incorporate the global information associated with the previously generated expression tree, the node state is recursively aggregated with its neighbor nodes in the expression tree at each time step. At time step t, all the generated nodes $(\mathbf{r_t})^0 = \{\mathbf{s_1},\mathbf{s_2},\ldots,\mathbf{s_t}\}$ are aggregated with a two-layer graph convolutional network (GCN) (Kipf and Welling, 2016). The aggregation functions are as follows:

$$\begin{aligned} &\mathrm{D_{ii}} = \sum\nolimits_{\mathrm{j}=1}^{\mathrm{n}} \mathrm{A}_{\mathrm{ij}}^{\mathrm{exp}}, \\ &(\mathbf{r_t})^{\gamma+1} = \sigma(\mathrm{D}^{-1}\mathrm{A}^{\mathrm{exp}}(\mathbf{r_t})^{\gamma}\mathrm{W_r}), \end{aligned} \tag{8}$$

where $\mathrm{W_r}$ is weight matrix. $\mathrm{A}^{\mathrm{exp}}$ is the adjacent matrix of the generated partial expression. If y_i is the child or parent of y_j or i = j, $\mathrm{A}_{\mathrm{ij}}^{\mathrm{exp}} = 1$. D means the number of adjacent nodes of each node plus 1. We use $\mathrm{D}^{-1}\mathrm{A}$ to normalize A. In this study, after two hops of GCN computation, we obtained the final context state $\mathbf{r_t}$ for each node in the partial expression.

2.6 Training

Given the training data $\mathrm{D} = (\mathrm{X}, \mathrm{Y})$, the objective function is to minimize the negative log likelihood:

$$\Delta(\mathrm{D}, \theta) = -\sum\nolimits_{\mathrm{i}=1}^{\mathrm{N_D}} \log \mathbf{P}(\mathrm{Y}|\mathrm{X}). \tag{9}$$

During training, for each question–answer pair (X, Y), we used the pre-order traversal of Y as the ground truth. The conditional probability is $\mathbf{P}(\mathrm{Y}|\mathrm{X})$:

$$\begin{aligned} \log \mathbf{P}(\mathrm{Y}|\mathrm{X}) = \prod_{t=1}^{n'} [\, &\mathbf{P}(y_t|y_{<t}, \mathrm{X}) \\ +\mathbf{P}(y_{t,l}|y_{<t}, \mathrm{X}) &+ \mathbf{P}(y_{t,r}|y_{<t}, \mathrm{X})] \end{aligned} \tag{10}$$

Here, $\mathbf{P}(y_{t,l}|y_{<t}, \mathrm{X})$ is an additional regular term about the child loss. At time step t, we only used the left child state $\mathbf{s_{t,l}}$ and right child state $\mathbf{s_{t,r}}$ to calculate the respective distribution scores $\mathbf{P}(y_{t,l}|y_{<t}, \mathrm{X})$ and $\mathbf{P}(y_{t,r}|y_{<t}, \mathrm{X})$, as shown in Equation 6. We expect that the distribution of node y_t is close to the ground truth, and that the distributions of its left and right children $y_{t,l}, y_{t,r}$ are also close to the ground truth.

3 Experiment

3.1 Dataset

We evaluated the proposed method on a large-scale dataset called Math23K, which was gathered by Wang et al. (2017) and contains 23,161 elementary school math word problems. Each problem was originally associated with an expression and answer. All problems in this dataset are described in Chinese and can be solved by a linear expression that contains only one unknown variable. We randomly split the dataset into a training set (80%) and testing set (20%).

Furthermore, we replaced all of the numbers in the problems with position tokens (e.g., N_1, N_2, N_3) in the preprocessing stage. After the model generated the expression, we replaced the position tokens in the expression with the numbers from the original problem, and executed this replaced expression to produce the answer.

We used Cilin (Mei, 1985) and Hownet (Dong et al., 2006) as our External Knowledge Source. Cilin is a Chinese synonym dictionary, where each word belongs to several different word groups. Hownet is a knowledge graph of Chinese words and concepts, where each word is labeled by several semantic units. We used these word groups and semantic units as our categories, and we set the max length of phrases in the phrase category to 3. We obtained 8,883 word-category pairs and 10,864 phrase category pairs.

3.2 Implementation Details

Our code was implemented with Pytorch [1]. We select the 4,000 words that appeared most frequently in the training data as the input vocabulary, and replaced the rest of the words in the problems with a token UNK. We set the dimension of hidden vectors d = 256. Both GCN and GAT have two layers. The number of heads K in GAT is 8. Model optimization was performed using an Adam optimizer (Kingma and Ba, 2014) with the learning rate set to 0.001. For the hyper-parameter setting, we set the dropout (Srivastava et al., 2014) rate to 0.5 and the batch size to 64. During training, it took 80 epochs to train the model. During decoding, the beam size was set to 5.

3.3 Baselines

To evaluate the performance of the proposed method, we compare it with the following baselines:

- **DNS (Wang et al., 2017):** This method has a two-layer GRU (Chung et al., 2014) encoder and a two-layer LSTM decoder. In addition, it uses a retrieval model to detect the problem that is most similar to the query problem from

---

[1] https://pytorch.org/

Models	Accuracy
DNS (Wang et al., 2017)	58.1%
DNS+Retrieval (Wang et al., 2017)	64.7%
Bi-LSTM (Wang et al., 2018a)	66.7%
ConvS2S (Wang et al., 2018a)	64.2%
Transformer (Wang et al., 2018a)	62.3%
Ensemble (Wang et al., 2018a)	68.4%
RecursiveNN (Wang et al., 2019)	68.7%
Tree-Decoder (Liu et al., 2019)	69.0%
GTS (Xie and Sun, 2019)	74.3%
KA-S2T (Our)	**76.3%**

Table 1: Answer accuracy of our model and other state-of-the-art models on Math23K dataset.

the training set, and uses its expression as a template for the query problem. It combines the retrieval model with the DNS model to form a hybrid model "**DNS+Retrieval**".

- **Ensemble (Wang et al., 2018a):** This ensemble model combines three types of Seq2Seq models: a bidirectional LSTM network (Wu et al., 2016), a convolutional Seq2Seq model (Gehring et al., 2017), and a transformer (Vaswani et al., 2017).

- **RecursiveNN (Wang et al., 2019):** A recursive neural network model first predicts the tree structure template using a Seq2Seq model, and then infers the expression based on the features extracted by a bidirectional LSTM and self-attention mechanism.

- **Tree-Decoder (Liu et al., 2019):** A Seq2Tree generative model with an auxiliary stack and a tree-structured decoder that generates the abstract syntax tree of the equation in a top-down manner. We call this method "**Tree-Decoder**".

- **GTS (Xie and Sun, 2019):** A tree structured neural model that generates an expression tree in a goal-driven manner based on the parent node and the left sibling tree of each node. It uses top-down goal decomposition and bottom-up subtree embedding to directly predict the expression tree.

3.4 Result Analysis

To assess the overall performance of our KA-S2T model, we compared it with the performances of other state-of-the-art models on the Math23K dataset. Table 1 shows the accuracy of the results obtained by executing the generated expressions of these models, from which we can conclude the following:

1) The tree-structured decoder can improve the performance of most baselines. For example, the Seq2Tree baseline Tree-Decoder and GTS performed better than the best-performing Seq2Seq baseline RecursiveNN. This result demonstrates the effect of the tree-structured decoder.

2) The deep-learning models DNS and Ensemble did not perform as well as the RecursiveNN with attention mechanism. Tree-Decoder and GTS both have an attention structure, which proves that an attention mechanism can effectively capture the key features of a problem.

3) GTS performed the best of all the baselines, even better than the Tree-Decoder, which also has a Seq2Tree structure. The reason for this may be that GTS directly uses the states of the parent node and left sibling node to generate the current node. Tree-Decoder still sequentially generates expressions based on the last node state, and takes the sibling node and parent node states as additional features.

4) Finally, compared with GTS, the accuracy of KA-S2T was 2.0% better. We attribute the superior performance of KA-S2T to two properties: KA-S2T incorporates external knowledge, which can better capture the relationship between words. KA-S2T recursively aggregates the neighbors of each node in the partial expression, and thus better captures the global information associated with the currently generated expression tree.

Models	Accuracy
GTS (Xie and Sun, 2019)	74.3%
KA-S2T w/o knowledge	75.5%
KA-S2T w/o multiple category	75.7%
KA-S2T w/o phrase category	76.0%
KA-S2T	76.3%

Table 2: Ablation study on reducing the amount of external knowledge incorporated into the model. "w/o phrase category" indicates the removal of knowledge about phrase categories from the KA-S2T model. "w/o multiple category" indicates that each entity in the knowledge base is connected to only one category that is most relevant to it.

3.5 Ablation Study

Effect of external knowledge: Table 2 shows the

Models	Accuracy
RecursiveNN (Wang et al., 2019)	68.7%
GTS (Xie and Sun, 2019)	74.3%
KA-S2T w/o child loss & state agg	72.9%
KA-S2T w/o state agg	73.5%
KA-S2T w/o child loss	75.2%
KA-S2T	75.5%

Table 3: Ablation study of different decoder structures. “w/o state agg” indicates that the model did not use the context state r_t to incorporate global expression information at each time step. “w/o child loss” indicates that the loss function did not use the additional regular terms defined in Equation 10 to introduce child loss. For a fair comparison, no external knowledge was used in KA-S2T and its variants.

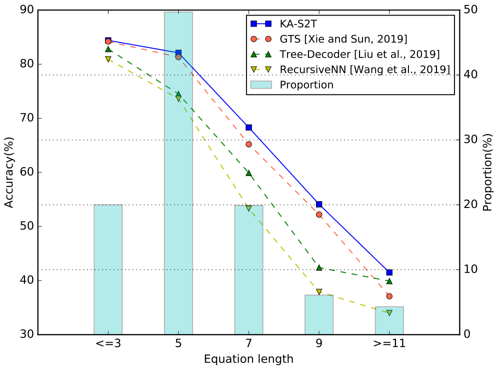

Figure 4: Model performance on expression trees of different lengths

results of ablation experiments conducted to reduce the amount of external knowledge incorporated into the model. We have the following observations:

1) Without external knowledge, the KA-S2T's answer accuracy would be reduced to 75.5%. However, “KA-S2T w/o knowledge” still outperforms the best-performing baseline GTS, which further verifies the effectiveness of our tree-structured decoder. We will analyze the effectiveness of these tree-structured decoder in the following section.

2) The use of multiple categories and phrase categories can improve accuracy by 0.2% and 0.5%, respectively. Their combination can provide further improvement in model performance. These results show that the external knowledge of the relationship between entities and categories enables the model to capture common-sense information and obtain better interaction between words.

Effect of KA-S2T tree-structured decoder: We designed several ablation experiments to measure the effect of our KA-S2T tree-structured decoder, the results of which are shown in Table 3. For a fair comparison, we used no external knowledge in these KA-S2T and variant models. From the table, we can see that:

1) The “KA-S2T w/o child loss & state agg” model, which can be regarded as a basic Seq2Tree model, achieved better accuracy than the best-performing Seq2Seq baseline RecursiveNN. The main difference between this model and RecursiveNN is that this model generates the current node state based on its parent node, and RecursiveNN generates the current node state based on the last node. This finding once again confirms the effectiveness of the Seq2Tree structure because facilitates the capture of long-distance dependencies.

2) The “KA-S2T w/o child loss” model outperformed the best-performing Seq2Tree baseline GTS, but the “KA-S2T w/o child loss & state agg” model did not perform as well as GTS. Compared with the basic Seq2Tree model, GTS uses bottom-up subtree embedding to introduce left sibling tree information. The state aggregation mechanism achieves further improvements, not only focusing on the left sibling subtree, but also incorporating the global information associated with the entire generated partial expression. This result proves the effectiveness of the state aggregation mechanism.

3) The KA-S2T model with child loss is better than the KS-S2T model without child loss, which proves that the child loss function obtains better performance.

Model performance on expression trees of different lengths: We compared the KA-S2T model with the other three best-performing state-of-the-art methods to investigate the performances of the models that have expression trees of different lengths. As shown in Figure 4, KA-S2T outperformed the other three state-of-the-art methods with respect to expression trees of different lengths, especially when the length of the expression tree was between 5 and 9. One possible explanation for this is that because the expression tree is complex, to achieve better performance, the model needs external knowledge and the global information associated with the expression. However, when the expression is too complex, the probability of the model producing correct results is too low, so the performance gap between the different models is not as obvious. These results further demonstrates the beneficial effect of incorporating

Problem 1: The library purchased N1 different types of books. Among them, there are N2 literary books and N3 encyclopedias. The number of science books is N4 more than N5 times the number of literary books. How many books are there in total?	
GTS: + + * N2 N5 N4 N2	**KA-S2T:** + + * N2 N5 N4 + N2 N3
Problem 2: A school spent N1 to buy N2 basketballs and N3 footballs. The price of each basketball is N4. How much does each basketball cost more than each football?	
GTS: - N4 / - N1 * N2 N4 N2	**KA-S2T:** - N4 / - N1 * N2 N4 N3

Table 4: Two examples of expressions generated by KA-S2T compared with GTS.

external knowledge and using state aggregation mechanism.

3.6 Case Study

Table 4 shows two examples generated by our KA-S2T model for comparison with GTS (Xie and Sun, 2019).

In Problem 1, without external knowledge, GTS does not know that encyclopedias are books much like literary books and scientific books, and therefore it generates incorrect results. By incorporating external knowledge, KA-S2T is able to obtain the relationship between these three types of books.

In Problem 2, there is a long distance between "N3" and the first two nodes [-, N4] of the expression tree. GTS does not realize that the current subexpression tree indicates the price of each football and generates "N2" based on the nearest node "N4". Our proposed method can capture long-distance features and therefore generate correct results.

4 Related Work

Solving math word problems has long been a challenging task (Fletcher, 1985; Bakman, 2007; Roy and Roth, 2016) and has attracted the attention of many researchers. Some methods on math word problem solving incorporate extra features by manually crafting fine-grained templates or defining math concepts. Huang et al. (2017) formulated fine-grained templates and aligned numbers in math word problems to those candidate templates. Roy and Roth (2018) developed declarative rules to transform math concepts into expressions. These methods require manually formulated features and may be difficult to apply to math word problems in different domains. Recently, many studies have used deep learning methods to incorporate external knowledge from the knowledge base into many NLP tasks, such as dialogue systems (Zhong et al., 2019) and reading comprehension (Wang and Jiang, 2019; Qiu et al., 2019). These methods extend knowledge triples into natural language sequences or build multi-hop inference graphs based on relationships in the knowledge base, and have achieved promising results. In this paper, we model the entities in the problem and their categories as entity graphs and use graph attention to generate knowledge-aware problem representations.

Seq2Seq neural networks (Sutskever et al., 2014) have achieved promising results on math word problem solving. For instance, Wang et al. (2017) used a Seq2Seq model to generate math expressions. Wang et al. (2018b) incorporated reinforcement learning into the model to construct a math expression step by step. Zou and Lu (2019) used a data-driven approach to semantically parsing text into math expressions. Recently, tree-structured decoder was used to further improve the seq2seq framework. Xie and Sun (2019) propose a seq2tree model to generate expression tree in a goal-driven manner based on the parent node and left sibling tree of each node. Liu et al. (2019) propose a tree-structured decoding method with an auxiliary stack that generates the abstract syntax tree of the equation in a top-down manner. In this paper, we generated the pre-order math expression tree based on parent node state of each node and recursively aggregated neighbors of each node in the partial expression tree to incorporate global information.

5 Conclusion

In this study, we proposed a novel knowledge-aware sequence-to-tree model that can automatically solve math word problems. We used an entity graph to incorporate common sense knowledge from external knowledge bases into the proposed model. In addition, we proposed a tree-structured decoder with a state aggregation mechanism for generating math expressions. Our experimental results confirmed that our KA-S2T model outperformed other state-of-the-art models.

Abstract

Fact checking at scale is difficult—while the number of active fact checking websites is growing, it remains too small for the needs of the contemporary media ecosystem. However, despite good intentions, contributions from volunteers are often error-prone, and thus in practice restricted to claim detection. We investigate how to increase the accuracy and efficiency of fact checking by providing information about the claim before performing the check, in the form of natural language *briefs*. We investigate passage-based briefs, containing a relevant passage from Wikipedia, entity-centric ones consisting of Wikipedia pages of mentioned entities, and Question-Answering Briefs, with questions decomposing the claim, and their answers. To produce QABriefs, we develop QABRIEFER, a model that generates a set of questions conditioned on the claim, searches the web for evidence, and generates answers. To train its components, we introduce QABRIEFDATASET which we collected via crowdsourcing. We show that fact checking with briefs — in particular QABriefs — increases the accuracy of crowdworkers by 10% while slightly decreasing the time taken. For volunteer (unpaid) fact checkers, QABriefs slightly increase accuracy and reduce the time required by around 20%.

1 Introduction

Fact checking is a challenging task. It requires deep knowledge of a claim's topic and domain, as well as an understanding of the intricacies of misinformation itself. Checking a single claim can take professional fact checkers 15 minutes to one day (Hassan et al., 2015). Volunteers on the other hand are not considered accurate enough; with access to a search engine, Roitero et al. (2020) report crowdsourced fact check accuracies of around 58%. This result corroborates earlier reports[1] by fact checking websites which attempted to engage volunteers, but reported success only for claim detection, which is considered a much simpler task (Konstantinovskiy et al., 2018). This is problematic, both from the perspective of using crowdsourced fact checking to combat misinformation and from the perspective of helping individuals fact check themselves.

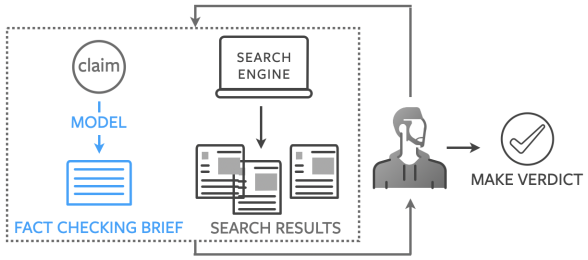

Figure 1: **Fact Checking Briefs.** Before conducting a fact check, we propose generating *briefs* to provide information about the claim. We show they make fact checking more accurate and efficient.

One path for scaling fact checking could be through full automation, taking a claim as input and producing a verdict (Vlachos and Riedel, 2014). Existing work has framed fact checking as classification, often supported by evidence (Wang, 2017; Thorne et al., 2018; Augenstein et al., 2019). However, due to the limitations of existing automated solutions, practitioners prefer solutions that improve efficiency in reaching a verdict, instead of approaches to the complete process (Graves, 2018).

In this work, we propose *briefs* to increase the accuracy and efficiency of fact checking (Figure 1). By generating fact checking briefs, our models aim to provide evidence a human fact checker would find useful. We investigate several approaches, in-

CLAIM Social Security was basically invented at the University of Wisconsin-Madison; that's where Franklin Roosevelt got the idea.

PASSAGE BRIEF

The idea of a federally funded pension plan was popularized by Francis Townsend in 1933, and the influence of the "Townsend Plan" movement on debate over social security persisted into the 1950s. Early debates on Social Security's design centered on how the program's benefits should be funded. Some believed that benefits to individuals should be funded by contributions that they themselves had made over the course of their careers. Others argued that this design would disadvantage those who had already begun their careers at

ENTITY BRIEF

Social security is "any government system that provides monetary assistance to people with an inadequate or no income". In the United States, this is usually called welfare or a social safety net [...]

Franklin Delano Roosevelt, often referred to by initials FDR, was an American statesman and political leader who served as the 32nd president of the United States from 1933 until his death in 1945. [...]

QUESTION ANSWERING BRIEF

What is social security?

Social security is "any government system that provides monetary assistance to people with an inadequate or no income"

When did Franklin Roosevelt implement social security?

The Social Security Act was enacted August 14, 1935.

Who invented social security?

Political Scientists at the University of Wisconsin-Madison, including Edwin Witte, known as the "Father of Social Security," Arthur J. Altmeyer, and Wilbur Cohen developed the 1934 proposal for a federally funded pension plan.

Figure 2: **Three Types of Briefs: (1) Passage Briefs**, based on information retrieval applied to the claim, **(2) Entity Briefs**, using entity linking to identify information about each entity, and **(3) Question Answering Briefs**, which condition on the claim to generate questions, then answer questions using open domain question answering

cluding returning Wikipedia passages that relate to the claim, and an entity linking approach that shows information about mentioned entities. Crucially, we introduce QABriefs — a set of relevant questions and their answers (see Figure 2).

To learn how to produce QABriefs and create training data, we use crowdsourcing to gather such briefs based on existing fact checks. We create QABRIEFDATASET, a collection of about 10,000 QABriefs with roughly 3 question and answer pairs each. We introduce QABRIEFER, a novel model that performs structured generation via claim-conditioned question generation and open domain question answering. Each question is used to identify evidence using a search engine. Finally, a pretrained question answering model is finetuned to generate answers and produce the full brief.

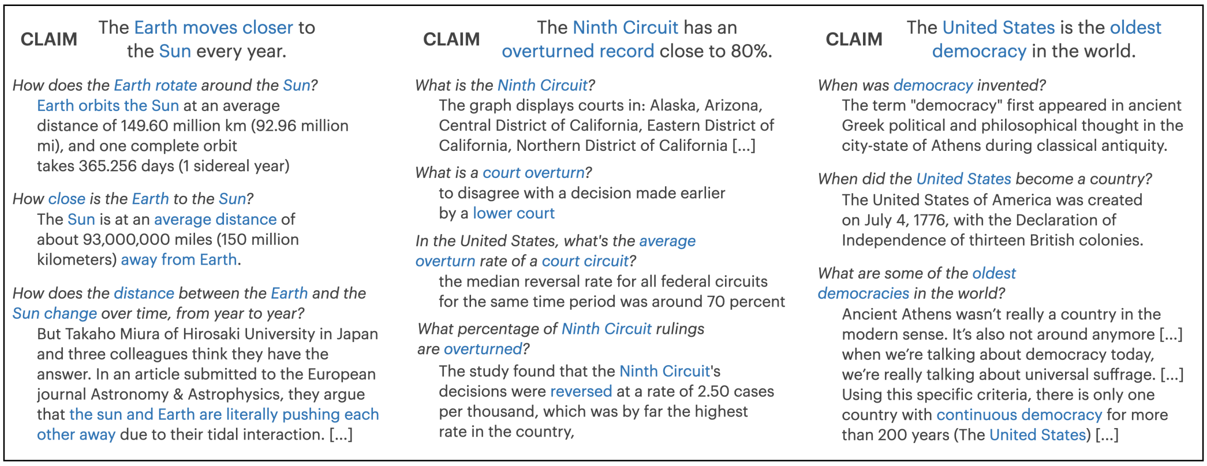
In experiments with crowdworkers, QABriefs improve accuracy by 10% compared to using only a search bar while reducing the time a fact check takes. For volunteer fact checkers, accuracy is improved by 4% and the process is 20% faster compared to using a search bar. Using QABriefs from human annotators leads to the largest improvement, followed by briefs generated by QABRIEFER and other proposed forms of briefs. This suggests that briefs are a promising avenue for improving crowdsourced fact checking. Further, QABRIEFDATASET can be used to develop models capable of answering challenging, real world questions.

2 Briefs for Fact Checking

Fact checkers must comprehend each part of a claim, which requires gathering information about a wide range of concepts— a precise definition of a term, how a politician voted, or the exact contents of a bill. Such knowledge is available in many sources: knowledge bases, statistical reports, or on the internet. We introduce the notion of *briefs* to provide relevant information to fact checkers—as if *briefing* them before fact checking— and explore three possible forms: Passage Briefs, Entity Briefs, and Question Answering Briefs. We show how they can be constructed with modern NLP approaches.

2.1 Passage Briefs

To provide information before checking a claim, Passage Briefs consist of relevant passages retrieved from Wikipedia. For the claim in Figure 2, information about the history and implementation of social security in the United States is retrieved and presented as background for the fact checker. To generate Passage Briefs, we identify relevant Wikipedia passages for each claim. Based on the results by Lewis et al. (2020) on open-Wikipedia tasks, we use the Dense Passage Retriever (DPR) (Karpukhin et al., 2020). This state of the art, pretrained retriever model learns a representation of questions and possible relevant paragraphs. In our case, we provide the claim as input instead of the question, rank the outputs, and select the top ranked passage. We limit to 500 tokens for readability. Initial experiments suggested web-based Passage Briefs returned poor results for most claims, as it relied on a finding a single passage addressing the entire claim, so we keep the Passage Brief focused on Wikipedia. Further, DPR is trained on Wikipedia, and we found the best performance within this domain.



CLAIM The Earth moves closer to the Sun every year.

How does the Earth rotate around the Sun?
Earth orbits the Sun at an average distance of 149.60 million km (92.96 million mi), and one complete orbit takes 365.256 days (1 sidereal year)

How close is the Earth to the Sun?
The Sun is at an average distance of about 93,000,000 miles (150 million kilometers) away from Earth.

How does the distance between the Earth and the Sun change over time, from year to year?
But Takaho Miura of Hirosaki University in Japan and three colleagues think they have the answer. In an article submitted to the European journal Astronomy & Astrophysics, they argue that the sun and Earth are literally pushing each other away due to their tidal interaction. [...]

CLAIM The Ninth Circuit has an overturned record close to 80%.

What is the Ninth Circuit?
The graph displays courts in: Alaska, Arizona, Central District of California, Eastern District of California, Northern District of California [...]

What is a court overturn?
to disagree with a decision made earlier by a lower court

In the United States, what's the average overturn rate of a court circuit?
the median reversal rate for all federal circuits for the same time period was around 70 percent

What percentage of Ninth Circuit rulings are overturned?
The study found that the Ninth Circuit's decisions were reversed at a rate of 2.50 cases per thousand, which was by far the highest rate in the country,

CLAIM The United States is the oldest democracy in the world.

When was democracy invented?
The term "democracy" first appeared in ancient Greek political and philosophical thought in the city-state of Athens during classical antiquity.

When did the United States become a country?
The United States of America was created on July 4, 1776, with the Declaration of Independence of thirteen British colonies.

What are some of the oldest democracies in the world?
Ancient Athens wasn't really a country in the modern sense. It's also not around anymore [...] when we're talking about democracy today, we're really talking about universal suffrage. [...] Using this specific criteria, there is only one country with continuous democracy for more than 200 years (The United States) [...]

Figure 3: **Examples of QABriefs in QABRIEFDATASET**

2.2 Entity Briefs

Passage briefs provide information from a single passage, but claims are complex and often require multiple pieces of information from different sources. Thus we propose entity briefs that focus on each entity referenced in the claim.

Entities in each claim are identified with BLINK (Wu et al., 2019), a model trained on Wikipedia data that links each entity to its nearest Wikipedia page. BLINK combines a bi-encoder (Urbanek et al., 2019; Humeau et al., 2019) that identifies candidates with a cross-encoder that models the interaction between mention context and entity descriptions. For each entity, we retrieve its Wikipedia and provide the first paragraph in the brief. In Figure 2, *Franklin Roosevelt* is an entity, and the brief communicates he is *an American politician who served as the 32nd president of the United States [...]*. However, unlike Passage Briefs, if several entities are identified, information from multiple pages is displayed in an Entity Brief.

2.3 Question Answering Briefs

Entity briefs provide information about entities mentioned in the claim, but not necessarily the evidence needed for the claim in question. For this reason we propose QABriefs, which decompose fact checking into a set of questions and answers. E.g. the claim in Figure 2 could be split into understanding what social security is, identifying who invented the concept, and finally where Franklin Roosevelt got the idea. Each step can be written into a question — *What is social security? Who invented social security?* — that is then answered. The decomposition into question-answer pairs is likely to be better amenable to the current generation of information retrieval systems, which typically assume simpler information needs, e.g. most QA datasets have questions about single factoids. Unfortunately, there are no existing datasets or models available to create QABriefs. Next, we describe how we create a dataset (Section 3) and a model (Section 4) to produce QABriefs.

3 QABrief Dataset

To train and evaluate models to generate QABriefs, we collect a dataset of questions based on claims, together with answers to those questions found on the open web. Crucially, annotators first read the article from a fact checking website that describes how the claim was checked, and then decompose the process into questions, for which answers are provided. The claims for the dataset are sourced from existing fact checking datasets, specifically DATACOMMONS[2] and MULTIFC (Augenstein et al., 2019). The annotator instructions are in the Appendix and examples are shown in Figure 3.

While numerous question generation and answering datasets exist, none of them focuses on using questions and answers to combat misinformation. QABRIEFDATASET focuses on this real world problem, with each question grounded in a claim that was actually fact checked. Further, existing datasets are quite different from our usecase — for example, many datasets are based on Wikipedia, but fact checkers find evidence from other sources. Many datasets have short answer spans, but our questions are complex, so require longer answers.

---

[2] https://datacommons.org/factcheck

3.1 Question Generation

Crowdworkers are asked to read a *claim* and its corresponding *fact checking article*[3], which details the investigative process used to perform the fact check. After reading the article, crowdworkers write *questions* to reconstruct the process taken by professional fact checkers. For each claim, crowdworkers write two to five questions that are at least five words long and standalone. For instance, the question *why did he do that* is invalid, as it is not clear what *he* or *that* is. We discourage questions with yes/no answers and discourage questions about the same claim from overlapping more than five words.

After the questions are collected, a *question validation* phase is conducted. A separate group of crowdworkers reviews the quality of the questions and flags those that are redundant and/or otherwise poor quality. For example, questions such as *What evidence is there that [claim] is true?* are rejected. Other instances of questions rejected at this phase include nonsensical questions and questions that simply rephrase the claim. Any questions that do not pass this review are re-annotated. Finally, a *question clarity* phase is conducted — crowdworkers read the questions and edit those that are unclear or underspecified. For example, questions may need to have a year added to them to accurately verify a statistic. Further, additional questions can be added if crowdworkers feel the existing questions are not sufficient. This can lead to more than five questions per claim. Spelling errors are highlighted and crowdworkers are encouraged to correct them.

3.2 Question Answering

After each claim is annotated with multiple questions, we proceed to collect the answers to them. To answer questions, crowdworkers are given the claim; the source of the claim (for example, the entity who said the quote being checked); and the question. Crowdworkers enter a *query* into a *search engine* to find information on the web. The search is restricted from accessing fact checking domains, to prevent the answer from being trivially found on a fact checker's website. The query does not need to be identical to the question, and is often rephrased to find better search results. After reading the returned results, crowdworkers can provide one of three possible answer types:

Train	Number of Claims	5,897
	Number of QA Pairs	18,281
Valid	Number of Claims	500
	Number of QA Pairs	1,431
Test	Number of Claims	500
	Number of QA Pairs	1,456
Avg Number Questions/Claim		3.16
Avg Number Words in Questions		10.54
Avg Number Words in Answers		43.56

Table 1: **Statistics of QABRIEFDATASET**

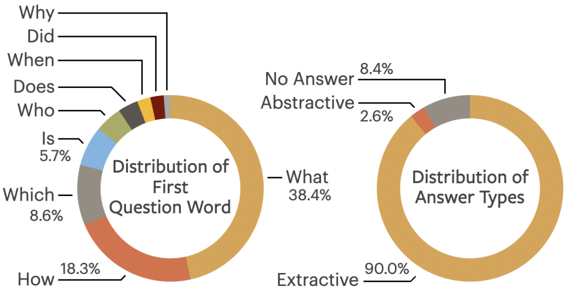


Figure 4: **Question and Answer Types**

- *Extractive* — the encouraged option, crowdworkers copy paste up to 250 words as an answer. We focus on extractive answers, as identifying such an answer is more straightforward compared to writing an answer.
- *Abstractive* — if the answer is present in an image or graph, crowdworkers write an abstractive answer of at least 20 words.
- *No Answer* — if no answer can be found, crowdworkers write an explanation of at least 20 words to describe why there is no answer.

Next, *validation* is conducted. The questions are complex, so we do not assume the answer is known. Crowdworkers instead flag answers that seem incorrect. For example, if the answer to *How many people live in California* is *three billion*, this would be flagged and re-annotated. A last step is conducted for answers that are *No Answer*. To verify that answers cannot be found, a second group of crowdworkers tries to find an answer. If an answer is found, the *No Answer* annotation is discarded.

3.3 QABrief Dataset Statistics

In summary, QABRIEFDATASET includes 6,897 claims and 21,168 questions paired with their answers. We use 500 claims as a validation set and 500 claims as a test set. The validation and test sets include around 1400 questions and answers each.

---

[3] For our running example, the reference article is: https://www.politifact.com/factchecks/2016/dec/16/russ-feingold/was-social-security-basically-invented-university-/

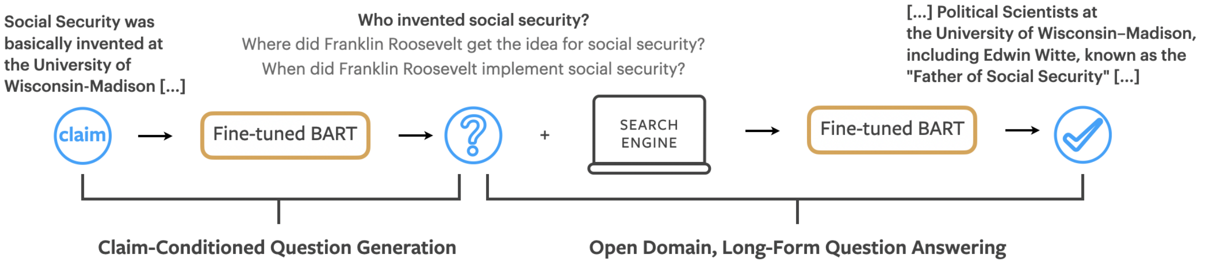

Figure 5: **QABriefer Model.** First, BART is finetuned to conduct claim-conditioned question generation and generates a sequence of questions that decompose a fact check. Second, we use an information retrieval system and a second finetuned BART model to extract long-form answers to each question.

We examine the types of questions to analyze the diversity. Table 1 shows that each claim on average requires around 3 questions to cover the different parts of the claim, and questions contain 10.5 words on average. The questions are quite diverse, as seen in Figure 4 (left), though the majority begin with *What, How, Which* question words. There are few *Why* questions, indicating a focus on verifying factual information, rather than causality.

The answers obtained have mainly extractive annotations, though a small portion of abstractive and no answer options exist (see Figure 4, right). Answers are around 43.5 words long (Table 1), though abstractive answers are generally shorter as crowdworkers must fully write them.

We examined a subset of 50 claims where we conducted multiple data collection trials with the same claim to understand the agreement rate between workers. We found that for the question annotation step, about half of the questions provided by different people on the same claim were very similar and could be considered paraphrases. For example, the questions *Who invented social security* and *Who was the invetor of social security*. For the answer annotation step, the identified answers varied in length but were often paraphrases — some crowdworkers tended to select only the specific span that answered the question (e.g. an entity name), while others chose several sentences to capture the context.

4 QABrief Model

The automatic generation of QABriefs presents numerous modeling challenges. Generating such a brief is a hierarchical process: writing the questions, and then conditioned upon the questions, searching the web and writing the answers. While many question answering datasets exist, questions in QABRIEFDATASET are grounded on real claims that were fact checked. The diversity of the claims renders reusing questions across claims unlikely to work, thus precluding the use of retrieve-and-rank approaches (Rao and Daumé III, 2018). Unlike previous question generation models (Du et al., 2017; Duan et al., 2017; Tang et al., 2017; Zhao et al., 2018) that generate based on an answer, we treat question generation closer to structured planning — laying out the format for the entire brief.

In contrast to most question answering datasets, the length of the answers in QABRIEFDATASET are long-form (Fan et al., 2019). For example, the average answer in SQuAD (Rajpurkar et al., 2016) is four words long, while the average answer in QABRIEFDATASET is forty. Further, datasets such as SQuAD, Natural Questions (Kwiatkowski et al., 2019), and HotpotQA (Yang et al., 2018) are built from Wikipedia, while QABriefs uses the web.

In this section, we describe QABRIEFER (see Figure 5). For each claim, the question generation model is used to generate multiple questions. For each question, an evidence document is retrieved using a search engine. We take the top search hit as the evidence and retrieve the text from CommonCrawl[4]. Finally, the generated question and retrieved evidence document is provided to the question answering model to generate an answer.

4.1 Question Generation

The first step of QABRIEFER is to create the questions that will form the structure of the brief. To create models that can take a claim as input and generate a sequence of questions as output, we use sequence-to-sequence (Sutskever et al., 2014) models. As QABRIEFDATASET is not large enough to train the language model needed for question generation, we leverage advances in pretraining and use QABRIEFDATASET to adapt it to the task at

---

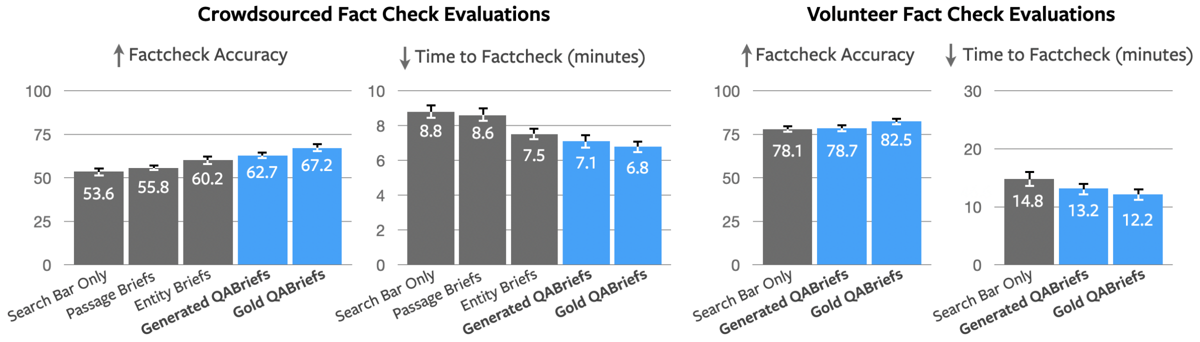

Figure 6: **Accuracy and Time Taken to fact check** by Crowdworkers (left) and Volunteer fact checkers (right). Briefs of various forms, but particularly QABriefs, increase fact checking accuracy and efficiency.

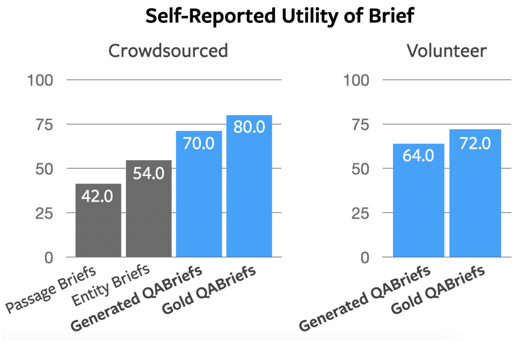

Figure 7: **Usefulness of Briefs** reported by Crowdsourced and Volunteer Fact Checkers.

hand. We use BART (Lewis et al., 2019), a denoising autoencoder that uses various noise functions and trains to recreate the input. In adapting BART for question generation based on claims, we explore three options: generating all questions based only on the claim, generating all questions based on the claim and the source of the claim (usually an entity), and generating questions one at a time. To write questions one at a time, the model conditions on the previous questions as well as the claim and source, and needs to predict the subsequent question or an *end of questions* token.

4.2 Question Answering

Given the question-based structure for QABriefs, the second part of the hierarchical process is to identify answers. Models take as input the question and evidence document that annotators indicated to contain the answer, and produce an answer. As QABRIEFDATASET does not have enough data to train a question answering model from scratch, we use BART finetuned on Natural Questions. and subsequently finetune it further on QABRIEFDATASET. As the dataset contains extractive and abstractive answers as well as questions where the model must provide an explanation to justify no answer, we use an abstractive approach with a generative model; abstractive models have shown strong performance on various question answering tasks (Lewis and Fan, 2018; Dong et al., 2019; Radford et al.; Raffel et al., 2019; Lewis et al., 2020).

5 Experimental Setup

Our main question is whether briefs can increase the accuracy and efficiency of fact checking. We focus on human evaluation with both crowdworkers and volunteers fact checking claims.

5.1 Human Evaluation

Metrics We evaluate the *accuracy* of a fact check by comparing the verdict from our human evaluators with professionals. The professional fact checking labels are obtained from the DATACOMMONS dataset. We measure the *time* taken to fact check from when the task is loaded to when the verdict and explanation is submitted.

Crowdsourced Evaluators Crowdworkers on Mechanical Turk are presented with the 500 test set claims and instructed to use a search bar to decide if the claim is true, false, or in the middle. They then write at least 20 words justifying their verdict. We indicate that if a claim is *mostly true* it should be labeled as true, and *mostly false* should be false. We discourage the middle option and suggest it should be used only if a verdict cannot be made, to prevent it from being the default. Previous work has shown that fine-grained labels, such as *sometimes true*, *half true*, *mostly true* are difficult to calibrate even with professional fact checkers (Lim, 2018), so we opt for a more simpler scale. The search bar queries the open web, but is restricted from searching known fact checking domains. Evaluators either use only the search bar, or are provided

Model	**BLEU**
Claim ⇒ Qs	12.8
Claim + Source ⇒ Qs	13.2
Claim + Source + Prev Qs ⇒ Next Q	13.4

Table 2: **Question Generation Models**

Model	**F1**

BART FT on NQ + QABRIEFDATASET	32.8

Table 3: **Question Answering Models.**

with a brief to read before the fact check. The same claims are evaluated with all methods. We repeat the study three times to assess variance.

Volunteer Evaluators Crowdsourced evaluation is scalable, but crowdworkers may be less motivated to spend a large amount of time fact checking. Thus, we conduct a smaller scale study using graduate student volunteer evaluators, recruited by asking for those interested in the challenge of fact checking real claims themselves. Volunteers are presented with 100 claims rather than 500, but otherwise conduct the same task as crowdworkers. Volunteers compare the search-bar-only fact checking process with generated QABriefs and gold QABriefs. We do not evaluate Passage Briefs or Entity Briefs, as we found volunteer fact checking to be less scalable than crowdsourcing.

5.2 Automatic Evaluation of Model Quality

To evaluate the quality of question generation, following existing work (Duan et al., 2017), we use BLEU. To evaluate the quality of question answering, we use F1 score (Rajpurkar et al., 2016).

5.3 Model Details

We use `fairseq-py` (Ott et al., 2019) to train the QABRIEFER. We use the open-sourced BART model (Lewis et al., 2019) and suggested finetuning hyperparameters, training for 10 epochs and taking the best epoch by validation loss. To generate, we use beam search with beam size 5. We tune the length penalty to decode such that written questions and answers approximately match the average length in the validation split. Exact training and generation commands, with further experimental details, can be found in the appendix.

6 Results

We show in human evaluations that fact checking efficiency and accuracy are improved with briefs.

6.1 Briefs Increase Fact Checking Quality

We examine the accuracy of crowdsourced and volunteer fact checkers when presented —in addition to a search bar— with different types of briefs: Passage, Entity, and QABriefs. For QABriefs, we examine briefs generated by QABRIEFER and the *Gold* briefs annotated in QABRIEFDATASET. We compare briefs against a *search bar only* baseline.

As shown in Figure 6 (left), when crowdworkers are presented with briefs, fact checking accuracy increases, even when taking into account variance in three repeated trials. The Passage Briefs are not more helpful in terms of accuracy compared to using the search bar alone, but Entity Briefs and QABriefs are both better than this baseline. Providing Gold rather than generated QABriefs performs best — suggesting modeling improvements could help bridge the gap. For crowdworkers, using briefs slightly reduces the time taken (from 8.8 minutes on average to around 7), but the overall time spent is low compared to professionals, who spend from 15 minutes to one day (Hassan et al., 2015).

For volunteer fact checkers (Figure 6, right), accuracy across all methods is higher compared to crowdworkers. Providing the Gold QABrief remains the best, though the gap is smaller than for crowdworkers. Providing the QABrief slightly decreases time taken to fact check. Note that the average volunteer spends twice the amount of time compared to a crowdworker, and this thoroughness probably contributes to higher accuracy, as well as the smaller improvement from providing briefs.

6.2 QABriefs are Preferred

Next, we further contrast QABriefs with Passage and Entity Briefs. We ask evaluators to consider if the brief made the fact check *easier* or provided useful *background context*. Crowdworkers rated QABriefs helpful twice as often as Passage Briefs (In Figure 7). When evaluators submit a fact check, they must write an explanation for their reasoning. Qualitatively examining these, we found many references to the QABrief. Evaluators noted that *based on [the QABrief], I searched for [X evidence]*. We hypothesize that the question-answer format may be easier to read, as it is naturally organized and possibly less redundant.

6.3 Generating QABriefs with QABriefer

Lastly, we assess the performance of our proposed QABriefer model. We display the BLEU scores for our proposed Question Generation models in Table 2 and find that iteratively writing questions one by one is the best performing method. Further, providing information about the source of the claim (usually the entity who made the claim) provides better results. Question Answering results are shown in Table 3. We find that first fine-tuning on a large question answering dataset, Natural Questions (NQ), and further fine-tuning on QABriefDataset provides the best results. Likely, this is because BART is a general purpose generative model, so fine-tuning for question answering first on a much larger dataset is useful.

7 Related Work

Previous work in NLP has focused on claim veracity. It has been treated as a classification problem (Wang, 2017), often using stance detection (Riedel et al., 2017). The FEVER Challenge (Thorne et al., 2018) proposed providing provenance for a decision along with classification, and various approaches developed combine information retrieval with stance detection or question answering (Li et al., 2018; Lee et al., 2018). Question generation and answering has been considered in the context of FEVER (Jobanputra, 2019) — the focus was on eliciting the right answer from a question answering system rather than improving the accuracy and efficiency of human fact checkers.

However, FEVER is based on modified Wikipedia sentences, not real world claims, which are arguably more difficult. To address this Hanselowski et al. (2019) considered the claims fact checked by the website Snopes, but used the reports accompanying them as evidence instead of finding the evidence directly. Popat et al. (2018) and Augenstein et al. (2019) used search engines, but without ensuring that they provide evidence supporting/refuting the claim instead of being related to it or that they were not fact checking reports. Finally, Kochkina et al. (2018) used responses on social media for rumour verification, but did not address evidence finding.

Various work studies how to improve the fact checking process. Analysis shows accuracy can improve by providing feedback (Hill, 2017), additional time (Bago et al., 2020), tooling (Karduni et al., 2019), or training (Zhang et al., 2018).

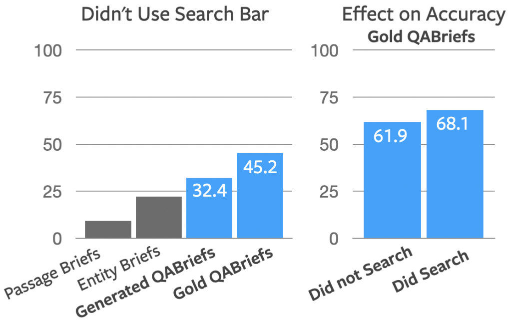

Figure 8: **Overconfidence** when given a QABrief.

These works are complementary to ours — we provide support in the form of briefs. Studies emphasize that current solutions for fully automated fact checking face various challenges (Graves, 2018) that must be addressed with interdisciplinary research (Karduni, 2019). Developing tools to aid human-in-the-loop fact checking has received increasing attention, from NLP to human-computer interaction and psychology, often with positive results when tested with journalists (Miranda et al., 2019) and professionals (Lurie, 2019).

8 Discussion

While our experiments show a generally positive impact of briefs for human fact checking, it is important to put them into a broader perspective.

Briefs for Professional Fact Checkers Crowdworkers and professional fact checkers perform different tasks under very different circumstances. Professionals often investigate alternative interpretations and produce an explanation of their process in an article. They often have years of experience and must check a variety of claims. Consequently, we do not claim that briefs will make a difference in their work. Nevertheless, QABriefs can provide insights into the fact checking process. As the QABrief dataset was created using professional fact checking articles describing how a claim was checked, by decomposing a claim into multiple components, we can encourage a more structured fact checking process.

Biases introduced by Briefs While briefs can increase accuracy, they can introduce biases. We found that providing a QABrief increased confidence — many submitted their fact check based on the brief alone, without the search bar. Figure 8 (left) displays that around 45% of crowdworkers did not use the search bar when given the Gold

QABrief, even though accuracy without the search bar is reduced. Briefs aid accuracy and efficiency, but are not fully sufficient to produce a verdict.

Metrics for Factchecking We focus on improving fact checking accuracy, but we note that agreement amongst professionals is not 100% (Lim, 2018). Professionals often agree if part of a claim is true or false, but disagree on the importance (Lim, 2018) or pursue different directions for checking the claim (Marietta et al., 2015; Amazeen, 2016). Different fact checkers have different scales, which are not calibrated. Nevertheless, improving the accuracy of crowd sourced fact checkers is still reflective of agreement with professionals.

9 Conclusion

We propose the concept of fact checking briefs, to be read before performing a fact check. Crucially, we develop QABRIEFER and release the accompanying QABRIEFDATASET, to create QABriefs. We show in extensive empirical studies with crowdworkers and volunteers that QABriefs can improve accuracy and efficiency of fact checking.

10 Appendix

10.1 Dataset Analysis

In this section, we describe qualitative observations about QABriefDataset to provide more insight.

How are fact checks decomposed into questions? We analyze the strategies taken by annotators to decompose the fact checking process of a claim into multiple questions. There are several distinct strategies that emerge:

For questions about comparison, annotators usually write 1-2 questions validating the first part of the comparison and 1-2 questions validating the second part of the comparison.

For questions about historical events, annotators usually clarify the entities involved and clarify the background. Annotators often ask questions about time and location. Several questions of the form *Did X event really happen* arise, but are often filtered by later steps of the dataset collection process (see description later in this Appendix).

For questions about what an individual may have said, annotators adopt a strategy very similar to professional fact checkers. A common trend in misinformation is misattribution, or saying an individual said a statement when they did not. Often, a misalignment in time or location can reveal this — if the person was not yet born, for example. Annotators often ask many questions to try to uncover this.

How are annotators finding answers? In many standard question answering datasets, the question-answer pairs already exist. For example, in TriviaQA (Joshi et al., 2017), the questions and answers are from Trivia enthusiasts, and in ELI5 (Fan et al., 2019), the questions and answers are from Reddit question answering subreddits. Other datsets collect questions and answers, but focus on identifying extractive answers in Wikipedia, an arguably easier task than finding them on the web. In SQuAD (Rajpurkar et al., 2016), questions are often written by modifying a sentence of Wikipedia into a question. In Natural Questions (Kwiatkowski et al., 2019) and MSMarco (Nguyen et al., 2016), the questions are real questions submitted to Google and Bing search engines, but the answers are much more straightforward (short, extractive spans).

In contrast, QABriefDataset faces challenges because the questions are complex and the answers must be found on the open web. In initial experiments, we attempted to restrict only to Wikipedia, but found that a large quantity of the questions were annotated with *No Answer*. To find answers on the web is a difficult task, as many answers depend heavily on context. Checking statistics, for example, is particularly difficult, as the year must be correct. We focus on using automated checks, described later on in this Appendix, to check for high quality answers. Further, we spot checked answers manually for quality control.

We analyzed the main strategies taken to find answers. About 50% of the annotators directly enter the question in the search bar, but the other 50% mainly use keyword searches to find better results. Around 83% of annotators only use the search bar once, but the rest use the search bar two to four times to refine their search query. Note this search query data will be released as part of QABriefDataset as well.

Most annotators submit an answer from the first three search results. Unfortunately, our interface cannot capture how many search results they opened and read before submitting a response. If Wikipedia was in the top search result, most annotators tended to submit a response from Wikipedia.

10.2 Additional Human Evaluation Results

In this section, we present additional results from our human evaluation studies. We contrast the process taken by professionals with our volunteer evaluators, analyze if evaluators can accurately assess how difficult a claim is to fact check, and display more detailed results to examine the time taken to fact check a claim.

Fact Checking Process of Non-Professionals In contrast to professionals, we find that crowdworkers and volunteer fact checkers often act on more general understanding rather than validating every detail. For example, for some claims, explanations written for a verdict included *It's not possible because the government cannot enforce*, but no evidence is cited. Over-reliance on common sense can lead to less evidence-based decision-making, and most likely contributes to less time-intensive checks compared to professionals. Another instance that commonly arises is checking certain statistics, such as *how many people purchased X item*. A professional fact checker will cross-reference the year carefully, examine how purchases are quantified in stores and through online retailers, and break it down by country. A volunteer examining the same claim will investigate with a search engine, but likely trust a holistic

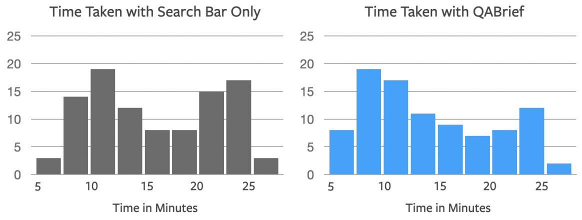

Figure 9: **Time Taken** to fact check by volunteer evaluators. The distribution is bimodal.

number they find, rather than breaking it down.

Self-Reported Fact Check Difficulty We found that crowdworkers and volunteer fact checkers were not accurate at assessing the difficulty of a fact check, and their assessments of difficulty did not correspond well to accuracy. We ask each fact checker to report the perceived difficulty of the process, either *easy, medium, hard* before they submitted their verdict. We found that their self-reported perceived difficulty did not correlate with their accuracy — even if evaluators felt the claim was *easy*, they were only 4% more accurate in accurately checking it. For *medium* and *hard* claims, the accuracy of fact checking was the same.

Time Taken to Factcheck We present additional results for volunteer fact checking and the time taken to examine claims. As shown in Figure 9, the time taken to fact check is bimodal, most likely because certain claims are easier and others require detailed investigation. Easier claims that were submitted more quickly tended to be checks based more on common sense, for example to fact check the claim *Shark found swimming on freeway in Houston*. When given QABriefs, the distribution of time taken shifts to smaller quantities.

10.3 Model Training Details

In this section, we provide detailed information about the training procedure of QABRIEFER as well as exact training and generation parameters used in `fairseq-py` to produce our results.

Question Generation We use the open sourced BART-large model. We finetune with learning rate $3e-05$, maximum tokens 2048 per batch, warming up for 500 updates and training for 10 epochs. Models are trained with label smoothing 0.1 and dropout 0.1. For optimization, we use the Adam optimizer and train with weight decay 0.01. We tuned only the dropout parameter, between values $0.1, 0.2, 0.3$, but otherwise took these parameters from the suggested parameter settings for BART finetuning. After training, we choose the best checkpoint by validation loss. The total training time is 8 hours on 1 GPU, though reasonable performance is reached after about 5 hours of training. As our model is finetuned BART large, it retains the same parameter count of 406M parameters.

For generation, we generate with beam size 5. We tune the length penalty between $0.5, 1, 1.5, 2$ and adjust the minimum and maximum length parameters. For minimum length, we examined values between $3, 5, 10$ and for maximum length, we examined values between $20, 30, 40, 50, 60$. To select the best generation hyperparameters, we generated on the validation set and chose the hyperparameters that maximized BLEU on validation to use on the test set.

Question Answering We use the open sourced BART-large model. We finetune with learning rate $3e-05$, maximum tokens 2048 per batch, warming up for 500 updates and training for 10 epochs. Models are trained with label smoothing 0.1 and dropout 0.1. For optimization, we use the Adam optimizer and train with weight decay 0.01. We use the suggested parameter settings for BART finetuning. After training, we choose the best checkpoint by validation loss. The total training time is 8 hours on 1 GPU, though reasonable performance is reached after about 7 hours of training. As our model is finetuned BART large, it retains the same parameter count of 406M parameters.

For generation, we generate with beam size 5, tuning the beam size between $4, 5$. We keep the length penalty fixed to 1. We adjust the minimum length parameter between $10, 50$. We adjust the maximum length parameter between $50, 100, 250$. To select the best generation hyperparameters, we generated on the validation set and chose the hyperparameters that maximized BLEU on validation to use on the test set.

10.4 Dataset Collection Details

In this section, we provide additional details on the instructions given to crowdworkers when constructing QABRIEFDATASET and describe all steps. Figure 10 illustrates the full dataset collection process.

10.4.1 Recruitment for the Task

We used the crowdworking platform Amazon Mechanical Turk. Evaluators were provided with the task and instructions, and could look at the task and

Figure 10: **QABriefDataset**: Annotators read the claim and professionally written fact checking article describing how the claim was checked. Questions and answers are annotated and validated for quality control. Questions are edited so each question is standalone, and *No Answer* options are verified.

opt to decline. For volunteer fact checkers, volunteers were given a description of our goals and the task they would perform. Volunteers were asked if they were interested in fact checking.

10.4.2 Question Generation Data Collection

Instructions for Writing Questions: Our goal is to understand how a claim is fact checked. Perform the following steps:

- *Read* the claim and the article that describes the fact checking process from a professional fact checker.
- *Think* what questions the fact checker had to answer to reach a verdict for the claim
- *Write* 3-5 questions that reflect the fact checking process used to reach a verdict.
- Questions must be *standalone* — do not write questions that refer to other questions, specify the names of people/places, etc

Important!

- *DO NOT* write questions with yes or no answers
- *DO NOT* write questions that rephrase the claim

Must Read Examples:

- *Good:* What was the population of California in 2000?
- *Bad:* What was the population of California? [No time specified to find a statistic]

- *Good:* How many education bills did Senator Smith vote for in March, 2000?
- *Bad:* How many education bills did he vote for? [Who is he? Also no time specified]

- *Good:* How do sharks move around?
- *Bad:* Is it true that sharks can walk on land? [Yes or no question, and directly asks if something is true or not]

In this data collection step, we used a number of automatic checks implemented into the task. Annotators could not submit without filling out at least 3 questions, each of at least 5 tokens in length. The questions could not overlap with each other more than 5 words. The questions could not exactly match the claim. Annotators could not submit in the first minute of the task. For each problem detected by the automatic check, an error message was displayed explaining why the current submission was not valid.

Instructions for Validating Questions : Our goal is to understand the steps necessary to fact check a claim. Perform the following steps:

- *Read* the claim and the article that describes the fact checking process
- *Read* the questions that describe the steps taken by the fact checker to reach a verdict
- *Write* additional questions **or** *Choose* no additional questions needed

Additional question writing guidelines are the same as for the original writing questions step. Annotators that write more questions are paid a bonus.

Instructions for Question Clarity : Our goal is to make sure each question is readable and could be used in a Google search to find an answer. Perform the following steps:

- *Read* the question
- Do you think the question could be Googled to find an answer? If not, *read* the article and add more detail to the question

Must Read Examples:

- *Original:* What was the population of California?
- *Edit:* What was the population of California in 2000? [Adds year]

- *Original:* How many education bills did he vote for?
- *Edit:* How many education bills did Senator Smith vote for in March, 2000? [Adds name and year]

10.4.3 Question Answering Data Collection

Instructions for Finding Answers: Our goal is to find answers to each of these questions. Perform the following steps:

- *Read* the question
- Use the *Search Bar* to find an answer
- If you cannot find an answer, you must write an explanation why you cannot find the answer

Important!

- *DO NOT* use any other search bar to find an answer. You MUST use the provided search bar only.
- *Do NOT* answer the claim or predict a verdict. Your job is to find an answer to the *QUESTION*
- *DO NOT* submit answers from politifact.com or factcheck.org. These answers will not be accepted. If you use our provided search bar, you will not have this problem. Use the provided search bar!

The task then has a dynamic workflow, which we now describe. After using the search bar, annotators had to select between one of three options:

- I found an answer, and I can copy paste the text of the answer from the webpage
- I cannot copy paste the answer because it is in a graph, table, or picture, but I can write the answer myself.
- I cannot find an answer. I understand I will need to write an explanation why an answer cannot be found

and these options correspond to extractive, abstractive, and no answer possibilities.

If the annotator chose the first option, an extractive answer, they were presented with a form with the following instructions: copy-paste the answer text, copy-paste the URL the answer is from. They are asked to *Copy paste the answer. DO NOT copy paste the entire site, only the part that answers the question. You can paste a maximum of 250 words.*

If the annotator chose the second option, an abstractive answer, they were presented with a form with the following instructions: write the answer text using at least 20 words, copy-paste the URL the answer is from.

If the annotator chose the third option, no answer, they were presented with a form with the following instructions: write an explanation for why no answer can be found using at least 20 words.

In this data collection step, we used a number of automatic checks implemented into the task. Annotators could not submit the task unless all requested areas (based on their chosen branch of the workflow) were filled out. The extractive answer could not be more than 250 words in length and could not be the empty string (one word answers were accepted). The abstractive answer and no answer explanation had to be at least 20 words in length. The copy pasted URL the annotators submitted as evidence for their answer had to match the URLs of their returned search results. This serves a dual purpose check — first that annotators used our search bar, which is restricted from accessing fact checking domains, and second that annotators submitted a real URL. Annotators could not submit in the first minute of the task. Annotators could not submit URLs that were known fact checking domains. For each problem detected by the automatic check, an error message was displayed explaining why the current submission was not valid.

Improving the Efficiency of Grammatical Error Correction with Erroneous Span Detection and Correction

Abstract

We propose a novel language-independent approach to improve the efficiency for Grammatical Error Correction (GEC) by dividing the task into two subtasks: Erroneous Span Detection (ESD) and Erroneous Span Correction (ESC). ESD identifies grammatically incorrect text spans with an efficient sequence tagging model. Then, ESC leverages a seq2seq model to take the sentence with annotated erroneous spans as input and only outputs the corrected text for these spans. Experiments show our approach performs comparably to conventional seq2seq approaches in both English and Chinese GEC benchmarks with less than 50% time cost for inference.

1 Introduction

Due to a growing number of error-corrected parallel sentences available in recent years, sequence-to-sequence (seq2seq) models with the encoder-decoder architecture (Bahdanau et al., 2014; Sutskever et al., 2014; Luong et al., 2015) have become a popular solution to GEC, which take the source (original) sentence as input and output the target (corrected) sentence. Although autoregressive seq2seq models facilitate correction for various grammatical errors and perform well, they are not efficient enough for GEC. As previous work (Zhao et al., 2019) points out, seq2seq models take most decoding steps to copy grammatically correct text spans from the source to the target during inference, which is the main efficiency bottleneck. If the time for the copying operations can be saved, the efficiency should be much improved.

With this motivation, we propose a simple yet novel language-independent approach to improve the efficiency of GEC by dividing the task into two subtasks: Erroneous Span Detection (ESD) and Erroneous Span Correction (ESC), shown in Figure 1. In ESD, we use an efficient sequence tagging model to identify the text spans that are grammatically incorrect in the source sentence, as Figure 1(a) shows. Then, we feed the sentence with erroneous span annotations to a seq2seq model for ESC. In contrast to conventional seq2seq approaches correcting the complete sentence, ESC only corrects the erroneous spans (see Figure 1(b)), which largely decreases the number of steps for decoding. Experiments in both English and Chinese GEC benchmarks demonstrate our approach performs comparably to the state-of-the-art transformer based seq2seq model with less than 50% time cost for inference. Furthermore, our approach offers more flexibility to control correction, allowing us to adapt the precision-recall trade-off to various application scenarios.

2 Related Work

Recently, many approaches have been proposed to improve GEC performance. However, except those adding synthetic erroneous data (Xie et al., 2018; Ge et al., 2018a; Grundkiewicz et al., 2019; Kiyono et al., 2019; Zhou et al., 2019) and Wikipedia revision logs (Lichtarge et al., 2019) for training, most methods cause an increase in latency. For example, language model and right-to-left (R2L) rescoring (Grundkiewicz et al., 2019; Kiyono et al., 2019) not only take time to rescore but also slow down the correction model with a larger beam size during inference; multi-round (iterative) decoding (Ge et al., 2018a,b; Lichtarge et al., 2019) needs to repeatedly run the model; BERT-fuse (Kaneko et al., 2020) adds extra computation for model fusion.

In contrast to extensive studies on GEC performance, little work focuses on improving the efficiency of GEC models until the last years.

---

[*] This work was done during the author's internship at Microsoft Research Asia.

[†] Co-first authors with equal contributions.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7162–7169,
November 16–20, 2020.

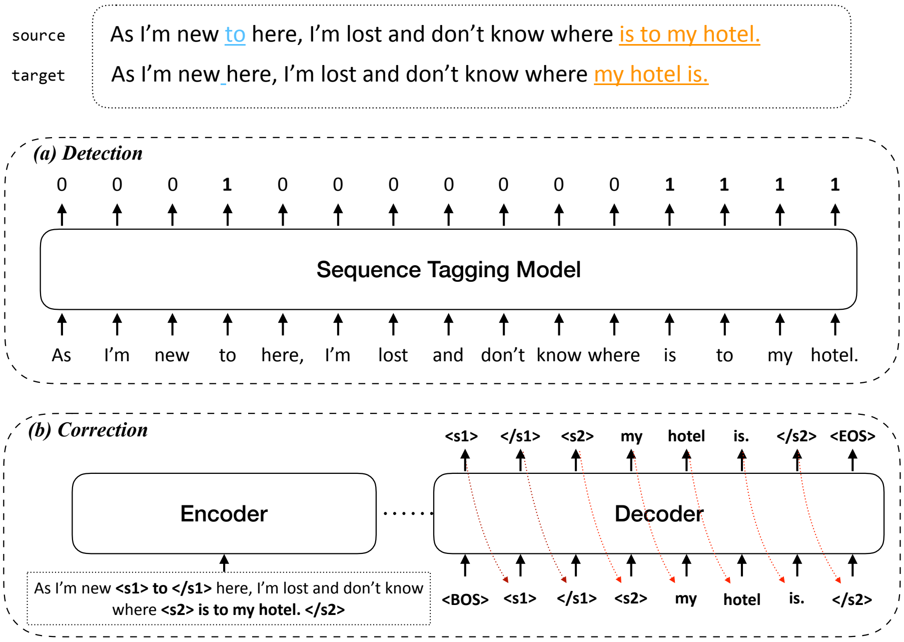

Figure 1: An overview of erroneous span detection (ESD) and erroneous span correction (ESC). The detection model is a sequence tagging model, while the correction model is a seq2seq model but only outputs the corrected texts for annotated spans (i.e., $\langle s1\rangle$ *to* $\langle/s1\rangle$ and $\langle s2\rangle$ *is to my hotel.* $\langle/s2\rangle$). For example, the text span "**is to my hotel.**" is identified as incorrect and then edited into "**my hotel is.**".

One branch of the work is language-dependent approaches, like PIE (Awasthi et al., 2019) and GECToR (Omelianchuk et al., 2020). They predict a sequence of token-level edit operations including a number of manually designed language-specific operations like changing verb forms (e.g., *VBZ→VBD*) and prepositions (e.g., *in→on*). However, they are difficult to be adapted to other languages. The other branch is language-independent models like LaserTagger (Malmi et al., 2019). They learn a vocabulary of edit operations from training data and thus can work for any language. However, their performance is inferior to their seq2seq counterpart. Our approach combines the advantages of both branches, which is language-independent and performs comparably to the state-of-the-art seq2seq approach with efficient inference.

3 Erroneous Span Detection

To identify incorrect spans, we use a binary sequence tagging model in which tag **0** means the token is in a correct span; while tag **1** means the token is in a grammatically incorrect span that needs to be edited, as shown in Figure 1(a). In order to train the tagging model, we align[1] tokens across the source and target sentence in training data. With token alignment, we can identify the text spans that are edited and thus can annotate the edited text spans in the original sentences as erroneous spans.

4 Erroneous Span Correction

With ESD, we can identify grammatically incorrect text spans in a sentence. If a sentence is identified as error-free, we take no further action; otherwise, we annotate the incorrect spans and use the ESC model to correct them, shown in Figure 1(b).

To avoid ESC being misled by span detection errors from ESD during inference, we randomly select text spans in the similar way to SpanBERT (Joshi et al., 2019) instead of only using gold erroneous spans in training data, to train the ESC model. In this way, the ESC model will see a large variety of span annotations and learn how to correct during training, and thus its robustness is improved: even if the detected spans during inference are not exactly accurate, the ESC model will not easily fail. With token alignment across the source and target sentence in GEC training data, we can generate training instances with span annotations and corrections like the example in Figure 1(b) for ESC.

---

[1] Alignment can be solved by dynamic programming like Levenshtein distance. We here use ERRANT (`https://github.com/chrisjbryant/errant`) for alignment.

Table 2: Performance and total inference time of models without pretraining under various batch sizes (1/8/16/32) using 1 Nvidia V100 GPU with CUDA 10.2 in the English (CoNLL-14: 1,312 sentences) and Chinese (NLPCC-18: 2,000 sentences) GEC test sets. The top group of models is implemented with Pytorch, while the bottom group is implemented with Tensorflow, thus their inference time cannot be compared. The performance of PIE in CoNLL-14 is not reported because it is pretrained with synthetic data and thus unfair to be compared here. Also, PIE has no result in NLPCC-18 because it is specific for English and difficult to be generalized to other languages.

5 Experiments

5.1 Experimental Setting

Following recent work in English GEC, we conduct experiments in the same setting with the restricted track of the BEA-2019 GEC shared task (Bryant et al., 2019), using FCE (Yannakoudakis et al., 2011), Lang-8 Corpus of Learner English (Mizumoto et al., 2011), NUCLE (Dahlmeier et al., 2013) and W&I+LOCNESS (Granger, 1998; Bryant et al., 2019) as training data. We use CoNLL-2013 test set as the dev set to choose the best-performing models, and evaluate on the well-known GEC benchmark datasets: CoNLL-2014 (Ng et al., 2014) and BEA-2019 test set with the official evaluation scripts (m2scorer[2] for CoNLL-14, ERRANT for BEA-19). As previous work (Grundkiewicz et al., 2019) trained with synthetic data, we synthesize 260M sentence pairs in the same way to try pretraining ESD and ESC. Also, we verify in Chinese GEC whether our approach can be adapted to other languages. We follow the setting of NLPCC-2018 Chinese GEC shared task (Zhao et al., 2018), using its official training[3] and evaluation datasets.

We fine-tune Roberta (Liu et al., 2019) base and Chinese Bert (Devlin et al., 2018) base model for English and Chinese ESD respectively. For ESC, we train a Transformer (big) model (Vaswani et al., 2017), using an encoder-decoder shared vocabulary of 32K Byte Pair Encoding (Sennrich et al., 2015) tokens for English and 8.4K Chinese character for Chinese. During inference, ESC decodes with a beam size of 5. We include more details of models, training and inference in the supplementary notes.

---

[2] `https://github.com/nusnlp/m2scorer`

[3] We sample 5,000 training instances as the dev set.

Model	#Sent for ESC/seq2seq	Batch size			P	R	$F_{0.5}$
		1	8	16			
ESD (base) + ESC	872	**137 (23+114)**	**34 (5+29)**	**21 (3+18)**	66.0	24.7	49.5
ESD (base) + seq2seq	872	284 (23+261)	66 (5+61)	41 (3+38)	**67.0**	**25.1**	**50.2**
ESD (large) + ESC	935	**167 (43+124)**	**40 (8+32)**	**25 (6+19)**	**67.2**	**26.4**	**51.3**
ESD (large) + seq2seq	935	318 (43+275)	77 (8+69)	47 (6+41)	66.6	25.5	50.3
seq2seq	1,312	363	85	51	64.9	26.6	50.4

Table 3: In-depth time cost (in second) analysis in CoNLL-14 which contains 1,312 test sentences. (base) and (large) indicate that the ESD models are fine-tuned from the Roberta base and large models respectively. ESD + seq2seq is implemented as follows: ESD first identifies the sentences that have grammatical errors, then the seq2seq baseline model only corrects these sentences. The column **#Sent for ESC/seq2seq** shows the actual number of sentences ESC/seq2seq processed. For the time cost in the brackets such as (23+114), the first term (e.g., 23) is the time cost by the ESD model while the last term is the cost (e.g., 114) by the other parts.

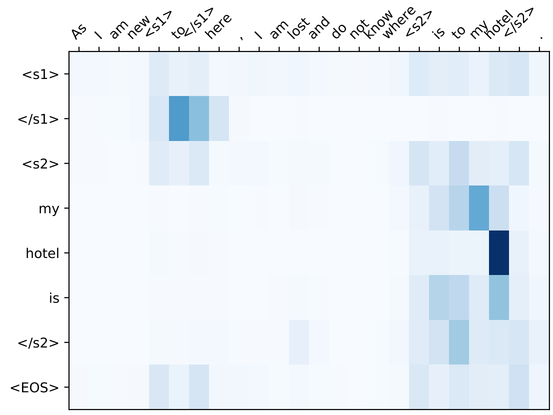

Figure 2: Attention Heatmap of ESC.

5.2 Experimental Results

Table 1 shows the performance of our approach and recent models in English GEC. Although the non auto-regressive models like Levenshtein Transformer and LaserTagger are faster than the seq2seq baseline, their performance is not desirable. Among the models without pretraining (**top group**), our approach is the only one that performs comparably to the *Seq2seq* baseline with faster inference. When we add the synthetic data to pretrain the ESD and ESC models, our approach's results are much improved, yielding state-of-the-art results among the models with good inference speed (**middle group**). Though our approach underperforms the best systems (**bottom group**) which improve results through various methods (e.g., model fusion, ensemble decoding and rescoring) that seriously hurt efficiency, it is much more efficient and thus applicable in real world applications.

Table 2 compares the inference time of various approaches. Compared to the *Seq2seq* implementation in Pytorch-fairseq, our approach saves over 50% time cost. It is notable that among the implementations in Table 2, LaserTagger is the most efficient though its results are not good enough.

threshold	0.2	0.3	0.4	0.5	0.6	0.7
P	62.4	63.8	64.8	66.0	66.2	**67.0**
R	**27.4**	26.8	25.6	24.7	23.4	21.7
$F_{0.5}$	49.7	**50.0**	49.6	49.5	48.4	47.2

Table 4: As the probability threshold of ESD increases, precision increases while recall drops in CoNLL-14.

Also, our approach consistently achieves comparable performance with the *Seq2seq* baseline in Chinese GEC, demonstrating that our approach can be easily adapted to other languages.

We further analyze the corresponding time cost of ESD and ESC. Table 3 shows that ESD is much faster than the auto-regressive ESC model. It not only efficiently filters out error-free sentences to save effort for the following process, but also pinpoints incorrect spans, allowing ESC to only focus on correcting the spans and reduce the decoding steps, as shown in Figure 2. For the 872 sentences ESD (base) identifies as incorrect, the total number of decoding time steps (in the best beam) of ESC is 7,647, accounting for the efficiency improvement over the seq2seq model whose corresponding decoding steps are 21,065. Furthermore, if we use a larger ESD model (Roberta large), we observe better results with a still marked reduction in time cost compared to the baseline. More detailed qualitative studies and analyses of ESD are presented in the supplementary notes due to the space limitation.

Besides its efficiency advantage, our approach offers more flexibility to control correction behavior during inference, making it adaptive to various real-world application scenarios. As shown in Table 4, if the model is intended for high precision, we can increase the probability threshold for ESD so that it identifies the incorrect spans only when it is very confident; on the other hand, if we want the model to be aggressive for higher recall, we can simply decrease the threshold.

6 Conclusion and Future Work

We propose a novel language-independent approach to improve the efficiency of GEC. Our approach performs comparably to the state-of-the-art seq2seq model with a considerable reduction in inference time, and can be easily adapted to other languages and offer more flexibility to control correction behavior (e.g., trading precision for recall).

Through our experiments in GEC, we verify the feasibility of span-specific decoding, which has been explored for text infilling (Raffel et al., 2019) and text rewriting. It is inspiring and promising to be generalized to more rewriting tasks, which will be studied as our future work.

BEA-19	4,477	89.3K	Test
CoNLL-14	1,312	30.1K	Test

Table 5: Statistics of the datasets used for pretraining, fine-tuning and evaluation.

Configurations	Values
Pretraining	
Model Architecture	Roberta (base) (Liu et al., 2019)
Number of parameters	125M
Number of epochs	5
Devices	8 Nvidia V100 GPU
Max tokens per GPU	12000
Optimizer	Adam (β_1=0.9, β_2=0.98, ϵ=1×10^{-6}) (Kingma and Ba, 2014)
Learning rate	3×10^{-5}
Learning rate scheduler	inverse sqrt
warmup	8000
weight decay	0.1
Dropout	0.3
Fine-tuning	
Number of epochs	50
Devices	4 Nvidia V100 GPU
Max tokens per GPU	8000
Learning rate	1×10^{-5}
warmup	4000
Dropout	0.2

Table 6: Hyper-parameters values of ESD during the pretraining and fine-tuning.

2018a; Zhang et al., 2019; Kiyono et al., 2019; Grundkiewicz et al., 2019) did, using back translation and sentence corruption. Specifically, we train a transformer (base) model (Vaswani et al., 2017) for back translation using the training data of the restricted track in the BEA-19 shared task. For sentence corruption, we follow Edunov et al. (2018) to randomly insert, delete, replace and swap adjacent tokens in a sentence.

Hyper-parameters for the ESD and ESC model for English GEC are listed in table 6 and table 7. The hyper-parameters for Chinese GEC are almost the same except that the ESD model is fine-tuned from Chinese Bert (Devlin et al., 2018) base model.

At last, we highlight that the Levenshtein Transformer baselines in this paper are implemented using the master branch of fairseq (previous versions may have different reproduced results).

Configurations	Values
Pretraining	
Model Architecture	Transformer (big) (Vaswani et al., 2017)
Number of parameters	209M
Number of epochs	5

B ESD performance

We followed the previous work (Rei, 2017; Rei and Yannakoudakis, 2017; Kaneko et al., 2017) in Grammatical Error Detection (GED), using token-level *precision*, *recall* and $F_{0.5}$ to evaluate our ESD model. Table 8 shows the results in CoNLL-14.

C Examples

In table 9 and table 10, we show examples that are corrected by our approach to demonstrate the effectiveness of our approach in practice. According to the results in these tables, it is clear that our approach can yield satisfying corrections without hurting fluency, which is consistent with our evaluation results in the JFLEG (Napoles et al., 2017) test set with respect to GLEU[7] (Napoles et al., 2015) – an automatic fluency metric for GEC.

---

[7] Our approach (without pretraining) achieves 53.0 GLEU, comparable to 52.7 by its seq2seq counterpart in JFLEG.

Source Sentence	Instead, we will post a seed and tag our friends to inform this kind of changments.
Annotation	Instead, we will post a seed and tag our friends to **<s1> inform this kind of changments. </s1>**
Correction	**<s1> inform them of these kinds of changes. </s1>**
Final Output	Instead, we will post a seed and tag our friends to inform them of these kinds of changes.
Source Sentence	Personally I feel that we still should take our responsibility to tell them the situation.
Annotation	**<s1> Personally I </s1>** feel that **<s2> we still should </s2>** take our responsibility to tell them the situation.
Correction	**<s1> Personally , I </s1> <s2> we should still </s2>**
Final Output	Personally, I feel that we should still take our responsibility to tell them the situation.
Source Sentence	The law 's spirit also include the fairness.
Annotation	The law 's spirit **<s1> also include the fairness. </s1>**
Correction	**<s1> also includes fairness. </s1>**
Final Output	The law 's spirit also includes fairness.
Source Sentence	Above all, life is more important than secret.
Annotation	Above all, life is more important **<s1> than secret. </s1>**
Correction	**<s1> than a secret. </s1>**
Final Output	Above all, life is more important than a secret.
Source Sentence	So, they have to also prepare mentally.
Annotation	So, **<s1> they have to also prepare </s1>** mentally.
Correction	**<s1> they also have to prepare </s1>**
Final Output	So, they also have to prepare mentally.
Source Sentence	To prevent the bigger problem to happen, it takes a lot of effort to take care of your body.
Annotation	To prevent the bigger **<s1> problem to happen, it </s1>** takes a lot of effort to take care of your body.
Correction	**<s1> problem from happening, it </s1>**
Final Output	To prevent the bigger problem from happening, it takes a lot of effort to take care of your body.

Table 9: Examples of our ESD & ESC approach in English for GEC. ESD first detects the grammatical incorrect text spans in the source sentence. Then the sentence with the erroneous span annotations (the **Annotation** row) are fed into the ESC model to generate the corresponding corrections (the **Correction** row) for the annotated spans. Finally, we replace the erroneous spans with the corresponding corrected text in ESC's outputs (the **Final Output** row).

Source Sentence	北京的空气太污染了，泛在北京的人一定要注意，别抽烟。
Annotation	北京的空气**<s1>太污染了，泛在北</s1>** 京的人一定要注意，别抽烟。
Correction	**<s1> 污染太严重了，在北</s1>**
Final Output	北京的空气污染太严重了，在北京的人一定要注意，别抽烟。
Source Sentence	因为几乎的人们还没感到污染对自己的直接的影响。
Annotation	因**<s1>为几乎的人们还</s1>**没感到污染对自己的直接的影响。
Correction	**<s1>为人们几乎</s1>**
Final Output	因为为人们几乎还没感到污染对自己的直接的影响。
Source Sentence	列车、汽车，飞机等人类科技发展的结果也重大问题。
Annotation	列车、汽车，飞机等人类科技发展的结果**<s1>也重大</s1>**问题。
Correction	**<s1>也存在重大</s1>**
Final Output	列车、汽车，飞机等人类科技发展的结果也存在重大问题
Source Sentence	中国，悠久的历史，灿烂的文化，真是在历史上最难忘的国家。
Annotation	中国，悠久的历史，灿烂的文化，真**<s1>是在历</s1>**史上最难忘的国家。
Correction	**<s1>是历</s1>**
Final Output	中国，悠久的历史，灿烂的文化，真是历史上最难忘的国家。
Source Sentence	以找到这些稳定的工作，我们有读书的必要
Annotation	**<s1>以找</s1>**到这些稳定的工作，我们有读书的必要。
Correction	**<s1>为了找</s1>**

Abstract

Language representation models such as BERT could effectively capture contextual semantic information from plain text, and have been proved to achieve promising results in lots of downstream NLP tasks with appropriate fine-tuning. However, most existing language representation models cannot explicitly handle coreference, which is essential to the coherent understanding of the whole discourse. To address this issue, we present CorefBERT, a novel language representation model that can capture the coreferential relations in context. The experimental results show that, compared with existing baseline models, CorefBERT can achieve significant improvements consistently on various downstream NLP tasks that require coreferential reasoning, while maintaining comparable performance to previous models on other common NLP tasks. The source code and experiment details of this paper can be obtained from `https://github.com/thunlp/CorefBERT`.

1 Introduction

Recently, language representation models such as BERT (Devlin et al., 2019) have attracted considerable attention. These models usually conduct self-supervised pre-training tasks over large-scale corpus to obtain informative language representation, which could capture the contextual semantic of the input text. Benefiting from this, language representation models have made significant strides in many natural language understanding tasks including natural language inference (Zhang et al., 2020), sentiment classification (Sun et al., 2019b), question answering (Talmor and Berant, 2019), relation extraction (Peters et al., 2019), fact extraction and verification (Zhou et al., 2019), and coreference resolution (Joshi et al., 2019).

However, existing pre-training tasks, such as masked language modeling, usually only require models to collect local semantic and syntactic information to recover the masked tokens. Hence, language representation models may not well model the long-distance connections beyond sentence boundary in a text, such as coreference. Previous work has shown that the performance of these models is not as good as human performance on the tasks requiring coreferential reasoning (Paperno et al., 2016; Dasigi et al., 2019), and they can be further improved on long-text tasks with external coreference information (Cheng and Erk, 2020; Xu et al., 2020; Zhao et al., 2020). Coreference occurs when two or more expressions in a text refer to the same entity, which is an important element for a coherent understanding of the whole discourse. For example, for comprehending the whole context of "*Antoine published The Little Prince in 1943. The book follows a young prince who visits various planets in space.*", we must realize that *The book* refers to *The Little Prince*. Therefore, resolving coreference is an essential step for abundant higher-level NLP tasks requiring full-text understanding.

To improve the capability of coreferential reasoning for language representation models, a straightforward solution is to fine-tune these models on supervised coreference resolution data. Nevertheless, on the one hand, we find fine-tuning on existing small coreference datasets cannot improve the model performance on downstream tasks in our preliminary experiments. On the other hand, it is impractical to obtain a large-scale supervised coreference dataset.

To address this issue, we present CorefBERT, a language representation model designed to better capture and represent the coreference information. To learn coreferential reasoning ability from large-scale unlabeled corpus, CorefBERT introduces a novel pre-training task called *Mention Reference Prediction* (MRP). MRP leverages those repeated mentions (e.g., noun or noun phrase) that appear

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7170–7186,
November 16–20, 2020.

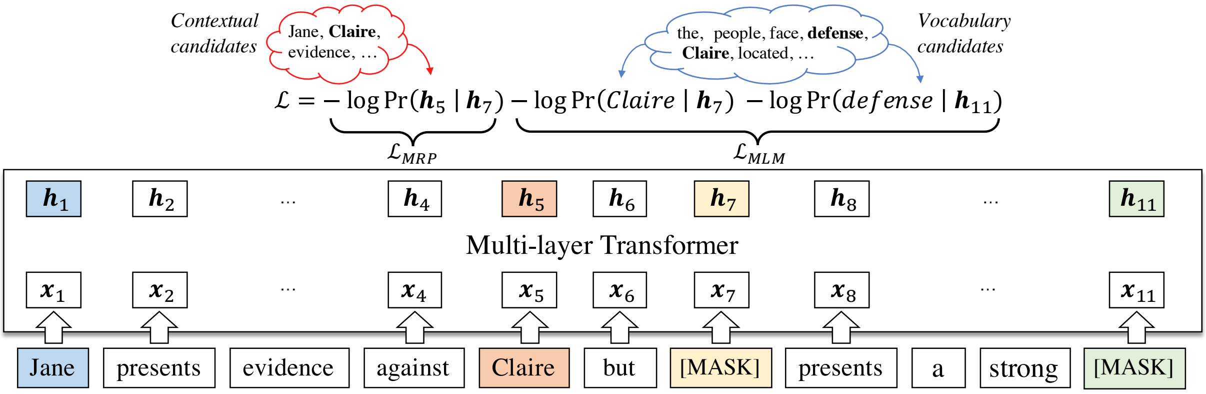

Figure 1: An illustration of CorefBERT's training process. In this example, the second *Claire* and a common word *defense* are masked. The overall loss of *Claire* consists of the loss of both Mention Reference Prediction (MRP) and Masked Language Modeling (MLM). MRP requires model to select contextual candidates to recover the masked tokens, while MLM asks model to choose from vocabulary candidates. In addition, we also sample some other tokens, such as *defense* in the figure, which is only trained with MLM loss.

multiple times in the passage to acquire abundant co-referring relations. Among the repeated mentions in a passage, MRP applies mention reference masking strategy to mask one or several mentions and requires model to predict the masked mention's corresponding referents. Figure 1 shows an example of the MRP task, we substitute one of the repeated mentions, *Claire*, with `[MASK]` and ask the model to find the proper contextual candidate for filling it. To explicitly model the coreference information, we further introduce a copy-based training objective to encourage the model to select words from context instead of the whole vocabulary. The internal logic of our method is essentially similar to that of coreference resolution, which aims to find out all the mentions that refer to the masked mentions in a text. Besides, rather than using a context-free word embedding matrix when predicting words from the vocabulary, copying from context encourages the model to generate more context-sensitive representations, which is more feasible to model coreferential reasoning.

We conduct experiments on a suite of downstream tasks which require coreferential reasoning in language understanding, including extractive question answering, relation extraction, fact extraction and verification, and coreference resolution. The results show that CorefBERT outperforms the vanilla BERT on almost all benchmarks and even strengthens the performance of the strong RoBERTa model. To verify the model's robustness, we also evaluate CorefBERT on other common NLP tasks where CorefBERT still achieves comparable results to BERT. It demonstrates that the introduction of the new pre-training task about coreferential reasoning would not impair BERT's ability in common language understanding.

2 Related Work

Pre-training language representation models aim to capture language information from the text, which facilitate various downstream NLP applications (Kim, 2014; Lin et al., 2016; Seo et al., 2017). Early works (Mikolov et al., 2013; Pennington et al., 2014) focus on learning static word embeddings from the unlabeled corpus, which have the limitation that they cannot handle the polysemy well. Recent years, contextual language representation models pre-trained on large-scale unlabeled corpora have attracted intensive attention and efforts from both academia and industry. SA-LSTM (Dai and Le, 2015) and ULMFiT (Howard and Ruder, 2018) pre-trains language models on unlabeled text and perform task-specific fine-tuning. ELMo (Peters et al., 2018) further employs a bidirectional LSTM-based language model to extract context-aware word embeddings. Moreover, OpenAI GPT (Radford et al., 2018) and BERT (Devlin et al., 2019) learn pre-trained language representation with Transformer architecture (Vaswani et al., 2017), achieving state-of-the-art results on various NLP tasks. Beyond them, various improvements on pre-training language representation have been proposed more recently, including (1) designing new pre-trainning tasks or objectives such as SpanBERT (Joshi et al., 2020) with span-based learning, XLNet (Yang et al., 2019) considering masked positions dependency with auto-regressive loss, MASS (Song et al., 2019) and BART (Wang et al., 2019b) with sequence-to-sequence pre-training, ELECTRA (Clark et al., 2020) learning from replaced token detection with generative adversarial networks and InfoWord (Kong et al., 2020) with contrastive learning; (2) integrating external knowledge such as factual knowledge in knowledge graphs (Zhang et al., 2019; Peters et al., 2019; Liu et al., 2020a); and (3) exploring multilingual learning (Conneau and Lample, 2019; Tan and Bansal, 2019; Kondratyuk and Straka, 2019) or multimodal learning (Lu et al., 2019; Sun et al., 2019a; Su et al., 2020). Though existing language representation models have achieved a great success, their coreferential reasoning capability are still far less than that of human beings (Paperno et al., 2016; Dasigi et al., 2019). In this paper, we design a mention reference prediction task to enhance language representation models in terms of coreferential reasoning.

Our work, which acquires coreference resolution ability from an unlabeled corpus, can also be viewed as a special form of unsupervised coreference resolution. Formerly, researchers have made efforts to explore feature-based unsupervised coreference resolution methods (Bejan et al., 2009; Ma et al., 2016). After that, Word-LM (Trinh and Le, 2018) uncovers that it is natural to resolve pronouns in the sentence according to the probability of language models. Moreover, WikiCREM (Kocijan et al., 2019) builds sentence-level unsupervised coreference resolution dataset for learning coreference discriminator. However, these methods cannot be directly transferred to language representation models since their task-specific design could weaken the model's performance on other NLP tasks. To address this issue, we introduce a mention reference prediction objective, complementary to masked language modeling, which could make the obtained coreferential reasoning ability compatible with more downstream tasks.

3 Methodology

In this section, we present CorefBERT, a language representation model, which aims to better capture the coreference information of the text. As illustrated in Figure 1, CorefBERT adopts the deep bidirectional Transformer architecture (Vaswani et al., 2017) and utilizes two training tasks:

(1) **Mention Reference Prediction** (MRP) is a novel training task which is proposed to enhance coreferential reasoning ability. MRP utilizes the mention reference masking strategy to mask one of the repeated mentions and then employs a copy-based training objective to predict the masked tokens by copying from other tokens in the sequence.

(2) **Masked Language Modeling** (MLM)[1] is proposed from vanilla BERT (Devlin et al., 2019), aiming to learn the general language understanding. MLM is regarded as a kind of cloze tasks and aims to predict the missing tokens according to its final contextual representation. Except for MLM, Next Sentence Prediction (NSP) is also commonly used in BERT, but we train our model without the NSP objective since some previous works (Liu et al., 2019; Joshi et al., 2020) have revealed that NSP is not as helpful as expected.

Formally, given a sequence of tokens[2] $X = (x_1, x_2, \ldots, x_n)$, we first represent each token by aggregating the corresponding token and position embeddings, and then feeds the input representations into deep bidirectional Transformer to obtain the contextual representations, which is used to compute the loss for pre-training tasks. The overall loss of CorefBERT is composed of two training losses: the mention reference prediction loss L_{MRP} and the masked language modeling loss L_{MLM}, which can be formulated as:

$$\mathcal{L} = \mathcal{L}_{\text{MRP}} + \mathcal{L}_{\text{MLM}}. \tag{1}$$

3.1 Mention Reference Masking

To better capture the coreference information in the text, we propose a novel masking strategy: mention reference masking, which masks tokens of the repeated mentions in the sequence instead of masking random tokens. We follow a distant supervision assumption: the repeated mentions in a sequence would refer to each other. Therefore, if we mask one of them, the masked tokens would be inferred through its context and unmasked references. Based on the above strategy and assumption, the CorefBERT model is expected to capture the coreference information in the text for filling the masked token.

In practice, we regard nouns in the text as mentions. We first use a part-of-speech tagging tool to extract all nouns in the given sequence. Then, we cluster the nouns into several groups where each group contains all mentions of the same noun. After that, we select the masked nouns from different groups uniformly. For example, when *Jane* occurs

---

[1] Details of MLM are in the appendix due to space limit.

[2] In this paper, tokens are at the subword level.

three times and *Claire* occurs two time in the text, all the mentions of *Jane* or *Claire* will be grouped. Then, we choose one of the groups, and then sample one mention of the selected group.

To maintain the universal language representation ability in CorefBERT, we utilize both the MLM (masking random word) and MRP (masking mention reference) in the training process. Empirically, the masked words for MLM and MRP are sampled on a ratio of 4:1. Similar to BERT, 15% of the tokens are sampled for both masking strategies mentioned above, where 80% of them are replaced with a special token `[MASK]`, 10% of them are replaced with random tokens, and 10% of them are unchanged. We also adopt whole word masking (WWM) (Joshi et al., 2020), which masks all the subwords belong to the masked words or mentions.

3.2 Copy-based Training Objective

In order to capture the coreference information of the text, CorefBERT models the correlation among words in the sequence. Inspired by copy mechanism (Gu et al., 2016; Cao et al., 2017) in sequence-to-sequence tasks, we introduce a copy-based training objective to require the model to predict missing tokens of the masked mention by copying the unmasked tokens in the context. Since the masked tokens would be copied from context, low-frequency tokens, such as proper nouns, could be well processed to some extent. Moreover, through copying mechanism, the CorefBERT model could explicitly capture the relations between the masked mention and its referring mentions, therefore, to obtain the coreference information in the context.

Formally, we first encode the given input sequence $X = (x_1, \ldots, x_n)$ into hidden states $\boldsymbol{H} = (\boldsymbol{h}_1, \ldots, \boldsymbol{h}_n)$ via multi-layer Transformer (Vaswani et al., 2017). The probability of recovering the masked token x_i by copying from x_j is defined as:

$$\Pr(x_j|x_i) = \frac{\exp((\boldsymbol{V} \odot \boldsymbol{h}_j)^T \boldsymbol{h}_i)}{\sum_{x_k \in X} \exp((\boldsymbol{V} \odot \boldsymbol{h}_k)^T \boldsymbol{h}_i)}, \quad (2)$$

where $\odot$ denotes element-wise product function and $\boldsymbol{V}$ is a trainable parameter to measure the importance of each dimension for token's similarity.

Moreover, since we split a word into several word pieces as BERT does and we adopt whole word masking strategy for MRP, we need to extend our copy-based objective into word-level. To this end, we apply the token-level copy-based training objective on both start and end tokens of the masked word, because the representations of these two tokens could typically cover the major information of the whole word (Lee et al., 2017; He et al., 2018). For a masked noun w_i consisting of a sequence of tokens $(x_s^{(i)}, \ldots, x_t^{(i)})$, we recover w_i by copying its referring context word, and define the probability of choosing word w_j as:

$$\Pr(w_j|w_i) = \Pr(x_s^{(j)}|x_s^{(i)}) \times \Pr(x_t^{(j)}|x_t^{(i)}). \quad (3)$$

A masked noun possibly has multiple referring words in the sequence, for which we collectively maximize the similarity of all referring words. It is an approach widely used in question answering (Kadlec et al., 2016; Swayamdipta et al., 2018; Clark and Gardner, 2018) designed to handle multiple answers. Finally, we define the loss of Mention Reference Prediction (MRP) as:

$$\mathcal{L}_{\text{MRP}} = -\sum_{w_i \in M} \log \sum_{w_j \in C_{w_i}} \Pr(w_j|w_i), \quad (4)$$

where M is the set of all masked mentions for mention reference masking, and C_{w_i} is the set of all corresponding words of word w_i.

4 Experiment

In this section, we first introduce the training details of CorefBERT. After that, we present the fine-tuning results on a comprehensive suite of tasks, including extractive question answering, document-level relation extraction, fact extraction and verification, coreference resolution, and eight tasks in the GLUE benchmark.

4.1 Training Details

Since training CorefBERT from scratch would be time-consuming, we initialize the parameters of CorefBERT with BERT released by Google[3], which is also used as our baselines on downstream tasks. Similar to previous language representation models (Devlin et al., 2019; Joshi et al., 2020), we adopt English Wikipeida[4] as our training corpus, which contains about 3,000M tokens. We employ spaCy[5] for part-of-speech-tagging on the corpus. We train CorefBERT with contiguous sequences of up to 512 tokens, and randomly shorten the input sequences with 10% probability in training. To verify the effectiveness of our method for the language

---

[3] https://github.com/google-research/bert

[4] https://en.wikipedia.org

[5] https://spacy.io

representation model trained with tremendous corpus, we also train CorefBERT initialized with RoBERTa[6], referred as CorefRoBERTa. Additionally, we follow the pre-training hyper-parameters used in BERT, and adopt Adam optimizer (Kingma and Ba, 2015) with batch size of 256. Learning rate of 5×10^{-5} is used for the base model and 1×10^{-5} is used for the large model. The optimization runs 33k steps, where the learning rate is warmed-up over the first 20% steps and then linearly decayed. The pre-training process consumes 1.5 days for base model and 11 days for large model with 8 RTX 2080 Ti GPUs in mixed precision. We search the ratio of MRP loss and MLM loss in 1:1, 1:2 and 2:1, and find the ratio of 1:1 achieves the best result. Beyond this, training details for downstream tasks are shown in the appendix.

4.2 Extractive Question Answering

Given a question and passage, the extractive question answering task aims to select spans in passage to answer the question. We first evaluate models on Questions Requiring Coreferential Reasoning dataset (QUOREF) (Dasigi et al., 2019). Compared to previous reading comprehension benchmarks, QUOREF is more challenging as 78% of the questions in QUOREF cannot be answered without coreference resolution. In this case, it can be an effective tool to examine the coreferential reasoning capability of question answering models.

We also adopt the MRQA, a dataset not specially designed for examining coreferential reasoning capability, which involves paragraphs from different sources and questions with manifold styles. Through MRQA, we hope to evaluate the performance of our model in various domains. We use six benchmarks of MRQA, including SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017), SearchQA (Dunn et al., 2017), TriviaQA (Joshi et al., 2017), HotpotQA (Yang et al., 2018), and Natural Questions (NaturalQA) (Kwiatkowski et al., 2019). Since MRQA does not provide a public test set, we randomly split the development set into two halves to generate new validation and test sets.

Model	Dev		Test	
	EM	F1	EM	F1
QANet*	34.41	38.26	34.17	38.90
QANet+BERT$_{\text{BASE}}$ *	43.09	47.38	42.41	47.20
BERT$_{\text{BASE}}$ *	58.44	64.95	59.28	66.39
BERT$_{\text{BASE}}$	61.29	67.25	61.37	68.56
CorefBERT$_{\text{Base}}$	**66.87**	**72.27**	**66.22**	**72.96**
BERT$_{\text{LARGE}}$	67.91	73.82	67.24	74.00
CorefBERT$_{\text{LARGE}}$	**70.89**	**76.56**	**70.67**	**76.89**
RoBERTa-MT^{+}	74.11	81.51	72.61	80.68
RoBERTa$_{\text{LARGE}}$	74.15	81.05	75.56	82.11
CorefRoBERTa$_{\text{LARGE}}$	**74.94**	**81.71**	**75.80**	**82.81**

Table 1: Results on QUOREF measured by exact match (EM) and F1. Results with *, $^+$ are from Dasigi et al. (2019) and official leaderboard respectively.

Baselines For QUOREF, we compare our CorefBERT with four baseline models: (1) **QANet** (Yu et al., 2018) combines self-attention mechanism with the convolutional neural network, which achieves the best performance to date without pre-training; (2) **QANet+BERT** adopts BERT representation as an additional input feature into QANet; (3) **BERT** (Devlin et al., 2019), simply fine-tunes BERT for extractive question answering. We further design two components accounting for coreferential reasoning and multiple answers, by which we obtain stronger BERT baselines; (4) **RoBERTa-MT** trains RoBERTa on CoLA, SST2, SQuAD datasets before on QUOREF. For MRQA, we compare CorefBERT to vanilla BERT with the same question answering framework.

Implementation Details Following BERT's setting (Devlin et al., 2019), given the question $Q = (q_1, q_2, \ldots, q_m)$ and the passage $P = (p_1, p_2, \ldots, p_n)$, we represent them as a sequence $\boldsymbol{X} = ([\text{CLS}], q_1, q_2, \ldots, q_m, [\text{SEP}], p_1, p_2, \ldots, p_n, [\text{SEP}])$, feed the sequence $\boldsymbol{X}$ into the pre-trained encoder and train two classifiers on the top of it to seek answer's start and end positions simultaneously. For MRQA, CorefBERT maintains the same framework as BERT. For QUOREF, we further employ two extra components to process multiple mentions of the answers: (1) Spurred by the idea from MTMSN (Hu et al., 2019) in handling the problem of multiple answer spans, we utilize the representation of [CLS] to predict the number of answers. After that, we first selects the answer span of the current highest scores, then continues to choose that of the second-highest score with no overlap to previous spans, until reaching the predicted answer number. (2) When answering a question from QUOREF, the relevant mention could possibly be a pronoun, so we attach a reasoning Transformer layer for pronoun resolution before the span boundary classifier.

---

Model	SQuAD	NewsQA	TriviaQA	SearchQA	HotpotQA	NaturalQA	Average
BERT$_{\text{BASE}}$	88.4	66.9	68.8	78.5	74.2	75.6	75.4
CorefBERT$_{\text{BASE}}$	**89.0**	**69.5**	**70.7**	**79.6**	**76.3**	**77.7**	**77.1**
BERT$_{\text{LARGE}}$	91.0	69.7	73.1	81.2	77.7	79.1	78.6
CorefBERT$_{\text{LARGE}}$	**91.8**	**71.5**	**73.9**	**82.0**	**79.1**	**79.6**	**79.6**

Table 2: Performance (F1) on six MRQA extractive question answering benchmarks.

Results Table 1 shows the performance on QUOREF. Our adapted BERT$_{\text{BASE}}$ surpasses original BERT by about 2% in EM and F1 score, indicating the effectiveness of the added reasoning layer and multi-span prediction module. CorefBERT$_{\text{BASE}}$ and CorefBERT$_{\text{LARGE}}$ exceeds our adapted BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$ by 4.4% and 2.9% F1 respectively. Leaderboard results are shown in the appendix. Based on the TASE framework (Efrat et al., 2020), the model with CorefRoBERTa achieves a new state-of-the-art with about 1% EM improvement compared to the model with RoBERTa. We also show four case studies in the appendix, which indicate that through reasoning over mentions, CorefBERT could aggregate information to answer the question requiring coreferential reasoning.

Table 2 further shows that the effectiveness of CorefBERT is consistent in six datasets of the MRQA shared task besides QUOREF. Though the MRQA shared task is not designed for coreferential reasoning, CorefBERT still achieves averagely over 1% F1 improvement on all of the six datasets, especially on NewsQA and HotpotQA. In NewsQA, 20.7% of the answers can only be inferred by synthesizing information distributed across multiple sentences. In HotpotQA, 63% of the answers need to be inferred through either bridge entities or checking multiple properties in different positions. It demonstrates that coreferential reasoning is an essential ability in question answering.

4.3 Relation Extraction

Relation extraction (RE) aims to extract the relationship between two entities in a given text. We evaluate our model on DocRED (Yao et al., 2019), a challenging document-level RE dataset which requires the model to extract relations between entities by synthesizing information from all the mentions of them after reading the whole document. DocRED requires a variety of reasoning types, where 17.6% of the relational facts need to be uncovered through coreferential reasoning.

Model	Dev		Test	
	IgnF1	F1	IgnF1	F1
CNN*	41.58	43.45	40.33	42.26
LSTM*	48.44	50.68	47.71	50.07
BiLSTM*	48.87	50.94	50.26	51.06
ContextAware*	48.94	51.09	48.40	50.70
BERT-TS$_{\text{BASE}}$ $^+$	-	54.42	-	53.92
HINBERT$_{\text{BASE}}$ $^\#$	54.29	56.31	53.70	55.60
BERT$_{\text{BASE}}$	54.63	56.77	53.93	56.27
CorefBERT$_{\text{BASE}}$	**55.32**	**57.51**	**54.54**	**56.96**
BERT$_{\text{LARGE}}$	56.51	58.70	56.01	58.31
CorefBERT$_{\text{LARGE}}$	**56.82**	**59.01**	**56.40**	**58.83**
RoBERTa$_{\text{LARGE}}$	57.19	59.40	57.74	60.06
CorefRoBERTa$_{\text{LARGE}}$	**57.35**	**59.43**	**57.90**	**60.25**

Table 3: Results on DocRED measured by micro ignore F1 (IgnF1) and micro F1. IgnF1 metrics ignores the relational facts shared by the training and dev/test sets. Results with *, $^+$, $^\#$ are from Yao et al. (2019), Wang et al. (2019a), and Tang et al. (2020) respectively.

Baselines We compare our model with the following baselines for document-level relation extraction: (1) **CNN / LSTM / BiLSTM / BERT**. CNN (Zeng et al., 2014), LSTM (Hochreiter and Schmidhuber, 1997), bidirectional LSTM (BiLSTM) (Cai et al., 2016), BERT (Devlin et al., 2019) are widely adopted as text encoders in relation extraction tasks. With these encoders, Yao et al. (2019) generates representations of entities for further predicting of the relationships between entities. (2) **ContextAware** (Sorokin and Gurevych, 2017) takes relations' interaction into account, which demonstrates that other relations in the context are beneficial for target relation prediction. (3) **BERT-TS** (Wang et al., 2019a) applies a two-step prediction to deal with the large number of irrelevant entities, which first predicts whether two entities have a relationship and then predicts the specific relation. (4) **HinBERT** (Tang et al., 2020) proposes a hierarchical inference network to aggregate the inference information with different granularity.

Results Table 3 shows the performance on DocRED. The BERT$_{\text{BASE}}$ model we implemented with mean-pooling entity representation and hyperparameter tuning[7] performed better than previous RE models with BERT$_{\text{BASE}}$ size, which provides a stronger baseline. CorefBERT$_{\text{BASE}}$ outperforms BERT$_{\text{BASE}}$ model by 0.7% F1. CorefBERT$_{\text{LARGE}}$ beats BERT$_{\text{LARGE}}$ by 0.5% F1. We also show a case study in the appendix, which further proves that considering coreference information of text is helpful for exacting relational facts from documents.

4.4 Fact Extraction and Verification

Fact extraction and verification aim to verify deliberately fabricated claims with trust-worthy corpora. We evaluate our model on a large-scale public fact verification dataset FEVER (Thorne et al., 2018). FEVER consists of $185,455$ annotated claims with all Wikipedia documents.

Baselines We compare our model with four BERT-based fact verification models: (1) **BERT Concat** (Zhou et al., 2019) concatenates all of the evidence pieces and the claim to predict the claim label; (2) **SR-MRS** (Nie et al., 2019) employs hierarchical BERT retrieval to improve the performance; (3) **GEAR** (Zhou et al., 2019) constructs an evidence graph and conducts a graph attention network for jointly reasoning over several evidence pieces; (4) **KGAT** (Liu et al., 2020b) conducts a fine-grained graph attention network with kernels.

Results Table 4 shows the performance on FEVER. KGAT with CorefBERT$_{\text{BASE}}$ outperforms KGAT with BERT$_{\text{BASE}}$ by 0.4% FEVER score. KGAT with CorefRoBERTa$_{\text{LARGE}}$ gains 1.9% FEVER score improvement compared to the model with RoBERTa$_{\text{LARGE}}$, and arrives at a new state-of-the-art on FEVER benchmark. It again demonstrates the effectiveness of our model. CorefBERT, which incorporates coreference information in distant-supervised pre-training, contributes to verify if the claim and evidence discuss about the same mentions, such as a person or an object.

4.5 Coreference Resolution

Coreference resolution aims to link referring expressions that evoke the same discourse entity. We examine models' coreference resolution ability under the setting that all mentions have been detected. We evaluate models on several widely-used datasets, including GAP (Webster et al., 2018), DPR (Rahman and Ng, 2012), WSC (Levesque, 2011), Winogender (Rudinger et al., 2018) and PDP (Davis et al., 2017). These datasets provide two sentences where the former has two or more mentions and the latter contains an ambiguous pronoun. It is required that the ambiguous pronoun should be connected to the right mention.

Model	LA	FEVER
BERT Concat*	71.01	65.64
GEAR*	71.60	67.10
SR-MRS$^+$	72.56	67.26
KGAT (BERT$_{\text{BASE}}$) $^\#$	72.81	69.40
KGAT (CorefBERT$_{\text{BASE}}$)	**72.88**	**69.82**
KGAT (BERT$_{\text{LARGE}}$) $^\#$	73.61	70.24
KGAT (CorefBERT$_{\text{LARGE}}$)	**74.37**	**70.86**
KGAT (RoBERTa$_{\text{LARGE}}$) $^\#$	74.07	70.38
KGAT (CorefRoBERTa$_{\text{Large}}$)	**75.96**	**72.30**

Table 4: Results on FEVER test set measured by label accuracy (LA) and FEVER. The FEVER score evaluates the model performance and considers whether the golden evidence is provided. Results with *, $^+$, $^\#$ are from Zhou et al. (2019), Nie et al. (2019) and Liu et al. (2020b) respectively.

Model	GAP	DPR	WSC	WG	PDP
BERT-LM$_{\text{BASE}}$	75.3	75.4	61.2	68.3	76.7
CorefBERT$_{\text{BASE}}$	**75.7**	**76.4**	**64.1**	**70.8**	**80.0**
BERT-LM$_{\text{LARGE}}$ *	76.0	80.1	70.0	78.8	81.7
WikiCREM$_{\text{LARGE}}$ *	**78.0**	84.8	70.0	76.7	86.7
CorefBERT$_{\text{LARGE}}$	76.8	**85.1**	**71.4**	**80.8**	**90.0**
RoBERTa-LM$_{\text{LARGE}}$	**77.8**	90.6	**83.2**	77.1	93.3
CorefRoBERTa$_{\text{LARGE}}$	**77.8**	**92.2**	**83.2**	**77.9**	**95.0**

Table 5: Results on coreference resolution test sets. Performance on GAP is measured by F1, while scores on the others are given in accuracy. WG: Winogender. Results with * are from Kocijan et al. (2019).

Baselines We compare our model with two coreference resolution models: (1) **BERT-LM** (Trinh and Le, 2018) substitutes the pronoun with `[MASK]` and uses language model to compute the probability of recovering the mention candidates; (2) **WikiCREM** (Kocijan et al., 2019) generates GAP-like sentences automatically and trains BERT by minimizing the perplexity of correct mentions on these sentences. Finally, the model is fine-tuned on supervised datasets. Benefiting from the augmented data, WikiCREM achieves state-of-the-art in sentence-level coreference resolution. For BERT-LM and CorefBERT, we adopt the same data split and the same training method on supervised datasets as those of WikiCREM in order to make a fair comparison.

---

[7] Details are in the appendix due to space limit.

Model	MNLI-(m/mm)	QQP	QNLI	SST-2	CoLA	STS-B	MRPC	RTE	Average
$\text{BERT}_{\text{BASE}}$	84.6/83.4	71.2	90.5	93.5	52.1	85.8	88.9	66.4	79.6

Table 7: Ablation study. Results are F1 scores on development set for QUOREF and DocRED, and on test set for others. $\text{CorefBERT}_{\text{BASE}}$ combines "-NSP, +MRM" scheme and copy-based training objective.

Results Table 5 shows the performance on the test set of the above coreference resolution dataset. Our CorefBERT model significantly outperforms BERT-LM, which demonstrates that the intrinsic coreference resolution ability of CorefBERT has been enhanced by involving the mention reference prediction training task. Moreover, it achieves comparable performance with state-of-the-art baseline WikiCREM. Note that, WikiCREM is specially designed for sentence-level coreference resolution and is not suitable for other NLP tasks. On the contrary, the coreferential reasoning capability of CorefBERT can be transferred to other NLP tasks.

4.6 GLUE

The Generalized Language Understanding Evaluation dataset (GLUE) (Wang et al., 2018) is designed to evaluate and analyze the performance of models across a diverse range of existing natural language understanding tasks. We evaluate CorefBERT on the main GLUE benchmark used in BERT.

Implementation Details Following BERT's setting, we add [CLS] token in front of the input sentences, and extract its representation on the top layer as the whole sentence or sentence pair's representation for classification or regression.

Results Table 6 shows the performance on GLUE. We notice that CorefBERT achieves comparable results to BERT. Though GLUE does not require much coreference resolution ability due to its attributes, the results prove that our masking strategy and auxiliary training objective would not weaken the performance on generalized language understanding tasks.

5 Ablation Study

In this section, we explore the effects of the Whole Word Masking (WWM), Mention Reference Masking (MRM), Next Sentence Prediction (NSP) and copy-based training objective using several benchmark datasets. We continue to train Google's released $\text{BERT}_{\text{BASE}}$ on the same Wikipedia corpus with different strategies. As shown in Table 7, we have the following observations: (1) Deleting NSP training task triggers a better performance on almost all tasks. The conclusion is consistent with that of RoBERTa (Liu et al., 2019); (2) MRM scheme usually achieves parity with WWM scheme except on SearchQA, and both of them outperform the original subword masking scheme especially on NewsQA (averagely +1.7% F1) and TriviaQA (averagely +1.5% F1); (3) On the basis of MRM scheme, our copy-based training objective explicitly requires model to look for mention's referents in the context, which could adequately consider the coreference information of the sequence. CorefBERT takes advantage of the objective and further improves the performance, with a substantial gain (+2.3% F1) on QUOREF.

6 Conclusion and Future Work

In this paper, we present a language representation model named CorefBERT, which is trained on a novel task, Mention Reference Prediction (MRP), for strengthening the coreferential reasoning ability of BERT. Experimental results on several downstream NLP tasks show that our CorefBERT significantly outperforms BERT by considering the coreference information within the text and even improve the performance of the strong RoBERTa model. In the future, there are several prospective research directions: (1) We introduce a distant supervision (DS) assumption in our MRP training task. However, the automatic labeling mechanism inevitably accompanies with the wrong labeling problem and it is still an open problem to mitigate the noise. (2) The DS assumption does not consider pronouns in the text, while pronouns play an important role in coreferential reasoning. Hence, it is worth developing a novel strategy such as self-supervised learning to further consider the pronoun.

Appendices

A Masked Language Modeling (MLM)

MLM is regarded as a kind of cloze tasks and aims to predict the missing tokens according to its contextual representation. In our work, 15% of the tokens in input sequence are sampled as the missing tokens. Among them, 80% are replaced with a special token `[MASK]`, 10% are replaced with random tokens and 10% are unchanged. The task aims to predict original tokens from corrupted input.

B Leaderboard Results on QUOREF

TASE (Efrat et al., 2020) converts the multi-span prediction problem as a sequence tagging problem, which substantially improves the model's ability in terms of handling multi-span answer. Though the study of TASE and our CorefBERT are conducted in the same period, we still run TASE with CorefRoBERTa encoder. As Table 8 shows, the performance of TASE with CorefRoBERTa encoder gains about 1% EM improvement compared to that with RoBERTa encoder, which demonstrates the effectiveness of CorefBERT for different question answering frameworks.

Model	EM	F1
XLNet (Dasigi et al., 2019)	61.88	71.51
RoBERTa-MT	72.61	80.68
CorefRoBERTa$_{\text{LARGE}}$	75.80	82.81
TASE (RoBERTa) (Efrat et al., 2020)	79.66	86.13
TASE (CorefRoBERTa)	**80.61**	**86.70**

Table 8: Leaderboard results on QUOREF test set.

C Case Study on QUOREF

Table 9 shows examples from QUOREF (Dasigi et al., 2019). For the first example, it is essential to obtain the fact that the asthmatic boy in question refers to Barry. After that, we should synthesize information from two Mr. Lee's mentions: (1) Mr. Lee trains Barray; (2) Mr. Lee is the uncle of

(1) Q: Whose uncle trains the asthmatic boy?
Paragraph: [1] `Barry Gabrewski` is an asthmatic boy ... [2] `Barry` wants to learn the martial arts, but is rejected by the arrogant dojo owner Kelly Stone for being too weak. [3] Instead, `he` is taken on as a student by an old Chinese man called ***Mr. Lee***, **Noreen**'s sly uncle. [4] ***Mr. Lee*** finds creative ways to teach Barry to defend himself from his bullies.

(2) Q: Which composer produced String Quartet No. 2?
Paragraph: [1] **Tippett**'s Fantasia on a Theme of Handel for piano and orchestra was performed at the Wigmore Hall in March 1942, with ***Sellick*** again the soloist, and the same venue saw the premiere of `the composer`'s String Quartet No. 2 a year later. ... [2] In 1942, Schott Music began to publish **Tippett**'s works, establishing an association that continued until the end of the `the composer`'s life.

(3) Q: What is the first name of the person who lost her beloved husband only six months earlier?
Pargraph: [1] Robert and ***Cathy*** Wilson are a timid married couple in 1940 London. ... [2] Robert toughens up on sea duty and in time becomes a petty officer. [3] His hands are badly burned when his ship is sunk, but he stoically rows in the lifeboat for five days without complaint. [4] He recuperates in a hospital, tended by **Elena**, a beautiful nurse. [5] He is attracted to `her`, but `she` informs him that `she` lost her beloved husband only six months earlier, kisses him, and leaves.

(4) Q: Who would have been able to win the tournament with one more round?
Paragraph: [1] At a jousting tournament in 14th-century Europe, young squires ***William*** Thatcher, Roland, and Wat discover that their master, Sir **Ector**, has died. [2] If `he` had completed one final pass `he` would have won the tournament. [3] Destitute, ***William*** wears **Ector**'s armour to impersonate him, winning the tournament and taking the prize.

Table 9: Examples from QUOREEF (Dasigi et al., 2019) that were correctly predicted by CorefBERT$_{\text{BASE}}$, but wrongly predicted by BERT$_{\text{BASE}}$. ***Answers from BERT$_{\text{BASE}}$***, **Answers from CorefBERT$_{\text{BASE}}$**, and `Clue` are colored respectively.

Eclipse (Meyer novel)

[1] ***Eclipse*** is the third novel in the **Twilight Saga** by **Stephenie Meyer**. It continues the story of Bella Swan and her vampire love, ***Edward Cullen***. [2] The novel explores Bella's compromise between her love for ***Edward*** and her friendship with shape-shifter ***Jacob Black***, ... [3] ***Eclipse*** is preceded by ***New Moon*** and followed by ***Breaking Dawn***. [4] The book was released on **August 7, 2007**, with an initial print run of one million copies, and sold more than 150,000 copies in the first 24 hours alone.

Subject: ***New Moon*** / ***Breaking Dawn***
Object: **Twilight Saga**
Relation: `Part of the series`

Subject: ***Edward Cullen*** / ***Jacob Black***
Object: **Stephenie Meyer**
Relation: `Creator`

Subject: ***Eclipse***
Object: **August 7, 2007**
Relation: `Publication date`

Table 10: An example from DocRED (Yao et al., 2019). We show some relational facts detected by CorefBERT$_{\text{BASE}}$ but missed by BERT$_{\text{BASE}}$.

Claim: ***Bob Ross*** created `ABC` drama **The Joy of Painting**.

[1] **[Bob Ross]** ***Robert Norman Ross*** was an American painter and television host.

[2] **[Bob Ross]** ***He*** was the creator and host of **The Joy of Painting**, an instructional television program that aired from 1983 to 1994 on `PBS` in the United States, and also aired in Canada, ...

[3] **[Bob Ross]** **The Joy of Painting** is an American half hour instructional television show hosted by painter ***Bob Ross*** which ran from January 11, 1983, until May 17, 1994.

[4] **[The Joy of Painting]** In each episode, ***Ross*** taught techniques for landscape oil painting, completing a painting in each session.

[5] **[The Joy of Painting]** The program followed the same format as its predecessor, The Magic of Oil Painting , hosted by ***Ross***'s mentor.

Label: REFUTES

Table 11: An example from FEVER (Thorne et al., 2018). Five pieces of evidence from article **[Bob Ross]** and **[The Joy of Painting]** are retrieved by the retriever.

Noreen. Reasoning over the above information, we could know that Noreen's uncle trains the asthmatic boy. For the second example, it needs to infer that Tippett is a composer from the second sentence for obtaining the final answer from the first sentence. After training on the mention reference prediction task, CorefBERT has become capable of reasoning over these mentions, summarizing messages from mentions in different positions, and finally figuring out the correct answer. For the third and fourth examples, it is necessary to know *she* refers to Elena, and *he* refers to Ector by respective coreference resolution. Benefiting from a large amount of distant-supervised coreference resolution training data, CorefBERT successfully finds out the reference relationship and provides accurate answers.

D Case Study on DocRED

Table 10 shows an example from DocRED (Yao et al., 2019). We show some relational facts detected by CorefBERT$_{\text{BASE}}$ but missed by BERT$_{\text{BASE}}$. For the first relational fact, it is necessary to connect the first and the third sentences through the coreference of Eclipse for acquiring the fact that New Moon and Breaking Dawn are also the novel in the Twilight Saga. For the second and the third relational fact, the referring expressions *it*, *the novel*, and *the book* should be linked to Eclipse correctly to increase model's confidence to find out all the characters and the publication date of the novel from the context. CorefBERT considers coreference information of text, which helps to discover relation facts beyond sentence boundary.

E Case Study on FEVER

Table 11 shows an example from FEVER (Thorne et al., 2018). The given claim is fabricated since the drama "The Joy of Painting" was aired on PBS instead of ABC. With the CorefBERT encoder, KGAT (Liu et al., 2020b) could propagate and aggregate the entity information from evidence for refuting the wrong claim more accurately.

F Task-Specific Model Details

All the models are implemented based on Huggingface transformers[8]. We train models on down-

---

[8] https://github.com/huggingface/transformers

stream tasks with Adam optimizer (Kingma and Ba, 2015).

F.1 Question Answering (QA)

For QA models, we uses a batch size of 32 instances with a maximum sequence length of 512.

We adopt the official data split for QUOREF (Dasigi et al., 2019), where train / development / test set contains 19399 / 2418 / 2537 instances respectively. And we submit our model to the test sever[9] for online evaluation. We conduct a grid search on the learning rate (lr) in $[1 \times 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}]$ and epoch number in $[2, 4, 6]$. The best BERT$_{\text{BASE}}$ configuration on development set used $lr = 2 \times 10^{-5}$, 6 epochs. We adopt this configuration for the BERT$_{\text{LARGE}}$ and RoBERTa$_{\text{LARGE}}$ models. We regard MRQA (Fisch et al., 2019) as a testbed to examine whether models can answer questions well across various data distributions. For fair comparison, we keep $lr = 3 \times 10^{-5}$, 2 epochs for all of the MRQA experiments.

For TASE (Efrat et al., 2020) with CorefRoBERTa encoder, we keep the same configuration[10] as that of the original paper, which used a batch size of 12, learning rate of 5×10^{-6}, 35 epochs.

F.2 Document-level Relation Extraction

We modify the official code[11] to implement BERT-based models for DocRED (Yao et al., 2019). In our implementation, the representation of a mention, which consists of several words, is the average of representations of those words. Furthermore, the representation of an entity is defined as the mean of all mentions referring to it. Finally, two entities' representations are fed to a bi-linear layer to predict relations between them.

We use the official data split for DocRED, where train / development / test set consists of 3053 / 1000 / 1000 documents respectively. We adopt batch size of 32 instances with maximum sequence length of 512 and conduct a grid search on the learning rate in $[2 \times 10^{-5}, 3 \times 10^{-5}, 4 \times 10^{-5}, 5 \times 10^{-5}]$ and number epochs in $[100, 150, 200]$. We find the configuration used learning rate of 4×10^{-5}, 200 epochs is best for both the base and the large model. We evaluate models on development set every 5 epochs and save the checkpoint with the highest F1 score. After that, the test results of the best model are submitted to the evaluation server[12].

F.3 Fact Extraction and Verification

We apply the released code[13] of KGAT (Liu et al., 2020b) for evaluating CorefBERT. We use the official data split for FEVER (Thorne et al., 2018), where train / development / test set contains 145449 / 19998 / 19998 claims respectively. We adopt a batch size of 32, maximum length of 512 tokens and search the learning rate in $[2 \times 10^{-5}, 3 \times 10^{-5}, 5 \times 10^{-5}]$. We achieved the best performance with learning rate of 5×10^{-5} for the base model and 2×10^{-5} for the large model. All models are trained with a batch size of 32 instances for 3 epochs and evaluated on development set every 1000 steps. After that, we submit test results of our best model to evaluation server[14].

F.4 Coreference Resolution

We use the released code[15] of WikiCREM (Kocijan et al., 2019) for fine-tuning BERT-LM (Trinh and Le, 2018) and CorefBERT on supervised datasets. For a sentence S, which possesses a correct candidate $\mathbf{a}$ and an incorrect candidate $\mathbf{b}$, the loss consists of two parts: (1) the negative log-likelihood of the correct candidate; (2) a max-margin between the log-likelihood of the correct candidate and the incorrect candidate:

$$\begin{aligned}\mathcal{L} = &-\log \Pr(\mathbf{a}|S) \\ &+ \alpha \max\left(0, \log \Pr(\mathbf{b}|S) - \log \Pr(\mathbf{a}|S) + \beta\right),\end{aligned} \tag{5}$$

where α, β are hyperparameters. We follow the data split and fine-tuning setting of WikiCREM, which adopts a batch size of 64, a maximum sequence length of 128 and 10 epochs training. We search the learning rate $lr \in [3 \times 10^{-5}, 1 \times 10^{-5}, 5 \times 10^{-6}, 3 \times 10^{-6}]$, hyperparameters $\alpha \in [5, 10, 20]$, $\beta \in [0.1, 0.2, 0.4]$. The best performance of models with base size and CorefBERT$_{\text{LARGE}}$ on validation set were achieved with $lr = 3 \times 10^{-5}$, $\alpha = 10$, $\beta = 0.2$. We keep this configuration for the RoBERTa-based models.

Model	QUOREF	MRQA	DocRED	FEVER	GLUE	Coref.
CorefBERT$_{\text{BASE}}$	13.23	13.15	117.37	18.88	2.95	4.27
CorefBERT$_{\text{LARGE}}$	43.40	43.37	180.65	54.03	9.22	10.90

Table 14: Average inference runtime per example for CorefBERTs on different benchmarks. Inference is done on a RTX 2080ti GPU with a batch of 32 instances and inference time is measured in milliseconds. The input sequence length is 512 for QUOREF, MRQA, DocRED, FEVER, and 128 for others. Coref.: Coreference resolution.

F.5 Generalized Language Understanding (GLUE)

We evaluate CorefBERT on the main GLUE benchmark (Wang et al., 2018) used in BERT, including MNLI (Williams et al., 2018), QQP[16], QNLI (Rajpurkar et al., 2016), SST-2 (Socher et al., 2013), CoLA (Warstadt et al., 2019) , STS-B (Cer et al., 2017), MRPC (Dolan and Brockett, 2005) and RTE (Giampiccolo et al., 2007).

We use a batch size of 32, maximum sequence length of 128, fine-tune models for 3 epochs for all GLUE tasks and select the learning rate of Adam among $[2\times10^{-5}, 3\times10^{-5}, 4\times10^{-5}, 5\times10^{-5}]$ for the best performance on the development set. After that, we submit the result of our best model to the official evaluation server[17]. Table 12 shows the best learning rate for CorefBERT$_{\text{BASE}}$ and CorefBERT$_{\text{LARGE}}$.

F.6 Number of Parameters and Average Runtime

CorefBERT's architecture is a multi-layer bidirectional Transformer (Vaswani et al., 2017). Tables 13 shows the parameter number of CorefBERTs with different model size. Compared to BERT (Devlin et al., 2019), CorefBERT add a few parameters for computing the copy-based objective. Hence, CorefBERT keeps similar number of parameters as BERT with the same size.

Table 14 shows the task-specific average inference runtime per example for CorefBERT. The inferenece is done on a RTX 2080ti GPU with a batch of 32 instances. The inference time includes time on CPU and time on GPU. CorefRoBERTa$_{\text{LARGE}}$ consumes a similar time as CorefBERT$_{\text{LARGE}}$ since they both use a 24-layer Transformer architecture.

F.7 Resolving the Coreference in the Corpus

In our preliminary experiment, we resolve the coreference of training corpus via the StanfordNLP tool[18] and apply our copy-based objective on this training corpus. We find the obtained model performs better than the BERT model without NSP but worse than the current CorefBERT. We think that considering coreference such as pronoun in pre-training could also enhance model's coreferential reasoning ability, while how to deal with the noise from coreference tools remains a problem to be explored.

Abstract

Recently, attempting to model texts as graph structure and introducing graph neural networks to deal with it has become a trend in many NLP research areas. In this paper, we investigate whether the graph structure is necessary for multi-hop question answering. Our analysis is centered on HotpotQA. We construct a strong baseline model to establish that, with the proper use of pre-trained models, graph structure may not be necessary for multi-hop question answering. We point out that both graph structure and adjacency matrix are task-related prior knowledge, and graph-attention can be considered as a special case of self-attention. Experiments and visualized analysis demonstrate that graph-attention or the entire graph structure can be replaced by self-attention or Transformers.

1 Introduction

Different from single-hop question answering, where the answer can be derived from a single sentence in a single paragraph, more and more studies focus on multi-hop question answering across multiple documents or paragraphs (Welbl et al., 2018; Talmor and Berant, 2018; Yang et al., 2018).

To solve this problem, the majority of existing studies constructed a graph structure according to co-occurrence relations of entities that scattered across multiple sentences or paragraphs. Dhingra et al. (2018) and Song et al. (2018) designed a DAG-styled recurrent layer to model the relations between entities. De Cao et al. (2019) first used GCN (Kipf and Welling, 2017) to tackle entity graph. Qiu et al. (2019) proposed a dynamic entity graph for span-based multi-hop QA. Tu et al. (2019b) extended the entity graph to a heterogeneous graph by introducing document nodes and query nodes.

Previous works argue that a fancy graph structure is a vital part of their models and demonstrate that by ablation experiments. However, in experiments, we find when we use the pre-trained models in the fine-tuning approach, removing the entire graph structure may not hurt the final results. Therefore, in this paper, we aimed to answer the following question: **How much does graph structure contribute to multi-hop question answering?**

To answer the question above, we choose the widely used multi-hop question answering benchmark, HotpotQA (Yang et al., 2018), as our testbed. We reimplement a graph-based model, Dynamically Fused Graph Network (Qiu et al., 2019), as our baseline model. The remainder of this paper is organized as follows.

- In Section 2, we first describe our baseline model. Then, we show that the graph structure can play an important role only when the pre-trained models are used in a feature-based manner. While the pre-trained models are used in the fine-tuning approach, the graph structure may not be helpful.
- To explain the results, in Section 3.1, we point out that graph-attention (Veličković et al., 2018) is a special case of self-attention. The adjacency matrix based on manually defined rules and the graph structure can be regarded as prior knowledge, which could be learned by self-attention or Transformers (Vaswani et al., 2017).
- In Section 3.2, we design experiments to show when we model text as an entity graph, both graph-attention and self-attention can achieve comparable results. When we treat texts as a sequence structure, only a 2-layer Transformer could achieve similar results as DFGN.
- In Section 3.4, visualized analysis show that there are diverse entity-centered attention patterns exist in pre-trained models, indicating the redundancy of entity-based graph structure.
- Section 4 gives the conclusion.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7187–7192,
November 16–20, 2020.

2 The Approach

We choose the widely used multi-hop QA dataset, HotpotQA as our testbed. We reimplement DFGN (Qiu et al., 2019) and modify the usage of the pre-trained model. The model first leverage a retriever to select relevant passages from candidate set and feed them into a graph-based reader. All entities in the entity graph are recognized by an independent NER model.

2.1 HotpotQA Dataset

HotpotQA is a widely used large-scale multi-hop QA dataset. There are two different settings in HotpotQA. In *distractor* setting, each example contains 2 gold paragraphs and 8 distractor paragraphs retrieved from Wikipedia. In *full wiki* setting, a model is asked to retrieve gold paragraphs from the entire Wikipedia. In this paper, all experiments are conducted in the *distractor* setting.

2.2 Model Description

Retriever. We use RoBERTa large model (Liu et al., 2019) to calculate the relevant score between the query and each candidate paragraphs. We filter the paragraphs whose score is less than 0.1, and the maximum number of selected paragraphs is 3. Selected paragraphs are concatenated as context **C**.

Encoding Layer. We concatenate the query **Q** and context **C** and feed the sequence into another RoBERTa large model. The results are further fed into a bi-attention layer (Seo et al., 2016) to obtain the representations from the encoding layer.

Graph Fusion Block. Given context representations $\mathbf{C}_{t-1}$ at hop $t-1$, the tokens representations are passed into a mean-max pooling layer to get nodes representations in entity graph $\mathbf{H}_{t-1} \in \mathbb{R}^{2d \times N}$, where N is the number of entity. After that, a graph-attention layer is applied to update nodes representations in the entity graph:

$$\beta_{i,j}^{(t)} = \text{LeakyReLU}(\mathbf{W}_t^\top [\mathbf{h}_i^{(t-1)}, \mathbf{h}_j^{(t-1)}]) \quad (1)$$

$$\alpha_{i,j}^{(t)} = \frac{\exp(\beta_{i,j}^{(t)})}{\sum_{k \in \mathcal{N}_i} \exp(\beta_{i,k}^{(t)})} \quad (2)$$

$$\mathbf{h}_i^{(t)} = \text{ReLU}(\sum_{k \in \mathcal{N}_i} \alpha_{i,k}^{(t)} \mathbf{h}_k^{(t-1)}) \quad (3)$$

where $\mathcal{N}_i$ is the set of neighbors of node i. We follow the same Graph2Doc module as Qiu et al. (2019) to transform the nodes representations into the tokens representations. Besides, there are several extra modules in the graph fusion block, including query-entity attention, query update mechanism, and weak supervision.

Setting	Joint EM	Joint F1
Baseline (Yang et al., 2018)	10.83	40.16
QFE (Nishida et al., 2019)	34.63	59.61
DFGN (Qiu et al., 2019)	33.62	59.82
TAP2 (Glass et al., 2019)	39.77	69.12
HGN (Fang et al., 2019)	43.57	71.03
SAE (Tu et al., 2019a)	**45.36**	71.45
Our Model	44.67	**72.73**

Table 1: Results on the test set of HotpotQA.

Setting	Joint EM	Joint F1
Baseline (Fine-tuning)	45.91	**73.93**
w/o Graph	**45.98**	73.78
Baseline (Feature-based)	36.45	63.75
w/o Graph	32.26	59.76

Table 2: Ablation of graph structure under different settings.

Prediction Layer. We follow the same cascade structure as Qiu et al. (2019) to predict the answers and supporting sentences.

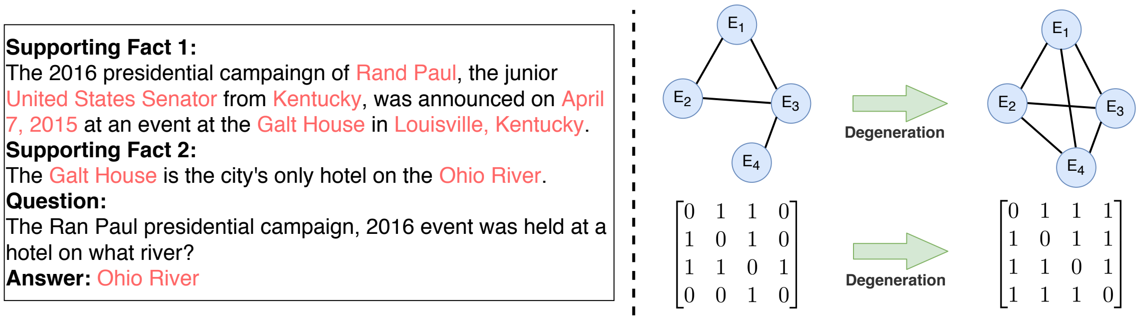
Entity Graph Construction. We fine-tune a pre-trained BERT base model on the dataset of the CoNLL'03 NER shared task (Tjong Kim Sang and De Meulder, 2003) and use it to extract entities from candidate paragraphs. Connections between entities are defined as following rules:

- Entities with the same mention text in context are connected.
- Entities appear in the same sentence are connected.

2.3 Model Results

In Table 1, we show the performance comparison with different models on the blind test set of HotpotQA. Our strong baseline model achieves state-of-the-art results on the official leaderboard.

In order to analyze how much the graph structure contributes to the entire model, we perform a set of ablation experiments. We remove the whole graph fusion block, and the outputs of the pre-trained model are directly fed into the prediction layer. By the reason that the main difference between our baseline model and DFGN is that we use a large pre-trained model in the fine-tuning approach instead of the feature-based approach, we perform the experiments in two different settings.



Supporting Fact 1:
The 2016 presidential campaingn of Rand Paul, the junior United States Senator from Kentucky, was announced on April 7, 2015 at an event at the Galt House in Louisville, Kentucky.
Supporting Fact 2:
The Galt House is the city's only hotel on the Ohio River.
Question:
The Ran Paul presidential campaign, 2016 event was held at a hotel on what river?
Answer: Ohio River

$$\begin{bmatrix}0&1&1&0\\1&0&1&0\\1&1&0&1\\0&0&1&0\end{bmatrix} \xrightarrow{\text{Degeneration}} \begin{bmatrix}0&1&1&1\\1&0&1&1\\1&1&0&1\\1&1&1&0\end{bmatrix}$$

Figure 1: Entities in raw texts are modeled as an entity graph and handled by graph attention networks. When the entity graph are fully connected, a graph-attention layer will degenerate into a vanilla self-attention layer.

The results are shown in Table 2. By using the fine-tuning approach, model with and without graph fusion block can reach almost equal results. When we fix parameters of the pre-trained model, the performances significantly degrade by 9% for EM and 10% for F1. If we further remove graph fusion block, both EM and F1 drop about 4%.

Taken together, only when pre-trained models are used in the feature-based approach, graph neural networks can play an important role. Nevertheless, when pre-trained models are used as a fine-tuning approach, which is a common practice, graph structure does not contribute to the final results. In other words, the graph structure may not be necessary for multi-hop question answering.

3 Understanding Graph Structure

Experimental results in Section 2.3 imply that self-attention or Transformer may have superiority in multi-hop question answering. To understand this, in this section, we will first discuss the connection between graph structure, graph-attention, and self-attention. We then verify the hypothesis by experiments and visualized analysis.

3.1 Graph Attention vs. Self Attention

The key to solving the multi-hop question is to find the corresponding entity in the original text through the query. Then one or more reasoning paths are constructed from these start entities toward other identical or co-occurring entities. As shown in Figure 1, previous works usually extract entities from multiple paragraphs and model these entities as an entity graph. The adjacency matrix is constructed by manually defined rules, which usually the co-occurrence relationship of entities. From this point of view, both the graph structure and the adjacency matrix can be regarded as task-related prior knowledge. The entity graph structure restricts the model can only do reasoning based on entities, and the adjacency matrix assists the model to ignore non-adjacent nodes in a hop. However, it is probably that the model without any prior knowledge can still learn the entity-to-entity attention pattern.

In addition, considering Eq.1-3, it is easy to find that graph-attention has a similar form as self-attention. In forward propagation, each node in the entity graph calculates attention scores with other connected nodes. As shown in Figure 1, graph-attention will degenerate into a vanilla self-attention layer when the nodes in the graph are fully connected. Therefore, the graph-attention can be considered as a special case of self-attention.

3.2 Graph Structure May Not Be Necessary

According to the discussion above, we aimed to evaluate whether the graph structure with an adjacency matrix is superior to self-attention.

To this end, we use the model described in Section 2 as our baseline model. The pre-trained model in the baseline model is used in the feature-based approach. Several different modules are added between the encoding layer and the prediction layer.

Model With Graph Structure. We apply graph-attention or self-attention on the entity graph and compare the difference in the final results. In order to make a fair comparison, we choose the self-attention that has the same form as graph-attention. The main difference is that the self-attention does not keep an adjacency matrix as prior knowledge and the entities in the graph are fully connected. Moreover, we define that the density of a binary matrix is the percentage of '1' in it. We sort each example in development set by the density of its adjacency matrix and divide them by different quantiles. We evaluate how different density of the adjacency matrix affects the final results.

Model Without Graph Structure. In this experi-

Setting	Joint EM	Joint F1
Baseline	32.26	59.76
+ Graph Fusion Block	**36.45**	63.75
+ Self Attention	35.41	61.77
+ Graph Attention	35.79	61.91
+ Transformer	36.23	**63.82**

Table 3: Performance comparison in terms of joint EM and F1 scores under different module settings.

Quantile	0.2	0.4	0.6	0.8	1.0	avg
Density	18.7	23.6	29.0	36.8	100	28.8

Table 4: The Adjacency Matrix density at different quantiles.

ment, we verify whether the whole graph structure can be replaced by Transformers. We directly feed the context representations from the encoding layer into the Transformers.

The experimental results are shown in Table 3. Compared with the baseline, the model with the graph fusion block obtains a significant advantage. We add the entity graph with self-attention to the baseline model, and the final results significantly improved. Compared with self-attention, graph-attention does not show a clear advantage. The density of examples at different quantile are shown in Table 4, the adjacency matrix in multi-hop QA is relatively dense, which may causes graph-attention can not make a significant difference. The results of graph-attention and self-attention in the different intervals of density are shown in Figure 2. Despite the different density of the adjacency matrix, graph-attention consistently achieves similar results as self-attention. This signifies that self-attention can learn to ignore irrelevant entities. Besides, examples with a more dense adjacency matrix are simpler for both graph-attention and self-attention, this probably because these adjacency matrices are constructed from shorter documents. Moreover, as shown in Table 3, Transformers show a powerful reasoning ability. Only stacking two layers of the Transformer can achieve comparable results as DFGN.

3.3 Training Details

For all experiments in this paper, the number of layers of different modules is two, and the hidden dimensions are set to 300. In feature-based setting, all models are trained for 30 epochs with a batch size of 24. In fine-tuning setting, models are trained for 3 epochs with a batch size of 8. The initial learning rate is 2e-4 and 3e-5 in the feature-based setting and fine-tuning setting respectively.

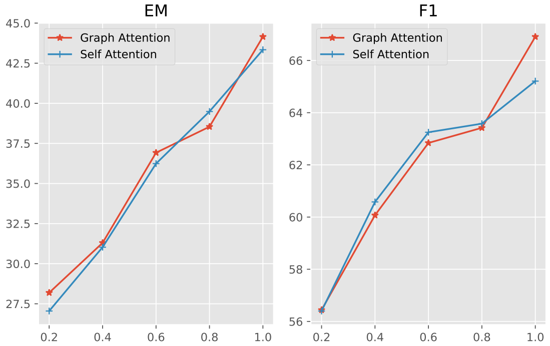


Figure 2: Results of graph-attention and self-attention on examples with different adjacency matrix density.

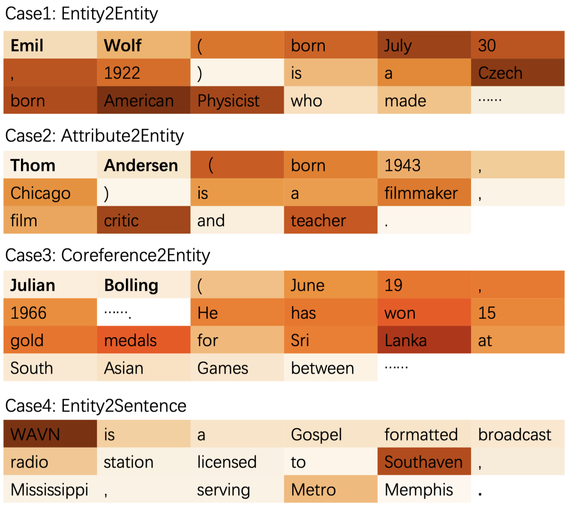
3.4 Entity-centered Attention Pattern in Pre-trained Model

Inspired by Kovaleva et al. (2019), we leverage an approximate method to find which attention head contains entity-centered attention patterns. We employ an NER model to identify tokens belong to a certain entity span. Then, for each attention head in the pre-trained model, we sum the absolute attention weights among those tokens belong to an entity and tokens not belong to an entity. The score of an attention head is the difference between the sum of weights from entities and non-entities tokens. We then average the derived scores over all the examples. Finally, the attention head with the maximum score is the desired head that contains entity-centered attention patterns.

We find four typical attention patterns and visualized it in Figure 3. In case 1-3, we visualized the attention weights of each token attending to the subject entity. In case 4, we visualized the attention weights of each token attending to the last token of the sentence. The results show pre-trained models are pretty skillful at capturing relations between entities and other constituents in a sentence.

Entity2Entity. We find entity-to-entity attention pattern is very widespread in pre-trained models. In this case, ‘American Physicist’ and ’Czech’ attend to ‘Emil Wolf’ with very high attention weights. Such attention pattern plays the same role as graph attention plays.

Attribute2Entity. In this case, ‘filmmaker’, ‘film critic’ and ‘teacher’ obtain higher weights, indicating the occupation of ‘Thom Andersen’. Note that



Case1: Entity2Entity

Emil	**Wolf**	(	born	July	30

Mississippi	,	serving	Metro	Memphis	.

Figure 3: Results of visualized attention patterns in the pre-trained model.

these tokens are not part of a certain entity, hence deem to be ignored by graph structure.

Coreference2Entity. We also find that coreference will not make the pre-trained model confused. In case 3, the entity 'Sir Lanka' in second sentence attends to 'Julian Bolling' in the first sentence, which means the pre-trained model understand 'He' refers to 'Julian Bolling' even though they belong to different sentences.

Entity2Sentence. We find many entities attend to the last token of sentence. In the prediction layer, the representations of the first and last token in a sentence are combined to determine whether a particular sentence is a supporting fact. Therefore, we suppose this is another attention pattern that entities attend to the whole sentence.

It is obvious that graph attention can not cover the last three attention patterns. Therefore, we draw a conclusion that self attention has advantages on generality and flexibility.

4 Conclusions

This study set out to investigate whether graph structure is necessary for multi-hop QA and what role it plays. We established that with the proper use of pre-trained models, graph structure may not be necessary. In addition, we point out the adjacency matrix and the graph structure can be regarded as some kind of task-related prior knowledge. Experiments and visualized analysis demonstrate both graph-attention and graph structure can be replaced by self-attention or Transformers. Our results suggest that future works introducing graph structure into NLP tasks should explain their necessity and superiority.

Abstract

The ability to correctly model distinct meanings of a word is crucial for the effectiveness of semantic representation techniques. However, most existing evaluation benchmarks for assessing this criterion are tied to sense inventories (usually WordNet), restricting their usage to a small subset of knowledge-based representation techniques. The Word-in-Context dataset (WiC) addresses the dependence on sense inventories by reformulating the standard disambiguation task as a binary classification problem; but, it is limited to the English language. We put forward a large multilingual benchmark, XL-WiC, featuring gold standards in 12 new languages from varied language families and with different degrees of resource availability, opening room for evaluation scenarios such as zero-shot cross-lingual transfer. We perform a series of experiments to determine the reliability of the datasets and to set performance baselines for several recent contextualized multilingual models. Experimental results show that even when no tagged instances are available for a target language, models trained solely on the English data can attain competitive performance in the task of distinguishing different meanings of a word, even for distant languages. XL-WiC is available at https://pilehvar.github.io/xlwic/.

1 Introduction

One of the desirable properties of contextualized models, such as BERT (Devlin et al., 2019) and its derivatives, lies in their ability to associate dynamic representations to words, i.e., embeddings that can change depending on the context. This provides the basis for the model to distinguish different meanings (senses) of words without the need to resort to an explicit sense disambiguation step. The conventional evaluation framework for this property has been Word Sense Disambiguation (Navigli, 2009, WSD). However, evaluation benchmarks for WSD are usually tied to external sense inventories (often WordNet (Fellbaum, 1998)), making it extremely difficult to evaluate systems that do not explicitly model sense distinctions in the inventory, effectively restricting the benchmark to inventory-based sense representation techniques and WSD systems. This prevents a direct evaluation of lexical semantic capacity for a wide range of inventory-free models, such as the dominating language model-based contextualized representations.

Pilehvar and Camacho-Collados (2019) addressed this dependence on sense inventories by reformulating the WSD task as a simple binary classification problem: given a target word w in two different contexts, c_1 and c_2, the task is to identify if the same meaning (sense) of w was intended in both c_1 and c_2, or not. The task was framed as a dataset, called Word-in-Context (WiC), which is also a part of the widely-used SuperGLUE benchmark (Wang et al., 2019). Despite allowing a significantly wider range of models for direct WSD evaluations, WiC is limited to the English language only, preventing the evaluation of models in other languages and in cross-lingual settings.

In this paper, we present a new evaluation benchmark, called XL-WiC , that extends the WiC dataset to 12 new languages from different families and with different degrees of resource availability: Bulgarian (BG), Chinese (ZH), Croatian (HR), Danish (DA), Dutch (NL), Estonian (ET), Farsi (FA), French (FR), German (DE), Italian (IT), Japanese (JA) and Korean (KO). With over 80K instances, our benchmark can serve as a reliable evaluation framework for contextualized models in a wide range of heterogeneous languages. XL-WiC can also serve as a suitable testbed for cross-lingual experimentation in settings such as zero-shot or

few-shot transfer across languages. As an additional contribution, we tested several pretrained multilingual models on XL-WiC, showing that they are generally effective in transferring sense distinction knowledge from English to other languages in the zero-shot setting. However, with more training data at hand for target languages, monolingual approaches gain ground, outperforming their multilingual counterparts by a large margin.

2 Related Work

XL-WiC is a benchmark for inventory-independent evaluation of WSD models (Section 2.1), while the multilingual nature of the dataset makes it an interesting resource for experimenting with cross-lingual transfer (Section 2.2).

2.1 Word Sense Disambiguation

The ability to identify the intended sense of a polysemous word in a given context is one of the fundamental problems in lexical semantics. It is usually addressed with two different kinds of approaches relying on either sense-annotated corpora (Bevilacqua and Navigli, 2020; Scarlini et al., 2020; Blevins and Zettlemoyer, 2020) or knowledge bases (Moro et al., 2014; Agirre et al., 2014; Scozzafava et al., 2020). Both are usually evaluated on dedicated benchmarks, including at least five WSD tasks in Senseval and SemEval series, from 2001 (Edmonds and Cotton, 2001) to 2015 (Moro and Navigli, 2015a) that are included in the Raganato et al. (2017)'s test suite. All these tasks are framed as classification problems, where disambiguation of a word is defined as selecting one of the predefined senses of the word listed by a sense inventory. This brings about different limitations such as restricting senses only to those defined by the inventory, or forcing the WSD system to explicitly model sense distinctions at the granularity level defined by the inventory.

Stanford Contextual Word Similarity (Huang et al., 2012) is one of the first datasets that focuses on ambiguity but outside the boundaries of sense inventories, and as a similarity measurement between two words in their contexts. Pilehvar and Camacho-Collados (2019) highlighted some of the limitations of the dataset that prevent a reliable evaluation, and proposed the Word-in-Context (WiC) dataset. WiC is the closest dataset to ours, which provides around 10K instances (1400 instances for 1184 unique target nouns and verbs in the test set), but for the English language only.

2.2 Cross-lingual NLP

A prerequisite for research on a language is the availability of relevant evaluation benchmarks. Given its importance, construction of multilingual datasets has always been considered as a key contribution in NLP research and numerous benchmarks exist for a wide range of tasks, such as semantic parsing (Hershcovich et al., 2019), word similarity (Camacho-Collados et al., 2017; Barzegar et al., 2018), sentence similarity (Cer et al., 2017), or WSD (Navigli et al., 2013; Moro and Navigli, 2015b). A more recent example is XTREME (Hu et al., 2020), a benchmark that covers around 40 languages in nine syntactic and semantic tasks.

On the other hand, pre-trained language models have recently proven very effective in transferring knowledge in cross-lingual NLP tasks (Devlin et al., 2019; Conneau et al., 2020). This has further magnified the requirement for rigorous multilingual benchmarks that can be used as basis for this direction of research (Artetxe et al., 2020b).

3 XL-WiC: The Benchmark

In this section, we describe the procedure we followed to construct the XL-WiC benchmark. Our framework is based on the original WiC dataset, which we extend to multiple languages.

3.1 English WiC

Each instance of the original WiC dataset (Pilehvar and Camacho-Collados, 2019) is composed of a target word (e.g., *justify*) and two sentences where the target word occurs (e.g., "*Justify* the margins" and "The end *justifies* the means"). The task is a binary classification: to decide whether the same sense of the target word (*justify*) was intended in the two contexts or not. The dataset was built using example sentences from resources such as Wiktionary, WordNet (Miller, 1995) and VerbNet (Schuler et al., 2009).

3.2 XL-WiC

We followed Pilehvar and Camacho-Collados (2019) and constructed XL-WiC based on example usages of words in sense inventories. Example usages are curated in a way to be self contained and clearly distinguishable across different senses of a word; hence, they provide a reliable basis for the binary classification task. Specifically, for a word

Lang.	Target Word	Sentence 1	Sentence 2	Label
EN	Beat	We beat the competition.	Agassi beat Becker in the tennis championship.	True
DA	Tro	Jeg tror på det, min mor fortalte.	Maria troede ikke sine egne øjne.	True
ET	Ruum	Ühel hetkel olin väljaspool aega ja ruumi.	Ümberringi oli lõputu tühi ruum.	True
FR	Causticité	Sa causticité lui a fait bien des ennemis.	La causticité des acides.	False
KO	틀림	틀림이 있는지 없는지 세어 보시오.	그 아이 하는 짓에 틀림이 있다면 모두 이 어미 죄이지요.	False
ZH	發	建築師希望發大火燒掉城市的三分之一 。	如果南美洲氣壓偏低,則印度可能發乾旱	True
FA	صرف	صرف غذا نیم ساعت طول کشید.	معلم صرف افعال ماضی عربی را آموزش داد.	False

Table 1: Sample instances from XL-WiC for different languages.

w and for all its senses $\{s_1^w, ..., s_n^w\}$, we extract from the inventory all the example usages. We then pair those examples that correspond to the same sense s_i^w to form a positive instance (True label) while examples from different senses (i.e., s_i^w and s_j^w where $i \neq j$) are paired as a negative instance (False label).

We leveraged two main sense inventories for this extension: Multilingual WordNet (Section 3.2.1) and Wiktionary (Section 3.2.2).

3.2.1 Multilingual WordNet

WordNet (Miller, 1995) is the *de facto* sense inventory for English WSD. The resource was originally built as an English lexical database in 1995, but since then there have been many efforts to extend it to other languages (Bond and Paik, 2012). We took advantage of these extensions to construct XL-WiC. In particular, we processed the WordNet versions of Bulgarian (Simov and Osenova, 2010), Chinese (Huang et al., 2010), Croatian (Raffaelli et al., 2008), Danish (Pedersen et al., 2009), Dutch (Postma et al., 2016), Estonian (Vider and Orav, 2002), Japanese (Isahara et al., 2008), Korean (Yoon et al., 2009) and Farsi (Shamsfard et al., 2010).[1]

Farsi: Semi-automatic extraction. FarsNet v3.0 (Shamsfard et al., 2010) comprises 30K synsets with over 100K word entries. Many of these synsets are mapped to the English database; however, each synset provides just one example usage for a target word. This prevents us from applying the automatic extraction of positive examples. Therefore, we utilized a semi-automatic procedure for the construction of the Farsi set. To this end, for each word, we extracted all example usages from FarsNet, and asked an annotator to group them into positive and negative pairs. The emphasis was to make a challenging dataset with sense distinctions that are easily interpretable by humans. This can also be viewed as a case study to understand the real gap between human and machine performance in settings where manual curation of instances is feasible.

Filtering. WordNet is often considered to be a fine-grained resource, especially for verbs (Duffield et al., 2007). In some cases, the exact meaning of a word can be hard to assess, even for humans. For example, WordNet lists 29 distinct meanings for the noun *line*, two of which correspond to the horizontally and the vertically organized line formations. Therefore, to cope with this issue, we followed Pilehvar and Camacho-Collados (2019) and filtered out all pairs whose target senses were connected by an edge (including sister-sense relations) in WordNet's semantic network or if they belonged to the same supersense, i.e., one of the 44 lexicographer files[2] in WordNet which cluster concepts into semantic categories, e.g., *Animal*, *Cognition*, *Food*, etc. For example, the Japanese instance "成長中の企業は大な指導者いなければならない" ("Growing *companies* must have bold leaders"), "彼は安定した大きな企業に投資するだけだ" ("He just invested in big stable *companies*") for the target word "企業" ("company") is discarded as its corresponding synsets, i.e., "An organization created for business ventures" and "An institution created to conduct business", are grouped under the same supersense in WordNet, i.e., *Group*.

Finally, all datasets are split into development[3] and test. At the end of this step, we ensure that both test and development sets have the same number of positive and negative instances. An excerpt of examples included in some of our datasets are

---

[1] We tried other WordNet versions such as Albanian (Ruci, 2008), Basque (Pociello et al., 2008), Catalan (Benítez et al., 1998), Galician (Guinovart, 2011), Hungarian (Miháltz et al., 2008), Italian (Pianta et al., 2002), Slovenian (Fišer et al., 2012) and Spanish (Atserias et al., 2004); but, they did not contain enough examples.

[2] wordnet.princeton.edu/documentation/lexnames5wn

[3] Development sets are intended to be used for different purposes, such as training or validation, as we will show in our experiments in Section 5.1.

Table 2: Statistics for WordNet and Wiktionary datasets for different languages.

shown in Table 1.

3.2.2 Wiktionary

Wiktionary is one of the richest free collaborative lexical databases, available for dozens of languages. In this online resource, each word is provided with definitions for its various potential meanings, some of which are paired with example usages. However, each language has a specific format, and therefore the compilation of these examples requires a careful language-specific parsing. We extracted examples for three European languages for which we did not have WordNet-based data, namely French, German, and Italian.[4] Once these examples were compiled, the process to build the final dataset was analogous to that for the WordNet-based datasets (see Section 3.2.1), except for the filtering step, which was not feasible as Wiktionary entries are not connected through paradigmatic relations as in WordNet.

For the case of Wiktionary, the number of examples was considerably higher; therefore, we also compiled language-specific training sets, which enabled a comparison between cross-lingual and monolingual models (see Section 5.2). All Wiktionary datasets are split into balanced training, development and test splits, in each of which there are equal number of positive and negative instances.

3.3 Statistics

Table 2 shows the statistics of all datasets, including the total number of instances, unique words, and the context length average.[5] Wiktionary-based datasets are substantially larger than the WordNet-based ones, and also provide training sets. The Chinese datasets feature longer contexts on average and contain the largest number of development and testing instances among WordNet-based datasets. Korean, on the other hand, is the one with the shortest contexts, which is expected given its agglutinative nature. As for the training corpora, German and French datasets contain almost ten times the number of instances in the English training set. This allows us to perform a large-scale comparison between cross-lingual and monolingual settings (see Section 5.2) as well as a few-shot analysis (Section 6.2).

3.4 Validation and human performance

To verify the reliability of the datasets, we carried out manual evaluation for those languages for which we had access to annotators. To this end, we presented a set of 100 randomly sampled instances from each dataset to the corresponding annotator in the target language.[6] Annotators were all native speakers of the target language with high-level education. They were provided with a minimal guideline: a brief explanation of their task and a few tagged examples. We did not provide any lexical resource (or any other detailed instructions) to the annotators with the emphasis to make a challenging dataset with sense distinctions that are easily interpretable to the layman. Given an instance, i.e., a pair of sentences containing the same target word, their task consisted of tagging it with a *True* or *False* label, depending on the the intended meanings of the word in the two contexts.

Table 3 reports human performance for eight

---

[4] French WordNet, WoNeF (Pradet et al., 2014), is built automatically; German WordNet, GermaNet (Hamp and Feldweg, 1997), has a very restrictive license; and the Italian WordNet (Pianta et al., 2002) provides too few examples.

[5] We used the multilingual Stanford NLP toolkit, Stanza (Qi et al., 2020), with the available pre-trained neural models.

[6] For Farsi, three checker annotators were involved in the validation, each annotating the 100-instance subset. In this case, we report the average accuracy.

WiC	WordNet						Wiktionary	
EN	DA	FA	IT	JA	KO	ZH	DE	IT
80.0*	87.0	97.0	82.0	75.0	76.0	85.0	74.0	78.0

Table 3: Human performance (in terms of accuracy) for different languages in XL-WiC. *From the original English WiC dataset.

datasets in XL-WiC. All accuracy figures are around 80%, i.e., in the same ballpark as the original WiC English dataset, which attests the reliability of underlying resources and the construction procedure. The only exception is for Farsi, for which the checker annotators agree with the gold labels in 97% of the instances (by average). This corroborates our emphasis on the annotation procedure for this manually-created dataset to have sense distinctions that are easily interpretable by humans. As for Wiktionary, the human agreements are lower than those for the WordNet counterparts.[7] This was partly expected given that the semantic network-based filtering step (see Section 3.2.1) was not feasible for the case of Wiktionary datasets due to the nature of the underlying resource.

4 Experimental Setup

For our experiments, we implemented a simple, yet effective, baseline based on a Transformer-based text encoder (Vaswani et al., 2017) and a logistic regression classifier, following Wang et al. (2019). The model takes as input the two contexts and first tokenizes them, splitting the input words into sub-tokens. The encoded representations of the target words are concatenated and fed to the logistic classifier. For those cases where the target word was split by the tokenizer into multiple sub-tokens, we followed Devlin et al. (2019) and considered the representation of its first sub-token.

As regards the text encoder, we carried out the experiments with three different multilingual models, i.e., the multilingual version of BERT (Devlin et al., 2019) (**mBERT**) and the base and large versions of XLM-RoBERTa (Conneau et al., 2020) (**XLMR-base** and **XLMR-large**, respectively). In the monolingual setting, we used the following language-specific models: BERT-de[8], CamemBERT-large (Martin et al., 2020)[9], BERT-it[10], and ParsBERT[11] (Farahani et al., 2020), respectively, for German, French, Italian, and Farsi. As for all the other languages covered by the WordNet datasets, i.e., Bulgarian, Chinese, Croatian, Danish, Dutch, Estonian, Japanese and Korean, we used the pre-trained models made available by TurkuNLP.[12] We refer to each language-specific model as L-BERT.

In all experiments we trained the baselines to minimize the binary cross-entropy loss between their prediction and the gold label with the Adam (Kingma and Ba, 2015) optimizer. Training is carried out for 10 epochs with the learning rate fixed to $1e^{-5}$ and weight decay set to 0. As for tuning, results are reported for the best training checkpoint (among the 10 epochs) according to the performance on the development set.

4.1 Evaluation settings

We evaluated the baselines with different configuration setups, depending on the data used for training and tuning.

Cross-Lingual Zero-shot. This setting aims at assessing the capabilities of multilingual models in transferring knowledge captured in the English language to other languages. As training set, we used the English training set of WiC. As for tuning, depending on the setting, we either used the English development set of WiC or language-specific development sets of XL-WiC (Section 3.2.1). We report results on all WordNet and Wiktionary datasets of XL-WiC, i.e., Bulgarian, Chinese, Croatian, Danish, Dutch, Estonian, Farsi, French, German, Italian, Japanese and Korean.

Multilingual Fine-Tuning. In this setting, models are first trained on the WiC's English training set, and then further fine-tuned on the development sets of the target languages in XL-WiC. Depending on the training set used, we report results for two configurations: (i) *EN+Target Language*, combining with WiC's training data and the language-specific WordNet development sets for each language, and (ii) *EN+All Languages*, combining that with all WordNet development sets for all languages in XL-WiC, merged as one dataset.

---

[7] Even if not part of XL-WiC, we also compiled and validated a small Italian WordNet dataset to compare it with its Wiktionary counterpart. Table 8 in Appendix includes an additional table comparing the nature of these two datasets (including zero-shot cross-lingual transfer results).

Table 4: Results on the WordNet test sets when using only English training data in WiC, either in zero-shot cross-lingual setting (top block) or translation-based settings (the lower two blocks). T-EN is a target language dataset, automatically constructed by translating English instances in WiC.

Monolingual. In this setting, we trained each model on the corresponding training set of the target language only. For the case of WordNet datasets (where no training sets are available), we used the development sets for training. In this case we split each development set into two subsets with 9:1 ratio (for training and development). As for the Wiktionary datasets, we used the corresponding training and development sets for each language (Section 3.2.2).

Translation. In this last setting we make use of existing neural machine translation (NMT) models to translate either the training or the test set, essentially reducing the cross-lingual problem to a monolingual one. In particular, we used the general-domain translation models from the Opus-MT project[13] (Tiedemann and Thottingal, 2020) available for the following language pairs: English–Bulgarian, English–Croatian, English–Danish, English–Dutch, English–Estonian, and English–Japanese. The models are trained on all OPUS parallel corpora collection (Tiedemann, 2012), using the state-of-the-art 6-layer Transformer-based architecture (Vaswani et al., 2017).[14] In this configuration, as the original target word may be lost during automatic translation, we view the task as context (sentence) similarity as proposed by Pilehvar and Camacho-Collados (2019).[15] Therefore, for each model, the context vector is given by the start sentence symbol. We note that while training custom optimized NMT models for each target language may result in better overall performance, this is beyond the scope of this work.

Evaluation Metrics. Since all datasets are balanced, we only report accuracy, i.e., the ratio of correctly predicted instances (true positives or true negatives) to the total number of instances.

5 Results

In this section, we report the results for the configurations discussed in the previous section on the XL-WiC benchmark. We organize the experiments into two parts, based on the test dataset: WordNet (Section 5.1) and Wiktionary (Section 5.2).

5.1 WordNet datasets

Using English data only. Table 4 shows results on the XL-WiC WordNet test sets, when only WiC's English data was used for training and tuning purposes. Across the board, XLMR-large consistently achieves the best results, while mBERT and XLMR-base attain scores in the same ballpark. Indeed, the massive pretraining and the number of

---

Table 5: Results on the WordNet test sets when using language-specific data, either for training or for tuning.

parameters of XLMR-large play key roles behind this lead in performance. As regards the translation-based settings (lower two blocks), the performance generally falls slightly behind the zero-shot cross-lingual counterpart. This shows that the usage of good quality English data and multilingual models provide a stronger training signal than noisy automatically-translated data. This somehow contrasts with the observations made on other cross-lingual tasks in XTREME (Hu et al., 2020), especially in question answering datasets (Artetxe et al., 2020a; Lewis et al., 2020; Clark et al., 2020), where translating data was generally better. This difference could perhaps be reduced with larger monolingual models or accurate alignment, but this would further increase the complexity, and extracting these alignments from NMT models is not trivial (Koehn and Knowles, 2017; Ghader and Monz, 2017; Li et al., 2019).

Utilizing language-specific data. Table 5 shows results for settings where target language-specific data was used for training or tuning. Comparing the results in the top block (where target language data was used for tuning) with the middle two blocks (where target language data was instead used for training) reveals that it is more effective to leverage the target language data for training, rather than using it for tuning only. Overall, it is clear that adding multilingual data during training drastically improves the results in all languages. In this case, training (fine-tuning) is performed on a larger dataset which, despite having examples from different languages, provides a stronger signal to the models, enabling them to better generalize across languages. On the contrary, when only using target language data for training and tuning (last block in the table), results drop for most languages. This highlights the fact that having additional training data is beneficial, reinforcing the utility of multilingual models and cross-lingual transfer.

5.2 Wiktionary Datasets

In Table 6 we show results for the Wiktionary datasets. Differently from the results reported for the WordNet datasets (Table 4), models are less effective in the zero-shot setting, performing from 10 to almost 20 points lower than their counterparts trained on data in the target language. This can be attributed to the size of the available training data. Indeed, while in the WordNet datasets we only have a very small amount of data at our disposal for training (see statistics in Table 2), Wiktionary training sets are much larger, hence providing enough data to the models to better generalize. Once again, XLMR-large proves to be the best model in the

	Model	DE	FR	IT
Z-Shot	mBERT	58.27	56.00	58.61
	XLMR-base	58.30	56.13	55.91
	XLMR-large	**65.83**	**62.50**	**64.86**
Mono	mBERT	81.58	73.67	71.96
	XLMR-base	80.84	73.06	68.58
	XLMR-large	**84.03**	76.16	72.30
	L-BERT	82.90	**78.14**	**72.64**

Table 6: Results on the Wiktionary test sets in different training settings: zero-shot (Z-Shot) and monolingual training (Mono). L-BERT stands for language-specific models, i.e., BERT-de, CamemBERT-large and BERT-it for German, French and Italian, respectively.

zero-shot setting and a competitive alternative to the language-specific models (L-BERT row) in the monolingual setting, performing 1.1 points higher in German and 2 and 0.3 lower in French and Italian, respectively.

6 Analysis

In this section, we delve into the performance of the models on XL-WiC and analyze relevant aspects about their behaviour.

6.1 Seen and Unseen Words

For this analysis, we aim at measuring the difference in performance when a given target word was seen (as a target word) at training time or not. To this end, we evaluate our baselines when trained on the German, French, and Italian Wiktionary training sets and tested on two different subsets of the larger language-specific Wiktionary test sets: In-Vocabulary (**IV**), containing only the examples whose target word was seen at training time; and Out-of-Vocabulary (**OOV**), containing only the examples whose target word was not seen during training. We report the results in Table 7.

In general, multilingual models are less reliable when classifying unseen instances, lagging between 1 and 12 points behind in performance, depending on the language and on the model considered. This can be attributed to the fact that their vocabulary is shared among several languages, and therefore may have less knowledge stored about particular words that do not occur often. The performance drop of language-specific models (L-BERT) is less pronounced, with the French architecture (CamemBERT-large) attaining even higher performance (0.4 points more) on the OOV set.

	Model	DE	FR	IT
IV	mBERT	81.86	72.92	73.15
	XLMR-base	81.17	71.92	70.69
	XLMR-large	**84.24**	75.61	**75.12**
	L-BERT	83.23	**77.62**	73.89
OOV	mBERT	70.08	71.24	68.54
	XLMR-base	71.31	71.14	62.36
	XLMR-large	72.54	73.93	65.17
	L-BERT	**76.64**	**78.00**	**69.10**

Table 7: Results on the in-vocabulary (**IV**) and out-of-vocabulary (**OOV**) Wiktionary test sets. L-BERT stands for each language-specific model, i.e., BERT-base-de, camemBERT and BERT-base-xxl-it for German, French and Italian, respectively.

6.2 Few-shot Monolingual

As an additional experiment, we investigate the impact of training size on performance. To this end, we leveraged the Wiktionary datasets for German, French and Italian, which allow us to use varying-sized training sets, and created 7 training sets with 10, 25, 50, 100, 250, 500, 1000 instances.[16]

The results of this experiment are displayed in Figure 1. When providing only 10 examples, most of the models perform similarly or even worse than random, i.e., 50% accuracy. In this setting, language-specific models (L-BERT) attain better results than their multilingual counterparts, showing better generalization capabilities when fewer examples are provided. This also goes in line with what we found in the previous experiment on seen and unseen words. With less than 5% of the training data (1000 instances in French and German and 50 instances in Italian), all models attain roughly 85% of their performance with full training data, comparable to results reported for the zero-shot setting (Table 6).

7 Conclusions

In this paper we have introduced XL-WiC, a large benchmark for evaluating context-sensitive models. XL-WiC comprises datasets for a heterogeneous set of 13 languages, including the original English data in WiC (Pilehvar and Camacho-Collados, 2019), providing an evaluation framework not only for contextualized models in those languages, but also for experimentation in a cross-lingual transfer setting. Our evaluations show that, even though cur-

---

[16] Bigger datasets are supersets of smaller ones.

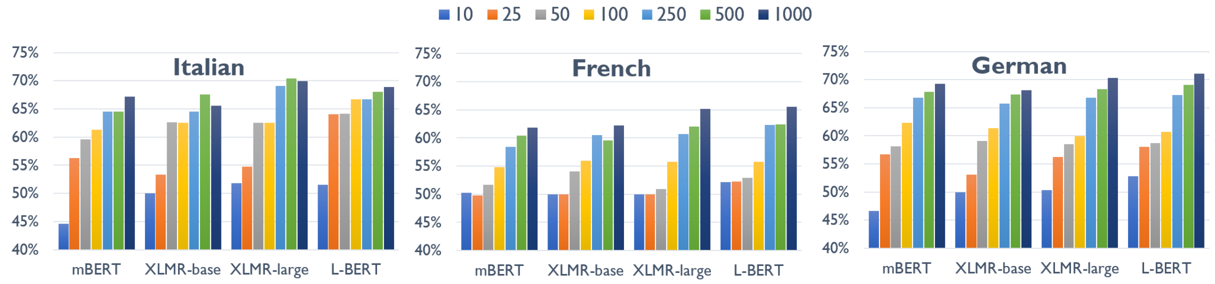

Figure 1: The impact of training set size (# of instances) on performance, for the Wiktionary datasets.

rent language models are effective performers in the zero-shot cross-lingual setting (where no instances in the target language are provided), there is still room for improvement, especially for far languages such as Japanese or Korean.

As for future work, we plan to investigate using languages other than English for training (e.g., our larger French and German training sets) in our cross-lingual transfer experiments, since English may not always be the optimal source language (Anastasopoulos and Neubig, 2020). Finally, while in our comparative analysis we have focused on a quantitative evaluation for all languages, an additional error analysis per language would be beneficial in revealing the weaknesses and limitations of cross-lingual models.

Acknowledgments

We would like to thank Qincheng Zhang (Chinese), Janine Siewert (Danish), Houman Mehrafarin, Hossein Mohebbi, and Ali Modarresi (Farsi), Ángela Collados Aís (German), Asahi Ushio (Japanese), and Yunseo Joung (Korean) for their help with the manual evaluation of the datasets.

Appendix

A Comparison between Italian WordNet and Wiktionary datasets

In Table 8 we provide a small comparison between the Italian WordNet and Wiktionary datasets, which is the only language that overlaps. While this comparison is quite limited, it provides a few hints on the qualitative differences between Wiktionary and WordNet datasets.

B Models' Parameters

In Table 9 we report the parameters of the models used in our experiments.

		WordNet	Wiktionary
Stats	Instances	260	592
	Unique Words	105	394
	Avg. Ctx length	14.53	23.39
	Human acc.	82.0	78.0
Z-shot	XLM-R base	66.15	55.91
	XLM-R large	80.00	64.86
	mBERT	70.00	58.61

Table 8: Statistics and comparison between the Italian WordNet and the Italian Wiktionary WiC datasets. Zero-shot results are computed by using the original English WiC (Pilehvar and Camacho-Collados, 2019) for training and development.

Model	Trainable Parameters
mBERT	110M
BERT-large	335M
XLMR-base	270M
XLMR-large	550M

Table 9: Number of parameters for our comparison systems.

C Additional experimental results

WordNet datasets. Table 10 includes details on the variability of the results, in particular the average results from three runs, including the standard deviation, for the zero-shot cross-lingual setting - this is the setting producing a higher variability in the results.

Wiktionary Datasets. In Table 11 we show the development and test results in the monolingual settings of the multilingual language models trained, tuned and tested on the XL-WiC language-specific datasets from Wiktionary.

Translation setting + Dictionary alignment. We include a setting where, after translating the English training set to each target language, we also retrieve the corresponding translation of the English target word through a multilingual dictionary. We use BabelNet (Navigli and Ponzetto, 2012) as multilingual dictionary for all languages, discarding the sentences where the translated target word could not be found. Table 12 shows the results.

D Translation models

Translation models are trained using the MarianNMT framework (Junczys-Dowmunt et al., 2018) on a filtered version of all OPUS parallel corpora collection using a language identifier (CLD2). As hyper-parameters, each model is based on the *base* version of the Transformer architecture (Vaswani et al., 2017). All models and training details are available at https://github.com/Helsinki-NLP/Opus-MT. To give an idea of the translation quality, Table 13 reports the BLEU scores (Papineni et al., 2002) for each model. We report the performance, as described within the Opus-MT project, on the latest available test sets from the series of WMT news translation shared tasks, or on 5K sentences taken from either the Tatoeba corpus (Tiedemann, 2012), or the Bible corpus (Christodouloupoulos and Steedman, 2015):

Abstract

Mainstream computational lexical semantics embraces the assumption that word senses can be represented as discrete items of a predefined inventory. In this paper we show this needs not be the case, and propose a unified model that is able to produce contextually appropriate definitions. In our model, Generationary, we employ a novel span-based encoding scheme which we use to fine-tune an English pre-trained Encoder-Decoder system to generate glosses. We show that, even though we drop the need of choosing from a predefined sense inventory, our model can be employed effectively: not only does Generationary outperform previous approaches in the generative task of Definition Modeling in many settings, but it also matches or surpasses the state of the art in discriminative tasks such as Word Sense Disambiguation and Word-in-Context. Finally, we show that Generationary benefits from training on data from multiple inventories, with strong gains on various zero-shot benchmarks, including a novel dataset of definitions for free adjective-noun phrases. The software and reproduction materials are available at `http://generationary.org`.

1 Introduction

Virtually all modern approaches to Word Sense Disambiguation (WSD), i.e. the task of automatically mapping a word in context to its meaning (Navigli, 2009), use predetermined word senses from a machine lexicon, both in supervised (Huang et al., 2019; Bevilacqua and Navigli, 2020; Scarlini et al., 2020b) and in knowledge-based settings (Tripodi and Navigli, 2019; Scarlini et al., 2020a; Scozzafava et al., 2020). Nevertheless, researchers in Natural Language Processing (NLP), lexical semantics, and lexicography, have long been warning the community about the cognitively inaccurate nature of discrete sense boundaries (Rosch and Mervis, 1975; Kilgarriff, 1997; Tyler and Evans, 2001). As Kilgarriff (2007) argued, different language users have different understandings of words. This fact explains why inter-annotator agreement (ITA) estimates on WSD annotation tasks have never exceeded the figure of 80% (Edmonds and Kilgarriff, 2002; Navigli et al., 2007; Palmer et al., 2007). Moreover, this casts doubt upon the reliability of human-made inventories and "gold standard" evaluation datasets (Ramsey, 2017). Having no indisputable way of determining where one sense of a word ends and another begins, together with the fact that little consensus about how to represent word meaning has hitherto existed (Pustejovsky, 1991; Hanks, 2000; Nosofsky, 2011), are issues lying at the core of what makes WSD hard (Jackson, 2019). Moreover, while English inventories of senses and corpora are widely available the same cannot be said for other languages (Scarlini et al., 2019; Barba et al., 2020; Pasini, 2020), and this limits the scalability of Natural Language Understanding tasks to multiple languages (Navigli, 2018).

In this paper we overcome these limitations by proposing a unified approach to computational lexical semantics that has as its central focus Definition Modeling (DM), i.e. the task of generating a gloss[1] from static or contextual embeddings (Noraset et al., 2017). Generating a meaning description (*definiens*) to define a given term in context (*definiendum*) avoids many of the concerns highlighted above, in that we are not limited to a pre-existing list of meanings. We show that we can use a single generation model, i.e. Generationary, not just to compete on the DM benchmarks, but also to achieve strong results on fully-discriminative tasks such as WSD and the recently-proposed Word-in-Context (Pilehvar and Camacho-Collados, 2019,

---

[*] These authors contributed equally.

[1] To ensure better readability, here we will use the term "gloss" as a synonym of the traditional dictionary "definition".

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7207–7221,
November 16–20, 2020.

WiC). This, in turn, results in a more solid assessment of the generation quality, a notorious problem in Natural Language Generation (NLG) evaluation (Gatt and Krahmer, 2018).

In contrast to previous approaches in DM (Gadetsky et al., 2018), we dispense with the requirement of having the *definiendum* represented by a single vector, and we condition gloss generation on a context of which the *definiendum* is an arbitrary span. This allows for the generation of contextual definitions for items that are rarely covered by sense inventories, such as free word combinations (e.g. *clumsy apology* or *nutty complexion*). Finally, the generative formulation makes it possible to train on several lexicographic resources at once, resulting in a versatile model that performs well across inventories, datasets, and tasks.

The main contributions of our approach are as follows:

1. We propose the use of a single conditional generation architecture to perform English DM, WSD and WiC;
2. Our model achieves competitive to state-of-the-art results despite dropping the need of choosing from a predefined sense inventory;
3. Thanks to our encoding scheme, we can represent the *definiendum* as a span in the context, thus enabling definition generation for arbitrary-sized phrases, and seamless usage of BART (Lewis et al., 2019), a pre-trained Encoder-Decoder model;
4. Additionally, we release a new evaluation dataset to rate glosses for adjective-noun phrases.

We envision many possible applications for Generationary, such as aiding text comprehension, especially for second-language learners, or extending the coverage of existing dictionaries.

2 Related Work

Recent years have witnessed the blossoming of research in Definition Modeling (DM), whose original aim was to make static word embeddings intepretable by producing a natural language definition (Noraset et al., 2017).[2] While subsequently released datasets have included usage examples to account for polysemy (Gadetsky et al., 2018; Chang et al., 2018), many of the approaches to "contextual" DM have nevertheless exploited the context merely in order to select a static sense embedding from which to generate the definition (Gadetsky et al., 2018; Chang et al., 2018; Zhu et al., 2019). Such embeddings, however, are non-contextual.

Other works have made a fuller use of the sentence surrounding the target, with the goal of explaining the meaning of a word or phrase as embedded in its local context (Ni and Wang, 2017; Mickus et al., 2019; Ishiwatari et al., 2019). However, these approaches have never explicitly dealt with WSD, and have shown limits regarding the marking of the target in the context encoder, preventing an effective exploitation of the context and making DM overly reliant on static embeddings or surface form information. For example, in the model of Ni and Wang (2017), the encoder is unaware of the contextual target, whereas Mickus et al. (2019) use a marker embedding to represent targets limited to single tokens. Finally, Ishiwatari et al. (2019) replace the target with a placeholder, and the burden of representing it is left to a character-level encoder and to static embeddings. This latter approach is interesting, in that it is the only one that can handle multi-word targets; however, it combines token embeddings via order-invariant sum, and thus it is suboptimal for differentiating instances such as *pet house* and *house pet*.

Recent approaches have explored the use of large-scale pre-trained models to score definitions with respect to a usage context. For example, Chang and Chen (2019) proposed to recast DM as a definition ranking problem. A similar idea was applied in WSD by Huang et al. (2019), leading to state-of-the-art results. However, both of these approaches fall back on the assumption of discrete sense boundaries, and are therefore unable to define targets outside a predefined inventory.

With Generationary, by contrast, we are the first to use a single Encoder-Decoder model to perform diverse lexical-semantic tasks such as DM, WSD and WiC. Moreover, we address the issue of encoding the target in context by using a simple, yet effective, encoding scheme which makes use of special tokens to mark the target *span*, producing a complete and joint encoding of the context without the need for other components. This allows the effective usage of a pre-trained model, which we fine-tune to generate a gloss given the context.

---

[2] With one single exception (Yang et al., 2020), DM has only been concerned with the English language.

3 Generationary

With this work we present a new approach to computational lexical semantics, by means of which we generate glosses for arbitrary-sized phrases in context. Our work has a wider scope than its predecessors, in that we put forward a unified method that overcomes the limits of both DM and WSD. With respect to DM, our full sequence-to-sequence framing of the task enables us to deal with units having different compositional complexity, from single words to compounds and phrases. Thus, Generationary can gloss a *definiendum* that is not found in dictionaries, such as *starry sky*, with the appropriate *definiens*, e.g.: 'The sky as it appears at night, especially when lit by stars'.

As regards WSD, instead, we are no longer bound by the long-standing limits of predefined sense inventories. Thus, it is possible to give (i) a meaningful answer for words that are not in the inventory, and (ii) one that fits the meaning and the *granularity* required by a given context better than any sense in the inventory. Consider the following:

(1) (a) Why cannot we teach our children to read, write and reckon?
(b) Mark or trace on a surface.
(c) To be able to mark coherent letters.

The target word in (1 a) is associated[3] with the gold gloss (1 b) from WordNet (Fellbaum, 1998), the most used sense inventory in WSD. However, Generationary arguably provides a better gloss (1 c). In what follows, we detail our approach.

3.1 Gloss Generation

In this work we address the task of *mapping* an occurrence of a target word or phrase t (in a context c) to its meaning, by reducing it to that of *generating* a textual gloss g which defines $\langle c, t\rangle$. The target t is a span in c, i.e. a pair of indices $\langle i, j\rangle$ corresponding to the first and the last token which make up the target in c. Formally, we propose to apply the standard sequence-to-sequence conditional generation formulation, in which the probability of a gloss, given a context-target pair, is computed by factorising it auto-regressively:

$$P(g|c,t) = \prod_{k=1}^{|g|} P(g_k|g_{0:k-1}, c, t) \qquad (1)$$

where g_k is the kth token of g and g_0 is a special start token. By means of this procedure we can readily perform contextual DM ($t \neq \langle 1, |c|\rangle$), as well as "static" DM, i.e. when the target encompasses the whole context ($t = \langle 1, |c|\rangle$).

To learn the function in Eq. (1) we employ a recent Encoder-Decoder model, i.e. BART (Lewis et al., 2019), which is pre-trained to reconstruct text spans on massive amounts of data. The use of a pre-trained model is particularly important in our case, as successfully generating a gloss for a wide range of different context-target pairs requires a model which can wield vast amounts of semantic and encyclopedic knowledge. BART can be fine-tuned to perform specific kinds of conditional generation by minimizing the cross-entropy loss on new training input-output pairs. In our approach we give as input to BART a $\langle c, t\rangle$ pair, and train to produce the corresponding gold gloss g, with $\langle c, t\rangle$ and g being gathered from various sources (see Section 4.1). We devise a simple encoding scheme that allows us to make the model aware of the target boundaries, without architectural modifications to BART. Particularly, we encode $\langle c, t\rangle$ pairs as sequences of subword tokens in which the boundaries of the t span in c are marked by two special tokens, i.e. `<define>` and `</define>`. For example, the sentence *I felt like the fifth wheel*, with the phrase fifth wheel as the target, will be encoded as `I felt like the <define> fifth wheel </define>`. We fine-tune BART to generate the corresponding gloss g: `(idiomatic, informal) Anything superfluous or unnecessary`.

3.2 Discriminative Sense Scoring

In this section we introduce three distinct techniques by means of which Generationary tackles discriminative tasks without additional training.

3.2.1 Gloss Probability Scoring

With Eq. (1) we are able to compute the probability of a certain gloss g given a pair $\langle c, t\rangle$. Thus, we can perform classification by picking the sense which is associated with the gloss with the highest probability. Formally, we select:

$$\hat{s} = \operatorname*{argmax}_{s \in S_t} P(\mathcal{G}(s)|c,t) \qquad (2)$$

where $S_t \subset S$ is the set of applicable senses for target t from the full inventory S, and $\mathcal{G} : S \to G$ is a function mapping senses to glosses ($\mathcal{G}$, G, S and S_t are determined by the reference dictionary).

---

[3] According to the human annotators of the Senseval-2 WSD evaluation dataset (Edmonds and Cotton, 2001).

3.2.2 Gloss Similarity Scoring

The usage of model gloss probability does not take into account the definitions that are actually generated. Thus, we adopt a simple best match approach where we compute similarity scores between the system-generated gloss and the glosses associated with the candidates, and we predict the candidate with the highest similarity. We employ a cosine similarity between the gloss vectors produced via the recently introduced Sentence-BERT model (Reimers and Gurevych, 2019, SBERT), and select a predicted sense $\hat{s}$ as follows:

$$\hat{s} = \underset{s \in S_t}{\operatorname{argmax}}\, sim(\hat{g}, \mathcal{G}(s)) \tag{3}$$

where $\hat{g}$ is the most probable output found by beam-search decoding, and sim is the SBERT similarity.

3.2.3 Gloss Similarity Scoring with MBRR

Using just the most probable sequence in the decoding process for the best match search is suboptimal, as more probability mass might be cumulatively assigned to a cluster of very similar outputs. To take this into account we propose the use of a simple approach inspired by Minimum Bayes Risk Re-Ranking (Kumar and Byrne, 2004, MBRR), which considers the mutual (dis)similarity within the set $\hat{G}$ of k generated outputs decoded with beam search. This is done by rescoring each output as the sum of the dissimilarities over all k outputs, weighted by their conditional probability:

$$\hat{g} = \underset{\hat{g}_i \in \hat{G}}{\operatorname{argmin}} \sum_{\hat{g}_j \in \hat{G}} (1 - sim(\hat{g}_i, \hat{g}_j)) P(\hat{g}_j | c, t) \tag{4}$$

The new prediction $\hat{g}$ is then plugged into Eq. (3) as in simple similarity-based scoring.

4 Datasets

4.1 Dictionary Gloss Datasets

We now move on to describe the datasets which we use to train Generationary models by fine-tuning BART. Each dataset includes $\langle c, t, g \rangle$ triples, which are used as our input and output for training.

CHA (Chang and Chen, 2019) is an online dataset[4] of examples and definitions from `oxforddictionaries.com`. It comes with two settings, each with its own train/dev/test splits: in the *Seen* setting (**CHA**$_S$), definitions in the training set are also present in the test set, while the *Unseen* setting (**CHA**$_U$) has a zero-shot test of lemmas not featured in the training set.

	instances			unique glosses		
dataset	**train**	**dev**	**test**	**train**	**dev**	**test**
CHA$_S$	555,695	78,550	151,306	78,105	32,953	37,400
CHA$_U$	530,374	70,401	15,959	73,104	29,540	3,958
SEM	333,633	-	-	116,698	-	-
UNI	1,832,302	-	-	947,524	-	-

Table 1: Training, dev and test instances and number of unique glosses in the datasets used.

SEM is a dataset built by exploiting the SemCor corpus (Miller et al., 1993) – which is manually tagged with WordNet senses – to associate sentence-level contexts with definitions. We filter out NER-like sense annotations (e.g. those mapping proper names such as *Frank Lloyd Wright* to the general sense of *person*). Moreover, to improve coverage, since not all WordNet senses appear in SemCor, we use synonymy information to build additional contexts, e.g. `<define> separate, part, split </define>` → `go one's own way; move apart.`

UNI is the concatenation of the train splits of SEM and CHA, plus the following: (i) a cleaned-up January 2020 dump of Wiktionary, from which circular definitions (e.g. starting with *synonym of*) have been filtered out, and (ii) the training split containing data from the GNU Collaborative International Dictionary of English (GCIDE), included in the dataset of Noraset et al. (2017).

We use CHA and SEM since they were employed by state-of-the-art approaches to DM (Chang and Chen, 2019) and WSD (Huang et al., 2019). With UNI, instead, we bring together diverse sense inventories to create a dataset that is less dependent on the idiosyncrasies of each of its sources. We report statistics in Table 1.

4.2 The Hei++ Evaluation Dataset

As of now, there is no publicly available dataset enabling the assessment of definition generation quality on free phrases (e.g. *exotic cuisine*), which are not commonly found in traditional dictionaries and benchmarks. Thus, we present Hei++, a dataset which associates human-made definitions with adjective-noun phrases. With Hei++ we can test the ability of Generationary to generate glosses, in a zero-shot setting, for items which are not featured in the training set. We encourage the community to use it for future evaluations.

As a first step in building Hei++ we retrieve the

---

[4] `github.com/MiuLab/GenDef`

test split of the HeiPLAS dataset (Hartung, 2016),[5] which we choose as our starting point since it contains commonly used adjective-noun phrases. After removing duplicates and discarding ill-formed phrases, we ask an expert lexicographer to write a single definition for each adjective-noun pair. At the end of the annotation process we obtain a dataset made up of 713 adjective-noun phrases with their definitions to be used as a gold standard.

5 Quantitative Experiments

We first perform a threefold automatic evaluation to test the strengths of Generationary in different settings. On the one hand, we assess its ability to produce suitable definitions by testing the generation quality on the DM setting (Section 5.1). On the other, we aim to further appraise how well the generated outputs describe the contextual meaning, by evaluating the performance they bring about on the discriminative benchmarks of WSD (Section 5.2) and WiC (Section 5.3).[6]

5.1 Definition Modeling

In this experiment we use different NLG measures to automatically assess how well generated definitions match gold glosses. We evaluate on the *Seen* (CHA$_S$) and *Unseen* (CHA$_U$) test splits of CHA, which is the largest contextual DM benchmark released so far. Moreover, we report results on our Hei++ (HEI) dataset of adjective-noun phrases. We do not include results on the datasets of Noraset et al. (2017) and Gadetsky et al. (2018), as the former only includes targets with no surrounding context, and the latter is largely included in CHA.[7]

5.1.1 Systems

For each evaluation dataset D we test two Generationary models: one trained on the corresponding train split (Gen-D), and one trained on UNI (Gen-UNI).[8] We compare against (i) a random baseline which predicts, for each test item, a random definition taken from the same test set; (ii) the model of Ishiwatari et al. (2019), which we have re-trained on the same data as Generationary (Ishiwatari-D), and (iii) the state-of-the-art approach of Chang and Chen (2019, Chang). On HEI, which has no training split, we only evaluate Gen-UNI and the random baseline, since Ishiwatari-UNI generates strings consisting of mostly unknown word placeholders (`<unk>`), and Chang and Chen (2019) cannot handle multi-word targets.

5.1.2 Measures

Previous approaches have employed both perplexity (PPL) and string-matching measures (e.g. BLEU) for scoring DM systems. PPL is very appropriate when, as in DM, there are many possible “good” answers.[9] PPL, however, produces a score just on the basis of a pre-existing gold definition, by collecting teacher forcing probabilities without taking into account any actual output generated through beam-search decoding, and thus not assessing the quality of the generation. To evaluate this quality, BLEU and ROUGE-L (Lin, 2004) are also reported. Note, however, that these two measures are based on simple string matches which, in many cases, are not good indicators of output quality. To counteract this problem, we also report results with METEOR (Banerjee and Lavie, 2005) – which uses stemming and WordNet synonyms – and BERTScore (Zhang et al., 2019), which uses vector-based contextual similarities.[10] Finally, to present a complete comparison against the ranking-based approach of Chang and Chen (2019), we report results (precision@k) on their retrieval task of recovering the correct definition, for the target in context, from the whole inventory of 79,030 unique glosses in their dataset. We rank definitions by applying the MBRR plus cosine similarity strategy described in Section 3.2.3.

5.1.3 Results

As shown in Table 2, Generationary models outperform competitors in every setting. On CHA$_S$, our specialized model (Gen-CHA$_S$) shows much better results than Gen-UNI, because NLG measures give high scores to glosses which are lexically similar to the gold ones, while multi-inventory training will, instead, expose the model to many other, differently formulated, but equally valid definitions. Note, moreover, that our Gen-CHA$_S$ model outperforms both Ishiwatari et al. (2019) and Chang and Chen (2019), even though the latter, being a ranking model, is obviously at an advantage, since it gets a perfect score when it ranks the gold definition first. In CHA$_U$ we observe that the Gen-UNI model

	Gen-UNI	1.4	66.9	72.0	47.0	90.7
CHA$_U$	Random	-	0.3	11.0	3.2	68.2
	Chang	-	7.1	19.3	-	-
	Ishiwatari-CHA$_U$*	-	2.1	19.9	7.1	71.7
	Ishiwatari-UNI*	-	2.1	19.7	6.7	71.5
	Gen-CHA$_U$	20.3	8.1	28.7	12.7	76.7
	Gen-UNI	**15.4**	**8.8**	**29.4**	**13.5**	**76.8**
HEI	Random	-	1.6	12.7	0.4	73.4
	Gen-UNI	**16.0**	**6.3**	**26.3**	**15.1**	**78.9**

Table 2: DM evaluation results. Columns: perplexity, BLEU, Rouge-L, METEOR, BERTScore (ppl/BL/R-L/MT/BS). Row groups are mutually comparable (**bold** = best). ↑/↓: higher/lower is better. *: re-trained.

attains higher performances than Gen-CHA$_U$, indicating that, when 'overfitting' on the inventory is factored out, multi-inventory training enables the model to generalize better in a zero-shot setting. Furthermore, figures for HEI are in the same ballpark as those on CHA$_U$, demonstrating that Generationary can easily deal, not only with unseen lemmas, but also with entirely different kinds of target.

Additionally, in Table 3 we report the results of the precision@k evaluation when macro-averaging on lemmas (left) and senses (right). Figures on the two different splits of CHA show very different trends. On the CHA$_S$ setting, the base model from Chang and Chen (2019) achieves, in most cases, the highest recovery rate. However, with $k = 1$, which is the most realistic case, Gen-CHA$_S$ outperforms the competitor by 4.6 points when macro-averaging on senses, i.e. items with the same gold definition. On the more challenging zero-shot CHA$_U$ setting, both Generationary models strongly outperform Chang (large), more than doubling the performance on $k = 1$ and showing an improvement of more than 75% on $k = 10$. Gen-UNI, which was underperforming Gen-CHA$_S$ in the *Seen* setting, now achieves better results across the board, since it can exploit the supervision of a wide array of different glosses from multiple inventories.

5.2 WSD Evaluation

We now move to the assessment of Generationary in a traditional WSD setting. Even though our approach goes beyond fixed sense inventories, here we want to show that this degree of freedom does not come at the expense of performance when presented with the task of choosing a sense from a finite predefined list.

	model	**P@k (lemmas)**			**P@k (senses)**		
		1	**5**	**10**	**1**	**5**	**10**
CHA$_S$	Chang (base)	**74.8**	**83.3**	**85.5**	63.3	**74.0**	**77.1**
	Chang (large)	73.9	82.6	84.9	62.4	73.2	76.3
	Gen-CHA$_S$	73.0	77.7	79.4	**67.9**	72.9	74.7
	Gen-UNI	63.0	70.2	72.7	55.5	63.1	65.8
CHA$_U$	Chang (base)	3.3	9.6	14.4	2.3	7.4	11.4
	Chang (large)	3.5	10.5	15.6	2.5	8.2	12.4
	Gen-CHA$_U$	7.8	19.9	25.5	6.5	16.8	22.0
	Gen-UNI	**9.3**	**21.3**	**27.7**	**7.4**	**18.0**	**23.8**

Table 3: Macro precision@k (lemmas and senses) on the retrieval task of Chang and Chen (2019). Row groups are mutually comparable (**bold** = best).

We test on the five datasets collected in the evaluation framework of Raganato et al. (2017), namely: Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013), SemEval-2015 (Moro and Navigli, 2015), which are all annotated with WordNet 3.0 senses (or converted to its inventory). We denote with ALL and ALL$^-$ the concatenation of all evaluation datasets, including or excluding, respectively, SemEval-2007, which is our development set for this experiment. Moreover, we test on the subset of ALL$^-$ containing instances whose lemmas are not covered in SemCor (0-shot).

5.2.1 Systems

To choose a possible sense from WordNet and perform WSD, we evaluate the techniques presented in Section 3.2, i.e. probability scoring (Prob.), simple similarity scoring (Sim.), and similarity scoring with MBRR. We evaluate our Gen-SEM, which is trained on examples specifically tagged according to the WordNet inventory, and Gen-UNI, which includes definitions from many different inventories. We compare against recent WSD approaches which make use of gloss knowledge, i.e. LMMS (Loureiro and Jorge, 2019) and the state-of-the-art approach of GlossBERT (Huang et al., 2019).

5.2.2 Results

We report the results of the WSD evaluation in Table 4. The MBRR scoring strategy proves to be the most versatile, with Gen-SEM (MBRR) achieving a higher F1 than Gen-SEM (Prob.) on almost every dataset, and outperforming Gen-SEM (Sim.) on

model	**S2**	**S3**	**S7**	**S13**	**S15**	**ALL**	**ALL$^-$**	**0-shot**	**N**	**V**	**A**	**R**

GlossBERT	77.7	75.9	**72.1**	76.8	**79.3**	**77.0**	**77.2***	68.7*	79.7*	**66.5***	79.3*	85.5*
Gen-SEM (Prob.)	76.9	73.7	69.2	74.6	78.2	75.3	75.7	60.6	77.5	65.0	78.4	**87.6**
Gen-SEM (Sim.)	77.5	**76.4**	71.6	76.8	77.4	76.7	77.0	63.3	**80.1**	64.8	79.1	85.0
Gen-SEM (MBRR)	**78.0**	75.4	71.9	77.0	77.6	76.7	77.0	65.0	79.9	64.8	79.2	86.4
Gen-UNI (MBRR)	77.8	73.7	68.8	**78.3**	77.6	76.3	76.8	**73.0**	79.8	63.3	80.1	84.7

Table 4: Results on the WSD evaluation. Row groups: (1) previous approaches; (2) Generationary. Columns: datasets in the evaluation framework (S2 to S15), ALL w/ and w/o the dev set (ALL/ALL$^-$), zero-shot set (0-shot), and results by PoS on ALL (N/V/A/R). F1 is reported. **Bold**: best. *: re-computed with the original code.

the 0-shot set. As both Sim. and MBRR outscore Prob., it is clear that generating a gloss and ranking candidates with similarity is a better strategy than directly ranking with model probability, which leaves room for further improvement as better similarity measures are developed.

On another note, Gen-SEM (MBRR) achieves performances which are overall comparable with those of the state of the art (GlossBERT) without having been explicitly trained to perform WSD. Compared to Gen-SEM (MBRR), Gen-UNI (MBRR) sacrifices 0.4 and 0.2 points on, respectively, ALL and ALL$^-$, but obtains 8 points more on the zero-shot set, also improving over GlossBERT by 4.3 points. This demonstrates that, when using Generationary with data from multiple inventories, (i) performances remain in the same ballpark as those of a state-of-the-art system, and (ii) much improved generalizability is achieved, as shown by the state-of-the-art results on the zero-shot setting.

5.3 Word-in-Context

In the task of Word-in-Context (WiC) (Pilehvar and Camacho-Collados, 2019), predefined sense inventories are not required and meaning identification is reduced to a binary problem in which, given two contexts, both featuring an occurrence of the same lemma, a model has to predict whether the two targets have the same meaning. We compare against Chang and Chen (2019), which is the only DM approach reporting results for WiC, following their setting in which no task-specific training is performed and the training set for the task is used for testing. Results are reported for both Gen-CHA$_S$, which is trained on the same data as Chang and Chen (2019), and Gen-UNI.[11]

To perform the task, for each pair in the WiC dataset we generate two sets, γ and γ', each of 10 glosses, for the two respective sentences in the pair. Then, for each generated gloss $\hat{g} \in \gamma$, we compute the score $z_{\hat{g}}$ as the mean SBERT similarity between $\hat{g}$ and the 10 generated glosses in γ'. Analogously, we compute $z_{\hat{g}'}$ as the mean similarity between $\hat{g}' \in \gamma'$ and the glosses in γ. For each gloss g we normalize z_g by subtracting an approximate mean similarity of g with random glosses, computed as the mean similarity between g and all other unrelated glosses in the batch. If the mean score $(\sum_{\hat{g}\in\gamma} z_{\hat{g}} + \sum_{\hat{g}'\in\gamma'} z_{\hat{g}'})/20$ exceeds a threshold t (tuned on the dev set), we predict that a WiC pair shares the same sense.

Gen-CHA$_S$, with an accuracy of 69.2, outperforms Chang and Chen (2019), which achieves 68.6, demonstrating the strength of our approach in this setting. Moreover, Gen-UNI, which attains a result of 71.1, outscores both Gen-CHA$_S$ and the competitor, once again bearing witness to the versatility of training on multiple inventories.

6 Qualitative Experiment

Given that the ability of Generationary to produce fluent and meaningful definitions is its key asset, in addition to the automatic evaluation reported in Section 5 we devised a qualitative experiment on two distinct datasets we constructed. While our previous experiments shed light upon the quality of Generationary in comparison with other automatic systems, here we employ human annotators to compare definitions produced with our approach against glosses written by human lexicographers.

The datasets that we use in this experiment are (i) our Hei++ dataset of definitions for adjective-nouns phrases (Section 4.2) and (ii) SamplEval, i.e. a sample of $1{,}000$ random instances made up of 200 items[12] for each of the five WSD datasets included in ALL (see Section 5.2), with at most one

---

[11] In this experiment we have excluded Wiktionary, which was used to build the WiC dataset, from the UNI training set.

[12] We do not sample instances annotated with many senses.

dataset	gold	Gen.	$\geq$
Hei++	4.43	3.58	29.9
SamplEval	3.75	3.62	51.3

Table 5: Qualitative evaluation results. Columns: dataset, average Likert for gold and Generationary, % of Generationary scores equal or better than gold ($\geq$).

total instance per sense. With Hei++ we assess the ability of Generationary to accurately gloss complex expressions, such as free phrases (e.g. *wrong medicine* or *hot forehead*), that are rarely covered by traditional dictionaries. With SamplEval, instead, we test whether generated glosses can improve over gold definitions associated with gold senses in WordNet.

6.1 Annotators and Annotation Scheme

For each context-target pair in Hei++ and SamplEval we have two definitions: a gold one, written by a lexicographer, and one generated by Gen-UNI, which is not tied to any specific inventory and has proven the most versatile model across tasks. We hired three annotators with Master's Degrees in Linguistics and effective operational proficiency in English and, in a similar fashion to Erk and McCarthy (2009), we asked them to assign a graded value to the definitions based on their pertinence to describing the target t in c, according to a five-level Likert scale (see Appendix F).[13] The annotators received a wage in line with the standards of their country of residence, and worked an overall amount of 90 person-hours (30 per annotator). The ITA was substantial, with an average pairwise Cohen's κ of 0.69 (SamplEval) and 0.67 (Hei++).

6.2 Results

As can be seen in Table 5, the quality of Generationary glosses in the SamplEval dataset is comparable to those drawn from WordNet. Note that, although it would be expected for gold annotations to come close to the top of the scale, this is not the case, as they received an average score of 3.75 out of 5, demonstrating the suboptimal nature of "ready-made" meaning distinctions. We report comparable scores on the Hei++ dataset. The gap with respect to gold definitions here is wider, probably because (i) Generationary is not specifically trained on complex expressions, and (ii) the gold score is higher since phrases are less ambiguous than single words. Interestingly, the annotators rated Generationary glosses at least as high as their gold counterparts on 51.3% and on 29.9% of the total cases on SamplEval and Hei++, respectively: this result provides evidence for the reliability of Generationary definitions as valid alternatives to glosses taken from established inventories of discrete word senses.

c_1	[...] I scooted them into the dog run.
$\hat{g}_1$	Cause to move along by pushing.
g_1	Run or move very quickly or hastily.
c_2	Exotic cuisine.
$\hat{g}_2$	A style of cooking that is out of the ordinary and unusual (as if from another country).
g_2	Cuisine involving unfamiliar foods.
c_3	He was never the same after the accident.
$\hat{g}_3$	Indicates that a person has lost the good qualities that were present before the accident.
c_4	Sam is in a better place now.
$\hat{g}_4$	A phrase used to express that one has learned about another's death.
c_5	Yesterday I had to undergo a beardectomy.
$\hat{g}_5$	The surgical removal of the beard.
c_6	You've got a hard coconut to smash here, Dr. Yang!
$\hat{g}_6$	Something difficult to deal with.
c_7	The mind is haunted by the ghosts of the past.
$\hat{g}_7$	People's memories of the past are still present in their mind, even after they have ceased to exist.
c_8	The fault, dear Brutus, is not in our stars, but in ourselves.
$\hat{g}_8$	The responsibility for a problem lies with the people who cannot see it themselves.

Table 6: Sample of Generationary definitions ($\hat{g}$) for several targets in context (c). g: gold definition.

7 Generation Examples

In Table 6 we show a sample of definitions generated via our Gen-UNI model for various spans in context.[14] As can be seen, the glosses $\hat{g}_1$ and $\hat{g}_2$ (extracted from SamplEval and Hei++, respectively) demonstrate that Generationary can indeed provide better, more specific definitions than gold standard ones. The following reported examples show the strength of our model on contexts which do not resemble those it is trained on: Generationary is proficient at (i) handling fixed or semi-fixed

---

[13] We presented glosses for each sentence in random order.

[14] See Appendix A for further samples of generated glosses.

idioms of different lengths ($\hat{g}_3$, $\hat{g}_4$) and (ii) defining non-conventional words and phrases ($\hat{g}_5$, $\hat{g}_6$); interestingly, Generationary is also able to (iii) provide high-level explanations for whole figurative contexts ($\hat{g}_7$, $\hat{g}_8$), which goes well beyond what is commonly referred to as *glossing*. This might result in interesting applications beyond the scope of this work, e.g. for paraphrase generation and metaphor interpretation (Rai and Chakraverty, 2020).

8 Error Analysis

To have a broader picture of the quality of the outputs produced by means of Generationary, we perform behavioural testing for our Gen-UNI model, in the spirit of Ribeiro et al. (2020). As a result, we can identify two main trends behind failures to generate an appropriate contextual definition, which we refer to as *disambiguation errors* and *hallucinations*, respectively.

Disambiguation errors When the model predicts a perfectly good definition for the target, but one that fits another common context of occurrence, a disambiguation error arises. For instance, given the $\langle c, t \rangle$ pair in (2 a), with the word pupil as the target, the model fails to identify the "aperture in the iris of the eye" sense, and instead produces an output gloss which is compatible with the meaning of the homograph (2 b):

(2) (a) The teacher stared into the pupils of her pupil.
    (b) A person receiving instruction, especially in a school.

Hallucinations Other errors stem from the fact that the model can only rely on the knowledge about possible *definienda* that it is able to store in the parameters during the pre-training and training stages. Thus, if the contextual knowledge is not sufficient to extrapolate a definition, the model – which is required to always generate an output – will hallucinate an answer on the basis of contextual clues, incurring the risk of introducing non-factualities. This particularly concerns named entities and domain-specific concepts, but the clearest examples can be seen with targets that do not correspond to any existing, fictional or non-fictional entity. For example, given the input sentence (3):

(3) Squeaky McDuck wasn't happy about it,

the model outputs the following:

(4) The title character in the "Squeaky Squeakety-Squeakiness" cartoon series.

In this case, the model picked the cue of the *cartoonish* Squeaky McDuck character, and hallucinated the name of a plausible cartoon series for it. Note that neither Squeaky McDuck nor the cartoon series actually exist.

9 Conclusion

With this work, we showed that generating a definition can be a viable, suitable alternative to the traditional use of sense inventories in computational lexical semantics, and one that better reflects the non-discrete nature of word meaning. We introduced Generationary, an approach to automatic definition generation which, thanks to a flexible encoding scheme, can (i) encode targets of arbitrary length (including unseen multi-word expressions), and (ii) exploit the vast amount of knowledge encoded in the BART pre-trained Encoder-Decoder, through fine-tuning.

From two points of view, Generationary represents a unified approach: first, it exploits multiple inventories simultaneously, hence going beyond the quirks of each one; second, it is able to tackle both generative (Definition Modeling) and discriminative tasks (Word Sense Disambiguation and Word-in-Context), obtaining competitive to state-of-the-art results, with particularly strong performances on zero-shot settings. Finally, human evaluation showed that Generationary is often able to provide a definition that is on a par with or better than one written by a lexicographer.

We make the software and reproduction materials, along with a new evaluation dataset of definitions for adjective-noun phrases (Hei++), available at `http://generationary.org`.

$\hat{g}_{10}$: A woman who entertains guests at their home and makes them feel welcome.
g_{10}: A woman host who shows liveliness.

Table 7: Random sample of Generationary definitions ($\hat{g}$) for Hei++ contexts (c). g: gold definition.

A Generation Examples

In the evaluation of NLG systems, human qualitative assessment is very important. Therefore, we choose to report a fair number of non-cherrypicked, zero-shot generation examples, produced by means of our GEN-UNI model.

c_1: Hipster guys #2 & #3.
$\hat{g}_1$: Members of the hipster subculture.

c_2: Because you have no estrogen... you could not possibly understand what chocolate means to a woman.
$\hat{g}_2$: The absence of estrogen in the body.

c_3: Mozilla Firebird bookmark toolbar doesn't hide command click to open link in new tab.
$\hat{g}_3$: A toolbar in the Mozilla browser.

c_4: Guy #2: On that table over there.
$\hat{g}_4$: The (usually specified) table on which something is located.

c_5: Man, why do chip manufacturers always put the crumbs at the bottom of the bag?
$\hat{g}_5$: A company that manufactures potato chips.

c_6: Install new theme without an internet connection.
$\hat{g}_6$: A connection to the internet.

c_7: It's a true story.
$\hat{g}_7$: A fictional story based on real events.

c_8: Seeking female friend, 40s, attractive 5 ft 5+.
$\hat{g}_8$: A friend who is not a man.

c_9: Clicking Get New Extensions in Options Dialog opens a new browser...
$\hat{g}_9$: A dialog box in a web browser, allowing the user to select from a number of options.

c_{10}: And he goes to my other roommate for advice.
$\hat{g}_{10}$: The other person with whom one shares a room.

Table 8: Generationary definitions ($\hat{g}$) for random targets and contexts (c) excerpted from `webtext`.

In Table 7 we show Generationary outputs and gold definitions for 10 randomly sampled phrases in the Hei++ dataset. In addition, in Table 8 we report gloss generation examples for random words and noun phrases taken from the `webtext` corpus included in the NLTK suite (Loper and Bird, 2002). We exclude swear words, slurs, numbers, and noun phrases consisting entirely of named entities. Moreover, every sampled item whose target was featured in our training set was filtered out.

B Reproducibility Details

To train our models we employ the `fairseq` library. Generationary has the same number of parameters as BART (Lewis et al., 2019), i.e. ca. 458M. For fine-tuning, we use the same hyperparameters used in Lewis et al. (2019) for summarization,[15] except that:

---

[15] `github.com/pytorch/fairseq/blob/master/examples/bart/README.summarization.md`

- the learning rate is set to 5×10^{-5} on the basis of preliminary experiments;
- due to memory concerns, we feed the input in batches of 1,024 tokens, updating every 16 iterations;
- we use inverse square root learning rate scheduling, which does not require to set a maximum number of iterations a priori;
- we double the number of warmup steps to 1,000.

Training is performed for at most 50 epochs. We employ a single NVIDIA GeForce RTX 2080 Ti GPU to perform all the reported experiments, with average runtimes per epoch of BART fine-tuning ranging from ca. 50 minutes (Gen-SEM) to >120 minutes (Gen-UNI).

On the DM task, we evaluate on the best epoch, i.e. the one with the lowest cross-entropy loss on the dev set, with no hyperparameter tuning.

On the WSD task, instead, we perform minimal hyperparameter tuning, with search trials just on beam size (testing with values of 1, 10, 25, and 50), choosing as the best configuration the one with the highest F1 on our dev set, SemEval-2007; with simple similarity scoring, the best Gen-SEM has a beam size of 10, while, with MBRR similarity scoring, the best Gen-SEM has a beam size of 25. We use only MBRR with Gen-UNI, with a beam size of 10, resulting in the best performance on the development set.

On the WiC task we only perform tuning of the threshold on the dev set, by trying every value in range between the lowest and the highest z score, with a minimum step of 0.025. We compute similarities in batches of 125 pairs.

For training and prediction of the models of Ishiwatari et al. (2019), we use the code provided by the authors.[16] We use the same hyperparameters, except that we increase the vocabulary size to 39,000, which results in much improved performances on our benchmarks.

C Additional Results on DM

In Table 9 we report results, for the DM evaluation described in Section 5.1, on two additional datasets.

NOR (Noraset et al., 2017) includes data from the GCIDE and WordNet. It features only "static" pairs, in which the context coincides with the word to be defined. Nonetheless, each lemma can be associated with multiple definitions.

	model	**ppl↓**	**BL↑**	**R-L↑**	**MT↑**	**BS↑**
NOR	Random	-	0.2	6.3	1.9	69.0
	Noraset et al. (2017)	48.2	-	-	-	-
	Ishiwatari-NOR*	-	1.9	15.7	5.0	**72.9**
	Gen-NOR	**28.6**	**3.8**	**17.7**	**8.1**	**72.9**
GAD	Random	-	0.2	8.7	2.8	68.6
	Gadetsky et al. (2018)	43.5	-	-	-	-
	Mickus et al. (2019)	34.0	-	-	-	-
	Ishiwatari-GAD*	-	2.5	18.7	7.0	72.8
	Gen-GAD	**12.3**	**9.9**	**28.9**	**12.8**	**77.9**

Table 9: DM evaluation results. Columns: perplexity, BLEU, Rouge-L, METEOR, BERTScore (ppl/BL/R-L/MT/BS). Row groups are mutually comparable (**bold** = best). ↑/↓: higher/lower is better. *: re-trained.

GAD (Gadetsky et al., 2018) collects context-target pairs and definitions from `oxforddictionaries.com`. The target lemma is not present in all contexts, so in these cases we prepend the lemma according to the following template: '*lemma*: *context*'.[17]

D Perplexity

Perplexity captures the confidence of the model in outputting a certain sequence. In approaches with word-level tokenization, evaluated at word-level, perplexity can be computed by exponentiating the negative log-likelihood that is used for training:

$$PPL_w^w = exp(-\sum_{w \in V} P(w|c,t,\bar{h}) \ln \hat{P}(w|c,t,\bar{h})) \quad (5)$$

$$= exp(-\ln \hat{P}(\bar{w}|c,t,\bar{h})) \quad (6)$$

where c is the context, t is the target, V is the vocabulary, $\bar{w}$ is the gold word, and $\bar{h}$ is the gold history of previous tokens. Generationary employs subword-level tokenization, but we can still obtain the word-level probabilities by applying the chain rule of conditional probability:

$$PPL_w^s = exp(-\ln \prod_{i=1}^{|\bar{w}^\star|} \hat{P}(\bar{w}_i^\star|c,t,\bar{h},\bar{w}_{1:i-1}^\star)) \quad (7)$$

where $\bar{w}^*$ is the n-ple that is the subword split of $\bar{w}$, e.g. $\langle$ `token`, `##ization` $\rangle$ for

---

[16] `github.com/shonosuke/ishiwatari-naacl2019`

[17] The train/dev/test splits of NOR and GAD are disjoint in the lemma of the target words.

`tokenization`. Do we maintain full comparability? There are two issues here. The first stems from the fact that, thanks to the application of the chain rule, the vocabulary is open, i.e. the support of the subword model is the set of possible words, so that every item receives non-zero probability.

In contrast, a word-level model without some kind of backoff strategy has a closed vocabulary. If the evaluation set includes a word outside V, the closed vocabulary model has a special `<unk>` token, on which it is trained to concentrate all the probability mass that the open vocabulary model, instead, would spread over all the possible words which are not in V. This entails an unfavorable advantage of the closed vocabulary model over the open vocabulary. Moreover, there is an additional complication arising from the fact that, while the subword tokenizers are usually deterministic, i.e. any word is always split in the same way, there might be multiple legal subword splits depending on the vocabulary, and to obtain the probability of the word we would need to marginalize over all splits. In other words, we would need to marginalize by summing the probability of ⟨ `token`, `##ization` ⟩, ⟨ `token`, `##iz`, `##ation` ⟩, ⟨ `to`, `##ken`, `##ization` ⟩ and so on. This is very burdensome, and in practice we only consider the deterministic split produced by the tokenizer. In doing this, we underestimate the probability of the word and, thus, overestimate the perplexity of the subword-level model.

E NLG Measures Details

In order to ensure comparability, here we report the BLEU, ROUGE, METEOR, and BERTScore configurations that we used. A scorer is available as part of the provided software.

BLEU We employ the reference implementation of corpus BLEU provided in the `sacrebleu` package (Post, 2018, `https://github.com/mjpost/sacreBLEU`). We use default parameters. Signature:
`BLEU+case.mixed+numrefs.1+smooth.exp+tok.13a+version.1.3.6.`

ROUGE We have employed the Python `rouge` library (`https://github.com/pltrdy/rouge`).

METEOR We have employed the Java `meteor` library (`https://www.cs.cmu.edu/~alavie/METEOR`), version 1.5. METEOR is calculated using the `-norm` and `-noPunct` flags. Signature:
`meteor-1.5-wo-en-norm_nopunct-0.85_0.2_0.6_0.75-ex_st_sy_pa-1.0_0.6_0.8_0.6`

BERTScore We evaluate using the Python BERTScore (`https://github.com/Tiiiger/bert_score`) library, with the `roberta-large-mnli` model and default parameters. Signature:
`roberta-large-mnli_L19_no-idf_version=0.3.0(hug_trans=2.8.0)`

F Likert Scale

We employ a five-level Likert scale to rank glosses in both the annotation experiments on SamplEval and Hei++ (see Section 6.1). In Table 10 we show one of the annotation examples that were provided to the annotators to be used as guidelines.

	Was he going to be saddled with a creep for a bar-buddy?
1	*Wrong gloss. May refer to a homonym of the target.* A heating element in an electric fire.
2	*Wrong gloss. Captures the domain of the target.* A counter where you can obtain food or drink.
3	*Correct gloss. Utterly vague and generic.* A person with whom you are acquainted.
4	*Correct gloss. Fits the context, but misses some details.* A close friend who accompanies his buddies in their activities.
5	*Correct gloss. Perfectly describes the target in its context.* A friend who you frequent bars with.

Table 10: Annotation guidelines excerpt. Rows: Likert score, *explanation* and example definition for target.

Probing Pretrained Language Models for Lexical Semantics

Abstract

The success of large pretrained language models (LMs) such as BERT and RoBERTa has sparked interest in probing their representations, in order to unveil what types of knowledge they implicitly capture. While prior research focused on morphosyntactic, semantic, and world knowledge, it remains unclear to which extent LMs also derive *lexical type-level knowledge* from words in context. In this work, we present a *systematic empirical analysis* across six typologically diverse languages and five different lexical tasks, addressing the following questions: **1)** How do different lexical knowledge extraction strategies (monolingual versus multilingual source LM, out-of-context versus in-context encoding, inclusion of special tokens, and layer-wise averaging) impact performance? How consistent are the observed effects across tasks and languages? **2)** Is lexical knowledge stored in few parameters, or is it scattered throughout the network? **3)** How do these representations fare against traditional static word vectors in lexical tasks? **4)** Does the lexical information emerging from independently trained monolingual LMs display latent similarities? Our main results indicate patterns and best practices that hold universally, but also point to prominent variations across languages and tasks. Moreover, we validate the claim that lower Transformer layers carry more type-level lexical knowledge, but also show that this knowledge is distributed across multiple layers.

1 Introduction and Motivation

Language models (LMs) based on deep Transformer networks (Vaswani et al., 2017), pretrained on unprecedentedly large amounts of text, offer unmatched performance in virtually every NLP task (Qiu et al., 2020). Models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019c), and T5 (Raffel et al., 2019) replaced task-specific neural architectures that relied on *static* word embeddings (WEs; Mikolov et al., 2013b; Pennington et al., 2014; Bojanowski et al., 2017), where each word is assigned a single (type-level) vector.

While there is a clear consensus on the effectiveness of pretrained LMs, a body of recent research has aspired to understand *why* they work (Rogers et al., 2020). State-of-the-art models are "probed" to shed light on whether they capture task-agnostic linguistic knowledge and structures (Liu et al., 2019a; Belinkov and Glass, 2019; Tenney et al., 2019); e.g., they have been extensively probed for syntactic knowledge (Hewitt and Manning, 2019; Jawahar et al., 2019; Kulmizev et al., 2020; Chi et al., 2020, *inter alia*) and morphology (Edmiston, 2020; Hofmann et al., 2020).

In this work, we put focus on uncovering and understanding *how and where lexical semantic knowledge* is coded in state-of-the-art LMs. While preliminary findings from Ethayarajh (2019) and Vulić et al. (2020) suggest that there is a wealth of lexical knowledge available within the parameters of BERT and other LMs, *a systematic empirical study across different languages* is currently lacking.

We present such a study, spanning six typologically diverse languages for which comparable pretrained BERT models *and* evaluation data are readily available. We dissect the pipeline for extracting lexical representations, and divide it into crucial components, including: the underlying source LM, the selection of subword tokens, external corpora, and which Transformer layers to average over. Different choices give rise to different *extraction configurations* (see Table 1) which, as we empirically verify, lead to large variations in task performance.

We run experiments and analyses on five diverse lexical tasks using standard evaluation benchmarks: lexical semantic similarity (LSIM), word analogy resolution (WA), bilingual lexicon induction (BLI), cross-lingual information retrieval (CLIR), and lex-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7222–7240,
November 16–20, 2020.

ical relation prediction (RELP). The main idea is to aggregate lexical information into static type-level "BERT-based" word embeddings and plug them into "the classical NLP pipeline" (Tenney et al., 2019), similar to traditional static word vectors. The chosen tasks can be seen as "lexico-semantic probes" providing an opportunity to simultaneously **1)** evaluate the richness of lexical information extracted from different parameters of the underlying pretrained LM on intrinsic (e.g., LSIM, WA) and extrinsic lexical tasks (e.g., RELP); **2)** compare different type-level representation extraction strategies; and **3)** benchmark "BERT-based" static vectors against traditional static word embeddings such as fastText (Bojanowski et al., 2017).

Our study aims at providing answers to the following key questions: **Q1)** Do lexical extraction strategies generalise across different languages and tasks, or do they rather require language- and task-specific adjustments?; **Q2)** Is lexical information concentrated in a small number of parameters and layers, or scattered throughout the encoder?; **Q3)** Are "BERT-based" static word embeddings competitive with traditional word embeddings such as fastText?; **Q4)** Do monolingual LMs independently trained in multiple languages learn structurally similar representations for words denoting similar concepts (i.e., translation pairs)?

We observe that different languages and tasks indeed require distinct configurations to reach peak performance, which calls for a careful tuning of configuration components according to the specific task–language combination at hand (Q1). However, several universal patterns emerge across languages and tasks. For instance, lexical information is predominantly concentrated in lower Transformer layers, hence excluding higher layers from the extraction achieves superior scores (Q1 and Q2). Further, representations extracted from single layers do not match in accuracy those extracted by averaging over several layers (Q2). While static word representations obtained from monolingual LMs are competitive or even outperform static fastText embeddings in tasks such as LSIM, WA, and RELP, lexical representations from massively multilingual models such as multilingual BERT (mBERT) are substantially worse (Q1 and Q3). We also demonstrate that translation pairs indeed obtain similar representations (Q4), but the similarity depends on the extraction configuration, as well as on the typological distance between the two languages.

2 Lexical Representations from Pretrained Language Models

Classical static word embeddings (Bengio et al., 2003; Mikolov et al., 2013b; Pennington et al., 2014) are grounded in distributional semantics, as they infer the meaning of each word type from its co-occurrence patterns. However, LM-pretrained Transformer encoders have introduced at least two levels of misalignment with the classical approach (Peters et al., 2018; Devlin et al., 2019). First, representations are assigned to word *tokens* and are affected by the current context and position within a sentence (Mickus et al., 2020). Second, tokens may correspond to subword strings rather than complete word forms. This begs the question: do pretrained encoders still retain a notion of lexical concepts, abstracted from their instances in texts?

Analyses of lexical semantic information in large pretrained LMs have been limited so far, focusing only on the English language and on the task of word sense disambiguation. Reif et al. (2019) showed that senses are encoded with finer-grained precision in *higher* layers, to the extent that their representation of the same token tends not to be self-similar across different contexts (Ethayarajh, 2019; Mickus et al., 2020). As a consequence, we hypothesise that abstract, type-level information could be codified in *lower* layers instead. However, given the absence of a direct equivalent to a static word type embedding, we still need to establish *how to extract* such type-level information.

In prior work, contextualised representations (and attention weights) have been interpreted in the light of linguistic knowledge mostly through *probes*. These consist in learned classifier predicting annotations like POS tags (Pimentel et al., 2020) and word senses (Peters et al., 2018; Reif et al., 2019; Chang and Chen, 2019), or linear transformations to a space where distances mirror dependency tree structures (Hewitt and Manning, 2019).[1]

In this work, we explore several unsupervised word-level representation extraction strategies and configurations for lexico-semantic tasks (i.e., probes), stemming from different combinations of the components detailed in Table 1 and illustrated in Figure 1. In particular, we assess the impact of: **1)** encoding tokens with monolingual LM-pretrained Transformers vs. with their mas-

---

[1] The interplay between the complexity of a probe and its accuracy, as well as its effect on the overall procedure, remain controversial (Pimentel et al., 2020; Voita and Titov, 2020).

Component	*Label*	*Short Description*
Source LM	MONO	Language-specific (i.e., monolingually pretrained) BERT
	MULTI	Multilingual BERT, pretrained on 104 languages (with shared subword vocabulary)
Context	ISO	Each vocabulary word w is encoded *in isolation*, without any external context
	AOC-M	*Average-over-context*: average over word's encodings from M different contexts/sentences
Subword Tokens	NOSPEC	Special tokens [CLS] and [SEP] are excluded from subword embedding averaging
	ALL	Both special tokens [CLS] and [SEP] are included into subword embedding averaging
	WITHCLS	[CLS] is included into subword embedding averaging; [SEP] is excluded
Layerwise Avg	AVG(L≤n)	Average representations over all Transformer layers up to the n-th layer L_n (included)
	L=n	Only the representation from the layer L_n is used

Table 1: Configuration components of word-level embedding extraction, resulting in 24 possible configurations.

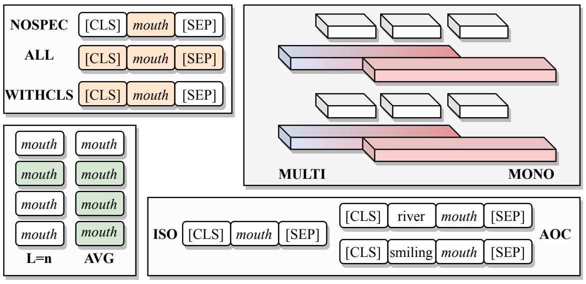

Figure 1: Illustration of the components denoting adopted extraction strategies, including source LM (top right), presence of context (bottom right), special tokens (top left), and layer-wise averaging (bottom left).

sively multilingual counterparts; **2)** providing context around the target word in input; **3)** including special tokens like [CLS] and [SEP]; **4)** averaging across several layers as opposed to a single layer.[2]

3 Experimental Setup

Pretrained LMs and Languages. Our selection of test languages is guided by the following constraints: **a)** availability of comparable pretrained (language-specific) monolingual LMs; **b)** availability of evaluation data; and **c)** typological diversity of the sample, along the lines of recent initiatives in multilingual NLP (Gerz et al., 2018; Hu et al., 2020; Ponti et al., 2020, *inter alia*). We work with English (EN), German (DE), Russian (RU), Finnish (FI), Chinese (ZH), and Turkish (TR). We use monolingual uncased BERT Base models for all languages, retrieved from the HuggingFace repository (Wolf et al., 2019).[3] All BERT models comprise 12 768-dimensional Transformer layers $\{L_1$ (bottom layer)$, \ldots, L_{12}$ (top)$\}$ plus the input embedding layer (L_0), and 12 attention heads. We also experiment with multilingual BERT (mBERT) (Devlin et al., 2019) as the underlying LM, aiming to measure the performance difference between language-specific and massively multilingual LMs in our lexical probing tasks.

Word Vocabularies and External Corpora. We extract type-level representations in each language for the top 100K most frequent words represented in the respective fastText (FT) vectors, which were trained on lowercased monolingual Wikipedias by Bojanowski et al. (2017). The equivalent vocabulary coverage allows a direct comparison to fastText vectors, which we use as a baseline static WE method in all evaluation tasks. To retain the same vocabulary across all configurations, in AOC variants we back off to the related ISO variant for words that have zero occurrences in external corpora.

For all AOC vector variants, we leverage 1M sentences of maximum sequence length 512, which we randomly sample from external corpora: Europarl (Koehn, 2005) for EN, DE, FI, available via OPUS (Tiedemann, 2009); the United Nations Parallel Corpus for RU and ZH (Ziemski et al., 2016), and monolingual TR WMT17 data (Bojar et al., 2017).

Evaluation Tasks. We carry out the evaluation on five standard and diverse lexical semantic tasks:

Task 1: Lexical semantic similarity (LSIM) is the most widespread intrinsic task for evaluation of traditional word embeddings (Hill et al., 2015). The evaluation metric is the Spearman's rank correlation between the average of human-elicited semantic similarity scores for word pairs and the cosine similarity between the respective type-level word vectors. We rely on the recent comprehensive multilingual LSIM benchmark Multi-SimLex (Vulić et al., 2020), which covers 1,888 pairs in 13 languages. We focus on EN, FI, ZH, RU, the

---

[2] For clarity of presentation, later in §4 we show results only for a representative selection of configurations that are consistently better than the others

[3] `https://huggingface.co/models`; the links to the actual BERT models are in the appendix.

languages represented in Multi-SimLex.

Task 2: Word Analogy (WA) is another common intrinsic task. We evaluate our models on the Bigger Analogy Test Set (BATS) (Drozd et al., 2016) with 99,200 analogy questions. We resort to the standard vector offset analogy resolution method, searching for the vocabulary word $w_d \in V$ such that its vector d is obtained by $argmax_d(cos(d, c - a + b))$, where a, b, and c are word vectors of words w_a, w_b, and w_c from the analogy $w_a : w_b = w_c : x$. The search space comprises vectors of all words from the vocabulary V, excluding a, b, and c. This task is limited to EN, and we report Precision@1 scores.

Task 3: Bilingual Lexicon Induction (BLI) is a standard task to evaluate the "semantic quality" of static cross-lingual word embeddings (CLWEs) (Gouws et al., 2015; Ruder et al., 2019). We learn "BERT-based" CLWEs using a standard mapping-based approach (Mikolov et al., 2013a; Smith et al., 2017) with VECMAP (Artetxe et al., 2018). BLI evaluation allows us to investigate the "alignability" of monolingual type-level representations extracted for different languages. We adopt the standard BLI evaluation setup from Glavaš et al. (2019): 5K training word pairs are used to learn the mapping, and another 2K pairs as test data. We report standard Mean Reciprocal Rank (MRR) scores for 10 language pairs spanning EN, DE, RU, FI, TR.

Task 4: Cross-Lingual Information Retrieval (CLIR). We follow the setup of Litschko et al. (2018, 2019) and evaluate mapping-based CLWEs (the same ones as on BLI) in a document-level retrieval task on the CLEF 2003 benchmark.[4] We use a simple CLIR model which showed competitive performance in the comparative studies of Litschko et al. (2019) and Glavaš et al. (2019). It embeds queries and documents as IDF-weighted sums of their corresponding WEs from the CLWE space, and uses cosine similarity as the ranking function. We report Mean Average Precision (MAP) scores for 6 language pairs covering EN, DE, RU, FI.

Task 5: Lexical Relation Prediction (RELP). We probe if we can recover standard lexical relations (i.e., *synonymy*, *antonymy*, *hypernymy*, *meronymy*, plus *no relation*) from input type-level vectors. We rely on a state-of-the-art neural model for RELP operating on type-level embeddings (Glavaš and Vulić, 2018): the Specialization Tensor Model (STM) predicts lexical relations for pairs of input word vectors based on multi-view projections of those vectors.[5] We use the WordNet-based (Fellbaum, 1998) evaluation data of Glavaš and Vulić (2018): they contain 10K annotated word pairs balanced by class. Micro-averaged F_1 scores, averaged across 5 runs for each input vector space (default STM setting), are reported for EN and DE.

4 Results and Discussion

A summary of the results is shown in Figure 2 for LSIM, in Figure 3a for BLI, in Figure 3b for CLIR, in Figure 4a and Figure 4b for RELP, and in Figure 4c for WA. These results offer multiple axes of comparison, and the ensuing discussion focuses on the central questions Q1-Q3 posed in §1.[6]

Monolingual versus Multilingual LMs. Results across all tasks validate the intuition that language-specific monolingual LMs contain much more lexical information for a particular target language than massively multilingual models such as mBERT or XLM-R (Artetxe et al., 2020). We see large drops between MONO.* and MULTI.* configurations even for very high-resource languages (EN and DE), and they are even more prominent for FI and TR.

Encompassing 100+ training languages with limited model capacity, multilingual models suffer from the "curse of multilinguality" (Conneau et al., 2020): they must trade off monolingual lexical information coverage (and consequently monolingual performance) for a wider language coverage.[7]

How Important is Context? Another observation that holds across all configurations concerns the usefulness of providing contexts drawn from external corpora, and corroborates findings from prior work (Liu et al., 2019b): ISO configurations cannot match configurations that average subword embeddings from multiple contexts (AOC-10 and AOC-100). However, it is worth noting that **1)** perfor-

---

[4] All test collections comprise 60 queries. The average document collection size per language is 131K (ranging from 17K documents for RU to 295K for DE).

[5] Note that RELP is structurally different from the other four tasks: instead of direct computations with word embeddings, called *metric learning* or *similarity-based* evaluation (Ruder et al., 2019), it uses them as *features* in a neural architecture.

[6] Full results are available in the appendix.

[7] For a particular target language, monolingual performance can be partially recovered by additional in-language monolingual training via masked language modeling (Eisenschlos et al., 2019; Pfeiffer et al., 2020). In a side experiment, we have also verified that the same holds for lexical information coverage.

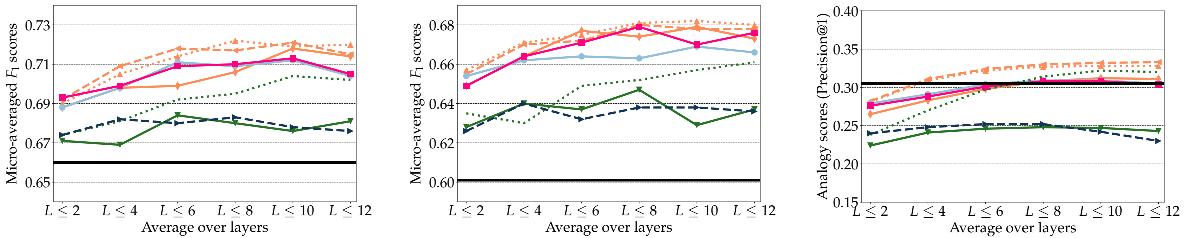
(a) Summary BLI results

(b) Summary CLIR results

Figure 3: Summary results for the two cross-lingual evaluation tasks: **(a)** BLI (MRR scores) and **(b)** CLIR (MAP scores). We report average scores over all language pairs; individual results for each language pair are available in the appendix. Thick solid horizontal lines denote performance of standard fastText vectors in exactly the same cross-lingual mapping setup.



(a) RELP: English

(b) RELP: German

(c) WA: English

Figure 4: Micro-averaged F_1 scores in the RELP task for **(a)** EN and **(b)** DE. The scores with 768-dim vectors randomly initalized via Xavier init (Glorot and Bengio, 2010) are 0.473 (EN) and 0.512 (DE); **(c)** EN WA results.

mance gains with AOC-100 over AOC-10, although consistent, are quite marginal across all tasks: this suggests that several word occurrences *in vivo* are already sufficient to accurately capture its type-level representation. **2)** In some tasks, ISO configurations are only marginally outscored by their AOC counterparts: e.g., for MONO.*.NOSPEC.AVG(L≤8) on EN–FI BLI or DE–TR BLI, the respective scores are 0.486 and 0.315 with ISO, and 0.503 and 0.334 with AOC-10. Similar observations hold for FI and ZH LSIM, and also in the RELP task.

In RELP, it is notable that 'BERT-based' embeddings can recover more lexical relation knowledge than standard FT vectors. These findings reveal that pretrained LMs indeed implicitly capture plenty of lexical type-level knowledge (which needs to be 'recovered' from the models); this also suggests why pretrained LMs have been successful in tasks where this knowledge is directly useful, such as NER and POS tagging (Tenney et al., 2019; Tsai et al., 2019). Finally, we also note that gains with AOC over ISO are much more pronounced for the under-performing MULTI.* configurations: this indicates that MONO models store more lexical information even in absence of context.

How Important are Special Tokens? The results reveal that the inclusion of special tokens [CLS] and [SEP] into type-level embedding extraction deteriorates the final lexical information contained in the embeddings. This finding holds for different languages, underlying LMs, and averaging across various layers. The NOSPEC configurations consistently outperform their ALL and WITHCLS counterparts, both in ISO and AOC-{10, 100} settings.[8]

Our finding at the lexical level aligns well with prior observations on using BERT directly as a sentence encoder (Qiao et al., 2019; Singh et al., 2019; Casanueva et al., 2020): while [CLS] is useful for sentence-pair classification tasks, using [CLS] as a sentence representation produces inferior representations than averaging over sentence's subwords. In this work, we show that [CLS] and [SEP] should also be fully excluded from subword averaging for type-level word representations.

How Important is Layer-wise Averaging? Averaging across layers bottom-to-top (i.e., from L_0 to L_{12}) is beneficial across the board, but we notice that scores typically saturate or even decrease in some tasks and languages when we include higher layers into averaging: see the scores with *.AVG(L≤10) and *.AVG(L≤12) configurations, e.g., for FI LSIM; EN/DE RELP, and summary BLI and CLIR scores. This hints to the fact that two strategies typically used in prior work, either to take the vectors only from the embedding layer L_0 (Wu et al., 2020; Wang et al., 2019) or to average across all layers (Liu et al., 2019b), extract suboptimal word representations for a wide range of setups and languages.

The sweet spot for n in *.AVG(L≤n) configurations seems largely task- and language-dependent, as peak scores are obtained with different n-s. Whereas *averaging across all layers* generally hurts performance, the results strongly suggest that averaging across layer subsets (rather than selecting a single layer) is widely useful, especially across bottom-most layers: e.g., $L \leq 6$ with MONO.ISO.NOSPEC yields an average score of 0.561 in LSIM, 0.076 in CLIR, and 0.432 in BLI; the respective scores when averaging over the 6 *top* layers are: 0.218, 0.008, and 0.230. This evidence implies that, although scattered across multiple layers, type-level lexical information seems to be concentrated in lower Transformer layers. We investigate these conjectures further in §4.1.

Comparison to Static Word Embeddings. The results also offer a comparison to static FT vectors across languages. The best-performing extraction configurations (e.g., MONO.AOC-100.NOSPEC) outperform FT in monolingual evaluations on LSIM (for EN, FI, ZH), WA, and they also display much stronger performance in the RELP task for both evaluation languages. While the comparison is not strictly apples-to-apples, as FT and LMs were trained on different (Wikipedia) corpora, these findings leave open a provocative question for future work: *Given that static type-level word representations can be recovered from large pretrained LMs, does this make standard static WEs obsolete, or are there applications where they are still useful?*

The trend is opposite in the two cross-lingual tasks: BLI and CLIR. While there are language pairs for which 'BERT-based' WEs outperform FT (i.e., EN–FI in BLI, EN–RU and FI–RU in CLIR) or are very competitive to FT's performance (e.g., EN–TR, TR–BLI, DE–RU CLIR), FT provides higher scores overall in both tasks. The discrepancy between results in monolingual versus cross-lingual tasks warrants further investigation in future work. For instance, is using linear maps, as in stan-

---

[8] For this reason, we report the results of AOC configurations only in the NOSPEC setting.

Table 2: Task performance of word representations extracted from different Transformer layers for a selection of tasks, languages, and language pairs. Configuration: MONO.AOC-100.NOSPEC. Highest scores per row are in bold.

tasks. For instance, while EN LSIM performance declines modestly but steadily when averaging over higher-level layers (AVG(L$\leq n$), where $n > 4$), performance on EN WA consistently increases for the same configurations. The BLI and CLIR scores in Figures 3a and 3b also show slightly different patterns across layers. Overall, this suggests that **1)** extracted lexical information must be guided by task requirements, and **2)** config components must be carefully tuned to maximise performance for a particular task–language combination.

4.1 Lexical Information in Individual Layers

Evaluation Setup. To better understand which layers contribute the most to the final performance in our lexical tasks, we also probe type-level representations emerging from each individual layer of pretrained LMs. For brevity, we focus on the best performing configurations from previous experiments: {MONO, MBERT}.{ISO, AOC-100}.NOSPEC.

In addition, tackling Q4 from §1, we analyse the similarity of representations extracted from monolingual and multilingual BERT models using the centered kernel alignment (CKA) as proposed by (Kornblith et al., 2019). The linear CKA computes similarity that is invariant to isotropic scaling and orthogonal transformation. It is defined as

$$\mathrm{CKA}(X, Y) = \frac{\left\|Y^{\top} X\right\|_{\mathrm{F}}^{2}}{\left(\left\|X^{\top} X\right\|_{\mathrm{F}}\left\|Y^{\top} Y\right\|_{\mathrm{F}}\right)}. \qquad (1)$$

$X, Y \in \mathbb{R}^{s \times d}$ are input matrices spanning s ℓ_2-normalized and mean-centered examples of dimensionality $d = 768$. We use CKA in two different experiments: **1)** measuring *self-similarity* where we compute CKA similarity of representations extracted from different layers for the same word; and **2)** measuring *bilingual layer correspondence* where we compute CKA similarity of representations extracted from the same layer for two words constituting a translation pair. To this end, we again use BLI dictionaries of Glavaš et al. (2019) (see §3) covering 7K pairs (training + test pairs).

Discussion. Per-layer CKA similarities are provided in Figure 7 (self-similarity) and Figure 5 (bilingual), and we show results of representations extracted from individual layers for selected evaluation setups and languages in Table 2. We also plot bilingual layer correspondence of true word translations versus randomly paired words for EN–RU in Figure 6. Figure 7 reveals very similar patterns for both EN and FI, and we also observe that self-similarity scores decrease for more distant layers (cf., similarity of L_1 and L_2 versus L_1 and L_{12}). However, despite structural similarities identified by linear CKA, the scores from Table 2 demonstrate that structurally similar layers might encode different amounts of lexical information: e.g., compare performance drops between L_5 and L_8 in all evaluation tasks.

The results in Table 2 further suggest that more type-level lexical information is available in lower layers, as all peak scores in the table are achieved with representations extracted from layers $L_1 - L_5$. Much lower scores in type-level semantic tasks for higher layers also empirically validate a recent hypothesis of Ethayarajh (2019) "that contextualised word representations are more context-specific in higher layers." We also note that none of the results with L=n configurations from Table 1 can match best performing AVG(L$\leq n$) configurations with layer-wise averaging. This confirms our hypothesis that type-level lexical knowledge, although predominantly captured by lower layers, is disseminated across multiple layers, and layer-wise averaging is crucial to uncover that knowledge.

Further, Figure 5 and Figure 6 reveal that even

LMs trained on monolingual data learn similar representations in corresponding layers for word translations (see the MONO.AOC columns). Intuitively, this similarity is much more pronounced with AOC configurations with mBERT. The comparison of scores in Figure 6 also reveals much higher correspondence scores for true translation pairs than for randomly paired words (i.e., the correspondence scores for random pairings are, as expected, random). Moreover, MULTI CKA similarity scores turn out to be higher for more similar language pairs (cf. EN–DE versus EN–TR MULTI.AOC columns). This suggests that, similar to static WEs, type-level 'BERT-based' WEs of different languages also display topological similarity, often termed *approximate isomorphism* (Søgaard et al., 2018), but its degree depends on language proximity. This also clarifies why representations extracted from two independently trained monolingual LMs can be linearly aligned, as validated by BLI and CLIR evaluation (Table 2 and Figure 3).[9]

We also calculated the Spearman's correlation between CKA similarity scores for configurations MONO.AOC-100.NOSPEC.AVG($L \leq n$), for all $n = 0, \ldots, 12$, and their corresponding BLI scores on EN–FI, EN–DE, and DE–FI. The correlations are very high: $\rho = 1.0, 0.83, 0.99$, respectively. This further confirms the approximate isomorphism hypothesis: it seems that higher structural similarities of representations extracted from monolingual pretrained LMs facilitate their cross-lingual alignment.

5 Further Discussion and Conclusion

What about Larger LMs and Corpora? Aspects of LM pretraining, such as the number of model parameters or the size of pretraining data, also impact lexical knowledge stored in the LM's parameters. Our preliminary experiments have verified that EN BERT-Large yields slight gains over the EN BERT-Base architecture used in our work (e.g., peak EN LSIM scores rise from 0.518 to 0.531). In a similar vein, we have run additional experiments with two available Italian (IT) BERT-Base models with identical parameter setups, where one was trained on 13GB of IT text, and the other on 81GB. In EN (BERT-Base)–IT BLI and CLIR evaluations we measure improvements from 0.548 to 0.572 (BLI), and from 0.148 to 0.160 (CLIR) with the 81GB IT model. In-depth analyses of these factors are out of the scope of this work, but they warrant further investigations.

Opening Future Research Avenues. Our study has empirically validated that (monolingually) pretrained LMs store a wealth of type-level lexical knowledge, but effectively uncovering and extracting such knowledge from the LMs' parameters depends on several crucial components (see §2). In particular, some universal choices of configuration can be recommended: i) choosing monolingual LMs; ii) encoding words with multiple contexts; iii) excluding special tokens; iv) averaging over lower layers. Moreover, we found that type-level WEs extracted from pretrained LMs can surpass static WEs like fastText (Bojanowski et al., 2017).

This study has only scratched the surface of this research avenue. In future work, we plan to investigate how domains of external corpora affect AOC configurations, and how to sample representative contexts from the corpora. We will also extend the study to more languages, more lexical semantic probes, and other larger underlying LMs. The difference in performance across layers also calls for more sophisticated lexical representation extraction methods (e.g., through layer weighting or attention) similar to meta-embedding approaches (Yin and Schütze, 2016; Bollegala and Bao, 2018; Kiela et al., 2018). Given the current large gaps between monolingual and multilingual LMs, we will also focus on lightweight methods to enrich lexical content in multilingual LMs (Wang et al., 2020; Pfeiffer et al., 2020).

---

[9] Previous work has empirically validated that sentence representations for semantically similar inputs from different languages are less similar in higher Transformer layers (Singh et al., 2019; Wu and Dredze, 2019). In Figure 5, we demonstrate that this is also the case for type-level lexical information; however, unlike sentence representations where highest similarity is reported in lowest layers, Figure 5 suggests that highest CKA similarities are achieved in intermediate layers L_5-L_8.

A Appendix

URLs to the models and external corpora used in our study are provided in Table 3 and Table 4, respectively. URLs to the evaluation data and task architectures for each evaluation task are provided in Table 5. We also report additional and more detailed sets of results across different tasks, word embedding extraction configurations/variants, and language pairs:

- In Table 6 and Table 7, we provide full BLI results per language pair. All scores are Mean Reciprocal Rank (MRR) scores (in the standard scoring interval, 0.0–1.0).
- In Table 8, we provide full CLIR results per language pair. All scores are Mean Average Precision (MAP) scores (in the standard scoring interval, 0.0–1.0).
- In Table 9, we provide full relation prediction (RELP) results for EN and DE. All scores are micro-averaged F_1 scores over 5 runs of the relation predictor (Glavaš and Vulić, 2018). We also report standard deviation for each configuration.

Finally, in Figures 8-10, we also provide heatmaps denoting bilingual layer correspondence, computed via linear CKA similarity (Kornblith et al., 2019), for several EN–L_t language pairs (see §4.1), which are not provided in the main paper

Table 6: Results in the BLI task across different language pairs and word vector extraction configurations. MRR scores reported. For clarity of presentation, a subset of results is presented in this table, while the rest (and the averages) are presented in Table 7. AVG($L \leq n$) means that we average representations over all Transformer layers up to the nth layer (included), where $L = 0$ refers to the embedding layer, $L = 1$ to the bottom layer, and $L = 12$ to the final (top) layer. Different configurations are described in §2 and Table 1. Additional diagnostic experiments with top-to-bottom layerwise averaging configs (REVERSE) are run for a subset of languages: {EN, DE, FI }.

Abstract

Despite the promising results of current cross-lingual models for spoken language understanding systems, they still suffer from imperfect cross-lingual representation alignments between the source and target languages, which makes the performance sub-optimal. To cope with this issue, we propose a regularization approach to further align word-level and sentence-level representations across languages without any external resource. First, we regularize the representation of user utterances based on their corresponding labels. Second, we regularize the latent variable model (Liu et al., 2019a) by leveraging adversarial training to disentangle the latent variables. Experiments on the cross-lingual spoken language understanding task show that our model outperforms current state-of-the-art methods in both few-shot and zero-shot scenarios, and our model, trained on a few-shot setting with only 3% of the target language training data, achieves comparable performance to the supervised training with all the training data.[1]

1 Introduction

Data-driven neural-based supervised training approaches have shown effectiveness in spoken language understanding (SLU) systems (Goo et al., 2018; Chen et al., 2019; Haihong et al., 2019). However, collecting large amounts of high-quality training data is not only expensive but also time-consuming, which makes these approaches not scalable to low-resource languages due to the scarcity of training data. Cross-lingual adaptation has naturally arisen to cope with this issue, which leverages the training data in rich-resource source languages and minimizes the requirement of training data in low-resource target languages.

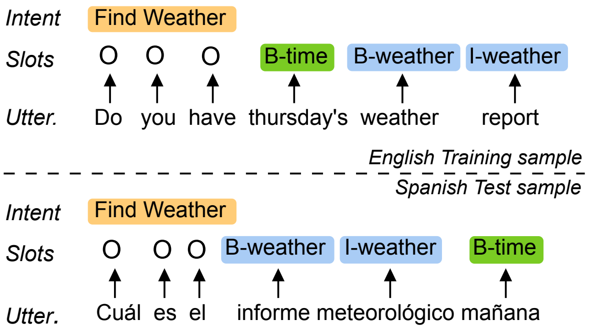

Figure 1: Illustration of cross-lingual spoken language understanding systems, where English is the source language and Spanish is the target language.

In general, there are two challenges in cross-lingual adaptation. First, the imperfect alignment of word-level representations between the source and target language limits the adaptation performance. Second, even though we assume that the word-level alignment is perfect, the sentence-level alignment is still imperfect owing to grammatical and syntactical variances across languages. Therefore, we emphasize that cross-lingual methods should focus on the alignments of word-level and sentence-level representations, and increase the robustness for inherent imperfect alignments.

In this paper, we concentrate on the cross-lingual SLU task (as illustrated in Figure 1), and we consider both few-shot and zero-shot scenarios. To improve the quality of cross-lingual alignment, we first propose a **L**abel **R**egularization (**LR**) method, which utilizes the slot label sequences to regularize the utterance representations. We hypothesize that if the slot label sequences of user utterances are close to each other, these user utterances should have similar meanings. Hence, we regularize the distance of utterance representations based on the corresponding representations of label sequences to further improve the cross-lingual alignments.

Then, we extend the latent variable model (LVM)

November 16–20, 2020.

proposed by Liu et al. (2019a). The LVM generates a Gaussian distribution instead of a feature vector for each token, which improves the adaptation robustness. However, there are no additional constraints on generating distributions, making the latent variables easily entangled for different slot labels. To handle this issue, we leverage **A**dversarial training to regularize the **LVM** (**ALVM**). We train a linear layer to fit latent variables to a uniform distribution over slot types. Then, we optimize the latent variables to fool the trained linear layer to output the correct slot type (one hot vector). In this way, latent variables of different slot types are encouraged to disentangle from each other, leading to a better alignment of cross-lingual representations.

The contributions of our work are summarized as follows:

- We propose LR and ALVM to further improve the alignment of cross-lingual representations, which do not require any external resources.
- Our model outperforms the previous state-of-the-art model in both zero-shot and few-shot scenarios on the cross-lingual SLU task.
- Extensive analysis and visualizations are made to illustrate the effectiveness of our approaches.

2 Related Work

Cross-lingual Transfer Learning Cross-lingual transfer learning is able to circumvent the requirement of enormous training data by leveraging the learned knowledge in the source language and learning inter-connections between the source and the target language. Artetxe et al. (2017) and Conneau et al. (2018) conducted cross-lingual word embedding mapping with zero or very few supervision signals. Recently, pre-training cross-lingual language models on large amounts of monolingual or bilingual resources have been proved to be effective for the downstream tasks (e.g., natural language inference) (Conneau and Lample, 2019; Devlin et al., 2019; Pires et al., 2019; Huang et al., 2019). Additionally, many cross-lingual transfer algorithms have been proposed to solve specific cross-lingual tasks, for example, *named entity recognition* (Xie et al., 2018; Mayhew et al., 2017; Liu et al., 2020a), *part of speech tagging* (Kim et al., 2017; Zhang et al., 2016), *entity linking* (Zhang et al., 2013; Sil et al., 2018; Upadhyay et al., 2018b), personalized conversations (Lin et al., 2020), and dialog systems (Upadhyay et al., 2018a; Chen et al., 2018).

Cross-lingual Task-oriented Dialog Systems Deploying task-oriented dialogue systems in low-resource domains (Bapna et al., 2017; Wu et al., 2019; Liu et al., 2020b) or languages (Chen et al., 2018; Liu et al., 2019a,b), where the number of training of samples is limited, is a challenging task. Mrkšić et al. (2017) expanded Wizard of Oz (WOZ) into multilingual WOZ by annotating two additional languages. Schuster et al. (2019) introduced a multilingual SLU dataset and proposed to leverage bilingual corpus and multilingual CoVe (Yu et al., 2018) to align the representations across languages. Chen et al. (2018) proposed a teacher-student framework based on a bilingual dictionary or bilingual corpus for building cross-lingual dialog state tracking. Instead of highly relying on extensive bilingual resources, Qin et al. (2020) introduced a data augmentation framework to generate multilingual code-switching data for cross-lingual tasks including the SLU task. Liu et al. (2019b) leveraged a mixed language training framework for cross-lingual task-oriented dialogue systems. And Liu et al. (2019a) proposed to refine the cross-lingual word embeddings by using very few word pairs, and introduced a latent variable model to improve the robustness of zero-shot cross-lingual SLU. Nevertheless, there still exists improvement space for the cross-lingual alignment. In this paper, we propose to further align the cross-lingual representations so as to boost the performance of cross-lingual SLU systems.

3 Methodology

Our model architecture and proposed methods are depicted in Figure 2, and combine label regularization (LR) and the adversarial latent variable model (ALVM) to conduct the intent detection and slot filling. In the few-shot setting, the input user utterances are in both the source and target languages, while in the zero-shot setting, the user utterances are only in the source language. Note that both the source and target languages contain only one language.

3.1 Label Regularization

3.1.1 Motivation

Intuitively, when the slot label sequences are similar, we expect the corresponding representations of user utterances across languages to be similar.

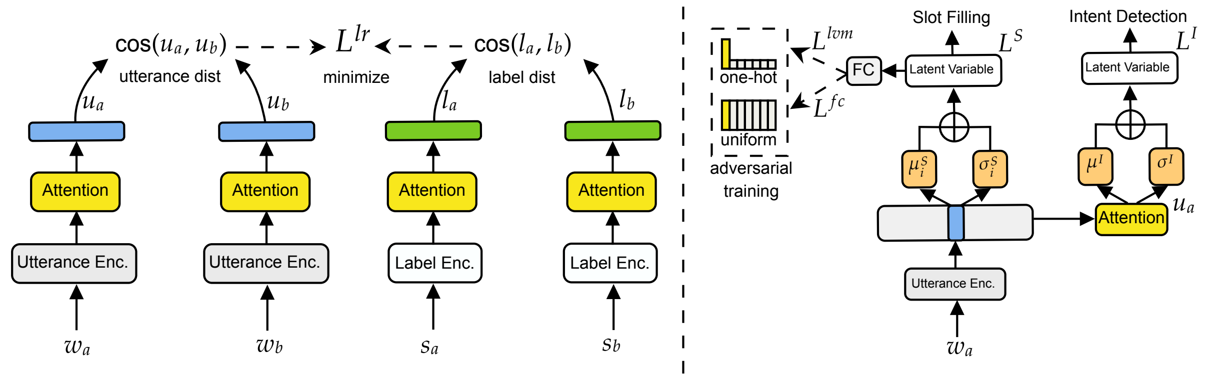

Figure 2: Left: Illustration of label regularization (LR). Right: The model architecture with adversarial latent variable model (ALVM), where FC consists of a linear layer and a softmax function.

For example, when the slot label sequences contain the weather slot and the location slot, the user utterances should be asking for the weather forecast somewhere. However, the representations of utterances across languages can not always meet these requirements because of the inherent imperfect alignments in word-level and sentence-level representations. Therefore, we propose to leverage existing slot label sequences in the training data to regularize the distance of utterance representations.

When a few training samples are available in the target language (i.e., few-shot setting), we regularize the distance of utterance representations between the source and target languages based on their slot labels. Given this regularization, the model explicitly learns to further align the sentence-level utterance representations across languages so as to satisfy the constraints. Additionally, it can also implicitly align the word-level BiLSTM hidden states across languages because sentence-level representations are produced based on them.

When zero training samples are available in the target language (i.e., zero-shot setting), we regularize the utterance representations in the source language. It can help better distinguish the utterance representations and cluster similar utterance representations based on the slot labels, which increases the generalization ability in the target language.

3.1.2 Implementation Details

Figure 2 (Left) illustrates an utterance encoder and a label encoder that generate the representations for utterances and labels, respectively.

We denote the user utterance as $\mathbf{w} = [w_1, w_2, ..., w_n]$, where n is the length of the utterance. Similarly, we represent the slot label sequences as $\mathbf{s} = [s_1, s_2, ..., s_n]$. We combine a bidirectional LSTM (BiLSTM) (Hochreiter and Schmidhuber, 1997) and an attention layer (Felbo et al., 2017) to encode and produce the representations for user utterances and slot label sequences. The representation generation process is defined as follows:

$$[h_1^w, h_2^w, ..., h_w^w] = \text{BiLSTM}_{\text{utter}}(\mathbf{E}(\mathbf{w})), \quad (1)$$

$$[h_1^s, h_2^s, ..., h_n^s] = \text{BiLSTM}_{\text{label}}(\mathbf{E}(\mathbf{s})), \quad (2)$$

$$m_i^w = h_i^w v^w, \quad \alpha_i^w = \frac{exp(m_i^w)}{\sum_{t=1}^n exp(m_t^w)}, \quad (3)$$

$$m_i^s = h_i^s v^s, \quad \alpha_i^s = \frac{exp(m_i^s)}{\sum_{t=1}^n exp(m_t^s)}, \quad (4)$$

$$u = \sum_{i=1}^n \alpha_i^w h_i^w, \quad l = \sum_{i=1}^n \alpha_i^s h_i^s, \quad (5)$$

where the superscript w and s represents utterance and label, respectively, v is a trainable weight vector in the attention layer, α_i is the attention score for each token i, $\mathbf{E}$ denotes the embedding layers for utterances and label sequences, and u and l denotes the representation of utterance $\mathbf{w}$ and slot label $\mathbf{s}$, respectively.

In each iteration of the training phase, we randomly select two samples for the label regularization. As illustrated in Figure 2 (Left), we first calculate the cosine similarity of two utterance representations u_a and u_b, and the cosine similarity of two label representations l_a and l_b. Then, we minimize the distance of these two cosine similarities. The objective functions can be described as follows:

$$\cos(u_a, u_b) = \frac{u_a \cdot u_b}{||u_a||\,||u_b||}, \quad (6)$$

$$\cos(l_a, l_b) = \frac{l_a \cdot l_b}{||l_a|| \; ||l_b||}, \tag{7}$$

$$L^{lr} = \sum_{a,b} \text{MSE}(\cos(u_a, u_b), \cos(l_a, l_b)), \tag{8}$$

where the superscript lr denotes label regularization, and MSE represents mean square error. In the zero-shot setting, both samples u_a and u_b come from the source language. While in the few-shot setting, one sample comes from the source language and the other one comes from the target language.

Since the features of labels and utterances are in different vector spaces, we choose not to share the parameters of their encoders. During training, it is easy to produce expressive representations for user utterances due to the large training samples, but it is difficult for label sequences since the objective function L^{lr} is the only supervision. This supervision is weak at the beginning of the training since utterance representations are not sufficiently expressive, which leads to the label regularization approach not being stable and effective. To ensure the representations for slot label sequences are meaningful, we conduct pre-training for the label sequence encoder.

3.1.3 Label Sequence Encoder Pre-training

We leverage the large amount of source language training data to pre-train the label sequence encoder. Concretely, we use the model architecture illustrated in Figure 2 to train the SLU system in the source language, and at the same time, we optimize the label sequence encoder based on the objective function L^{lr} in Eq (8). The label sequence encoder learns to generate meaningful label sequence representations that differ based on their similarities since the extensive source language training samples ensure the high quality of the utterance encoder.

3.2 Adversarial Latent Variable Model

In this section, we first give an introduction to the latent variable model (LVM) (Liu et al., 2019a), and then we describe how we incorporate the adversarial training into the LVM.

3.2.1 Latent Variable Model

Point estimation in the cross-lingual adaptation is vulnerable due to the imperfect alignments across languages. Hence, as illustrated in Figure 2 (Right), the LVM generates a Gaussian distribution with mean μ and variance σ for both word-level and sentence-level representations instead of a feature vector, which eventually improves the robustness of the model's cross-lingual adaptation ability. The LVM can be formulated as

$$\begin{bmatrix} \mu_i^S \\ \log(\sigma_i^S)^2 \end{bmatrix} = \mathbf{W}_l^S h_i, \begin{bmatrix} \mu^I \\ \log(\sigma^I)^2 \end{bmatrix} = \mathbf{W}_l^I u, \tag{9}$$

$$z_i^S \sim q_i^S(z|h_i), \;\; z^I \sim q^I(z|u), \tag{10}$$

$$p_i^S(s_i|z_i^S) = \text{Softmax}(\mathbf{W}_p^S z_i^S), \tag{11}$$

$$p^I(I|z^I) = \text{Softmax}(\mathbf{W}_p^I z^I), \tag{12}$$

where W_l^S and W_l^I are trainable parameters to generate the mean and variance for word-level hidden states h_i and sentence-level representations r, respectively, from user utterances. $q_i^S \sim \mathcal{N}(\mu_i^S, (\sigma_i^S)^2\mathbf{I})$ and $q^I \sim \mathcal{N}(\mu^I, (\sigma^I)^2\mathbf{I})$ are the generated Gaussian distributions, which latent variables z_t^S and z^I are sampled from, and p_i^S and p^I is the predictions for the slot of the i^{th} token and the intent of the utterance, respectively.

During training, all the sampled points from the same generated distribution will be trained to predict the same slot label, which makes the adaptation more robust. In the inference time, the true mean μ_i^S and μ^I is used to replace z_i^S and z^I, respectively, to make the prediction deterministic.

3.2.2 Adversarial Training

Since there are no constraints enforced on the latent Gaussian distribution during training, the latent distributions of different slot types are likely to be close to each other. Hence, the distributions for the same slot type in different user utterances or languages might not be clustered well, which could hurt the cross-lingual alignment and prevent the model from distinguishing slot types when adapting to the target language.

To improve the cross-lingual alignment of latent variables, we propose to make the latent variables of different slot types more distinguishable by adding adversarial training to the LVM. As illustrated in Figure 2 (Right), we train a fully connected layer to fit latent variables into a uniform distribution over slot types. At the same time, the latent variables are regularized to fool the trained fully connected layer by predicting the correct slot type. In this way, the latent variables are trained to be more recognizable. In other words, the generated distributions for different slot types are more likely to repel each other, and for the same slot type are more likely to be close to each other, which leads to a more robust cross-lingual adaptation. We denote the size of the whole training data as J and the length for data sample j as $|Y_j|$. Note that in the few-shot setting, J includes the number of data samples in the target language. The process of adversarial training can be described as follows:

$$p_{jk} = \mathcal{FC}(z^S_{jk}), \tag{13}$$

$$L^{fc} = \sum_{j=1}^{J} \sum_{k=1}^{|Y_j|} \text{MSE}(p_{jk}, \mathcal{U}), \tag{14}$$

$$L^{lvm} = \sum_{j=1}^{J} \sum_{k=1}^{|Y_j|} \text{MSE}(p_{jk}, y^S_{jk}), \tag{15}$$

where $\mathcal{FC}$ consists of a linear layer and a Softmax function, and z^S_{jk} and p_{jk} is the latent variable and generated distribution, respectively, for the k^{th} token in the j^{th} utterance, MSE represents the mean square error, $\mathcal{U}$ represents the uniform distribution, and y^S_{jk} represents the slot label. The slot label is a one-hot vector where the value for the correct slot type is one and zero otherwise. We optimize L^{fc} to train only $\mathcal{FC}$ to fit a uniform distribution, and L^{lvm} is optimized to constrain the LVM to generate more distinguishable distributions for slot predictions. Different from the well-known adversarial training (Goodfellow et al., 2014) where the discriminator is to distinguish the classes, and the generator is to make the features not distinguishable, in our approach, the $\mathcal{FC}$ layer, acting as the discriminator, is trained to generate uniform distribution, and the generator is regularized to make latent variables distinguishable by slot types.

3.3 Optimization

The objective functions for the slot filling and intent detection tasks are illustrated as follows:

$$L^S = \sum_{j=1}^{J} \sum_{k=1}^{|Y_j|} -log(p^S_{jk} \cdot (y^S_{jk})^\top), \tag{16}$$

$$L^I = \sum_{j=1}^{J} -log(p^I_j \cdot (y^I_j)^\top), \tag{17}$$

where p^S_{jk} and y^S_{jk} is the prediction and label, respectively, for the slot of the k^{th} token in the j^{th} utterance, and p^I_j and y^I_j is the intent prediction and label, respectively, for the j^{th} utterance.

The optimization for our model is to minimize the following objective function:

$$L = L^S + L^I + L^{lr} + \alpha L^{fc} + \beta L^{lvm}, \tag{18}$$

where α and β are hyper-parameters, L^{fc} only optimizes the parameters in $\mathcal{FC}$, and L^{lvm} optimizes all the model parameters excluding $\mathcal{FC}$.

# Utterance	English	Spanish	Thai
Train	30,521	3,617	2,156
Validation	4,181	1,983	1,235
Test	8,621	3,043	1,692

Table 1: Number of utterances for the multilingual SLU dataset. English is the source language, and Spanish and Thai are the target languages.

4 Experiments

4.1 Dataset

We conduct our experiments on the multilingual spoken language understanding (SLU) dataset proposed by Schuster et al. (2019), which contains English, Spanish, and Thai across the weather, reminder, and alarm domains. The corpus includes 12 intent types and 11 slot types, and the data statistics are shown in Table 1.

4.2 Training Details

The utterance encoder is a 2-layer BiLSTM with a hidden size of 250 and dropout rate of 0.1, and the size of the mean and variance in the latent variable model is 150. The label encoder is a 1-layer BiLSTM with a hidden size of 150, and 100-dimensional embeddings for label types. We use the Adam optimizer with a learning rate of 0.001. We use *accuracy* to evaluate the performance of intent detection and BIO-based *f1-score* to evaluate the performance of slot filling. For the adversarial training, we realize that the latent variable model is not able to make slot types recognizable if the $\mathcal{FC}$ is too strong. Hence, we decide to first learn a good initialization for $\mathcal{FC}$ by setting both α and β parameters in Eq (18) as 1 in the first two training epochs, and then we gradually decrease the value of α. We use the refined cross-lingual word embeddings in Liu et al. (2019a) [2] to initialize the cross-lingual word embeddings in our models and let them not be trainable. We use the delexicalization (delex.) in Liu et al. (2019a), which replaces the tokens that represent numbers, time, and duration with special tokens. We use **36** training samples in Spanish and **21** training samples in Thai on the 1% few-shot setting, and **108** training samples in Spanish and **64** training samples in Thai on the 3%

[‡]denotes supervised training on both the source and target language datasets. The bold numbers denote the best results in the few-shot or zero-shot settings. The underlined numbers represent that the results are comparable (distances are within 1%) to the all-shot experiment with all the target language training samples. The results of Multi. CoVe and Multi. CoVe + Auto-encoder are taken from Schuster et al. (2019), and the results of XL-SLU in the zero-shot settings are taken from Liu et al. (2019a).

few-shot setting. Our models are trained on GTX 1080 Ti. The number of parameters for our models is around 5 million.

4.3 Baselines

We compare our model to the following baselines.

BiLSTM-CRF This is the same cross-lingual SLU model structure as Schuster et al. (2019).

BiLSTM-LVM We replace the conditional random field (CRF) in BiLSTM-CRF with the LVM proposed in Liu et al. (2019a).

Multi. CoVe Multilingual CoVe (Yu et al., 2018) is a bidirectional machine translation system that tends to encode phrases with similar meanings into similar vector spaces across languages. Schuster et al. (2019) used it for the cross-lingual SLU task.

Multi. CoVe w/ auto-encoder Based on Multilingual CoVe, Schuster et al. (2019) added an auto-encoder objective so as to produce better-aligned representations for semantically similar sentences across languages.

Multilingual BERT (M-BERT) It is a single language model pre-trained from monolingual corpora in 104 languages (Devlin et al., 2019), which is surprisingly good at cross-lingual model transfer.

Mixed Language Training (MLT) Liu et al. (2019b) utilized keyword pairs to generate mixed language sentences for training cross-lingual task-oriented dialogue systems, which achieves promising zero-shot transfer ability.

CoSDA-ML Qin et al. (2020) proposed a multilingual code-switching data augmentation framework to enhance the cross-lingual systems based on M-BERT (Devlin et al., 2019). It is a concurrent work of this paper.

XL-SLU It is a previous state-of-the-art model in the zero-shot cross-lingual SLU task, which combines Gaussian noise, cross-lingual embeddings refinement, and the LVM (Liu et al., 2019a).

Translate Train Schuster et al. (2019) trained a supervised machine translation system to translate English data into the target language, and then trained the model on the translated dataset.

All-shot Settings We train the BiLSTM-CRF model (Lample et al., 2016) on all the target language training samples, and on both the source and target language training set.

5 Results & Discussion

5.1 Few-shot Setting

Quantitative Analysis The few-shot results are illustrated in Table 2, from which we can clearly see consistent improvements made by label regularization and adversarial training. For example, on the 1% few-shot setting, our model improves on BiLSTM-LVM in terms of accuracy/f1-score by 1.85%/1.16% in Spanish, and by 4.16%/6.93% in Thai. Our model also surpasses a strong baseline, M-BERT, while our model based on BiLSTM has many fewer parameters compared to M-BERT. For example, on the 1% few-shot setting, our model improves on M-BERT in terms of accuracy/f1-score by 3.80%/3.83% in Thai. Instead of generating a feature point like CRF, the LVM creates a more robust cross-lingual adaptation by generating a distribution for the intent or each token in the utterance. However, distributions generated by the LVM for the same slot type across languages might not be sufficiently close. Incorporating adversarial training into the LVM alleviates this problem by regularizing the latent variables and making them more distinguishable. This improves the performance in both intent detection (a sentence-level task) and slot filling (a word-level task) by 0.92%/3.16% in Spanish and by 1.89%/4.67% in Thai on the 1% few-shot setting. This proves that both sentence-level and word-level representations are better aligned across languages.

In addition, LR aims to further align the sentence-level representations of target language utterances into a semantically similar space of source language utterances. As a result, there are 0.93%/2.82% improvements in intent detection for Spanish/Thai on the 1% few-shot setting after we add LR to BiLSTM-LVM. Interestingly, the performance gains are not only on the intent detection but also on the slot filling, with an improvement of 1.77%/3.94% in Spanish/Thai. This is attributed to the fact that utterance representations are produced based on word-level representations from BiLSTM. Therefore, the alignment of word-level representations will be implicitly improved in this process. Furthermore, incorporating LR and ALVM further tackles the inherent difficulties for the cross-lingual adaptation and achieves the state-of-the-art few-shot performance. Notably, by only leveraging 3% of target language training samples, the results of our best model are on par with the supervised training on all the target language training data.

Model	Thai	
	Intent	**Slot**
few-shot on 5% target language training set		
BiLSTM-CRF	90.05	72.11
+ LR	91.11	73.71
BiLSTM-LVM	91.02	73.11
+ LR	91.45	75.18
+ ALVM	91.08	74.67
+ LR & ALVM	91.58	75.87

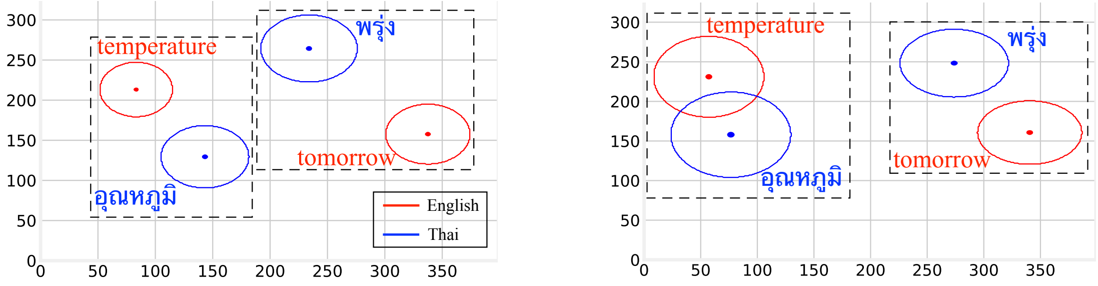
XL-SLU	91.05	73.43
M-BERT	92.02	75.52

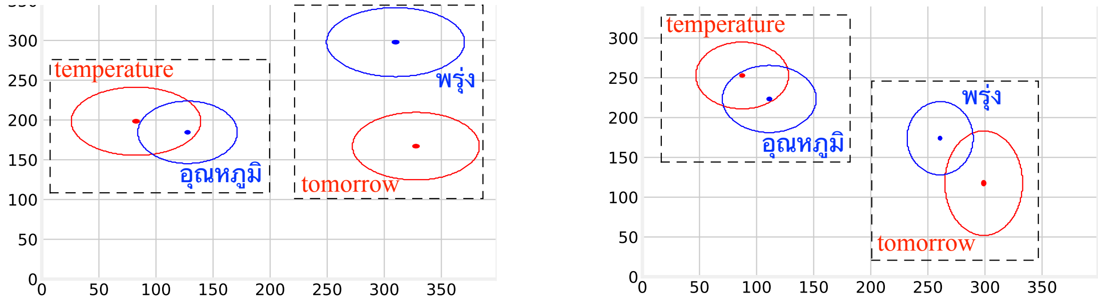
Table 3: Results of few-shot learning on 5% Thai training data, which are averaged over three runs. We make the training samples in Thai the same as the 3% Spanish training samples (**108**).

Adaptation ability to unrelated languages From Table 2, we observe impressive improvements in Thai, an unrelated language to English, by utilizing our proposed approaches, especially when the number of target language training samples is small. For example, compared to the BiLSTM-LVM, our best model significantly improves the accuracy and f1-score by ∼4%/∼7% in intent detection and slot filling in Thai in the few-shot setting on 1% data. Additionally, in the same setting, our model surpasses the strong baseline, M-BERT, in terms of accuracy and f1-score by ∼4%. This illustrates that our approaches provide strong adaptation robustness and are able to tackle the inherent adaptation difficulties to unrelated languages.

Comparison between Spanish and Thai To make a fair comparison for the few-shot performance in Spanish and Thai, we increase the training size of Thai to the same as 3% Spanish training samples, as depicted in Table 3. We can see that there is still a performance gap between the Spanish and Thai (3.11% in the intent detection task and 8.15% in the slot filling task). This is because



(a) LVM (b) LVM + LR



(c) ALVM (d) ALVM + LR

Figure 3: Visualization for latent variables of parallel word pairs in English and Thai over different models trained on 1% target language training set. We choose the word pairs "temperature- อุณหภูมิ" and "tomorrow- พรุ่ง" from the parallel sentences "what will be the temperature tomorrow" and "อุณหภูมิ จะ อยู่ ท เท่า ไหร่ พรุ่ง" in English and Thai, respectively. To draw the contour plot, we sample 3000 points from the distribution of latent variables for the selected words, use PCA to project those points into 2D and calculate the mean and variance for each word.

Table 4: Results of the ablation study for the label sequence encoder pre-training (averaged over three runs). Our model refers to the one that combines LR, ALVM and delex. with BiLSTM-LVM.

Spanish is grammatically and syntactically closer to English than Thai, leading to a better quality of cross-lingual alignment.

Visualization of Latent Variables The effectiveness of the LR and ALVM can be clearly seen from Figure 3. The former approach decreases the distance of latent variables for words with similar semantic meanings in different languages. For the latter approach, to make the distributions for different slot types distinguishable, our model regularizes the latent variables of different slot types far from each other, and eventually it also improves the alignment of words with the same slot type. Incorporating both approaches further improves the word-level alignment across languages. It further proves the robustness of our proposed approaches when adapting from the source language (English) to the unrelated language (Thai).

5.2 Zero-shot Setting

From Table 2, we observe the remarkable improvements made by LR and ALVM on the state-of-the-art model XL-SLU in the zero-shot setting, and the slot filling performance of our best model in Spanish is on par with the strong baseline Translate Train, which leverages large amounts of bilingual resources. LR improves the adaptation robustness by making the word-level and sentence-level representations of similar utterances distinguishable. In addition, integrating adversarial training with the LVM further increases the robustness by disentangling the latent variables for different slot types. However, the performance boost for slot filling in Thai is limited. We conjecture that the inherent discrepancies in cross-lingual word embeddings and language structures for topologically different languages pairs make the word-level representations between them difficult to align in the zero-shot scenario. We notice that Multilingual CoVe with auto-encoder achieves slightly better performance than our model on the slot filling task in Thai. This is because this baseline leverages large amounts of monolingual and bilingual resources, which largely benefits the cross-lingual alignment between English and Thai. CoSDA-ML, a concurrent work of our model, utilizes additional augmented multilingual code-switching data, which significantly improves the zero-shot cross-lingual performance.

5.3 Effectiveness of Label Sequence Encoder Pre-training

Label sequence encoder pre-training helps the label encoder to generate more expressive representations for label sequences, which ensures the effectiveness of the label regularization approach. From Table 4, we can clearly observe the consistent performance gains made by pre-training in both few-shot and zero-shot scenarios.

6 Conclusion

Current cross-lingual SLU models still suffer from imperfect cross-lingual alignments between the source and target languages. In this paper, we propose label regularization (LR) and the adversarial latent variable model (ALVM) to regularize and further align the word-level and sentence-level representations across languages without utilizing any additional bilingual resources. Experiments on the cross-lingual SLU task illustrate that our model achieves a remarkable performance boost compared to the strong baselines in both zero-shot and few-shot scenarios, and our model has a robust adaptation ability to unrelated target languages in the few-shot scenario. In addition, visualization for latent variables further proves that our approaches are effective at improving the alignment of cross-lingual representations.

Abstract

Spoken Language Understanding infers semantic meaning directly from audio data, and thus promises to reduce error propagation and misunderstandings in end-user applications. However, publicly available SLU resources are limited. In this paper, we release SLURP, a new SLU package containing the following: (1) A new challenging dataset in English spanning 18 domains, which is substantially bigger and linguistically more diverse than existing datasets; (2) Competitive baselines based on state-of-the-art NLU and ASR systems; (3) A new transparent metric for entity labelling which enables a detailed error analysis for identifying potential areas of improvement. SLURP is available at `https://github.com/pswietojanski/slurp`

1 Introduction

Traditionally, Spoken Language Understanding (SLU) uses a pipeline transcribing audio into text using Automatic Speech Recognition (ASR), which is then mapped into a semantic structure via Natural Language Understanding (NLU). However, this modular approach is prone to error propagation from noisy ASR transcriptions, and ASR in turn is not able to disambiguate based on semantic information. End-to-end (E2E) approaches on the other hand, can benefit from joint modelling. One of the main bottlenecks for building E2E-SLU systems, however, is the lack of large and diverse datasets of audio inputs paired with corresponding semantic structures. Publicly available datasets to date are limited in terms of lexical and semantic richness (Lugosch et al., 2019b), number of vocalizations (Coucke et al., 2018), domain coverage (Hemphill et al., 1990; Dahl et al., 1994) and semantic contexts (Godfrey et al., 1992; Jurafsky and Shriberg, 1997). In this paper, we present the Spoken Language Understanding Resource Package (SLURP), a publicly available multi-domain dataset for E2E-SLU, which is substantially bigger and more diverse than existing SLU datasets. SLURP is a collection of ~72k audio recordings of single turn user interactions with a home assistant, annotated with three levels of semantics: Scenario, Action and Entities, as in Fig. 1, including over 18 different scenarios, with 46 defined actions and 55 different entity types as listed on `https://github.com/pswietojanski/slurp`.[1]

User: "*Make a calendar entry for brunch on Saturday morning with Aaronson.*"
Scenario: Calendar
Action: Create_entry
Entity tags and lexical fillers: [`event_name`: brunch], [`date`: Saturday], [`timeofday`: morning], [`person`: Aaronson]

Figure 1: Example annotation from SLURP dataset.

In order to further support SLU development, we propose SLU-F1, a new metric for entity prediction, which is specifically designed to assess error propagation in structured E2E-SLU tasks. This metric has 3 main advantages over the commonly used accuracy/F1 metric, aimed at supporting SLU developers: First, it computes a distribution rather than a single score. This distribution is (1) inspectable and interpretable by system developers, and (2) can be converted into a confidence score which can be used in the system logic (akin to previously available ASR confidence scores). Finally, the distribution reflects errors introduced by ASR and their impact on NLU and thus (3) gives an indication of the scope of improvement that can be gained by E2E approaches. Using this metric, we evaluate 4 baseline systems that represent competitive

pipeline approaches, i.e. 2 state-of-the-art NLU systems and 2 ASR engines. We conduct a detailed error analysis of cases where E2E could have made a difference, i.e. error propagation and semantic disambiguation.

2 Related Work

The first corpora containing both audio and semantic annotation reach as far back as the The Air Travel Information System (ATIS) corpus (Hemphill et al., 1990) and the Switchboard-DAMSL Labeling Project (Jurafsky and Shriberg, 1997). However, it was not until recently when the first E2E approaches to SLU were introduced (Serdyuk et al., 2018; Haghani et al., 2018). Since then, one of the main research questions is how to overcome data sparsity by e.g. using transfer learning (Schuster et al., 2019; Tomashenko et al., 2019), or pre-training (Lugosch et al., 2019b). Here, we present a new corpus, SLURP, which is considerably bigger than previously available corpora. In particular, we directly compare our dataset to the two biggest E2E-SLU datasets for the English language: The Snips benchmark (Coucke et al., 2018) and the Fluent Speech Command (FSC) corpus (Lugosch et al., 2019b). With respect to these resources, SLURP contains ~6 times more sentences than Snips, ~2.5 times more audio examples than FSC, while covering 9 times more domains and being on average 10 times lexically richer than both FSC and Snips, see Section 3.3. SLURP represents the first E2E-SLU corpus of this size for the English language. The only existing comparable project is represented by the CASTLU dataset (Zhu et al., 2019) for Chinese Mandarin.

3 SLURP data

3.1 Data Collection

SLURP was collected for developing an in-home personal robot assistant (Miksik et al., 2020). First, we collected textual data by prompting Mechanical Turk (AMT) workers to formulate commands towards the robot, using 200 pre-defined prompts such as "How would you ask for the time/ set an alarm/ play your favourite music?" etc. We carefully designed the prompts to avoid lexical priming and thus increase linguistic variability of the collected data. This data has been manually annotated at scenario, action and entity level, and released as a text-only NLU benchmark (Liu et al., 2019). The textual data also serves as gold standard transcriptions for the audio data.

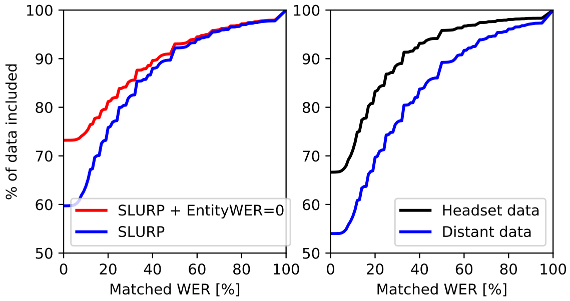

Figure 2: Amounts of data in SLURP matching given WER levels.

The audio data was collected in acoustic conditions matched to a typical home or office environment. We asked 100+ participants to read out the collected prompts on a tablet and to provide demographic background information, see Table 1. Speech was captured at distance with a microphone array, but some users were also equipped with a close-talking headset microphone (though, distant and close-talk channels are not synchronised at the sample level). Most recording sessions lasted 1 hour and were split into 4 parts. In each part, the technician changed position of the microphone array in the collection place. Users were encouraged to vary their location in the room from utterance to utterance (seating, standing or walking), and for some utterances not to speak directly to the mic array in order to resemble realistic conditions. These parameters are not logged with the dataset, however, they do pose increased challenges for ASR (Marino and Hain, 2011).

Female	Male	Native	Non-Native	Unk.
37.3%	32.2%	25.5%	44%	30.5%

Table 1: Participants' demographic statistics.

3.2 Audio Data Processing

For quality control of the audio data, we automatically verified i) whether the participant uttered the right / complete SLU query as prompted and ii) if the files were appropriately end-pointed. We used the transcriptions of two ASR systems (referred to as Multi-ASR and Google-ASR, see Sec 5.1). These systems were not estimated from SLURP acoustic data, thus remain unbiased and do not reinforce potential errors. First, we removed all data that failed to force-align to transcripts using Multi-ASR. Then for the remainder we derived the SLU related confidences based on the matched Word-Error Rate (WER) between textual prompts and the obtained ASR hypotheses (calculated for both utterance and entity fillers), as well as cross-mic validation between close and distant microphones, see Figure 2 (Right). Note that the higher matched WER does not necessarily imply the file lacks the expected content, as simply the file could be more challenging to automatically recognise. At the same time, from SLU perspective, one does not necessarily need grammatically correct utterances, as long as the they carry the information necessary to understand and execute the query. Figure 2 (Left) shows that for nearly 60% of the data at least one ASR system achieved a perfect score (WER=0), and this increases to ~73% after including utterances with imperfect sentence error rates but correct entity fillers (EntityWER=0). After filtering, SLURP comprises ~58 hours of acoustic material. See Table 2 for detailed statistics.

In addition, we provide SLURP-synth following (Lugosch et al., 2019a), where we replace filtered or missing recordings with synthetic vocalisations from Google's Text-to-Speech system[2] using 34 different synthetic English voices.

3.3 Linguistic Analysis and Comparison

In this Section, we compare SLURP with the most recent publicly available E2E-SLU datasets: The Fluent Speech Command (FSC) corpus (Lugosch et al., 2019b) and the Snips benchmark (Coucke et al., 2018), which are also set in the smart-home domain. Snips covers 10 domains. However, only 2 domains have been vocalised, resulting in ~6K audio files. FSC, on the other hand, is considerably bigger than Snips in terms of audio recordings, including ~30k vocalisations. However, the provided semantics only cover a small subset of actions with no more than two fixed entity types as arguments. In the following, we compare these dataset along four dimensions in order to get a first estimate of SLURP's level of complexity.

Audio analysis: Table 2 summarises the audio data for each dataset. Audio files are differentiated in *close* and *far* range microphone. As shown, SLURP has ~1.8× more speakers, more than double the audio files than the biggest dataset FSC, however FSC has an higher audio-per-sentence ratio. Demographic statistics are reported in Table 1.

	FSC	Snips	SLURP	SLURP -synth
Speakers	97	69	**177**	34
Audio files	30,043	5,886	**72,277**	69,253

Duration [hrs]	19	5.5	**58**	43.5
Avg. length [s]	2.3	**3.4**	2.9	2.3

Table 2: Audio file statistics.

Lexical analysis: Table 3 provides an overview of different measures of lexical richness and diversity, following (Novikova et al., 2017), using both lexicalised (LEX) and delexicalised (DELEX) versions of the datasets (delexicalisation is performed by replacing each entity span with the entity label). Note that delexicalisation has a more severe effect on FSC and Snips, which indicates that most of their lexical richness and diversity stems from entity names. On average SLURP has ~100× more tokens, lemmas, bigrams and trigrams than FSC, and ~10× more than Snips. In addition, we compute the following lexicographic measures using the Lexical Complexity Analyser (Lu, 2012). *Lexical Sophistication* (LS2) (Laufer, 1994) is defined as T_s/T, with T_s being the number of sophisticated types of (unique) words[3] and T being the number of types of words in a dataset. The *Corrected Verb Sophistication* (CSV1) (Wolfe-Quintero et al., 1998) is evaluated as $T_{svb}/\sqrt{2N_{vb}}$, with T_{svb} the number of types of sophisticated verbs and N_{vb} the total number of verbs in a dataset. The *Mean Segmental Text-to-Token Ratio* (MSTTR) (Johnson, 1944) is the average Text-to-Token Ratio (TTR – T/N) over all the segments of 10[4] words, with N the number of words in a dataset. The MSTTR is used to capture the variation of classes of words. Again, SLURP shows higher levels of lexical sophistication and richness than the other datasets, especially in the delexicalised case. Note that lexicalised version of Snips contains many names of artists and bands in the music scenario, which contributes to enlarge the set of sophisticated words T_s. The only measure where SLURP doesn't outperform the other datasets is average sentence length. SLURP contains, among others, shorter interactions, such short acknowledgements, elliptic questions and atomic commands, whereas Snips is

---

[2] `https://cloud.google.com/text-to-speech`

[3] Sophisticated words are considered words not in the 2000 more frequent words in English language.

[4] Standard size of a segment for written text is 50, but we are here considering short utterances, so we lowered this number to 10.

mostly composed of commands of similar length, often including multiword named entities.

Syntactic analysis: Next, we use the D-Level Analyser (Lu, 2009) to evaluate the syntactic complexity of user utterances according to the revised D-Level scale (Covington et al., 2006), where higher levels correspond to more complex, deeper syntactic structures, e.g. 0-1 levels include simple sentences, while higher levels presents embedded structures, subordinating conjunction, etc. Figure 3 shows the percentages on the D-Level scale for each dataset. Overall, all the datasets present a majority of Level 0 and 1 sentences. This can be explained with the nature of the application domain, i.e. a smart-home assistant. FSC contains mostly Level 0 sentences (~89%), with some (~9%) Level 4 ones. 89% of Snips sentences fall into Level 0 and 1, against only 74% of SLURP. The remaining 11% of Snips are mostly Level 4 sentences, while SLURP appears more mixed, with even a ~5% of Level 7 sentences.

Semantic Analysis: Finally, we compare the datasets according to their semantic content. SLURP is annotated with three layers of semantics, namely *scenarios*, *actions* and *entities*, where each sentence is annotated with one scenario and one action, see Fig. 1, similar to annotations used in (Budzianowski et al., 2018; Schuster et al., 2019). FSC and Snips contain actions and entities as well, although they do not explicitly annotate the scenarios, however these can be deducted from the dataset file structure. The results in Table 4 show that SLURP's semantic coverage is 9 times wider than other datasets in terms of scenarios, and ~6.5 times in terms of actions, where a higher number of scenarios results in a higher number of actions. FSC has the highest entity/sentence ratio, though it only has 16 unique entities. Snips appears to be the dataset with highest Unique Entities/Total Entities ratio, ~50%, against ~33% of SLURP. Again, this is due to the frequent use of proper names.

4 SLURP Metrics

The standard metric for evaluating E2E-SLU is accuracy, which is defined as "the accuracy of all slots for an utterance taken together – that is, if the predicted intent differs from the true intent in even one slot, the prediction is deemed incorrect" (Lugosch et al., 2019b). However, this notion of accuracy is problematic when it comes to evaluating entities, as it does not account for the interplay between semantic mislabelling and textual misalignment. Nor does it differentiate between entity label and lexical

Gold: [`event_name`: brunch], [`date`: Saturday], [`timeofday`: morning], [`person`: Aaronson]
SLU: [`event_name`: brunch], [`date`: Saturday], [`date`: morning], [`person`: Aron's son]

Figure 4: Continued example from Figure 1: Errors in SLU entity tagging.

filler, as in Fig. 4, where lexical filler is defined as span over tokens in the original sentence.[5]

Formally, given a sentence s, let $\mathcal{E}$ and $\hat{\mathcal{E}}$ be the set of gold and predicted entities, respectively. Each $e_i = \langle l_i, f_i \rangle \in \mathcal{E}$ is a tuple where $l_i \in \mathcal{L}$ is the label drawn from the list of available entity labels $\mathcal{L}$, while $f_i = [t_m, \ldots, t_n]$ is the lexical filler, defined as a span of consecutive tokens of s such that $1 \leq m \leq n \leq |s|$. Similarly, predicted entities are of the form $\hat{e}_k = \langle \hat{l}_k, \hat{f}_k \rangle \in \hat{\mathcal{E}}$. In span-based metrics, two entities e_1 and e_2 are identical ($e_1 =:= e_2$) when both labels and lexical fillers are the same ($l_1 = l_2 \wedge f_1 = f_2$). A match is thus found only whenever the gold and predicted entities are identical, i.e. $e_i =:= \hat{e}_k$. This evaluation method holds in NLU because entities are tagged over the same textual sequence. When evaluating E2E-SLU, where entities are identified out of a wave form, this strict coupling with the token sequence may no longer apply. Note that pipeline systems for SLU are affected as well since they operate over ASR transcribed sentences, which can consistently differ from the original gold transcription.

To account for this mismatch, we propose SLU-F1, a new metric which does not overly penalise misalignments caused by ASR errors. In addition, it is able to capture the quality of transcriptions and entity tagging errors at the same time in a single metric. As such, this metric allows to directly compare E2E and pipeline systems. In particular, SLU-F1 combines span-based F1 evaluation with a text-based distance measure *dist*, e.g. WER. The equality property $=:=$ is relaxed by allowing gold and predicted entities (e_i and $\hat{e}_k$) to match ($e_i =:= \hat{e}_k$) when the corresponding labels are identical ($l_i = \hat{l}_k$), even when the fillers are not identical. In this case we increment the True Positives (TPs) by 1. To account for lexical distance/ mismatch, we compute the *dist* between gold and predicted fillers ($dist(f_i, \hat{f}_k)$), and increment the False Positives (FPs) and False Negatives (FNs) of this amount, as in Algorithm 1. In the case of a predicted entity label matching with more than one gold entity, e.g. when two or more entities with the same label are present, we opt for a non-conservative approach, selecting the gold annotation minimising the *dist* as a candidate. The assumption is that the pair of entities is most likely referring to the same text span. We use two distance functions to capture different aspects of possible transcription mistakes: WER (Word-F1) and the normalised Levenshtein distance on character level (Char-F1). WER is a strict token-level metric, which outputs errors/null matches whenever a mismatching or misalignment of tokens is observed. The character-based Levenshtein distance, on the other hand, offers the opposite perspective. By computing character-based similarities, it is much less susceptible to small variations of input strings, and thus better accounting for local transcription errors which do not affect NLU tagging. For example, Word-F1 will penalise small morphological differences e.g. singular vs. plural as in *pizza* vs. *pizzas*, which are often seen in transcriptions. This over-penalises NLU outputs, e.g. the tagging of *pizzas* may be semantically correct. Char-F1 on the other hand does not over-penalise NLU, but it also may provide a positive score when two fillers have similar characters, but are semantically and phonetically unrelated. In other words, Word-F1 shows the influence of ASR on NLU, whereas Char-F1 gives an indication of NLU performance despite transcription noise. These *dist*-F1 metrics ($dist$ = Word or Char) metric are similar to the fuzzy matching mechanism proposed in (Rastogi et al., 2020). They fundamentally differ for the adopted string matching schema: any *dist*-F1 considers string ordering to score string similarity, while the fuzzy mechanism is instead order invariant.

Consider the illustrative entity tagging example in Figure 4. Here, *Aaronson* has been wrongly transcribed into *Aron's son*, and *morning* has been wrongly tagged with `date`. A *dist*−F1 will score the predicted entities as follows: both [`event_name`: *brunch*] and [`date`: *Saturday*] contribute with a $+1$ to the TPs, since both label and filler correspond to gold information. The wrong label associated with *morning* increases the FPs of 1, although it is correctly transcribed. It follows that the entity `timeofday` is not predicted, increasing the FNs of 1. Finally, [`person`: *Aron's son*] is correctly labelled, but its filler is

---

[5] In traditional NLU systems this is identified with pairs of start-end tokens or chars, or token index spans.

partially wrong. It thus contributes to the TPs by 1, but FPs and FNs are both incremented by $dist(Aaronson, Aron's\ son)$.

Algorithm 1 $dist$-F1 for a sentence s

```
Input $\mathcal{E}$, $\hat{\mathcal{E}}$,
    $TP, FP, FN \leftarrow 0$
    $\mathcal{L}_s \leftarrow$ set of gold entity labels in $s$
    $dist \leftarrow$ a text-based distance metric
Output: $TP, FP, FN$
for each $\hat{e} \in \hat{\mathcal{E}}$ do
    if $\hat{e}.label \in \mathcal{L}_s$ then
        $\mathcal{P}_l \leftarrow \{(e, \hat{e}) \mid \forall e \in \mathcal{E}.\ e.label = \hat{e}.label\}$
        if $\mathcal{P}_l.size > 0$ then
            $(e, \hat{e}) \leftarrow \arg\min_{(e,\hat{e}) \in \mathcal{P}_l} dist(e, \hat{e})$
            $TP$ += 1
            $FP$ += $dist(e.filler, \hat{e}.filler)$
            $FN$ += $dist(e.filler, \hat{e}.filler)$
            $\mathcal{E}.remove(e)$, $\hat{\mathcal{E}}.remove(\hat{e})$
        else
            $FP$ += 1, $\hat{\mathcal{E}}.remove(\hat{e})$
        end if
    else
        $FP$ += 1, $\hat{\mathcal{E}}.remove(\hat{e})$
    end if
end for
for $e \in \mathcal{E}$ do
    $FN$ += 1, $\mathcal{E}.remove(e)$
end for
```

Finally, we combine Word-F1 and Char-F1 in a single number SLU-F1, which evaluates the final performance over the sum of the confusion matrices obtained with Word-F1 and Char-F1.[6]

5 Experiments

We now establish the performance of different baseline systems on the SLURP corpus. As demonstrated in Section 3.1, SLURP is linguistically more diverse than previous datasets, and therefore more challenging for SLU. We first provide an evaluation of two ASR baselines to show the complexity of the acoustic dimension. We then evaluate the semantic dimension, by testing the corpus against state-of-the-art NLU systems. We finally combine ASR and NLU, implementing several SLU pipelines.

Note that so far, the direct comparison of E2E-SLU with pipeline approaches are mainly limited to baselines developed on the same dataset, e.g. a multistage neural model in which the two stages that correspond to ASR and NLU are trained independently, but using the same training data (Desot et al., 2019; Haghani et al., 2018). We follow a different approach, which, as we argue, is closer to the real-life application scenario: We use competitive ASR systems and state-of-the-art NLU systems.

5.1 Acoustic evaluation

We run the analysis of the SLURP acoustic complexity by testing 2 different ASR systems: In-domain ASR trained on SLURP data, and Multi-ASR, which leverages a large amount of out-of-domain data. Both are built with the Kaldi ASR toolkit (Povey et al., 2011). Multi-ASR is a large-scale system estimated from publicly available acoustic data pooled together – Acoustic data including, among others, LibriSpeech (Panayotov et al., 2015), Switchboard (Godfrey et al., 1992), Fisher (Cieri et al., 2004), CommonVoice (Ardila et al., 2019), AMI (Carletta, 2007) and ICSI (Janin et al., 2003),[7] which is further augmented to increase environmental robustness following (Ko et al., 2017). In total, a time-delay neural network acoustic model (Peddinti et al., 2015) is trained on 24,000 hours of augmented audio material with lattice-free maximum mutual information objective (Povey et al., 2016). For decoding, we use a tri-gram Language Model (LM) that is an interpolation of an in-domain LM estimated from 60k voice-command sentences[8] and a background LM estimated from Fisher transcripts. As shown in the first block of Table 5, Multi-ASR offers a competitive performance on this data when compared to the off-the-shelf Google-ASR.[9]

SLURP-ASR shares the overall pipeline with Multi-ASR, except the acoustic model is estimated from the 40 hours of SLURP training data (83 hours when pooled with SLURP-Synth) and bootstrapped from forced-alignments obtained with Gaussian mixture model build for Multi-ASR. Results for this scenario are reported in the second block of Table 5, where adding synthetic data shows 1.6% improvement. For comparison, estimating acoustic models from synthetic data alone (no augmentations) results in 98% WER on Test partition.

Finally, we perform supervised acoustic domain adaptation (Bell et al., 2020) of Multi-ASR with SLURP-Train by a method proposed in (Swietojanski et al., 2016), which achieves the best perfor-

Table 7: System accuracy of Scenario and Action.

mance by around 1% absolute on Test.

In sum, the large out-of-domain Multi-ASR system performs better than the systems trained on in-domain SLURP data. Best results are achieved by using a pre-training approach, i.e. Multi-ASR adapted to SLURP. This shows that, despite SLURP's absolute size, the acoustic data is still too scarce to fully account for its lexical richness and noise conditions. As such, SLURP is a challenging dataset for ASR as well as for SLU.

5.2 Semantic evaluation

System Descriptions: We evaluate SLURP against two state-of-the-art NLU models: HerMiT (Vanzo et al., 2019) and SF-ID (E et al., 2019). Both systems achieved state-of-the-art results on the NLU Benchmark (Liu et al., 2019) and on ATIS/Snips respectively. HerMiT's architecture is a hierarchy of self-attention mechanisms and Bidirectional Long Short-Term Memory (BiLSTM) encoders followed by Conditoinal Random Field (CRF) tagging layers. Its multi-layered structure resembles a top-down approach of Scenario, Action and, Entity prediction, where each task benefits from the information encoded by the previous stages, e.g. Entity detection can benefit from sentence-level encodings.

SF-ID's architecture is also based on attention, using a BiLSTM encoder and CRF tagger. The model defines two subnets that communicate through a reinforce vector. In order to compare with HerMiT's top-down approach, we choose the opposite Entity-first propagation direction for SF-ID, i.e. the entity detection task is executed first and its encodings are used to feed the Intent detection task. Note that while HerMiT uses a multi-layered annotation scheme (Scenario and Action), SF-ID can only handle a single layer of annotation. To this end, we generate another combined semantic layer, Scen_Act, to feed SF-ID with a label composed by the concatenation Scenario and Action.

Scenario and Action Prediction: We split SLURP in train, development and test as in Table 6. We first evaluate accuracy for Scenario, Action and a combination of the two. Table 7 summarises the results, where the top two rows are upper bounds based on gold transcriptions. Note that even for the gold transcriptions, both NLU systems perform substantially below their state-of-the-art results on the NLU benchmark (HerMiT=87.55) and Snips respectively (SF-ID= 97.43). This further demonstrates the complexity of SLURP, which also makes it a challenging test bed for future research not only for SLU, but also NLU. When moving on to ASR transcribed data, the results in the middle of Table 7 show the Multi-ASR system in combination with HerMiT achieves top performance for all 3 tasks. Finally, the 3rd block reports HerMiT with ASR from in-domain SLURP audio data (also see Table 5). The results show that our best performing system, HerMiT with Multi-ASR + Adapt w/ SLURP, is only ~5% below the gold standard despite 16% WER. We hypothesise that this is due to robust Scenario and Action encodings, which we will further examine in our error analysis in Section 6.

Entity Prediction: We now analyse the results for entity prediction in more detail using our proposed metric SLU-F1. The results in Table 8 confirm that HerMiT is the stronger NLU system on gold-transcribed data and outperforms the other system combinations for SLU in combination with Multi-ASR. Again, these results suggest that the top-down information flow of HerMiT (i.e. first decoding Scenario, then Action and lastly Entity in a sequence) is better suited for this complex dataset, which we will further demonstrate in the following.

	Word-F1	Char-F1	SLU-F1	F1
Gold/HerMiT	–	–	–	**78.19**
Gold/SF-ID	–	–	–	69.87
Multi/HerMiT	67.78	71.38	69.53	62.69

Multi-SLURP/HerMiT	**69.34**	**72.39**	**70.84**	**64.16**

Table 8: System performance on entity prediction

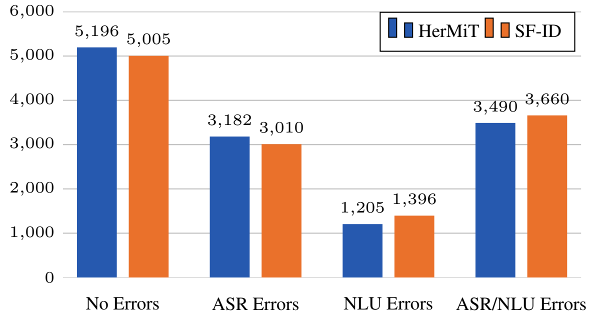

Figure 5: Error propagation: *No Errors* refer to the number of predicted entities that match the gold transcriptions perfectly. *ASR Errors* count the number of predictions where ASR outputs an unmatched candidate but the NLU system is nevertheless able to recover the correct entities from the transcriptions. *NLU Errors* count sentences where transcriptions are correct, but entities do not match. *ASR/NLU Errors* count the sentences where both ASR and NLU errors are present.

6 Error Analysis

6.1 Analysis of Error Propagation for different NLU Approaches

We further describe the types of errors produced by HerMiT and SF-ID for Entity Prediction on noisy ASR data, as shown in Figure 5. Overall, HerMiT has lower error rates for all but ASR errors. Nevertheless, it is able to recover the correct entities from the transcriptions. These results indicate that HerMiT, using a top-down decoding approach – going from the more general Scenario to the more specific Action and Entity Prediction, is more robust to noise propagation than the bottom-up SF-ID system.

6.2 Expressiveness of the SLU-F1 Metric

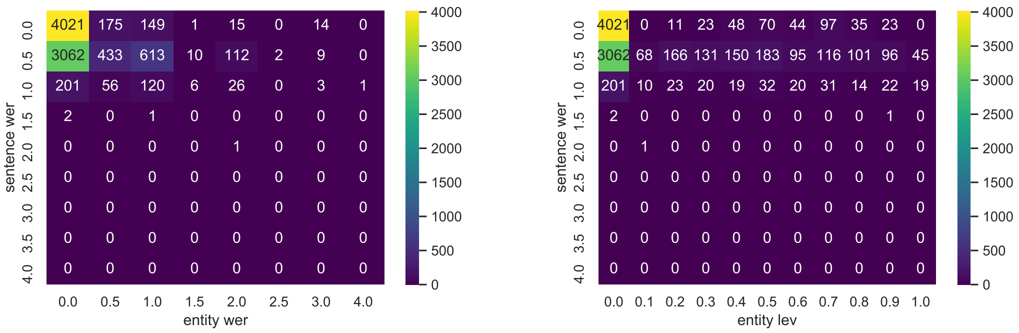
The results in Table 8 show that our proposed metrics Word-F1 and Char-F1 both produce the same ordering as F1. However, a Pearson's correlation between Word-F1 and Char-F1 shows that the two metrics are only weakly correlated ($\rho = 0.2$, $p \ll 0.0001$), which confirms that they are indeed measuring two different aspects despite producing the same final ordering. In addition to an overall performance score, the metrics give us a distribution of value ranges, which can give us insight on system behaviour. Figure 6 shows distributions of entity-level $dist$ value ranges over the WER of the sentence for our top performing system HerMiT/Multi-ASR. For entity-WER (Figure 6a), the distribution shows high density of entities falling between sentence-WER= $[0, 1]$ and entity-WER= $[0, 1]$. When analysing sentences with correct transcriptions, i.e. sentence-WER=0, we find only NLU errors, due to span misalignments. When sentence-WER > 0, most of the entities are scored with a values either in $(0, 0.5]$, or in $(0.5, 1]$. In the first case, we find NLU mistakes caused by shortening entity spans, e.g. “football” instead of “football match”. The second range includes span shortening and extensions, e.g. “Saturday morning” instead of “Saturday”, as well as many mis-transcribed entities, e.g. due to either morphological errors (singular vs. plural), or transcription errors.

The distribution for entity-level normalised Levenshtein is less spiked, as shown in Fig. 6b. As for WER, all the entries with sentence-WER=0 and entity-Lev>0 correspond to correctly labelled entities, whose span has been shortened or extended. Entities assigned with character-based Lev values falling between $(0, 0.2]$ mostly contain negligible ASR errors, such as morphological errors, compound merging or explosion, or general transcription mistakes, e.g. *Sara* vs. *Sarah*. Entities with Lev= $(0.2, 0.5]$ comprise both ASR errors, as well as including minor NLU errors such as shortened or extended entity spans. When entity-Lev= $(0.5, 0.8]$, we find mostly NLU errors due to wrong span tagging. Finally, two types of NLU errors fall in the range $(0.8, 1.0]$: Either span errors with a substantial mismatch in length with gold annotations, or more severe ASR errors.

7 Discussion

SLURP is not only bigger, but also a magnitude more challenging than previous datasets. The purpose of this new data release is not to provide yet another benchmark dataset, but to provide a use-case inspired new challenge, which is currently beyond the capabilities of SOTA E2E approaches (due to scalability, lack of data efficiency, etc.).

We have tested several SOTA E2E-SLU systems on SLURP, including (Lugosch et al., 2019b) which



(a)

(b)

Figure 6: Correlation between sentence-level WER (intervals of 0.5) and entity-level (a) WER values (intervals of 0.5), (b) normalised character-based Levenshtein values (intervals of 0.1).

produces SOTA results on the FSC corpus. However, re-training these models on this more complex domain did not converge or result in meaningful outputs. Note that these models were developed to solve much easier tasks (e.g. a single domain). Developing an appropriate model architecture is left for future work. For this reason, in this work we focus on benchmarking existing approaches.

We show that SOTA modular approaches are able to provide a strong baseline for this challenging data, which has yet to be met by SOTA E2E systems. We also argue that our modular baseline is closer to how real-world applications build SLU systems, nevertheless often overlooked when testing E2E systems. As such, we consider our SOTA modular baseline a major novel contribution.

8 Conclusion

In this paper, we present SLURP, a new resource package for SLU. First, we present a novel dataset, which is substantially bigger than other publicly available resources. We show that this dataset is also more challenging by first conducting a linguistic analysis, and then demonstrating the reduced performance of state-of-the-art ASR and NLU systems. Second, we propose the new SLU-F1 metric for evaluating entity prediction in SLU tasks. In a detailed error analysis we demonstrate that the distribution of this metric can be inspected by system developers to identify error types and system weaknesses. Finally, we analyse the performance of two state-of-the-art NLU systems on ASR data. We find that a sequential decoding approach for SLU, which starts from the more abstract notion of scenario and action produces better results for entity tagging, than an approach which works bottom up, i.e. starting from the entities. Our error analysis suggests that this is due to the former approach being able to better account for noise by priming entity tagging, which is a more challenging task than scenario or action recognition.

In future work, we hope that SLURP will be a valuable resource for developing E2E-SLU systems, as well as more traditional pipeline approaches to SLU. The next step is to extend SLURP with spontaneous speech, which would again increase its complexity, but also move it one step closer to real-life applications.

Abstract

Neural Conversational QA tasks like ShARC require systems to answer questions based on the contents of a given passage. On studying recent state-of-the-art models on the ShARC QA task, we found indications that the models learn spurious clues/patterns in the dataset. Furthermore, we show that a heuristic-based program designed to exploit these patterns can have performance comparable to that of the neural models. In this paper we share our findings about four types of patterns found in the ShARC corpus and describe how neural models exploit them. Motivated by the aforementioned findings, we create and share a modified dataset that has fewer spurious patterns, consequently allowing models to learn better.

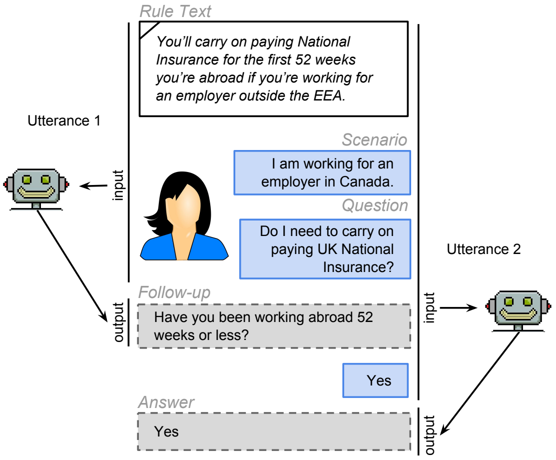

Figure 1: Dialog Flow in ShARC ((Saeidi et al., 2018))

1 Introduction

ShARC, a conversational QA task (Saeidi et al., 2018), requires a system to answer user questions based on *rules* expressed in natural language text. An example in Figure 1 shows a user sharing some background information (referred to as *scenario*) and asking a question about continuing to pay for 'UK National Insurance'. The *rule text* associated with this dialog exchange defines the policy that guides the conversation flow. At any turn in the conversation, a system may choose to respond with a final Yes/No answer; ask a follow-up question to obtain more information from the user; or reply that the question is irrelevant to the context.

Several deep learning models such as BERT-QA (Devlin et al., 2019), E3 (Zhong and Zettlemoyer, 2019), and BiSon (Lawrence et al., 2019) perform reasonably well on this task. However, our exploration of the ShARC dataset indicates that there are multiple spurious patterns that could be exploited by neural models. We observe that the performance of the models mentioned above drops when they are tested on a perturbed dataset, suggesting that the underlying neural models do not generalize and are rather over-sensitive (Welbl et al., 2020) to minor textual perturbations. By sensitivity we refer to a model's ability to generalize itself but not overfit, while still being invariant to perturbations or text transformations (Teney et al., 2020; Szegedy et al., 2013). Our observations about conversational QA models designed for ShARC learning spurious statistical clues are in line with those reported by Niven and Kao (2019). To the best of our knowledge, we are the first to demonstrate this problem in conversational QA.

Patterns in the ShARC dataset: We discover four types of patterns in the ShARC dataset: (1) correlation between the last answer to a follow-up question and the predicted answer to a user question; (2) a high correlation between asking a new follow-up question and the number of turns in the dialog history; (3) correlation between the sequence of follow-up questions in the dialog history and the sequence of rule clauses in the rule-text; and (4) correlation between an empty history/scenario and the answer being irrelevant.

Contributions: The main contributions of this work are as follows: (1) We present a simple

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7263–7269,
November 16–20, 2020.

heuristics driven program designed to exploit the aforementioned patterns which has performance comparable to the state-of-the-art models. (2) The performance of the state-of-the-art models drops when they are tested on a *perturbed* test set that has these patterns diluted or removed. (3) We also identify a weakness in the current evaluation procedure, and propose an improved evaluation criteria which penalizes BLEU scores if a follow-up question is not generated when it should be. We refer to this criteria as BLEU-P (BLEU penalized) in the rest of the paper. (4) We generate a new dataset which reduces the patterns identified in the original dataset, and re-benchmark existing state-of-the-art models published on the leaderboard. We find that the models learn better on this dataset and their performance is consistent across the original and the perturbed dev sets. Our dataset and all accompanying scripts are available at `https://github.com/nikhilweee/neural-conv-qa`.

2 Patterns in the ShARC Dataset

This section describes the spurious patterns in the ShARC dataset and presents a simple heuristic based program designed to exploit these patterns.

Pattern 1: Last follow-up answer is the predicted answer: Based on the asterisk ('*') as a separator between rule clauses, we found that 54.52% of the instances consist of a list of only-*conjunctive* or only-*disjunctive* clause conditions. Consider a case where a *rule* consists of only conjunctive clause statements. If any single follow-up question, generated based on one of these clauses, is answered with a 'No' by a user, the answer to the user's question shall be 'No'. In this case, no follow-up questions need to be asked. Thus, one often finds the sequence of follow-up answers in the dialog history as ('Yes', . . . , 'Yes', 'No'), for which the answer to the user question is a 'No'. Similarly, corresponding to a case where the *rule* consists of only disjunctive clauses, the follow-up answer sequence is ('No', . . . , 'No', 'Yes'), the answer to which is a 'Yes'. This indicates a high correlation between the final answer and the last answer of the history. We found that 74.6% of the instances in the train set with a 'Yes'/'No' answer have the same answer as that of the last follow-up question. Although this is reflective of real-world conversations, a model can do a good job on this task by exploiting just this pattern.

Pattern 2: Likelihood of asking a follow-up question decreases with number of turns: It is intuitive to expect that as the number of follow-up questions that have been asked increases, the likelihood of asking another follow-up question decreases (clauses are finite). Appendix A.1, contains an empirical study on the training data, and demonstrates the decrease in the probability of asking a follow-up question with the increase in the number of turns in the dialog history.

Pattern 3: Follow-up questions occur in the same sequence as the rule clauses in the passage: As discussed earlier, many of the rule clauses tend to be conjunctive/disjunctive. Thus, the next follow-up question that one needs to ask is not unique, since one can always consider any of the statements in the clause that has not been considered so far. However, the ground truth data considers these clauses in sequential order to generate the follow-up questions. Among all instances where a conjunctive/disjunctive clause can be discerned and have a follow-up question generated as a part of the ground truth, 62.8% satisfy the condition that the first clause that has not yet been asked is indeed the next follow-up question. We explain this pattern in detail and discuss how it affects computation of the BLEU metric in Appendix A.2.

Pattern 4: Answer as 'Irrelevant': Amongst the train instances where user background information and dialog history is empty, 66.67% have the final answer as *Irrelevant*.

2.1 A Simple Heuristics-based Program

To demonstrate the ease with which these patterns can be exploited by a model, we create a simple program that follows a set of hand-crafted rules. The program takes the following actions:

1. Answer 'Irrelevant': If the following conditions are jointly satisfied: a) no follow-up questions have been asked so far; b) the background information (scenario) is empty; c) there is low word overlap between the rule and the question; then the program answers *Irrelevant*.

2. Generate 'Follow-up Question': If the previous condition fails and the number of clauses in the rule are more than the number of follow-up questions asked, then a follow-up question is predicted, and the model asks the next clause in the rule text as a question by appending the words "*Are you*" in the beginning and a question mark at the end.

3. Answer with a 'Yes' or a 'No': If both the above scenarios are false, then the model response to the user question is the user's response to the last follow-up question.

3 Evaluation Metrics in ShARC

The following metrics are used in the evaluation of the ShARC task:

1. **Micro and Macro Accuracy:** At each turn, the model response is either a *Yes/No/Irrelevant* or a *follow-up* question. The micro and macro accuracy measures the ability of a model to correctly predict these four classes.
2. **BLEU:** This is used to assess the correctness of the follow-up question generated in case the model chooses to generate one.

Our experiments with the dataset suggest two weaknesses in the evaluation of follow-up questions which we discuss below.

1. Incomplete reference set: Recall that Pattern 3 suggests the existence of a sequential correlation between the rule clauses[1] in the rule text and the follow-up questions. This means that if an out of sequence follow-up question is generated by a model, then it is incorrectly penalized because the evaluation script expects the next follow-up question that would have occured in the original rule sequence. To mitigate this penalization, we create a list of alternative candidate references using the clauses in *conjunctive*-only or *disjunctive*-only instances in dataset. We make use of the standard implementation of BLEU which supports multiple references (Papineni et al., 2002). To generate multiple candidate references for the ShARC dataset, we identify instances which have a follow-up question as the gold answer and the follow-up question seems to be based on one of the clause statements in the rule text. We then create alternative follow-up questions from each of the clause statements which have not been a part of any follow-up question in the history. Please see Appendix A.3 for details about the algorithm to generate these alternative follow-ups. These alternative follow-up questions constitute a set of candidate questions. In the rest of the paper, we refer to this BLEU score computed using multiple references as *Multi-BLEU*, to distinguish it from the officially reported BLEU metric.

2. Improper Penalization for BLEU: As mentioned in the section 1, the official evaluation scripts do not penalize BLEU scores of a model if it does not predict a follow-up question, and rather predicts a final answer (*Yes/No* or *Irrelevant*). This is because it considers only those cases where both the ground-truth and the model predictions are *follow-ups*. A hypothetical model which classifies only 1 test instance as follow-up and produces it perfectly can get a BLEU score of 100 in this metric. We therefore update the evaluation script to penalize BLEU score in such cases, and refer to this as BLEU-P (BLEU-Penalized). This considers all instances where the ground truth is a follow-up question. We use the predicted response from the model as the answer to evaluate. This effectively counts a BLEU of 0 in almost all cases for these instances. When we use multiple references for computing BLEU, we refer to this as Multi-BLEU-P.

4 Evidence of Patterns

Table 1 and 2 report results of our experimental study, providing evidence to support the following: (a) The heuristics-based program has performance comparable to the state-of-the-art models. (b) The performance of models drops when they are trained on the original dev set and tested on the perturbed dev set that has diluted or reduced patterns, indicating a reliance on patterns (c) The official evaluation scripts do not penalize BLEU scores and do not consider other candidate answers in their calculations.

To prepare a perturbed dev set, we modify the official dev set by shuffling the dialog turns of the history of a conversation (We modify approximately 20% of the dev set. For more details, please refer to Appendix A.5). We refer to this set as the "History-Shuffled" dev set, a perturbation introduced by shuffling dialog history to dilute Patterns 1 & 3. Note that shuffling the dialog history introduces examples which are unlikely to occur in real conversations (Eg. Asking a follow-up question based on a set of conjunctive rule-clauses even though a user has already responded with a "No"). For model details, please refer to Section 6.

Using the evaluation metrics (micro and macro accuracy for turn level classification; and Multi-BLEU and Multi-BLEU-P for answer generation accuracy), we report the performance of the top two ranked models [2] (E3 (Zhong and Zettlemoyer,

E3	67.63	**73.79**	46.29	**54.64**	39.36
BiSon	65.95	70.79	46.62	54.06	14.25

Table 1: Models trained on the original ShARC training set and tested on the original dev set. The maximum score for every metric is highlighted in bold.

2019) and BiSon (Lawrence et al., 2019)), the BERT based model (BERT-QA (Devlin et al., 2019)) and our heuristic based model by training them on the official ShARC training set and evaluating them on the original and History-Shuffled dev sets. We use the code released by respective authors for E3 and BiSon. We also use the same hyperparameters as mentioned in the respective papers.

Weakness in Offical BLEU scores: In Table 1, the BLEU scores are lower than the Multi-BLEU scores, by an average of 16.03%. This is as expected since the official scripts do not account for valid alternatives and the gold answers have been generated in accordance with Pattern 3. Furthermore the models result in significantly lower BLEU scores on the Multi-BLEU-P metric as it penalizes models if they dont generate a follow-up question when they were supposed to. This suggests that the official scripts grossly over-estimate model performance (BiSon's actual Multi-BLEU-P is score is only 14.25). In the rest of the experiments we only report Multi-BLEU and Multi-BLEU-P scores.

Heuristic model and effect of Patterns: Tables 1 and 2 show that the heuristic-based model not only has comparable performance across all other models but also across both dev sets (original and History-Shuffled). If we look at the first two columns (micro and macro accuracy), all models tested on the History-Shuffled dev set report a drop in performance. The average drops in micro & macro accuracies are 8.16% and 5.3% respectively. While changes in performance are can be attributed to change in train and test distributions, the goal of this experiment is to demonstrate that all models are relying on a spurious pattern induced by the sequence of follow-up answers in dialog history. Thus, it is interesting to note that a dilution of just 20% of the patterns leads to a sizeable drop in performance.

5 Modified ShARC dataset

In an attempt to mitigate the effects of the patterns listed in section 2 and to reduce the sensitivity of neural models, we create a modified version of the ShARC dataset. For each occurence of an instance conforming to any of the patterns, we automatically construct alternatives where we choose to either *replace* the current instance with an alternative instance which does not exhibit the pattern; or *retain* the original instance. The alternative instances are generated using pattern-specific modifications. For example, we shuffle dialog history to reduce the effect of Patterns 1 & 3 (For more details, please see appendices A.4 and A.5). We individually modify both the official train and dev datasets and refer to them as `ShARC-Mod`.

5.1 Benchmarking Experiments

We train and evaluate all models using the ShARC-Mod train dataset and then test on ShARC-Mod dev set as well as the original dev set (containing all patterns) and the History-Shuffled dev set (con-

Table 5: Models trained using ShARC-Mod and evaluated on the History-Shuffled dev set

taining diluted patterns). Studying tables 3, 4 and 5 shows that all models perform consistently across all dev sets. This suggests that models that were earlier sensitive to perturbations now show consistent performance after being trained on a more robust data set. Note that, except for the heuristic model, this performance is indeed lower than what we had when trained on original data sets. This suggests that the neural models have been merely exploiting patterns in the training data and the performance sharply drops when these cues are absent from training data. The heuristic model has the same numbers as before. This is because the heuristic model is based on rules and is never actually trained. Its performance is indeed invariant to the training data.

6 Recommendations & Conclusion

In this paper we demonstrate how a popular Neural Conversational QA dataset inadvertently encodes patterns. We would like to emphasize that the patterns found, by their very nature, are likely to occur in real world tasks but the same patterns can also cause neural models to learn poorly. We release a modified version of this dataset and also improve evaluation criteria that better reflects model performance. We conclude the paper with a few recommendations for the community.

For Dataset creators: Patterns may exist in a real-world task and artificially introducing perturbations may be an easy way to help reduce their effects. This may result in 'unnatural' instances in the dataset but could help train better models.

For Model creators: (1) Model probing and experimenting with perturbed inputs can give deep insights about how a model is reasoning (2) Experimenting with adversarial inputs early on in the design process can help build better models.

A Appendix

A.1 Empirical Study for Pattern 2

Figure 2 plots the number of turns in an instance vs the probability of asking a follow-up question. It can be seen that with each response, the probability of asking another follow-up question decreases.

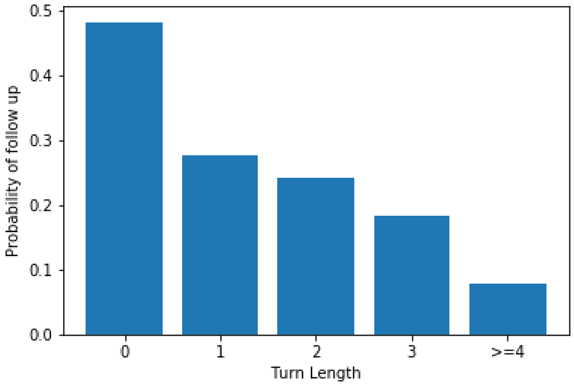

Figure 2: Probability of asking a follow-up question plotted against the number of turns in the instance.

A.2 Detailed explanation for Pattern 3

Due to the presence of conjunctive/disjunctive clause statements, it becomes ambiguous as to which one to consider for framing the next possible question. As an example, consider the instance described in Table 6. The gold answer is a followup question which was framed using the first clause statement. However, follow-up questions framed using any of the other clause statements in the rule such as "Is the item a lifeboat or an associated equipment, including fuel?", "Is it medicine or an ingredient for a medicine?", or "Is it a resuscitation training model?" would have been equally valid. We found that this is a common pattern found in the dataset. More generally, the gold follow-up answer tends to be framed using the first clause which has not been asked so far. To quantify this hypothesis, we followed these steps.

1. We filter the instances with a follow-up question as the gold answer and identify clause statements which start with an asterisk (*).

2. For each follow-up question in the history, we use the longest common substring (LCS) algorithm to compute an intersecting span with the rule text. We then identify the clause statements which intersect with this span.

3. We use the same process as above to find a matching clause statement for the follow-up question listed as the answer of the instance.

Amongst the instances identified, we found that 62.8% of them were such that the follow-up question in the answer (step 3) intersects with the first clause statement identified in step 1 that does not appear in the history of the instance.

In an attempt to break this pattern, we identify clause statements in the rule text in the same way as step 1 above and then shuffle them to create a new instance in `ShARC-Mod`.

Rule	## Items that qualify for the zero rate You may be able to apply zero VAT when you sell the following to an eligible charity: * equipment for making 'talking' books and newspapers * lifeboats and associated equipment, including fuel * medicine or ingredients for medicine * resuscitation training models
Scenario	I used to work for the company, but I quit last month.
Question	Can I apply zero VAT to this item?
History	
Answer	Is it equipment for making 'talking' books and newspapers?

Table 6: A sample instance from the dev set (utterance id: 0cdee38a5a9cbdda40849861c1edffc1432a3004)

A.3 Details on creating multiple references

We discuss the details on how we add additional gold references to the dev dataset. This augmentation only affects the instances which have a follow-up question as the gold answer. If the LCS of the gold answer with the rule text intersects with one of the clause statements (identified in step 1), we suspect that other clause statements might also have been one of the possible answers. So we first eliminate the clauses that have already been asked in the history, and again use LCS to find the best matching span for each follow-up question that has been asked in the history so far. If the intersection is with one of the clauses, we eliminate the same. The remaining clauses are then considered potential candidates for the next follow-up question to consider. To create a question from the clause statement, we use a simple heuristic as to finding the words preceeding and following the best match span for the gold answer. These words are then prefixed and suffixed with the other candidate clauses to form potential questions. Algorithm 1 describes this process in a formal manner. For more details, please refer to the accompanying repository.

On running this algorithm on the original dev dataset, we were able to add additional references in 183 out of the 2270 instances. It is interesting to

Algorithm 1: Adding additional references

```
for $inst \in \mathcal{D}$ do
    if $inst.answer$ is $follow\text{-}up$ then
        Let $\mathcal{C} = \{C_1, C_2, ...\}$ be the sequence of clause statements detected ($\mathcal{C} = \emptyset$ if no clause);
        $span \leftarrow$ LCS(inst.gold, inst.rule);
        if $\exists\ i$ such that $C_i \cap span \neq \emptyset$ then
            $\mathcal{C}_{\text{asked}} \leftarrow \{C_j : C_j \cap q \neq \emptyset$ for some $q$ in $inst.follow\text{-}ups\}$;

            $\mathcal{C}_{\text{candidates}} \leftarrow \mathcal{C} \setminus \mathcal{C}_{\text{asked}}$;
            for $c \in \mathcal{C}_{\text{candidates}}$ do
                Generate follow-up question from $c$ and use it as an additional reference;
            end
        end
    end
end
```

note that 96 out of the 183 instances had an empty history, and a follow-up question formed using any of the clause statements in the rule text could have been a valid answer. We also manually evaluate 10% of the generated references and find that barring a few that had minor tense related grammatical issues, all of them were semantically correct.

A.4 Algorithm for creating `ShARC-Mod`

To create our modified dataset, we perform different modifications depending on whether an instance has scenario or history. Listing 1 describes the algorithm to perform these modifications on an instance. More details can be found in the repository accompanying this paper.

A.5 Statistics on the modified datasets

In this section, we present some statistics on our modified datasets.

History-Shuffled dataset: For every instance in the original dataset having more than one questions in its *history*, we either retain or shuffle the order of questions, both with equal probability. This leads to a modification of 5512 out of 21890 instances in the training dataset and 468 out of 2270 instances in the dev dataset.

ShARC-Mod dataset: Using the algorithm in A.4, out of 21890 training instances, 3287 have the order of *history* shuffled, 3202 have the order of *rules* shuffled, and 2903 instances have both, *history* and *rule* shuffled. Moreover, 596 instances have a random *scenario* added to them. For the dev dataset, out of 2270 instances, 340 have the order of *history* shuffled, 316 have the order of *rules* shuffled, and 323 instances have both, *history* and *rule* shuffled. In this case, 66 instances have a random *scenario* added to them. More details are listed in Appendix A.4.

Counterfactual Generator: A Weakly-Supervised Method for Named Entity Recognition

Abstract

Past progress on neural models has proven that named entity recognition is no longer a problem if we have enough labeled data. However, collecting enough data and annotating them are labor-intensive, time-consuming, and expensive. In this paper, we decompose the sentence into two parts: entity and context, and rethink the relationship between them and model performance from a causal perspective. Based on this, we propose the Counterfactual Generator, which generates counterfactual examples by the interventions on the existing observational examples to enhance the original dataset. Experiments across three datasets show that our method improves the generalization ability of models under limited observational examples. Besides, we provide a theoretical foundation by using a structural causal model to explore the spurious correlations between input features and output labels. We investigate the causal effects of entity or context on model performance under both conditions: the non-augmented and the augmented. Interestingly, we find that the non-spurious correlations are more located in entity representation rather than context representation. As a result, our method eliminates part of the spurious correlations between context representation and output labels. The code is available at `https://github.com/xijiz/cfgen`.

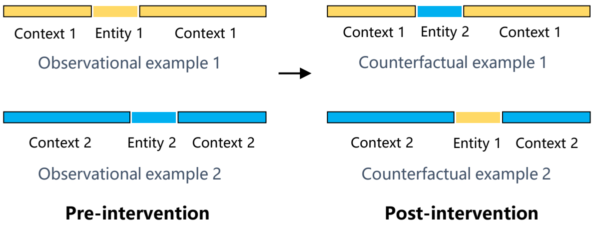

Figure 1: Interventions on observational examples of named entity recognition. More details can be found in Figure 3

1 Introduction

The natural language processing community has witnessed the paradigm shift from small data to big data, such as transformer (Vaswani et al., 2017) and its successors. It is not surprising that machine learning methods can easily surpass human performance if sufficient data is available (Wang et al., 2018). However, data acquisition is a challenging task for some special domains. For example, medical concept normalization, a basic subtask of named entity recognition (NER) in the medical area, has always been troubled by lack of enough Electronic Health Records due to the privacy protection. Small data with selection biases (Torralba and Efros, 2011) often induce the poor performance of machine learning models on inputs whose distribution is different from that of training data, which yet seems trivial to humans. The same issues are also mentioned in terms like *dataset bias*, *model robustness*, and *real understanding*. In natural language inference, models trained on hypotheses-only (vs hypotheses-premises) can outperform a majority-class baseline (Poliak et al., 2018; Gururangan et al., 2018). In reading comprehension, models trained on question-only or passage-only (vs question-passage) still achieve high accuracy (Kaushik and Lipton, 2018), models predicted on a broken question (vs original question) still make the same correct prediction (Feng et al., 2018a).

The key challenge behind this phenomenon is caused by spurious correlations of statistical learning. Spurious correlations can be vividly explained by an example in computer vision (Arjovsky et al., 2019): If we consider an image dataset of cows and camels in their natural habitat, a classifier

---

November 16–20, 2020.

trained on this dataset will establish spurious correlations between the output labels (cows, camels) and the landscape of the image (green pastures, deserts). As a result, an image of cows taken on sandy beaches makes the classifier make a wrong prediction. In this background, we could not help thinking that *is there any way to eliminate spurious correlations except more data annotated by humans?* From a causal perspective, spurious correlations are caused by confounding factors rather than a direct or indirect causal path. If we directly intervene on the precursor variable in spurious correlations to create counterfactual data, we can eliminate the impact of spurious correlations in models to a certain degree (Volodin et al., 2020).

In this paper, based on the above analysis, we mainly focus on exploring the spurious correlations in NER from a causal perspective. We decompose the sentence into two different parts: entity and context, and rethink the relationship between them and the generalization ability of the NER model. Considering the sentence "John lives in New York", we observe that the location entity "New York" and the context "John lives in" are highly correlated but are not causal to each other. In other words, we can intervene on the location entity to set it to another different location entity without destroying the sentence correctness at the grammatical level.

Therefore, we propose the **Counterfactual Generator**, which generates new counterfactual examples by the interventions on the existing observational examples. Our method requires neither an additional entity dictionary nor a similar domain dataset. Figure 1 demonstrates the intervention process for observational examples. We utilize new counterfactual examples to enhance the existing observational examples. Experiments show that our method improves the generalization ability under limited observational examples. Before the enhancement, we find that the model performance is mainly driven by entity representation. After the enhancement, the importance of entity representation increases in most cases, and generalization ability improves in all cases. We conclude that the non-spurious correlations between input features and output labels do locate in context representation (Lin et al., 2020), but the previous two phenomena show that they are more located in entity representation.

In summary, our work have the following contributions:

- We provide a theoretical foundation from a causal perspective to describe the mechanism of the NER model inference and explore the spurious correlations between input features and output labels.
- Based on the interventions on the entity, we propose a weakly-supervised method for named entity recognition under limited observational examples. Experiments across three NER datasets demonstrate that our method boosts model performance.

2 Counterfactual Generator

In this section, we firstly define the NER problem. Then, we present our method by introducing a structural causal model to describe the mechanism of the NER model inference.

2.1 Task Definition

In this paper, we regard named entity recognition as a sequence labeling problem. In general, we let $\mathbf{x} = (x_1, x_2, ..., x_n)$ to denote a sequence of tokens. For each token x_i, we have a label y_i where $y_i \in \mathcal{Y}$. For example, $\mathcal{Y}$ can be $\{O, \textit{B-Diagnosis}, \textit{I-Diagnosis}\}$ in the medical area. The possible labels come from *BIO* tagging schema for labeling tokens from the sentence. For each sentence, we have an entity set $\mathcal{E}$ that contains all entities in this sentence. Finally, we have a labeled dataset $\mathcal{D} = \{(x, y)\}$.

2.2 Causal Model

What determines a certain segment in a sentence to be an entity mention? Why is this entity mention to be a diagnosis entity? These are causal questions because they require some information about the generation process of the data rather than observational data alone (Pearl et al., 2009). Observational data with selection biases often gives rise to the problem of the spurious correlations that results in low generalization ability of the NER model under limited data. For this problem, causality can provide an in-depth view of its essence.

To investigate the causal relationship between the NER model and data clearly, we introduce a Structural Causal Model (SCM) (Judea, 2000) to describe the mechanism of the inference process of the NER model. SCM is expressed visually by using directed acyclic graphs (DAGs). In the graph, vertices are random variables, and directed edges represent direct causation from variable A

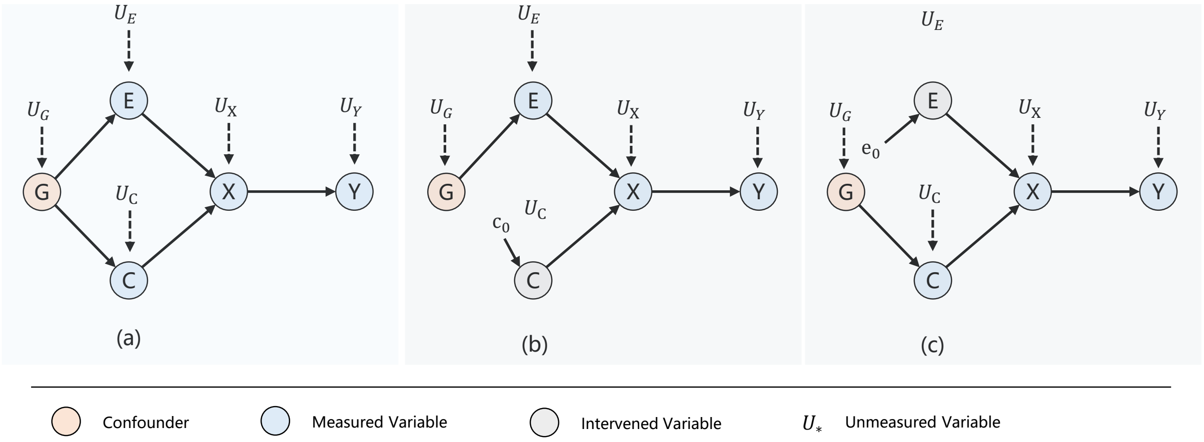

Figure 2: Structural Causal Models (SCMs) that describes the mechanism of the NER model inference. (a) Complete SCM without interventions. (b) Intervening on the variable *C* by the value c_0, denoted as $do(C = c_0)$. (c) Intervening on the variable *E* by the value e_0, denoted as $do(E = e_0)$.

to variable B. Here, for simplifying the problem, we decompose the sentence into the two variables: entity E and context C. As shown in Figure 2(a), we assume the following SCM:

$$\begin{aligned} g &:= f_G(U_G) \\ e &:= f_E(g, U_E) \\ c &:= f_C(g, U_C) \\ x &:= f_X(e, c, U_X) \\ y &:= f_Y(x, U_X) \end{aligned} \tag{1}$$

where G is a confounding variable that influences the generation of both entity E and context C, X is the input example that is generated by E and C, Y is the evaluation result (the $F1$ score) of the NER model, and U_* represents the unmeasured variable.

Causal effects help us better understand the causal relationship in a system. The basic method of estimating causal effects is simulating interventions in SCM. We use a mathematical operator $do(v_0)$ to simulate physical interventions by fixing the value of a variable v as v_0. For example, in order to simulate an intervention $do(c_0)$ in the structural causal model M, we fix the variable C to c_0 as shown in Figure 2(b), denoted as:

$$c := c_0 \tag{2}$$

This intervention blocks the influence of the variable G on the variable C. The post-intervention distribution $P(y|do(c_0))$ gives the proportion of individual that would attain response in level $Y = y$ under the hypothetical situation in which treatment $C = c_0$ is administered uniformly to the population (Pearl et al., 2009). Here, we have $P(y|do(c_0)) = 1$. More proof information can be found in the appendix.

A way to estimate the treatment effect or causal effect is to measure the average difference of the former distribution by using the expectation **E**, called Average Causal Effect (ACE), denoted as:

$$ACE_C = \mathbf{E}(y|do(c_0)) - \mathbf{E}(y|do(c)) \tag{3}$$

where c_0 and c are the intervened value and the original value. Similarly, in order to estimate the causal effects of the variable E on the variable Y, we can also intervene on the variable E, denoted as $do(e_0)$ (See Figure 2(c)).

2.3 Method

Our method tries to automatically replace an entity in an observational example with another different entity for creating a new counterfactual example. These counterfactual examples help our NER model deal with spurious correlations on limited observational examples and learn more invariant and stable features. As shown in Figure 3, our method mainly has the following three parts:

1) Set Preparation The core idea of our method is finding a different entity for intervening on an entity in the observational example. However, finding a new entity set in a specific domain needs human efforts to collect entities, which has no difference

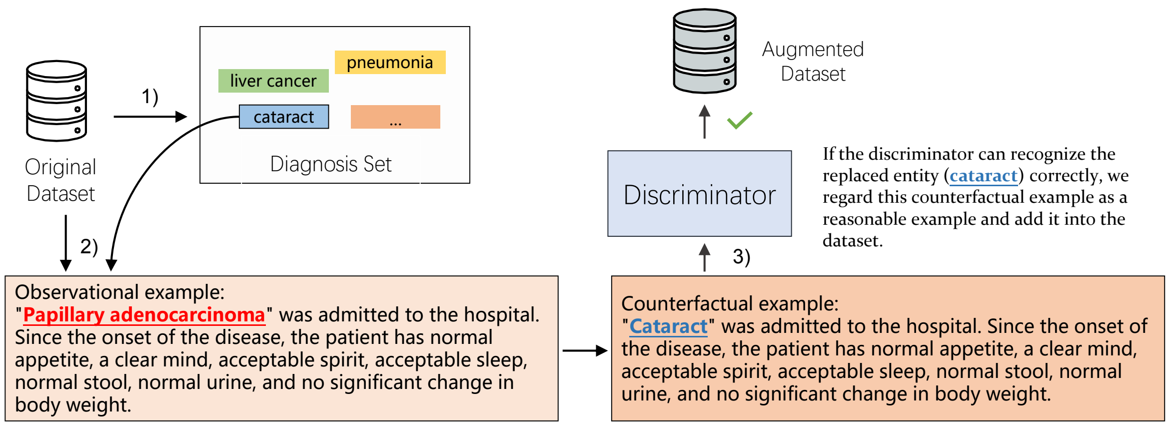

Figure 3: An example of the workflow of the Counterfactual Generator on the medical dataset. 1) We prepare the entity sets by the entity type (*diagnosis*) from the original dataset. 2) We randomly choose an entity (*papillary adenocarcinoma*) in the observational example and replace it with another different entity (*cataract*) from the entity set to form a new counterfactual example. It is noteworthy that the replaced entity and the candidate entity have the same entity type. 3) We send the counterfactual example to the discriminator for finding out the good one.

from annotating more data. Hence, as shown in Figure 3(1), we adopt local entities as the entity set, which is extracted from the original dataset. For example, we iterate all observational examples in the training dataset to collect all diagnoses to form a diagnosis set $\mathcal{E}_d$.

2) Entity Intervention We consider using the intervention on the entity to create new counterfactual examples. As shown in Figure 2(c) and Figure 3(2), for each observational example, we randomly select an entity $e \in \mathcal{E}$ with the entity type *diagnosis*, and replace it with another entity $e^{'} \in \mathcal{E}_d$. Importantly, in order to preserve the linguistic correctness of the new counterfactual example, we keep the replaced entity and the candidate entity have the same entity type.

3) Example Discrimination A key conflict is that not all counterfactual examples are correct or useful. We need a mechanism to discriminate which counterfactual example is good and make sure it does not bring in the noise. An intuitive solution is that we regard the NER model trained on the original dataset as the discriminator that provides well prior knowledge for inspecting our counterfactual examples. More specifically, as shown in Figure 3(3), the discriminator assists us to check whether the replaced entity is successfully predicted. If no, the counterfactual example will be discarded, otherwise, it will be outputted.

Dataset	Train	Dev	Test	Total
CNER	1322	164	164	1650
IDiag	9274	1157	1157	11588
CLUENER	9674	1208	1208	12090

Table 1: Statistics of datasets: CNER, IDiag, and CLUENER. All datasets are divided into three parts of *train set* (80%), *dev set* (10%), and *test set* (10%).

After executing all procedures, we have an augmented dataset that mixes observational examples and counterfactual examples. Afterwards, we can train the NER model on the augmented dataset.

3 Experiments

In this section, we mainly evaluate our method across three NER datasets, including two medical concept recognition datasets, and a conventional NER dataset.

3.1 Dataset

CNER[1] CNER is a Chinese clinical NER dataset in the CCKS-2019 challenge, including anatomy, disease, imaging examination, laboratory examination, drug, and operation. We extract 1650 available medical records from CNER, which contains entities of the disease type only.

IDiag For guaranteeing the diversity of the experimental data, we use Label Studio[2] to create

---

[1] http://www.ccks2019.cn/?page_id=62

[2] https://labelstud.io/

a new medical NER dataset. We collect 12127 health record images from the hospital, which are converted into text paragraphs by optical character recognition (OCR). We hire some people to annotate diagnoses in these text paragraphs. To ensure the high quality of the dataset, we removed 539 data examples in the final dataset. It is worth noting that the distribution of IDiag, compared to CNER, has a big difference due to error text recognition from OCR.

CLUENER (Xu et al., 2020) In addition to the medical NER datasets, we also use a conventional NER dataset CLUENER released by CLUE organization[3], which is a well-defined and fine-grained dataset for named entity recognition in Chinese, including 10 categories like *Person Name*, *Organzation*, *Book*, etc. We extract 12090 available instances from this dataset.

All datasets are separately divided into three portions of 80% D_1, 10% D_2 and 10% D_3. D_1 is used to train models. D_2 is used to tune hyperparameters. D_3 is used to test the model performance (See Table 1).

3.2 Models

We conduct our experiments by using the following two classic models: LSTMTagger (Chiu and Nichols, 2016) and BERTTagger (Devlin et al., 2019). Our LSTMTagger consists of a bidirectional LSTM for encoding the input example and a dense layer (Tagger) for tagging all tokens. Each token is embedded by the pretrained word embedding (Song et al., 2018). Similarly, our BERTTagger consists of a pretrained BERT for encoding the input example and a dense layer (Tagger) for tagging all tokens.

3.3 Setup

In our experiments, we evaluate our method in two settings: *NoAug* and *Aug*. *NoAug* represents we train our models on the original dataset. *Aug* represents we train our models on the augmented dataset. We also set up five groups of experiments for each dataset. In each group, we only select N (*100, 200, 300, 400, and 500*) data from the *train set* to train models for evaluating performance under limited observational examples. At the same time, we always keep the *dev set* and *test set* unchanged in all experiments.

Additionally, we also conduct another experiment to calculate ACE of entity E or context C on the model performance Y. We design a special token [EMPTY] to replace tokens in entity E and tokens in context C separately, which is viewed as interventions. Once a token is replaced with [EMPTY] in an input example, all dimensions of token embedding will be zero. There are two intervened schemes corresponding to Figure 2(b) and Figure 2 (c) respectively, denoted as:

- $do(e_0)$ Replacing all tokens in entities with [EMPTY] and keeping context unchanged.
- $do(c_0)$ Replacing all tokens in the input example with [EMPTY] except tokens in entities.

3.4 Metrics

3.4.1 NER Evaluation

In this work, we mainly consider the performance at the entity level, which means the ground truth and the result have the same entity type and overlap boundaries are just taken into account. Hence, we use the relaxed metrics (Chinchor and Sundheim, 1993): micro-average F1 score (*F1*), precision (*P*), and recall (*R*). Besides, we also use the micro-average *F1* score at the token level for the later causal analysis, which evaluates predictions only by tokens.

3.4.2 RI Index

We design an index to evaluate the Relative Importance (RI) between entity E and context C, denoted as:

$$RI = ACE_C - ACE_E \tag{4}$$

This index indicates that the higher the RI is, the more important the entity representation is during the process of the model inference. Otherwise, the representation of context is more important. For example, they have the same importance when $RI = 0$. We adopt two different ways (Entity Level and Token Level) to calculate the variable Y (the $F1$ score) for attaining both the coarse-grained and the fine-grained results.

3.5 Main Results

As we can see, table 2 shows the comparisons between *NoAug* and *Aug*. We can see that our method achieves a huge improvement in almost all settings. For CNER, our method achieves the best results and yields a boost of 8.68% on average. Even

Table 3: Average Causal Effect (ACE) of entity E or context C on the model performance Y. Entity Level and Token Level are two different evaluation methods for the NER model (See Section 3.4). ACE_C denotes the ACE when intervening on the variable C by c_0. ACE_E denotes the ACE when intervening on the variable E by e_0. The RI index denotes the difference between ACE_C and ACE_E, which indicates the relative importance between entity representation and context representation. The higher the RI index, the more important the entity representation is during the process of the model inference.

for IDiag that has much noise, our method still achieves a huge gain of +5.2% improvement on average. We notice that our method only achieves a boost of 4.43% on average for CLUENER. Compared to the former two datasets, the reason for a lesser performance boost is that CLUENER contains more entity types than CNER and IDiag (10 vs 1, 1).

Table 3 demonstrates the ACE results for different combinations between datasets, models, and evaluation ways in *test set* without augmentation. Interestingly, we check the RI index and observe that the importance of entity representation is always far greater than the importance of representation of context.

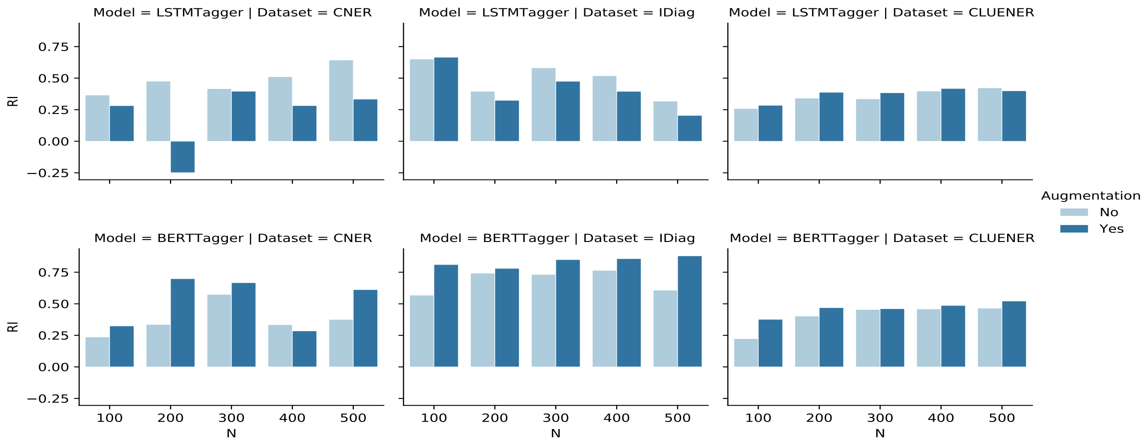

Figure 4: RI Index Changes between the non-augmented and the augmented. Different rows represent different models (LSTMTagger, BERTTagger); Different columns represent different datasets (CNER, IDiag, and CLUENER); N denotes the number of examples taken out from the *train set*.

4 Discussion

In this section, we will firstly review our previous results, and then try to answer some potential questions that others may ask for a deep understanding of our method. Secondly, we will provide some real counterfactual examples to vividly illustrate our method. Finally, some limitations of our method that we have found so far are presented to guide future research. We hope these limitations can help readers understand our method better.

4.1 Analysis

Our method achieves significant improvements across three datasets, but there are always a few mysteries that haunt us. **Q1**: *Do counterfactual examples change the causal effect between entity E and context C on model performance Y?* **Q2**: *Why does this simple method perform well on small training data?* **Q3**: *Are those counterfactual examples that were created out of air correct or reasonable?* A similar research also makes use of entity replacement to enhance the pretrained language model for improving zero-shot fact completion task. However, it considers the replaced entity as a negative sample (Xiong et al., 2020). **Q4**: *Why can making use of a counterfactual example as a positive sample here still improve performance?*

4.1.1 Answer for Q1

Since the RI index is huge under the circumstance that there is no data augmentation by using counterfactual examples, a question arises in our mind: how will the RI index change after using counterfactual examples to train NER model? Hence, we design another experiment to compare the RI changes between the non-augmented and the augmented. As shown in Figure 4, we observe that the RI index boosts in most cases after using counterfactual examples. Even for the RI index in those experimental groups which does not increase, it is almost always a positive number. Compared to context representation, entity representation dominates the performance of the NER model in most cases, especially for models based on BERT. This phenomenon suggests that the non-spurious correlations are more located in entity representation rather than context representation.

4.1.2 Answer for Q2

The essence of our method is forcing the disentanglement of entity E and context C in the input example, and to recombine them for generating new counterfactual examples. Before, we claim that the rationality of this operation is that entity and context are not a causal relationship. Our causal results show that the NER model will pay more attention to entities in the prediction process rather than context. Agarwal et al. also find that entity representation contributes more than context representation to system performance. Hence, to a certain extent, context representation may have more spurious correlations between the input features and output labels. The recombination of entity and context can increase the diversity of training

samples and eliminate the spurious correlations between variant features in context representation and output labels.

4.1.3 Answer for Q3&Q4

It would be interesting to ask a question: counterfactual examples have factual errors, and are they correct or reasonable? We have two answers from different views. On one hand, these counterfactual examples do have factual errors and are wrong. So we can regard the counterfactual example as a negative sample for improving the model performance at high-level tasks, such as semantic level or factual level (Xiong et al., 2020). On the other hand, these counterfactual examples are reasonable for named entity recognition because the task only focuses on better finding out entities and ignores the factual information. More importantly, our method preserves the linguistic correctness of the counterfactual example since the replaced entity and the candidate entity have the same entity type. These are the deep reason why the generalization ability of the NER model gets better after we treat the counterfactual example as a positive sample.

4.2 Case Study

As shown in Figure 5, we illustrate counterfactual generation and entity recognition, using the model LSTMTagger trained on the dataset CNER with training sample size $N = 200$.

When the original SCENE entity *Mt. Rainier National Park* is replaced by the other two SCENE entity, *Fraser Island* and *Kiyomizu Temple*, the discriminator judges the first counterfactual example to be reasonable, while the second is unreasonable. The second counterfactual example violates common sense because there are no canyons or colorful flowers all over the mountains in the temple. The real examples mean that our discriminator is able to filter out some extreme unreasonable counterfactual examples, and preserve some reasonable counterfactual examples that may appear in the real world.

Surprisingly, we can see the NER model augmented with counterfactual examples outperforms the NER model trained with only observational examples. Due to the help of the counterfactual example, *"Fraser Island has very complete roads and service facilities, allowing you to see the turquoise waters under the deep canyons and the colorful wildflowers all over the mountains."*, the NER model with counterfactual data augmentation can recognize all island entities with type SCENE, while the model without augmentation can not recognize these entities.

This illustration shows that our method can break the entanglement of the spurious features and the non-spurious features in the input example in the setting of limited observational examples.

4.3 Limitations

Although experimental results have shown the effectiveness of our method, our method can be further improved in terms of obtaining the most reasonable counterfactual examples. The capability of current discriminator is limited and the number of counterfactual examples regarded reasonable is large, which is not allowed especially for the large train set ($N > 500$). Although these examples increase the diversity of the combination between the entity and the context from the existing observational examples, there are lots of repeated text fragments in these examples. As far as we know, too many repeated text fragments would cause the CRF layer not to converge.

5 Related Works

We introduce the related works from two aspects:

Data Modification and Causality Recently, there is an increasing number of research works about data modification for providing the interpretability of neural models. For example, Feng et al. and Gururangan et al. reveal that neural models are overconfident in their predictions by reducing words or sentences; Ebrahimi et al. also find that adversarial examples generated by some manipulations at a character-level or a word-level can trick neural classifier. Additionally, considerable attention has been paid to utilize data modification for augmenting dataset or providing a supervised signal in the training process. For example, a rule-based data augmentation protocol has been proposed to provide a compositional inductive bias (Andreas, 2020); Kaushik et al. create new counterfactual sentences by modifying the original sentence for ameliorating the harm of spurious correlations; Xiong et al. introduce the type-constrained entity replacements to provide extra training signal for learning better factual knowledge. Interestingly, the above two points about data modification have high connections with causal inference because we can regard data modification as an intervention (Pearl et al., 2016) from a causal perspective. For instance, Ilse et al. provide a theoretical foundation from a causal perspective for explaining current data augmentation in computer vision. Kaushik et al. investigate the spurious correlations in two tasks: sentiment analysis and natural language inference.

Named Entity Recognition In this paragraph, we mainly focus on named entity recognition with limited supervision. One way to train the NER model with low-resource is dictionary-based distantly supervision (Fries et al., 2017; Shang et al., 2018; Yang et al., 2018; Liu et al., 2019) which builds a dictionary of entities for creating training data without too much effort. Few-shot learning is another promising way for training the NER model under limited supervision by transferring prior knowledge of the source domain to a new domain (Fritzler et al., 2019; Hou et al., 2019). There are also some works that focus on redefining NER as a different problem for reducing the need of hand-labeled training data. For example, Linking Rules (Safranchik et al., 2020) based on votes recognize entities through whether adjacent elements in a sequence belong to the same class; Lin et al. propose a new effective proxy of human explanation, "entity triggers", for encouraging label-efficient learning of NER models.

6 Conclusion

In this paper, we propose a weakly-supervised method from a causal perspective and provide the interpretability of our method with the structural causal model. Our method improves generalization ability under limited observational examples. Our causal experiments suggest the spurious correlations are more located in entity representation rather than context representation. Importantly, our method eliminates part of the spurious correlations between input features and output labels.

A Appendix

A.1 Proof of the Post-intervention Distribution

In this section, we give the proof of the post-intervention distribution $P(y|do(c_0)) = 1$.

Firstly, we review the definition of the structural causal model (SCM) (See Figure 2(a)):

$$\begin{aligned} e &:= f_E(g) \\ c &:= f_C(g) \\ x &:= f_X(e, c) \\ y &:= f_Y(x) \end{aligned} \tag{5}$$

where G is a confounding variable that influences the generation of both entity E and context C, X is the input example that is generated by E and C, and Y is the evaluation result (the $F1$ score) of the NER model. For clarity, we omit the unmeasured variables.

We use a mathematical operator $do(c_0)$ to simulates physical interventions by fixing the value of the variable c as c_0 (See Figure 2(b)). The post-intervention distribution $P(y|do(c_0))$ gives the proportion of individual that would attain response in level $Y = y$ under the hypothetical situation in which treatment $C = c_0$ is administered uniformly to the population. In order to calculate $P(y|do(c_0))$, based on Bayes' rule, we have

$$\begin{aligned} P(y|do(c_0)) &= \sum_x P(y|do(c_0), x) P(x|do(c_0)) \\ &= \sum_x P(y|do(x_0)) P(x|do(c_0)) \end{aligned} \tag{6}$$

For gauging the effect of context C on the input example X, we need to calculate $P(x|do(c_0))$. However, there is a confounding variable G affects both entity E and context C. Fortunately, the variable E meets the backdoor criterion, and blocks the backdoor path $C \leftarrow G \rightarrow E \rightarrow X$. Using the adjustment formula, we have

$$P(x|do(c_0)) = \sum_e P(x|c_0, e) P(e) \tag{7}$$

In such condition, we have $P(e) = 1$ because our entity $E = e$ is unchanged and unique for each input example. Besides, we also have $P(x|do(c_0)) = 1$ though our input example $X = x$ is changed but unique. Therefore, we have $P(y|do(c_0)) = 1$ due to the certainty of the NER model for an input example. Similarly, as shown in Figure 2(c), we can also intervene on the variable E, denoted as $do(e_0)$ and have the same post-intervention distribution $P(y|do(e_0)) = 1$.

Understanding Procedural Text using Interactive Entity Networks

Abstract

The task of procedural text comprehension aims to understand the dynamic nature of entities/objects in a process. Here, the key is to track how the entities interact with each other and how their states are changing along the procedure. Recent efforts have made great progress to track multiple entities in a procedural text, but usually treat each entity separately and ignore the fact that there are often multiple entities interacting with each other during one process, some of which are even explicitly mentioned. In this paper, we propose a novel Interactive Entity Network (IEN), which is a recurrent network with memory equipped cells for state tracking. In each IEN cell, we maintain different attention matrices through specific memories to model different types of entity interactions. Importantly, we can update these memories in a sequential manner so as to explore the causal relationship between entity actions and subsequent state changes. We evaluate our model on a benchmark dataset, and the results show that IEN outperforms state-of-the-art models by precisely capturing the interactions of multiple entities and explicitly leverage the relationship between entity interactions and subsequent state changes. Our code is available at: `https://github.com/esddse/IEN`.

1 Introduction

Procedural texts, e.g., scientific articles, instruction books, or recipes, are widely spread and useful. Entity state tracking is the key task for procedural text comprehension. Usually, an entity could have several targets (e.g., existence, location) to be tracked, and the system needs to predict the target changes of each entity involved in the process. State tracking is challenging because of the dynamic nature, the involvement of multiple entities, and the complexity of tracking targets.

Most recent approaches often use an RNN-based method to model the state changes across the process in an entity-by-entity manner, and use different classifiers for different targets (Dalvi et al., 2018; Tandon et al., 2018; Gupta and Durrett, 2019).

While these models can learn to leverage either local or global information and make state predictions to one entity with fair accuracy, they ignore the fact that there are often multiple entities interacting with each other during the procedure. Here is an example that describes a chemical transformation step in the photosynthesis process:

> The water breaks into oxygen, hydrogen, and electrons.

To perfectly capture this chemical conversion in the process, ”entity-by-entity” systems need to separately find out that water is destroyed at this step, oxygen is created, hydrogen is created, and electrons are created at the same step, respectively. It is easy to see that if the system ignores the interactions among multiple entities, it will be prone to misunderstanding the role of different entities in the conversion, and consequently make similar state prediction for water as the other entities, although they are opposite in fact.

Another challenge is how to properly capture the relationship between entity interactions and their state changes. For example, consider the following steps in blood circulation:

> Blood travels to the lungs.
> Carbon dioxide is removed from the blood.
> Oxygen is added to your blood.

In order to figure out where the carbon dioxide is after the second sentence, humans may first want to see what role the carbon dioxide acts in that sentence, and quickly find that carbon dioxide is

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7281–7290,
November 16–20, 2020.

just taken away from the blood thus impossible to be in the blood. Furthermore if we look back to the first sentence, we can finally get the right answer, lung. This tells us that an entity's location is closely related or even determined by the most recent event it involves in. However, current systems either model a general state of an entity regardless of specific tracking targets (Dalvi et al., 2018), or model different tracking targets (e.g., action, location) completely separately (Gupta and Durrett, 2019), without considering the relationship between different tracking targets.

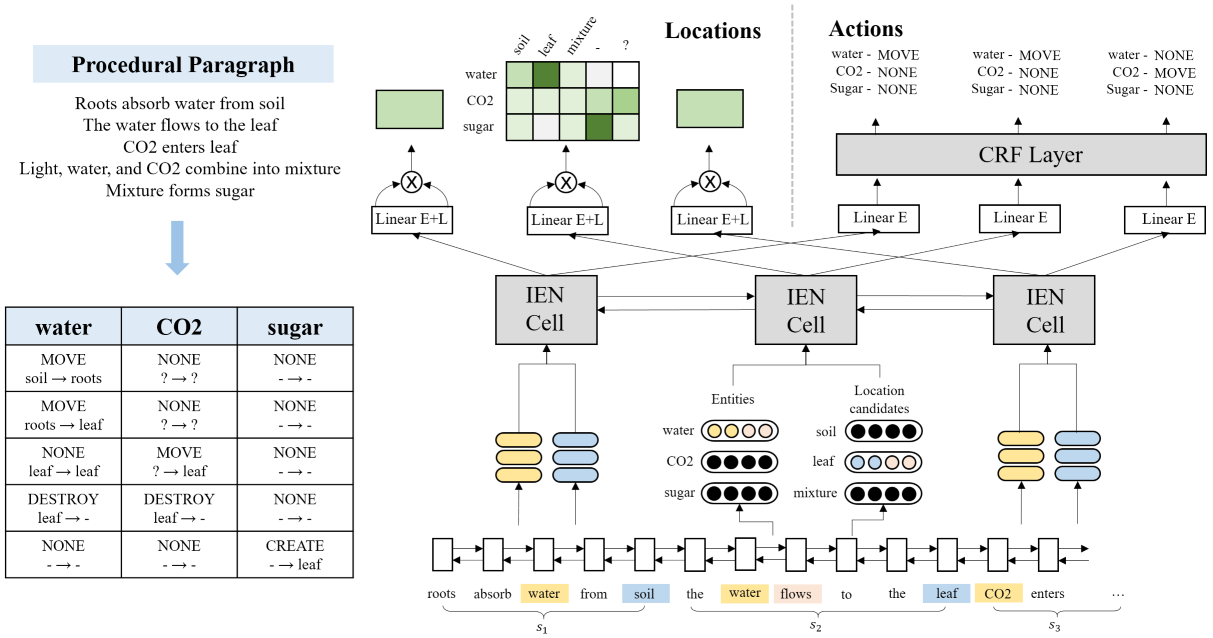
In this work, we focus on the scientific process understanding task (Dalvi et al., 2018), in which the tracking targets are action and location of entities. We propose a novel Interactive Entity Network, IEN, that explicitly models the interactions among multiple entities and explores the relationship between an entity's action and its location. IEN is a two-layer RNN model, the bottom RNN encodes word-level information, and the upper RNN encodes the sentence-level information while keeping tracking entities' states. Specifically, we design a new RNN cell, the IEN cell, for the upper RNN, which contains two types of memory slots, entity slots, and location slots, for recording the states of all entities and location candidates, respectively. To track the state changes, all memory slots will be updated at each time step. We use two attention modules to model entity-entity interaction and location-entity interaction, respectively, thus each entity/location slot is able to obtain information from other entities before updating. To model the causal relationship between different tracking targets, we arrange the entity updating module to precede the location updating module in a sequential manner. In this way, we can use the action-aware entity information to update the location slots. We evaluate IEN on ProPara, and the results show that our model can effectively model the interaction among multiple entities and leverage the causal relationship between entity actions and locations, thus outperforms existing systems.

Our contributions are in two-fold: 1) We propose a new model, IEN, and design a new recurrent unit that explicitly models the interactions among multiple entities and leverages the causal relationship between entity actions and their subsequent state changes. 2) We conduct intensive experiments to show how our IEN learns to encourage the synergy among different entities involved in one event, and explain how multiple tracking targets can be properly leveraged to improve context reasoning.

2 Related Work

Recently, many procedural text comprehension datasets are constructed and relesed to prompt the research in this direction. **bAbI** (Weston et al., 2015) is a QA dataset that the questions are about movements of entities, however it is synthetically generated and the language expression is relatively simple. **RECIPES** (Kiddon et al., 2015) dataset introduces the task of predicting the locations of cooking ingredients. **ProPara** (Dalvi et al., 2018) includes scientific procedural paragraphs, and the task is to predict the entities' actions and locations. In this paper, we continue this line of exploration using ProPara.

The solutions are mainly RNN based or memory network based. Most early models are designed for QA task, e.g., bAbI, and thus researchers pay more attention to question processing. **EntNet** (Henaff et al., 2016) uses dynamic memories to maintain entity states, with a gated update at each step. These states are decoded to answer questions after each sentence is read. **QRN** (Seo et al., 2016) is an RNN-based model. Given a question, QRN recurrently reduces the original query to a more informed query as it observes each context sentence through time. More recently, ProPara becomes the popular testbed and methods on ProPara focus more on state tracking. **ProLocal** (Dalvi et al., 2018) locally predicts the state changes described in each individual sentence. **ProGlobal** (Dalvi et al., 2018) considers the entire paragraph while predicting states for an entity. As the whole context is incorporated, more state changes are captured, and result in a higher recall. However, this may lead to over-prediction. To address these problems, several models are proposed to incorporate different constraints. **ProStruct** (Tandon et al., 2018) reformulate the procedural text comprehension task as a structured prediction task, and incorporates a set of commonsense constraints for globally consistent predictions. **LACE** (Du et al., 2019) leverages label consistency among different paragraphs on the same topic during training. **NCET** (Gupta and Durrett, 2019) uses a neural CRF to explicitly capture the constrains. Other interesting attempts include **KG-MRC** (Das et al., 2018), which constructs dynamic bipartite graphs from the procedural text, and updates the graphs



Procedural Paragraph

Roots absorb water from soil
The water flows to the leaf
CO2 enters leaf
Light, water, and CO2 combine into mixture
Mixture forms sugar

water	CO2	sugar
MOVE soil → roots	NONE ? → ?	NONE - → -
MOVE roots → leaf	NONE ? → ?	NONE - → -
NONE leaf → leaf	MOVE ? → leaf	NONE - → -
DESTROY leaf → -	DESTROY leaf → -	NONE - → -
NONE - → -	NONE - → -	CREATE - → leaf

Figure 1: The left is an example of the procedural text comprehension task and ProPara dataset. The paragraph describes the process of photosynthesis in five sentences, and the system needs to track the actions and locations of the three entities listed below, water, CO2, and sugar. The right is the architecture of IEN.

recurrently at each step.

3 Task Formulation

In this paper, we focus on the task of tracking multiple entities' states in scientific procedural text. Formally, given:

- A paragraph of procedural text $S = \{s_t\}_{t=1}^{T}$, consisting of T sentences, which describes a process about a given topic (e.g., photosynthesis, fossil formation) in detailed steps, with multiple entities involved.
- A set of entities $E = \{e_i\}_{i=1}^{n}$, representing the entities mentioned in S that need to be tracked.
- A set of tracking targets $P = \{p_j\}_{j=1}^{k}$. Each p_j is a specific property of an entity, e.g., existence or location, and each can have limited or infinite numbers of values.

The state tracking task is to predict the states of each entity e_i after reading each sentence s_t, where an entity's state is a value of a property p_j. For example, after reading *CO2 enters leaf*, the system should predict that the existence of CO2 is true, and the location of CO2 is *leaf*.

We use the ProPara dataset (Dalvi et al., 2018) for experiments. ProPara contains 488 procedural texts, 391 for training, 43 for development and 54 for testing. Each paragraph describes a particular scientific process. There are in total 3302 sentences, and 6.77 sentences per paragraph. On average, each paragraph contains 3.92 entities. The dataset tracks two types of entity property, action and location. For action, the model needs to determine which of the following actions the entity performed in the sentence: (1) CREATE, the entity is created at this step. (2) DESTROY, the entity is destroyed at this step. (3) MOVE, the entity is moved from one location to another. (4) NONE, none of above. For location, the model needs to determine where the entity locates before and after one sentence. The location could be any arbitrary span in the paragraph and needs to be extracted. There are two special locations: ”-” denotes non-existence and ”?” denotes unknown location. Figure 1 gives an example of ProPara dataset.

4 Methods

Our complete approach consists of 3 stages: 1) Preprocessing: we use off-the-shelf NLP tools to prepare the neural network inputs, including entity recognition and location candidates generation. 2) Main Model: we use Interactive Entity Network to predict all entities' actions and locations sequentially. 3) Postprocessing: we use human-written rules to revise some of the predictions to keep com-

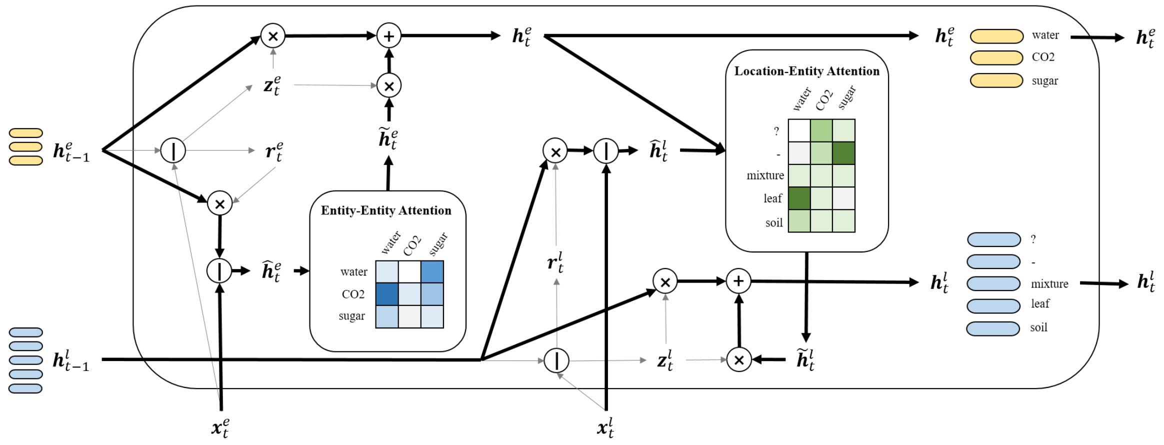


Figure 2: The structure of an IEN cell. The thick arrows indicate the directions of data flow.

monsense consistency.

4.1 Preprocessing

We use NLTK [1] and Stanford CoreNLP (Manning et al., 2014) for lemmatization and POS tagging. For entity recognition, we just use the simple string matching algorithm. Unlike entities, location information in this task is not given initially. To predict the entities' location, there are mainly two approaches. One is to view this problem as a SQuAD-style QA task(Rajpurkar et al., 2016), and to find a location span sentence by sentence from the paragraph, e.g., ProLocal (Dalvi et al., 2018) or KG-MRC (Das et al., 2018). The other approach is to first dig out all possible location candidates during preprocessing, and then use a classifier to select one candidate as the best location at each step, e.g., NCET (Gupta and Durrett, 2019). We use the latter paradigm and collect the location candidate set $L = \{l_j\}_{j=1}^{m}$ by gathering all nouns and noun phrases. This strategy has a 86.75% recall rate on the training set.

4.2 Interactive Entity Networks

We design a new model, Interactive Entity Network (IEN), to characterize the process with multiple entities involved. Figure 1 shows the architecture of our model. IEN consists of three levels. The bottom is for word-level language comprehension, which encodes words to distributed vectors. The middle is for sentence-level process understanding, which conducts entity state tracking. At the top, we use different classifiers to predict entities' actions and locations, respectively.

Word-Level Encoding Given a procedural text, our model first encodes each word w_i in the paragraph to a vector $\boldsymbol{w}_i = [\mathrm{emb}(w_i); v_i]$. Here, $\mathrm{emb}(w_i)$ is an embedding function, and we use fastText (Bojanowski et al., 2017) and ELMo (Peters et al., 2018) for experiments. v_i is a scalar binary indicator for identifying whether w_i is a verb. Then we use a BiLSTM (Hochreiter and Schmidhuber, 1997) over the whole paragraph for contextual encoding. We denote $\boldsymbol{u}_i = \mathrm{BiLSTM}([\boldsymbol{w}_i])$ as the output of BiLSTM with respect to word w_i.

Sentence-Level Encoding and IEN cell To track the state changes, we extract sentence features from word-level encodings by running another RNN at the sentence level. In order to take entity interactions into consideration, we propose a novel IEN cell that leverages attention mechanisms to help entities or locations get information from each other.

The inputs to an IEN cell include the representations of all entities and all location candidates in a single sentence s_t, or a mask vector if the entity or location candidate is not in s_t. Formally, let $\boldsymbol{x}_t^{e_i} \in \mathbb{R}^d$ denote the representation of entity e_i in sentence s_t, $\boldsymbol{x}_t^{l_j} \in \mathbb{R}^d$ denote the representation of location candidate l_j in sentence s_t. Then,

$$\boldsymbol{x}_t^{e_i} = \begin{cases} [\boldsymbol{u}_t^{e_i}; \boldsymbol{u}_t^{v}], & \text{if} \quad e_i \in s_t \\ \mathbf{0}, & \quad \text{otherwise} \end{cases} \tag{1}$$

$$\boldsymbol{x}_t^{l_j} = \begin{cases} [\boldsymbol{u}_t^{l_j}; \boldsymbol{u}_t^{v}], & \text{if} \quad l_j \in s_t \\ \mathbf{0}, & \quad \text{otherwise} \end{cases} \tag{2}$$

where $\boldsymbol{u}_t^e$, $\boldsymbol{u}_t^l$ and $\boldsymbol{u}_t^v$ denote the contextual encodings of the entity, location candidate and the

---

[1] http://www.nltk.org/

predicate verb, respectively. If the entity or location candidate consists of multiple words, mean pooling over the word representations is used. We stack all the entity representations together to get $\boldsymbol{x}_t^e \in \mathbb{R}^{n \times d}$, and similarly get $\boldsymbol{x}_t^l \in \mathbb{R}^{m \times d}$. $\boldsymbol{x}_t^e$ and $\boldsymbol{x}_t^l$ are the inputs to the tth IEN cell.

Inspired by GRU (Chung et al., 2014) and key-value memory networks (Miller et al., 2016), we place memory slots inside IEN cells and let them recurrently update as GRU. In each IEN cell, there are n entity slots and m location slots, corresponding to the given entity set E and the extracted location candidate set L, respectively. Each memory slot represents the state of a specific entity or a location candidate. We use $\boldsymbol{h}_t^e \in \mathbb{R}^{n \times d}$ to represent all the entity memory slots in the tth IEN cell, and use $\boldsymbol{h}_t^l \in \mathbb{R}^{m \times d}$ to represent all the location memory slots in the tth IEN cell. The detailed structure of an IEN cell is shown in Figure 2.

First, we update the entity memory slots as follows:

$$\boldsymbol{z}_t^e = \sigma([\boldsymbol{h}_{t-1}^e; \boldsymbol{x}_t^e] \cdot \boldsymbol{W}_z^e) \tag{3}$$

$$\boldsymbol{r}_t^e = \sigma([\boldsymbol{h}_{t-1}^e; \boldsymbol{x}_t^e] \cdot \boldsymbol{W}_r^e) \tag{4}$$

$$\hat{\boldsymbol{h}}_t^e = [\boldsymbol{r}_t^e \odot \boldsymbol{h}_{t-1}^e; \boldsymbol{x}_t^e] \tag{5}$$

$$\tilde{\boldsymbol{h}}_t^e = \tanh(\mathrm{Att}(\hat{\boldsymbol{h}}_t^e, \hat{\boldsymbol{h}}_t^e, \hat{\boldsymbol{h}}_t^e) \cdot \boldsymbol{W}^e) \tag{6}$$

$$\boldsymbol{h}_t^e = (1 - \boldsymbol{z}_t^e) \odot \boldsymbol{h}_{t-1}^e + \boldsymbol{z}_t^e \odot \tilde{\boldsymbol{h}}_t^e \tag{7}$$

where $\odot$ represents element-wise multiplication. $\boldsymbol{W}_z^e \in \mathbb{R}^{2d \times d}$, $\boldsymbol{W}_r^e \in \mathbb{R}^{2d \times d}$ and $\boldsymbol{W}^e \in \mathbb{R}^{d \times d}$ are trainable parameters. Att is a scaled key-value attention function (Vaswani et al., 2017), defined as:

$$\mathrm{Att}(\boldsymbol{q}, \boldsymbol{k}, \boldsymbol{v}) = \mathrm{Softmax}(\frac{(\boldsymbol{q}\boldsymbol{W}^q)(\boldsymbol{k}\boldsymbol{W}^k)^T}{\sqrt{d_a}})(\boldsymbol{v}\boldsymbol{W}^v) \tag{8}$$

where $\boldsymbol{W}^q \in \mathbb{R}^{d \times d_a}$, $\boldsymbol{W}^k \in \mathbb{R}^{d \times d_a}$ and $\boldsymbol{W}^v \in \mathbb{R}^{d \times d_a}$ are trainable parameters.

Then we update the location slots similarly:

$$\boldsymbol{z}_t^l = \sigma([\boldsymbol{h}_{t-1}^l; \boldsymbol{x}_t^l] \cdot \boldsymbol{W}_z^l) \tag{9}$$

$$\boldsymbol{r}_t^l = \sigma([\boldsymbol{h}_{t-1}^l; \boldsymbol{x}_t^l] \cdot \boldsymbol{W}_r^l) \tag{10}$$

$$\hat{\boldsymbol{h}}_t^l = [\boldsymbol{r}_t^l \odot \boldsymbol{h}_{t-1}^l; \boldsymbol{x}_t^l] \tag{11}$$

$$\tilde{\boldsymbol{h}}_t^l = \tanh(\mathrm{Att}(\hat{\boldsymbol{h}}_t^l, \boldsymbol{h}_t^e, \boldsymbol{h}_t^e) \cdot \boldsymbol{W}^l) \tag{12}$$

$$\boldsymbol{h}_t^l = (1 - \boldsymbol{z}_t^l) \odot \boldsymbol{h}_{t-1}^l + \boldsymbol{z}_t^l \odot \tilde{\boldsymbol{h}}_t^l \tag{13}$$

where $\boldsymbol{W}_z^l \in \mathbb{R}^{2d \times d}$, $\boldsymbol{W}_r^l \in \mathbb{R}^{2d \times d}$ and $\boldsymbol{W}^l \in \mathbb{R}^{d \times d}$ are trainable parameters. We initialize $\boldsymbol{h}_0^e$ and $\boldsymbol{h}_0^l$ using zero matrices.

The two key steps are Eq 6 and Eq 12. We use key-value attention to explicitly model the entity-entity interactions and the location-entity interactions. According to our intuition that an entity location is closely related by its most recent action, in Eq 12, we use $\boldsymbol{h}_t^e$, the newly-updated entity representation, as the input to the location-entity attention.

The newly updated entity and location representations $\boldsymbol{h}_t^e$ and $\boldsymbol{h}_t^l$ are then sent to different classifiers to predict the actions and locations, respectively, at this timestep.

Output 1: Entity Actions Following NCET (Gupta and Durrett, 2019), We use CRF to model the dependency of actions. We use $\boldsymbol{h}_t^{e_i}$, which is the ith row of $\boldsymbol{h}_t^e$, to generate emission potentials for each action tag y_t at each time step t with respect to entity e_i:

$$\phi(y_t, t, e_i) = \boldsymbol{h}_t^e \cdot \boldsymbol{H} \tag{14}$$

where $\boldsymbol{H} \in \mathbb{R}^{d \times 1}$ is a trainable matrix. Additionally, we train a transition matrix to get the transition potentials among the 4 action tags and two extra tags (”START” and ”END”) which we denote by $\psi(y_{t-1}, y_t)$. Finally for an action sequence $\boldsymbol{y}$, we get the probability as:

$$P(\boldsymbol{y}|e_i) \propto \exp(\sum_{t=0}^{T} \phi(y_t, t, e_i) + \psi(y_{t-1}, y_t)) \tag{15}$$

Output 2: Entity Locations To get the probability that entity e_i at location l_i at step t, we simply compute the probability matrix as follows:

$$\boldsymbol{M}_t = \mathrm{Softmax}((\boldsymbol{h}_t^e \boldsymbol{U}) \cdot (\boldsymbol{l}_t^e \boldsymbol{V})^T) \tag{16}$$

where $\boldsymbol{U} \in \mathbb{R}^{d \times d}$, $\boldsymbol{V} \in \mathbb{R}^{d \times d}$ are trainable parameter matrices. And the probability $P(e_i, l_j)$ is the element at the ith row and jth column of $\boldsymbol{M}_t$.

Training and Loss Function We jointly train the action prediction task and location prediction task, and the objective is to minimize the sum of their log likelihood losses. For each training step, we only use one paragraph. We use Adam (Kingma and Ba, 2014) with learning rate 0.0002 for training.

4.3 Postprocessing

Following previous conventions (Dalvi et al., 2018) to make the predictions consistent with commonsense (e.g., an entity cannot be destroyed if it is

not exist), we apply two kinds of rules to the predictions: 1) correct invalid actions according to the whole action sequence, and 2) locally correct the locations according to the corresponding actions.

5 Experiments

We evaluate our model on the two comprehension tasks of ProPara dataset using the official evaluator[2], and compare against competitive systems on the official leaderboard[3].

5.1 Evaluation Metrics

Document Level (Tandon et al., 2018) Given the predictions of a paragraph, the document level evaluation is to answer four templated questions, whose answers are deterministically computed from the predictions:

Q1: What are the inputs to the process?

Q2: What are the outputs of the process?

Q3: What conversions occur, when and where?

Q4: What movements occur, when and where?

Inputs are entities that exist at the start of the process, but not at the end. Outputs are entities that do not exist at the start, but do at the end. A conversion is when some entities are destroyed and others created. A movement is an event where an entity changes its location. For each paragraph, the evaluator compute a F1 score for each question, and the overall F1 score is the macro-average of the four questions.

Sentence Level (Dalvi et al., 2018) Given the predictions of an entity e in a paragraph, the sentence level task aims to answer 10 fine grained sentence level templated questions, which can be summarized into 3 categories:

Cat-1: Is e Created (Moved, Destroyed) in the process?

Cat-2: When was e Created (Moved, Destroyed)?

Cat-3: Where was e Created (Moved from/to, Destroyed)?

The evaluator automatically extracts the answer from the predictions and compute the accuracy for each question. Each category's accuracy is the macro-average of the containing questions, and the overall macro-average is the mean of the three categories' accuracy.

In this paper, we particularly concern about the ability of modeling entity interaction in event granularity (e.g., a conversion, which often contains more than one entities), and thus give more detailed results and analysis on document level evaluation.

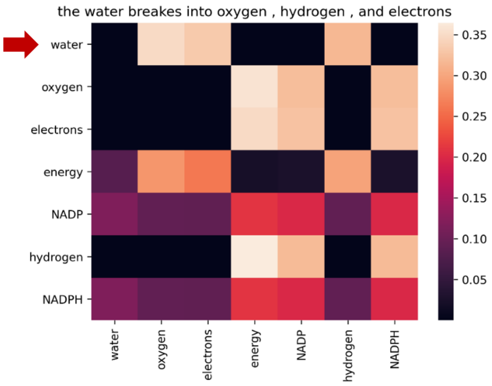

Figure 3: Case 1. The heatmap shows the entity-entity attention matrix for the example sentence.

5.2 Comparison Models

We compare our IEN with the following models: **ProLocal** (Dalvi et al., 2018) predicts the state changes described in each individual sentence, and then uses commonsense rules of inertia to propagate state values forwards and backwards in time. **ProGlobal** (Dalvi et al., 2018) predicts states of an entity across all timesteps by considering the entire paragraph. **ProStruct** (Tandon et al., 2018) adopts a structured prediction method and incorporates a set of commonsense constraints for global consistency. **LACE** (Du et al., 2019) leverages label consistency during training and allows consistency bias to be built into the model. **KG-MRC** (Das et al., 2018) constructs dynamic bipartite graphs from the text, and updates the graphs at each step. It also extends a machine reading comprehension model for location extraction. **NCET** (Gupta and Durrett, 2019) proposes a two-layer LSTM model to model state changes. Additionally, a neural CRF is used over the top to explicitly capture the constrains.

5.3 Results

As the size of ProPara is small and the variance cannot be ignored, we train NCET and IEN 10 times separately with different random seeds and take the average results.

Table 1 summarizes the main results. In the document level evaluation, ProLocal has the highest precision and ProGlobal gets the highest recall. Other models from the leaderboard use different methods to introduce constraints and get more balanced precision and recall scores, which lead to higher F1 scores. Among them, NCET achieves the previously best result with 59.4% in F1. Although NCET can well model the sequential context of a single entity, it ignores the context from another dimension, the interaction among different entities in the same event. We can see that IEN significantly outperforms all other models in the official leaderboard, achieving a new high in F1 (61.4%), 2% more than NCET, while getting the second place in recall (55.1%) and maintaining a relatively high precision (69.5%). This suggests that by exploiting the entity interactions, IEN is able to leverage a broader context for prediction, and thus correctly predicts more state changes compared to other methods. As (Gupta and Durrett, 2019) indicate that a pre-trained language model, e.g., ELMo (Peters et al., 2018) or BERT (Devlin et al., 2019), can help improve model performance when the training set is small, we apply ELMo to IEN, and obtain great improvement in recall, leading to 0.9% more in F1.

Table 2 shows the detailed results with respect to the four kinds of questions asked by the document level evaluator. Compared to NCET, although IEN has a lower precision, only 65.1%, to identify Conversions, it achieves a higher recall for Conversions, 6.8% more than NCET, resulting in a substantial increase in F1. Besides, we can see that IEN performs better than NCET on both Inputs and Outputs: IEN gets a higher recall for Inputs, with a 6.6% margin, and a higher precision to recognize Outputs. These two indicators suggest that more CREATE and DESTROY actions are correctly found in the process by IEN. We can see that IEN can better understand the role of each entity in a conversion by explicitly modeling the entity-entity interactions, thus can capture more accurate state changes that NCET may ignore.

As can be seen in columns Moves of Table 2, IEN outperforms NCET in recall by 2.3%. This is because by modeling location-entity interaction and the causal relationship of action and location, IEN is able to maintain the location information of each entity, and bring it to the next time step to prevent the absence of location information in

NCET:

blood	carbon dioxide	oxygen
MOVE heart → lung	NONE ? → ?	NONE ? → ?
NONE lung → lung	MOVE blood → blood	MOVE blood → blood
NONE lung → lung	MOVE blood → blood	MOVE blood → blood

IEN:

blood	carbon dioxide	oxygen
MOVE heart → lung	NONE ? → ?	NONE ? → ?
NONE lung → lung	MOVE lung → lung	NONE ? → ?
NONE lung → lung	NONE lung → lung	MOVE lung → blood

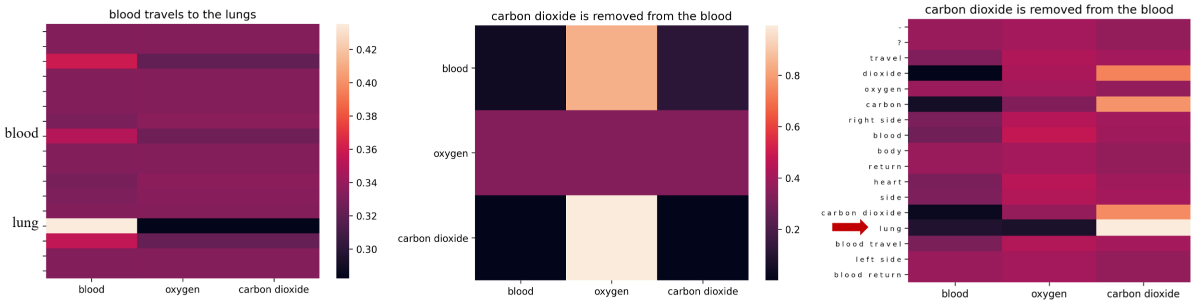

Figure 4: Case 2. Below are excerpts of three heatmaps, the left is the location-entity attention matrix of the first sentence, the middle and the right is the entity-entity attention matrix, and the location-entity attention matrix of the second sentence. There are some inconsistencies in the results, e.g., after the first step, oxygen locates at ”?”, but before the second step, oxygen locates at ”blood”. This is due to the rule-based postprocessing, which keeps local consistency, e.g., keeps the location before and after a step to be the same when this step's action is ”NONE”.

the sentence. We will use the ”carbon dioxide and lung” case in Sec. 5.5 for a detailed illustration.

As for sentence level evaluation, IEN also achieves higher overall macro- and micro- accuracy than the previous best method, NCET. More precisely, IEN gets higher Cat-1 and Cat-2 accuracy and competitive Cat-3 accuracy. The improvement of Cat-1 and Cat-2 accuracy can be attributed to the effectiveness of modeling entity interactions.

5.4 Ablation Analysis

We perform ablation studies to evaluate each component of IEN cells. We design two variants: 1) **IEN (no l2e)** tracks entity actions using simplified IEN cells that only contain entity slots and entity updating module, i.e., $\boldsymbol{h}_t^l$ and Eq 9 to Eq 13 are removed from the cells. For location prediction, we separately use BiLSTM like NCET. 2) **IEN (parallel)** contains IEN cells that run the entity updating module and location updating module in a parallel manner, i.e., in Eq 12, the input to location-entity attention module changes to $\hat{\boldsymbol{h}}_t^e$ instead of $\boldsymbol{h}_t^e$.

From table 2, compared to NCET, IEN (no l2e) performs well in the recall of Conversions, while the recall of Moves is similar to NCET and lower than IEN. This result confirms the effect of entity-entity interaction and location-entity interaction we discussed in the previous subsection.

As for IEN (parallel), even though this model explicitly models entity-entity interactions and location-entity interactions, the recall of Moves is lower than IEN by 2.5%, which indicates the importance of understanding the causal relationship between entity action and its location. As an entity's action is a decisive property, it is definitely helpful to have thorough and accurate information about the entity's action before figuring out its location.

5.5 Case Study

To better understand how the IEN works, here we conduct a case study using the examples in Sec. 1.

Figure 3 shows the results of NCET and IEN in the first case, in which 4 entities are involved in a chemical transformation. The key is to correctly identify the role of each entity in the conversion. Even though NCET correctly predicts the actions of oxygen, hydrogen, and electrons, it makes a wrong prediction on water, this is because NCET performs separate predictions for multiple entities in the same event. IEN models all entities and their interactions simultaneously, and perfectly predict all their actions. The heatmap in Figure 3 is the corresponding entity-entity attention matrix in the IEN cell. We find that the water row presents which entities have a higher probability of changing from water. Surprisingly, if we notice the oxygen (or hydrogen, electrons) row, the model even makes a *pre-filtering* about what the oxygen will become, which even appears before the actual description. We think this may be because that oxygen, hydrogen, and electrons are simultaneously come from water, thus are less likely to be the next product. Such pre-filtering mechanism may help future prediction by reducing the candidates. Besides, IEN correctly predicts all the locations which are not explicitly mentioned in the sentence. In fact, ”plant” comes from a previous sentence that describes ”the plant absorbs water from soil”. To pass the correct location from water to oxygen, the model needs first to identify which entity is the reactant in the chemical reaction, and then pass the reactant's location information to other entities. This shows that feeding up-to-date entity information for subsequent location prediction can help the model better understand what happens to the entity in the current action and know which states of the entity may change accordingly.

The second case is more complicated because it requires context reasoning across three sentences. As shown in Figure 4, similar to the case 1, NCET does not identify the role of all entities well, and confuses carbon dioxide with oxygen, resulting in redundant predictions for MOVEs, while IEN performs well on action prediction. As for predicting locations, IEN is able to correctly predict that, after removed from the blood, carbon dioxide locates at the lung, while the lung is actually mentioned in the previous sentence. IEN manages to capture the interaction between carbon dioxide and blood, and that between lung and blood in nearby sentences, making a reasoning chain from carbon dioxide to blood, and to lung. To see how IEN achieves this, we show the excerpts of 3 heatmaps in Figure 4. In the first step, IEN builds a connection between location lung and entity blood through location-entity interaction. At the second step, from the entity-entity attention matrix, we can see that IEN correctly finds out that carbon dioxide is moving apart from blood and thus gives a low attention weight. And from the location-entity attention matrix, we notice that carbon dioxide has correctly got the location information from the blood. Another interesting finding is that IEN can correctly predict that the oxygen is originally located at the lung even before reading the third sentence, where the oxygen first appears. This may be the combined effect of location-entity interactions and pre-filtering.

6 Conclusion

In this paper, we propose the Interactive Entity Network, IEN, for the multi-entity state tracking task, which learns to interpret complex processes by explicitly modeling the synergy among different entities involved in one event and leveraging the causal relationship between entity actions and their subsequent state changes. Experiments on ProPara show that IEN can better understand scientific procedural texts and outperforms state-of-the-art models.

Abstract

Fine-tuning pretrained model has achieved promising performance on standard NER benchmarks. Generally, these benchmarks are blessed with strong name regularity, high mention coverage and sufficient context diversity. Unfortunately, when scaling NER to open situations, these advantages may no longer exist. And therefore it raises a critical question of whether previous creditable approaches can still work well when facing these challenges. As there is no currently available dataset to investigate this problem, this paper proposes to conduct randomization test on standard benchmarks. Specifically, we erase name regularity, mention coverage and context diversity respectively from the benchmarks, in order to explore their impact on the generalization ability of models. To further verify our conclusions, we also construct a new open NER dataset that focuses on entity types with weaker name regularity and lower mention coverage to verify our conclusion. From both randomization test and empirical experiments, we draw the conclusions that 1) name regularity is critical for the models to generalize to unseen mentions; 2) high mention coverage may undermine the model generalization ability and 3) context patterns may not require enormous data to capture when using pretrained encoders.

1 Introduction

Named entity recognition (NER), or more generally name tagging, aims to identify text spans pertaining to specific entity types. NER is a fundamental task of information extraction which enables many downstream NLP applications, such as relation extraction (GuoDong et al., 2005; Mintz et al., 2009), event extraction (Ji and Grishman, 2008; Li et al., 2013) and machine reading comprehension (Rajpurkar et al., 2016; Wang et al., 2016). Recently, neural network-based supervised models dominate the NER task. By supervised fine-tuning upon large-scale language model pretrained architectures (e.g., ELMo (Peters et al., 2018), BERT (Devlin et al., 2018), XLNet (Yang et al., 2019), etc.), we have witnessed superior performances on almost all widely-used NER benchmarks, including CoNLL03, ACE2005 and TAC-KBP datasets (Li et al., 2019b; Akbik et al., 2019; Zhai et al., 2019; Li et al., 2019a).

	Regular NER	**Open NER**
Typical Categories	Person, Location, Organization, etc.	Movie, Song, Book, TV Series, etc.
Name Regularity	Entity types with strong regularity	Entity types with weak or no regularity
Mention Coverage	Training set with high mention coverage	Many new and unseen mentions
Context Pattern	With decent training instances to capture	Fully-annotated training data is rare
Examples	**Location** Train *starting from [**Cherry Street**]* *... at [**8th Avenue**] ...* Test ⇩ *... at [**Cherry Street**]...* *... go to [**9th Avenue**] ...*	**Movie** Train *I watched [**avatar**]last night* *...[**the matrix**] is the best...* Test ⇩ *Wow...[**Joker**] was great!* *Love [**inception**] so much.*

Figure 1: Comparison between regular NER benchmarks and open NER tasks in reality.

Despite the success of recent models, there are specific advantages in current NER benchmarks which significantly facilitate supervised neural networks. First, these benchmarks focus on limited entity types, and most mentions of these types have strong ***name regularity***. For example, nearly all person names follow the "FirstName LastName" or "LastName FirstName" patterns, while location names mostly end with indicator words such as "street" or "road". Second, the training and test data in these benchmarks are sampled from the same corpus, and therefore the training data usually have high ***mention coverage***

on the test data, i.e., a large proportion of mentions in the test set have been observed in the training set. However, it is obvious that this high coverage is inconsistent with the primary goal of NER models, which is expected to identify unseen mentions from new data by capturing the generalization knowledge about names and contexts. For observed mentions, other techniques, such as entity linking (Lin et al., 2012), would be more appropriate and effective. Third, these benchmarks generally provide decent training data, and therefore the ***context diversity*** of all entity types can be sufficiently learned. In this paper, we refer to the NER tasks with strong name regularity, high mention coverage and with sufficient training instances as *regular NER*. And it proves that the state-of-the-art neural networks can easily exploit such name regularity, mention coverage and context diversity knowledge, and therefore achieve state-of-the-art performance in these benchmarks.

Unfortunately, when it comes to a more general scenario, there are significant discrepancies between regular benchmarks and NER in open settings. Table 1 overviews their discrepancies on name regularity, mention coverage and context pattern acquisition. Specifically, mentions of many entity types do not follow regular compositional structures. For example, a movie name can be any n-gram utterance and even is not a regular noun phrase(e.g., “Gone with the Wind”). Furthermore, fully-annotated training data will be rare due to the expensive cost. As a consequence, training set can only cover a minor part of test mentions and diverse context patterns must be learned from minimal instances. It is obvious that these discrepancies will lead to the biased estimation of the open NER performance using regular NER benchmarks.

In this paper, we want to shed some light on the impact of the discrepancies between regular and open NER, and provides some valuable insights into the construction of general NER models in a more effective and efficient way. Specifically, we want to answer the following question:

Can pretrained supervised neural networks still generalize well on NER when either weaker name regularity, lower mention coverage or inadequate context diversity exists?

It is non-trivial to answer this question because currently no well-established benchmark concentrates on these issues. To this end, this paper exploits the efficacy of the above three kinds of information by conducting a series of experiments based on *randomization test* (Edgington and Onghena, 2007; Zhang et al., 2016). Specifically, we design several mention replacing mechanisms, which can erase specific kinds of information on-demand from current NER benchmarks. By applying the same supervised models on both vanilla and information-erased data, we can investigate how much the models will rely on particular erased information to identify entity mentions. Generally, we propose to erase name regularity, mention coverage and context diversity respectively using the following kinds of randomization test, whose examples are shown in Table 1:

- **Name Permutation (NP)** is used to investigate the necessity of name regularity for NER, which replaces the same entity mention with an identical, random n-gram string. In this way, the structural correlation between mentions of the same type is removed. For the example in Table 1, all mention “Putin” is replaced by the same utterance “the united”.

- **Mention Permutation (MP)** is used to investigate the impact of mention coverage. Different from NP, MP replaces each mention with a unique n-gram string, and even two mentions with the same utterance will be replaced by different strings. For the example in Table 1, two mentions of “Putin” are replaced by “the united” and “which girl” respectively. In this way, the mention coverage is erased and the model should merely rely on context knowledge for NER prediction.

- **Context Reduction (CR)** and **Mention Reduction (MR)** are used to investigate the influence of less training data. CR decreases the diversity of sentences but preserves all mentions in vanilla data, while MR keeps all sentences but only preserves a small part of the original mentions. We compare these two settings, to figure out how much original training data are needed to learn context patterns and name regularity.

To verify the above findings, we further conduct a verification experiment by constructing a new dataset derived from Wikipedia, which focuses on entity types with weak name regularity. To the best of our knowledge, this is the first work that tries to investigate such critical differences between regular and open NER. From both the randomization

Settings	**Name**	**Mention**	**Context**	**Examples**

Table 1: Illustration of our four kinds of randomization test. The utterances in square brackets are entity mentions. Name: name regularity knowledge; Mention: high mention coverage; Context: sufficient training instances for context diversity √: the knowledge is preserved in this setting; ×: the knowledge is erased from the data in the setting; ↓: the knowledge decreases.

test and the verification experiment, we reach the following main conclusions:

- ***Decent name regularity is vital to the generalization over unseen entity mentions.*** When name regularity is erased, the performance on unseen mentions will be significantly undermined. This finding indicates that it will be challenging to build models for open entity types with weak name regularity.

- ***High mention coverage weakens the model ability to capture informative context knowledge.*** In other words, high mention coverage will mislead models to memorize popular mentions, rather than to learn generalization knowledge. This also reveals that current performance on regular NER benchmarks is highly biased, i.e., the performance on open NER will be significantly lower than that on regular benchmarks.

- ***Sufficient context diversity may not require enormous training data to capture.*** We show that with simple data augmentation techniques to preserving name regularity, required training data can be significantly reduced. This observation also raises the possibility of designing more effective NER models with less annotated data.

2 Experiment Settings

2.1 Dataset Summary

We use ACE2005 (LDC2006T06) as our primary experiment dataset for randomization test. Other openly-available datasets, such as CoNLL03 and Ontonotes, are not suitable for our randomization test. This is because they only annotate named mentions but ignore nominal and pronominal mentions. However, the context of named and nominal/pronominal mentions is generally identical, and therefore the models will be unable to distinguish between them once name regularity is removed.

For better illustration and reproduction, we will report experiment results using the same dataset splits corresponding to Wang et al. (2018); Wang and Lu (2018); Lin et al. (2019a); Xia et al. (2019). For all experiments, we only consider the outmost mentions similar to the majority of the previous work. Finally, there are 18739/2531/2314 mentions in the train/dev/test set respectively. We found that 58.4% mentions in the test set have appeared in the training data, which confirms our high mention coverage concern. We also have conducted multiple experiments using the 8:1:1 train/dev/test data split. And we found all the above experiments lead to the same conclusions which we will illustrate in the next section.

Data Setting	PER	ORG	GPE	FAC	LOC	WEA	VEH	ALL
Baseline	86.31	76.49	80.89	69.23	40.58	74.70	61.97	81.76
Name Permutation	73.41	44.34	49.71	37.96	28.24	33.33	23.93	62.28
- Drop Compared with Baseline	15%	42%	39%	45%	44%	55%	61%	24%
Mention Permutation	61.78	39.40	33.27	32.16	18.60	9.38	21.92	51.58
- Drop Compared with Baseline	28%	48%	59%	54%	54%	87%	65%	34%

Table 2: Micro-F1 scores of BERT-CRF tagger on original data, name permutation setting and mention permutation setting respectively. We can see that erasing name regularity and mention coverage will significantly undermine the model performance.

2.2 Baseline

We use the BERT-CRF tagger as our baseline. Specifically, a Transformer (Vaswani et al., 2017) is used as the encoder and then two dense layers are used to map the hidden representation into the label space. Finally, a linear-chain CRF is applied. The transformer is initialized using *bert_uncased_L-24_H-1024_A-16*, which achieves the best performance on our auxiliary experiments. All model parameters are fine-tuned later. We used Adam (Kingma and Ba, 2014) as the optimizer and set the learning rate to 10^{-5}. Finally, this model achieves 81.76 micro F1 score on ACE2005.

3 Randomization Test on NER

To investigate the discrepancies between regular and open NER, this paper controllably erases target information from the vanilla data via a variant of randomization test (Edgington and Onghena, 2007; Zhang et al., 2016) in non-parametric statistics. Concretely, to probe the effect of a specific kind of information, we erase it in vanilla data by randomly replacing entity mentions with particular irregular utterances. After that, we learn and compare NER models on both the vanilla benchmark and the information-erased version, in order to evaluate the models' robustness and generalization ability when target information is absent. The results of our randomization test can serve as a frame of reference for open NER, where the erased information is often truly absent.

Specifically, three kinds of information are particularly considered, and four kinds of strategies are used in our randomization test. Table 1 shows all our randomization test with examples. In the following, we will illustrate the empirical findings through the test, with one subsection for one kind of information. For each kind of information, we first present the critical conclusion and then demonstrate how we reach the conclusion.

3.1 Effect of Name regularity

Conclusion 1 *Name regularity is critical for supervised NER model to generalize over unseen entity mentions.*

One critical difference between regular and open NER is whether names of the same entity type share inner compositional structure. In regular NER, entities (e.g., PER, ORG and LOC) have long been observed with strong name regularity. In open NER, however, most entities (e.g., movie, song and book) do not have such strong name regularity, and some of mentions can even be random utterances. Therefore, it is critical to evaluate the impact of name regularity on generalization.

To address this issue, we propose *name permutation*, which replaces each mention utterance with a randomly sampled n-gram string, and the mentions with the same name will all be replaced by the same string. To ensure that no structural correlation between these mentions will be retained, the replacing strings are randomly sampled. For example in Table 1, all mentions "Putin" are replaced by "the united", and all "Bush" are replaced by "analysts"". In this way, the name regularity will be erased, but the mention coverage will still retain because the same mention in the training and test data will still be the same.

Table 2 shows the overall results. We can see that when we erase name regularity from the dataset, the performance significantly undermined. The overall drop on micro-F1 is 24%. Moreover, in the majority of entity types, the performance slips more than 40%. This verifies the importance of name regularity on model generalization ability. To investigate the reasons behind, we split mentions for evaluation by whether the predicted/golden mention is covered by the training data, which we refer to as the in-dictionary portion (InDict) and the out-of-dictionary portion (OutDict) respectively. The results [1] of these two portions on the vanilla dataset and name permutation setting are shown in Table 3.

Vanilla Baseline

	Precison			Recall		
	InDict	OutDict	**Diff**	InDict	OutDict	**Diff**
PER	88.03	75.40	14%	92.90	85.20	8%
ORG	73.51	72.77	1%	81.93	76.56	7%
GPE	79.55	78.21	2%	85.37	77.22	10%
FAC	65.91	65.67	0%	86.05	65.67	24%
ALL	83.37	72.97	**12%**	89.08	79.11	**11%**

Name Permutation

	Precison			Recall		
	InDict	OutDict	**Diff**	InDict	OutDict	**Diff**
PER	88.58	46.91	47%	87.00	62.30	28%
ORG	70.40	37.01	47%	51.76	27.80	46%
GPE	70.20	18.60	74%	64.63	30.38	53%
FAC	63.64	27.40	57%	48.84	29.85	39%
ALL	82.47	38.29	**54%**	76.31	46.72	**39%**

Table 3: Comparasion between baseline and name permutation on in-dictionary and out-of-dictionary portions. We can see that the performance gap between InDict and OutDict is significantly enlarged when name regularity was erased.

From Table 3, we can find that erasing name regularity leads to more severe performance drop on mentions not covered by training set (OutDict) than those appearing in the training set (InDict). For the vanilla dataset, the performance gap between InDict and OutDict is not very large, which shows the good generalizing ability of pretrained supervised model over unseen mentions with strong name regularity. However, after erasing name regularity, this gap is significantly enlarged. The performance on the InDict portion does not drop too much, but the performance on the OutDict portion drops dramatically. This result shows that it is quite difficult to recognize unseen entity mentions when name regularity is missing. Besides, we can see that after erasing name regularity, the model can still perform quite well on the in-dictionary portion, whose precision is still quite high. This demonstrates the strong ability of neural networks to memorize and disambiguate observed mentions even their names are irregular.

Note that Name permutation may result in ambiguous entity instances with only sentence contexts. However, this phenomenon is very common in real world, open-ended NER tasks. For example, a twitter is often a simple sentence like “La La Land is great, we like it”, where “La La Land” is ambiguous in this context and can only be recognized as a Movie using world knowledge about movie. Our experiments also confirm that the less context provides, the more name knowledge is needed.

To summarize, name regularity is very critical for model generalization over unseen mentions. Without name regularity, current models can only work well on mentions covered by training data via memorizing and disambiguating names, but cannot generalize well to unseen mentions.

3.2 Effect of Mention Coverage

Conclusion 2 *High mention coverage weakens the models’ ability of capturing informative generalization knowledge for NER.*

Another critical difference between regular and open NER is whether the training data can cover a majority of mentions in the test scenario. High mention coverage can provide misleading evidence during model learning because neural networks can achieve considerable performance by just memorizing and disambiguating observed entity names. This ability, obviously, is not what we desire because 1) in real world applications, most entity mentions are new and unseen, which means out-of-dictionary mentions will dominate the test process; 2) because the training instances are very limited in open situations, it is too expensive to achieve high mention coverage; 3) many long-tail mentions in the training set would be one-shot, i.e., the mention only appears once in the training data. Therefore, it is necessary to exploit whether NER models can still reach reasonable performance in low mention coverage situation.

To this end, we conducted experiments via *mention permutation*, which replaces each mention with a random n-gram similar to the name permutation. However, to erase mention coverage information, the replacing string for each mention is independently sampled, and therefore even mentions with the same utterance in vanilla data will be replaced by different strings. For example, two “Putin” in Table 1 are replaced by different utterances. In this way, (almost) no mention in the test set is covered by the training data, and no name information remains in the data. Consequently, the models should only rely on context knowledge for NER prediction.

The mention permutation results are shown in

---

[1] We only present the performance on four entity types with sufficient training and testing instances.

	Precision		Recall	
	NP	MP	NP	MP
PER	46.91	**58.01**	62.30	**66.21**
ORG	37.01	**40.76**	27.80	**38.94**
GPE	18.60	**32.92**	30.38	**34.05**
FAC	27.40	**27.74**	29.85	**36.54**
ALL	38.29	**49.40**	46.72	**54.01**

Table 4: Experiment results on *OutDict* portion. We can see that mention permutation significantly performs better than name permutation, which indicates that high mention coverage may undermine the generalization ability of models.

Table 2. We can see that the performance of MP further drops compared with NP, which demonstrates high mention coverage can make mention detection much simpler. To further investigate whether high mention coverage will influence the models' generalization ability, we also compared MP with NP on the *out-of-dictionary portion*. The results are shown in Table 4.

Surprisingly, the model performs significantly better in the MP setting than in the NP setting in all entity types. In other words, high mention coverage undermines the models' ability to generalize to unseen mentions. We believe this is because, as some previous studies in other tasks (Zhang et al., 2016; Lu et al., 2019) have pointed out, neural networks have strong ability and tendency to memorize training instances. Consequently, the high mention coverage will mislead the models to mainly memorize and disambiguate frequent entity names even though they are irregular, but ignore informative context patterns which are useful for generalization over unseen mentions. These results reveal that NER models should focus more on context knowledge for generalization, rather than memorizing popular mentions. This is even more important for entity types without or with weak name regularity because context patterns are more critical in this circumstance.

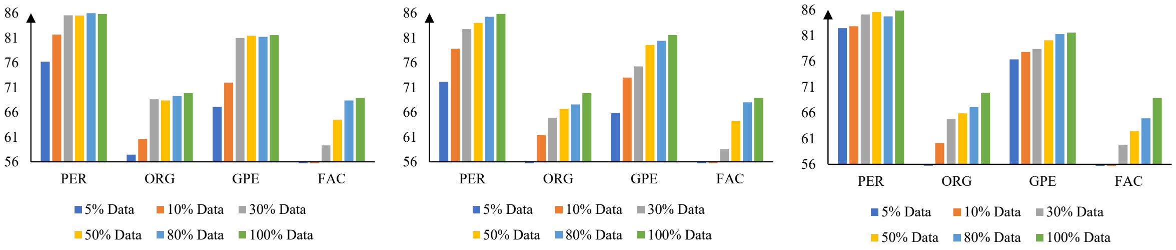
3.3 Effect of Context Diversity

Conclusion 3 *Sufficient context patterns may not require enormous training data to capture when learning upon pretrained neural networks.*

Current NER benchmarks commonly provide decent training data for learning context patterns of entities. However, due to the expensive cost, it is usually impractical for open NER to assume enough fully-annotated training data. If we can figure out how many training instances are sufficient for context pattern and name regularity respectively, it will provide valuable insights for constructing open NER datasets and models more effectively and efficiently.

To this end, we conduct *context reduction (CR)* and *mention reduction (MR)* on the vanilla training set using simple data augmentation strategies. The purpose of context reduction is to reduce context diversity in training data but still keeps all name regularity in the vanilla setting. Specifically, CR only keeps a subset of sentences in the vanilla training data, and then duplicates preserved sentences and randomly replace mentions in them with mentions of the same type in the vanilla training data. In this way, all mentions will share identical frequency in the vanilla and CR dataset. On the contrast, MR aims to reduce mention diversity for name regularity, but retains context diversity by keeping all of the original contexts. For this, MR only keeps a part of mentions in the original training set as seeds, and replace other mentions in the training data with a mention randomly sampled from the seeds of the same type. In this way, only part of name knowledge will retain, but all contexts will be preserved. Furthermore, we also compare CR and MR with a naive reduction strategy which simply subsamples sentences in the training data, and we refer it as *sentence reduction*.

We varied the ratio of preserved information in each setting ranging from 5% to 100% respectively. The overall results are shown in Figure 2. We can see that in the sentence reduction setting, the performance steadily improved as the training data grows. This phenomenon is also observed in the mention permutation setting, which indicates that increasing training data will introduce more name regularity knowledge, and thus results in better performance. However, for context permutation setting, there is no significant performance improvement on PER, ORG and GPE when the preserved sentences are more than 30% of the vanilla data. But for FAC, increasing the preserving data will still improve the performance. This may because the number of FAC instances are significantly smaller than PER, ORG and GPE in the vanilla dataset. From the above experiments, it seems that once it reaches a certain amount, the instances in training data are enough to capture sufficient context patterns. And increasing training instances can mainly provide more name



(a) Context Reduction (b) Sentence Reduction (c) Mention Reduction

Figure 2: Experiments on context reduction, mention reduction and sentence reduction when the kept information ratio varies. We can see that when preserving all name regularity information, sufficient context patterns can be captured once the training sentences reaches a certain amount, and introducing more training data does not significantly improve the performance.

regularity knowledge rather than more context diversity.

The above results provide a valuable insight that the name regularity and the context patterns for NER can be learned separately, rather than jointly. For example, we can learn context patterns using a moderate number of training instances and attempt to incorporate more name regularity knowledge using other resources, e.g., gazetteers.

4 Experiments on Open NER

4.1 Data Preparation

To further verify the conclusions from our randomization test, we propose to conduct experiments on a real-world open NER dataset, which focuses on real world entity types with weaker name regularity than previously-used benchmarks. Because currently no suitable dataset is available for verifying our conclusions, this paper constructs a new dataset from Wikipedia. Specifically, we consider four entity types in our experiments, including *movie*, *song*, *book* and *tv series*. We extract all sentences in Wikipedia which contain mentions linking to entities of these types as our experiment dataset. From them, we randomly sample 10,000 sentences as the test set and 2,000 sentences as the development set, and part of the remaining data will be used as the training data according to the following different settings. Finally, there are 2875, 2791, 598 and 580 mentions for movie, tv series, song and book in the test set respectively. Note that different from real scenarios, this dataset only keeps sentences containing at least one mention, Due to the partial labeling nature of Wikipedia, this dataset only keeps sentences containing at least one mention, and the performance on this dataset may over-estimate the precision than in real applications. Although this may different from real scenarios, we believe it can still lead to reasonable conclusions.

4.2 Generalizing over Unseen Mentions

The first group of experiments was conducted to verify the influence of name regularity on in-dictionary and out-of-dictionary mentions. To this end, we randomly sampled 5,000 sentences from the dataset as the training set, which is close to the training data size of ACE2005. We use *bert_cased_L-24_H-1024_A-16* rather than the uncased version of the pretrained model because we find that capitalization may have a significant impact on this dataset. Furthermore, different from the ACE2005 whose training data covers nearly 58% test set mentions, the training set of our Wikipedia dataset can only cover 27% mentions in the test set. This confirms our concern that the mention coverage is much lower in open NER than in regular NER.

	Baseline					
	Precison			Recall		
	InDict	OutDict	**Diff**	InDict	OutDict	**Diff**
Movie	80.68	71.48	11%	88.43	71.43	19%
Tv Series	91.48	65.77	28%	88.03	74.73	15%
Song	77.94	56.42	28%	68.83	62.50	9%
Book	83.72	53.99	36%	68.57	55.03	20%
ALL	87.44	66.59	**24%**	86.30	71.13	**18%**

Table 5: Comparasion between in-dictionary portion and out-of-dictionary portion on Wikipedia dataset. We can see that there is a significant gap between these two portions.

Table 5 reports the experiment results on in-dictionary portion and out-of-dictionary portion respectively. We can see that the performance gap between in-dictionary portion and out-of-dictionary portion significant due to the weak name regularity. This confirms our Conclusion 1 that name regularity is vital for NER system to generalize over unseen mentions. Compared with the name permutation setting shown in Table 3, the InDict-outDict performance gap is not so large. We believe this is because: 1) there still exist some kinds of name regularity for these entity types, e.g., the capitalization of the first letter; 2) Wikipedia documents are much formal than ACE2005 documents, which makes the context patterns much easier to capture. For example, a movie mention in Wikipedia will frequently share the same context of "in the film Xxx Xxx", where "Xxx" is mention word with the first letter being capitalized. Despite this, the performance gap between InDict and OutDict portions is still significant – more than 24% and 18% on precision and recall respectively, which verifies the necessity of name regularity for NER to achieve good generalization.

4.3 Influence of Training Data Size

To investigate the impact of training data size to the model performance, we varied the size of training set from 500 to 10,000, and investigate the performance improvement over the test set. Because the entity types we considered are with weak name regularity, the increment of training instances will mainly increase the context diversity. Therefore, this group of experiments can be used to verify the Conclusion 3 we proposed before.

Figure 3 shows the results. We can see that the performance improvements on all entity types are less significant after training data size exceeding 3000. This phenomenon is to the Figure 2 (a) results on the context reduction setting on ACE2005. This further verifies our Conclusion 3 and confirms that when sample size reaches a certain level, introducing more training data will not improve the learning of context knowledge.

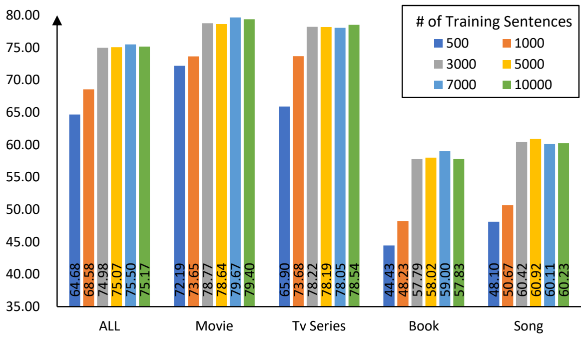


Figure 3: F1 scores on Wikipedia dataset when training data size varies. We can see that there are little improvement when training data size exceeds 3000.

5 Related Work

Named entity recognition has long been studied and has attracted much attention. Conventional methods (Zhou and Su, 2002; Chieu and Ng, 2002; Bender et al., 2003; Settles, 2004) commonly rely on handcraft features to build NER models, which are hard to transfer among different languages, domains and entity types. Recently, deep learning methods, which automatically extract high-level features and perform sequence tagging with neural networks (Santos and Guimaraes, 2015; Chiu and Nichols, 2016; Lample et al., 2016; Yadav and Bethard, 2019), have achieved significant progress especially under strong pretraining and fine-tuning paradigm (Li et al., 2019b; Akbik et al., 2019; Zhai et al., 2019; Li et al., 2019a; Xia et al., 2019; Lin et al., 2019a). These methods have achieved promising results in almost all popular NER benchmarks considering regular entity types.

Several researches have shift attention to name tagging in open scenarios, where entity types may have weaker name regularity and training data are often insufficient. These papers mainly focus on how to exploit weakly-supervised data (Täckström et al., 2013; Ni et al., 2017; Cao et al., 2019; Xue et al., 2019), or devoted to incorporate external resources (Yang et al., 2017; Peng and Dredze, 2016; Pan et al., 2017; Lin et al., 2018; Xie et al., 2018; Lin et al., 2019b).

By contrast, to the best of our knowledge, this is the first work which investigates the essential difference between regular and open NER. By conducting both randomization test (Edgington and Onghena, 2007) and verification experiments, we analyze the impact of name regularity, mention coverage and context pattern sufficiency and shed light on future open NER studies.

6 Conclusion and Future work

This paper investigates whether current state-of-the-art models on regular NER can still work well on open NER. From the perspective of name regularity, mention coverage and context diversity, we conducted both randomization test and verification experiments to evaluate the generalization ability of models. Our investigation leads to three valuable conclusions, which shows the necessity of decent name regularity to identify unseen mentions, the hazard of high mention coverage to model generalization, and the redundancy of enormous data to capture context patterns.

The above findings shed light on the promising directions for open NER, including 1) exploiting name regularity more efficiently with easily-obtainable resources such as gazetteers; 2) preventing the overfit on popular in-dictionary mentions with constraints or regularizers; and 3) reducing the need of training data by decoupling the acquisition of context knowledge and name knowledge.

DyERNIE: Dynamic Evolution of Riemannian Manifold Embeddings for Temporal Knowledge Graph Completion

Abstract

There has recently been increasing interest in learning representations of temporal knowledge graphs (KGs), which record the dynamic relationships between entities over time. Temporal KGs often exhibit multiple simultaneous non-Euclidean structures, such as hierarchical and cyclic structures. However, existing embedding approaches for temporal KGs typically learn entity representations and their dynamic evolution in the Euclidean space, which might not capture such intrinsic structures very well. To this end, we propose DyERNIE, a non-Euclidean embedding approach that learns evolving entity representations in a product of Riemannian manifolds, where the composed spaces are estimated from the sectional curvatures of underlying data. Product manifolds enable our approach to better reflect a wide variety of geometric structures on temporal KGs. Besides, to capture the evolutionary dynamics of temporal KGs, we let the entity representations evolve according to a velocity vector defined in the tangent space at each timestamp. We analyze in detail the contribution of geometric spaces to representation learning of temporal KGs and evaluate our model on temporal knowledge graph completion tasks. Extensive experiments on three real-world datasets demonstrate significantly improved performance, indicating that the dynamics of multi-relational graph data can be more properly modeled by the evolution of embeddings on Riemannian manifolds.

1 Introduction

Learning from relational data has long been considered as a key challenge in artificial intelligence. In recent years, several sizable knowledge graphs (KGs), e.g. Freebase (Bollacker et al., 2008) and Wikidata (Vrandečić and Krötzsch, 2014), have been developed that provide widespread availability of such data and enabled improvements to a plethora of downstream applications such as recommender systems (Hildebrandt et al., 2019) and question answering (Zhang et al., 2018). KGs are multi-relational, directed graphs with labeled edges, where each edge corresponds to a fact and can be represented as a triple, such as (John, lives in, Vancouver). Common knowledge graphs are static and store facts at their current state. In reality, however, multi-relational data are often time-dependent. For example, the political relationship between two countries might intensify because of trade fights. Thus, temporal knowledge graphs were introduced, such as ICEWS (Boschee et al., 2015) and GDELT (Leetaru and Schrodt, 2013), that capture temporal aspects of facts in addition to their multi-relational nature. In these datasets, temporal facts are represented as a quadruple by extending the static triplet with a timestamp describing when these facts occurred, i.e. (Barack Obama, inaugurated, as president of the US, 2009). Since real-world temporal KGs are usually incomplete, the task of link prediction on temporal KGs has gained growing interest. The task is to infer missing facts at specific timestamps based on the existing ones by answering queries such as (US, president, ?, 2015).

Many facts in temporal knowledge graphs induce geometric structures over time. For instance, increasing trade exchanges and economic cooperation between two major economies might promote the trade exports and economic growths of a series of countries in the downstream supply chain, which exhibits a tree-like structure over time. Moreover, an establishment of diplomatic relations between two countries might lead to regular official visits between these two countries, which produces a cyclic structure over time. Embedding methods in Euclidean space have limitations and suffer from large distortion when representing large-scale hier-

archical data. Recently, hyperbolic geometry has been exploited in several works (Nickel and Kiela, 2017; Ganea et al., 2018) as an effective method for learning representations of hierarchical data, where the exponential growth of distance on the boundary of the hyperbolic space naturally allows representing hierarchical structures in a compact form. While most graph-structured data has a wide variety of inherent geometric structures, e.g. partially tree-like and partially cyclical, the above studies model the latent structures in a single geometry with a constant curvature, limiting the flexibility of the model to match the hypothetical intrinsic manifold. Thus, using a product of different constant curvature spaces (Gu et al., 2018) might be helpful to match the underlying geometries of temporal knowledge graphs and provide high-quality representations.

Existing non-Euclidean approaches for knowledge graph embeddings (Balazevic et al., 2019; Kolyvakis et al., 2019) lack the ability to capture temporal dynamics available in underlying data represented by temporal KGs. The difficulty with representing the evolution of temporal KGs in non-Euclidean spaces lies in finding a way to integrate temporal information to the geometric representations of entities. In this work, we propose the **dy**namic **e**volution of **R**iemannian ma**ni**fold **e**mbeddings (DyERNIE), a theoretically founded approach to embed multi-relational data with dynamic relationships on a product of Riemannian manifolds with different curvatures. To capture both the stationary and dynamic characteristics of temporal KGs, we characterize the time-dependent representation of an entity as movements on manifolds. For each entity, we define an initial embedding (at t_0) on each manifold and a velocity vector residing in the tangent space of the initial embedding to generate a temporal representation at each timestamp. In particular, the initial embeddings represent the stationary structural dependencies across facts, while the velocity vectors capture the time-varying properties of entities.

Our contributions are the following: (i) We introduce Riemannian manifolds as embedding spaces to capture geometric features of temporal KGs. (ii) We characterize the dynamics of temporal KGs as movements of entity embeddings on Riemannian manifolds guided by velocity vectors defined in the tangent space. (iii) We show how the product space can be approximately identified from sectional curvatures of temporal KGs and how to choose the dimensionality of component spaces as well as their curvatures accordingly. (iv) Our approach significantly outperforms current benchmarks on a link prediction task on temporal KGs in low- and high-dimensional settings. (v) We analyze our model's properties, i.e. the influence of embedding dimensionality and the correlation between node degrees and the norm of velocity vectors.

2 Preliminaries

2.1 Riemannian Manifold

An n-dimensional Riemannian *manifold* $\mathcal{M}^n$ is a real and smooth manifold with locally Euclidean structure. For each point $\mathbf{x} \in \mathcal{M}^n$, the metric tensor $g(\mathbf{x})$ defines a positive-definite inner product $g(\mathbf{x}) = \langle \cdot, \cdot \rangle_{\mathbf{x}} : \mathcal{T}_{\mathbf{x}}\mathcal{M}^n \times \mathcal{T}_{\mathbf{x}}\mathcal{M}^n \rightarrow \mathbb{R}$, where $\mathcal{T}_{\mathbf{x}}\mathcal{M}^n$ is the tangent space of $\mathcal{M}^n$ at $\mathbf{x}$. From the tangent space $\mathcal{T}_{\mathbf{x}}\mathcal{M}^n$, there exists a mapping function $\exp_{\mathbf{x}}(\mathbf{v}) : \mathcal{T}_{\mathbf{x}}\mathcal{M}^n \rightarrow \mathcal{M}^n$ that maps a tangent vector $\mathbf{v}$ at $\mathbf{x}$ to the manifold, also known as the *exponential map*. The inverse of an exponential map is referred to as the *logarithm map* $\log_{\mathbf{x}}(\cdot)$.

2.2 Constant Curvature Spaces

The sectional curvature $K(\tau_{\mathbf{x}})$ is a fine-grained notion defined over a two-dimensional subspace $\tau_{\mathbf{x}}$ in the tangent space at the point $\mathbf{x}$ (Berger, 2012). If all the sectional curvatures in a manifold $\mathcal{M}^n$ are equal, the manifold then defined as a space with a constant curvature K. Three different types of constant curvature spaces can be defined depending on the sign of the curvature: a positively curved space, a flat space, and a negatively curved space. There are different models for each constant curvature space. To unify different models, in this work, we choose the stereographically projected hypersphere $\mathbb{S}_K^n$ for positive curvatures ($K > 0$), while for negative curvatures ($K < 0$) we choose the Poincaré ball $\mathbb{P}_K^n$, which is the stereographic projection of the hyperboloid model:

$$\mathcal{M}_K^n = \begin{cases} \mathbb{S}_K^n = \{\mathbf{x} \in \mathbb{R}^n : \langle \mathbf{x}, \mathbf{x} \rangle_2 > -1/K\} \\ \mathbb{E}^n = \mathbb{R}^n, \text{ if } K = 0 \\ \mathbb{P}_K^n = \{\mathbf{x} \in \mathbb{R}^n : \langle \mathbf{x}, \mathbf{x} \rangle_2 < -1/K\} \end{cases}$$

Both of the above spaces $\mathbb{S}_K$ and $\mathbb{P}_K$ are equipped with the Riemannian metric: $g_{\mathbf{x}}^{\mathbb{S}_K} = g_{\mathbf{x}}^{\mathbb{P}_K} = (\lambda_{\mathbf{x}}^K)^2 g^{\mathbb{E}}$, which is conformal to the Euclidean metric $g^{\mathbb{E}}$ with the conformal factor $\lambda_{\mathbf{x}}^K = 2/(1 + K||\mathbf{x}||_2^2)$ (Ganea et al., 2018). As explained in

(Skopek et al., 2019), $\mathbb{S}_K$ and $\mathbb{P}_K$ have a suitable property, namely the distance and the metric tensors of these spaces converge to their Euclidean counterpart as the curvature goes to 0, which makes both spaces suitable for learning sign-agnostic curvatures.

2.3 Gyrovector Spaces

An important analogy to vector spaces (vector addition and scalar multiplication) in non-Euclidean geometry is the notion of gyrovector spaces (Ungar, 2008). Both the projected hypersphere and the Poincaré ball share the following definition of *Möbius addition*:

$$\mathbf{x} \oplus_K \mathbf{y} = \frac{(1 - 2K\langle \mathbf{x}, \mathbf{y}\rangle_2 - K||\mathbf{y}||_2^2)\mathbf{x} + (1 + K||\mathbf{x}||_2^2)\mathbf{y}}{1 - 2K\langle \mathbf{x}, \mathbf{y}\rangle_2 + K^2||\mathbf{x}||_2^2||\mathbf{y}||_2^2}$$

where we denote the Euclidean norm and inner product by $||\cdot||$ and $\langle \cdot, \cdot \rangle_2$, respectively. Skopek et al. (2019) show that the distance between two points in $\mathbb{S}_K$ or $\mathbb{P}_K$ is equivalent to their variants in gyrovector spaces, which is defined as

$$d_{\mathcal{M}_K}(\mathbf{x}, \mathbf{y}) = \frac{2}{\sqrt{|K|}} \tan_K^{-1}(\sqrt{|K|}||-\mathbf{x} \oplus_K \mathbf{y}||_2),$$

where $\tan_K = \tan$ if $K > 0$ and $\tan_K = \tanh$ if $K < 0$. The same gyrovector spaces can be used to define the exponential and logarithmic maps in the Poincaré ball and the projected hypersphere. We list these mapping functions in Table 8 in the appendix. As Ganea et al. (2018) use the exponential and logarithmic maps to obtain the *Möbius matrix-vector multiplication*: $\mathbf{M} \otimes_K \mathbf{x} = \exp_{\mathbf{0}}^K(\mathbf{M} \log_{\mathbf{0}}^K(\mathbf{x}))$, we reuse them in hyperbolic space. This operation is defined similarly in projected hyperspherical space.

2.4 Product Manifold

We further generalize the embedding space of latent representations from a single manifold to a product of Riemannian manifolds with constant curvatures. Consider a sequence of Riemannian manifolds with constant curvatures, the product manifold is defined as the Cartesian product of k component manifolds $\mathcal{M}^n = \times_{i=1}^k \mathcal{M}_{K_i}^{n_i}$, where n_i is the dimensionality of the $i-$th component, and K_i indicates its curvature, with choices $\mathcal{M}_{K_i}^{n_i} \in \{\mathbb{P}_{K_i}^{n_i}, \mathbb{E}^{n_i}, \mathbb{S}_{K_i}^{n_i}\}$. We call $\{(n_i, k_i)\}_{i=1}^k$ the *signature* of a product manifold. Note that the notation $\mathbb{E}^{n_i}$ is redundant in Euclidean spaces since the Cartesian product of Euclidean spaces with different dimensions can be combined into a single space, i.e. $\mathbb{E}^n = \times_{i=1}^k \mathbb{E}^{n_i}$. However, this equality does not hold in the projected hypersphere and the Poincaré ball. For each point $\mathbf{x} \in \mathcal{M}^n$ on a product manifold, we decompose its coordinates into the corresponding coordinates in component manifolds $\mathbf{x} = (\mathbf{x}^{(1)}, ..., \mathbf{x}^{(k)})$, where $\mathbf{x}^{(i)} \in \mathcal{M}_{K_i}^{n_i}$. The distance function decomposes based on its definition $d_{\mathcal{M}^n}^2(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^k d_{\mathcal{M}_{K_i}^{n_i}}^2(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})$. Similarly, we decompose the metric tensor, exponential and logarithmic maps on a product manifold into the component manifolds. In particular, we split the embedding vectors into parts $\mathbf{x}^{(i)}$, apply the desired operation on that part $f_{K_i}^{n_i}(\mathbf{x}^{(i)})$, and concatenate the resulting parts back (Skopek et al., 2019).

2.5 Temporal Knowledge Graph Completion

Temporal knowledge graphs (KGs) are multi-relational, directed graphs with labeled timestamped edges between entities. Let $\mathcal{E}$, $\mathcal{P}$, and $\mathcal{T}$ represent a finite set of entities, predicates, and timestamps, respectively. Each fact can be denoted by a quadruple $q = (e_s, p, e_o, t)$, where $p \in \mathcal{P}$ represents a timestamped and labeled edge between a subject entity $e_s \in \mathcal{E}$ and an object entity $e_o \in \mathcal{E}$ at a timestamp $t \in \mathcal{T}$. Let $\mathcal{F}$ represents the set of all quadruples that are facts, i.e. real events in the world, the temporal knowledge graph completion (tKGC) is the problem of inferring $\mathcal{F}$ based on a set of observed facts $\mathcal{O}$, which is a subset of $\mathcal{F}$. To evaluate the proposed algorithms, the task of tKGC is to predict either a missing subject entity $(?, p, e_o, t)$ given the other three components or a missing object entity $(e_s, p, ?, t)$. Taking the object prediction as an example, we consider all entities in the set $\mathcal{E}$, and learn a score function $\phi : \mathcal{E} \times \mathcal{P} \times \mathcal{E} \times \mathcal{T} \rightarrow \mathbb{R}$. Since the score function assigns a score to each quadruple, the proper object can be inferred by ranking the scores of all quadruples $\{(e_s, p, e_{o_i}, t), e_{o_i} \in \mathcal{E}\}$ that are accompanied with candidate entities.

3 Related work

3.1 Knowledge Graph Embedding

Static KG Embedding Embedding approaches for static KGs can generally be categorized into bilinear models and translational models. The bilinear approaches are equipped with a bilinear score function that represents predicates as linear transformations acting on entity embeddings (Nickel et al., 2011; Trouillon et al., 2016; Yang et al., 2014; Ma et al., 2018a). Translational approaches measure the plausibility of a triple as the distance between the translated subject and object entity embeddings, including TransE (Bordes et al., 2013) and its variations (Sun et al., 2019; Kazemi and Poole, 2018). Additionally, several models are based on deep learning approaches (Dettmers et al., 2018; Schlichtkrull et al., 2018; Hildebrandt et al., 2020) that apply (graph) convolutional layers on top of embeddings and design a score function as the last layer of the neural network.

Temporal KG Embedding Recently, there have been some attempts of incorporating time information in temporal KGs to improve the performance of link prediction. Ma et al. (2018b) developed extensions of static knowledge graph models by adding a timestamp embedding to the score functions. Also, Leblay and Chekol (2018) proposed TTransE by incorporating time representations into the score function of TransE in different ways. HyTE (Dasgupta et al., 2018) embeds time information in the entity-relation space by arranging a temporal hyperplane to each timestamp. The number of parameters of these models scales with the number of timestamps, leading to overfitting when the number of timestamps is extremely large.

3.2 Graph Embedding Approaches in non-Euclidean Geometries

There has been a growing interest in embedding graph data in non-Euclidean spaces. Nickel and Kiela (2017) first applied hyperbolic embedding for link prediction to the lexical database WordNet. Since then, hyperbolic analogs of several other approaches have been developed (De Sa et al., 2018; Tifrea et al., 2018). In particular, Balazevic et al. (2019) proposed a translational model for embedding multi-relational graph data in the hyperbolic space and demonstrated advancements over state-over-the-art. More recently, Gu et al. (2018) generalized manifolds of constant curvature to a product manifold combining hyperbolic, spherical, and Euclidean components. However, these methods consider graph data as static models and lack the ability to capture temporally evolving dynamics.

4 Temporal Knowledge Graph Completion in Riemannian Manifold

Entities in a temporal KG might form different geometric structures under different relations, and these structures could evolve with time. To capture heterogeneous and time-dependent structures, we propose the DyERNIE model to embed entities of temporal knowledge graphs on a product of Riemannian manifolds and model time-dependent behavior of entities with dynamic entity representations.

4.1 Entity Representation

In temporal knowledge graphs, entities might have some features that change over time and some features that remain fixed. Thus, we represent the embedding of an entity $e_j \in \mathcal{E}$ at instance t with a combination of low-dimensional vectors $\mathbf{e}_j(t) = (\mathbf{e}_j^{(1)}(t), ..., \mathbf{e}_j^{(k)}(t))$ with $\mathbf{e}_j^{(i)}(t) \in \mathcal{M}_{K_i}^{n_i}$, where $\mathcal{M}_{K_i}^{n_i} \in \{\mathbb{P}_{K_i}^{n_i}, \mathbb{E}^{n_i}, \mathbb{S}_{K_i}^{n_i}\}$ is the i-th component manifold, K_i and n_i denote the curvature and the dimension of this manifold, respectively. Each component embedding $\mathbf{e}_j^{(i)}(t)$ is derived from an initial embedding and a velocity vector to encode both the stationary properties of the entities and their time-varying behavior, namely

$$\mathbf{e}_j^{(i)}(t) = \exp_{\mathbf{0}}^{K_i}\left(\log_{\mathbf{0}}^{K_i}(\bar{\mathbf{e}}_j^{(i)}) + \mathbf{v}_{e_j^{(i)}} t\right), \quad (1)$$

where $\bar{\mathbf{e}}_j^{(i)} \in \mathcal{M}_{K_i}^{n_i}$ represents the initial embedding that does not change over time. $\mathbf{v}_{e_j^{(i)}} \in \mathcal{T}_{\mathbf{0}}\mathcal{M}_{K_i}^{n_i}$ represents an entity-specific velocity vector that is defined in the tangent space at origin $\mathbf{0}$ and captures evolutionary dynamics of the entity e_j in its vector space representations over time. As shown in Figure 1 (a), we project the initial embedding to the tangent space $\mathcal{T}_{\mathbf{0}}\mathcal{M}_{K_i}^{n_i}$ using the logarithmic map $\log_{\mathbf{0}}^{K_i}$ and then use a velocity vector to obtain the embedding of the next timestamp. Finally, we project it back to the manifold with the exponential map $\exp_{\mathbf{0}}^{K_i}$. Note that in the case of Euclidean space, the exponential map and the logarithmic map are equal to the identity function. By learning both the initial embedding and velocity vector, our model characterizes evolutionary dynamics of entities as movements on manifolds and thus predict unseen entity interactions based on both the stationary and time-varying entity properties.

4.2 Score Function

Bilinear models have been proved to be an effective approach for KG completion (Nickel et al., 2011; Lacroix et al., 2018), where the score function is a bilinear product between subject entity, predicate, and object entity embeddings. However, there is

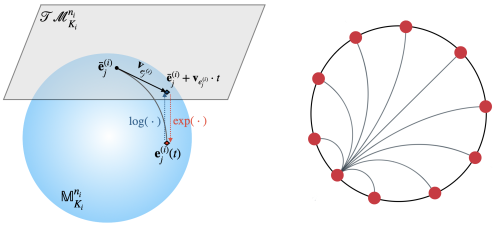

Figure 1: (a) Evolution of an entity embedding on the i-th component manifold (left). For convenience in drawing, the tangent space $\mathcal{TM}^{n_i}_{K_i}$ is defined at $\bar{\mathbf{e}}_j^{(i)}$. (b) Geodesics in the Poincaré disk (right), where red dots represent nodes on the disk.

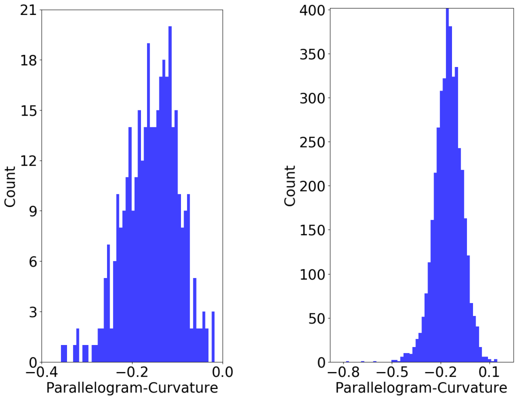

Figure 2: Histogram of sectional curvatures at each timestamps on ICEWS14 (left), and ICEWS05-15 (right).

no clear correspondence of the Euclidean inner-product in non-Euclidean spaces. We follow the method suggested in Poincaré Glove (Tifrea et al., 2018) to reformulate the inner product as a function of distance, i.e. $\langle \mathbf{x}, \mathbf{y} \rangle = \frac{1}{2}(d(\mathbf{x}, \mathbf{y})^2 + ||x||^2 + ||y||^2)$ and replace squared norms with biases $b_{\mathbf{x}}$ and $b_{\mathbf{y}}$. In addition, to capture different hierarchical structures under different relations simultaneously, Balazevic et al. (2019) applied relation-specific transformations to entities, i.e. a stretch by a diagonal predicate matrix $\mathbf{P} \in \mathbb{R}^{n \times n}$ to subject entities and a translation by a vector offset $\mathbf{p} \in \mathbb{P}^n$ to object entities.

Inspired by these two ideas, we define the score function of DyERNIE as

$$\phi(e_s, p, e_o, t) = \sum_{i=1}^{k} -d_{\mathcal{M}^{n_i}_{K_i}} \Big(\mathbf{P}^{(i)} \otimes_{K_i} \mathbf{e}_s^{(i)}(t), \mathbf{e}_o^{(i)}(t) \oplus_{K_i} \mathbf{p}^{(i)} \Big)^2 + b_s^{(i)} + b_o^{(i)}$$

where $\mathbf{e}_s^{(i)}(t)$ and $\mathbf{e}_o^{(i)}(t) \in \mathcal{M}^{n_i}_{K_i}$ are embeddings of the subject and object entities e_s and e_o in the i-th component manifold, respectively. $\mathbf{p}^{(i)} \in \mathcal{M}^{n_i}_{K_i}$ is a translation vector of predicate p, and $\mathbf{P}^{(i)} \in \mathbb{R}^{n_i \times n_i}$ represents a diagonal predicate matrix defined in the tangent space at the origin. Since multi-relational data often has different structures under different predicate, we use predicate-specific transformations $\mathbf{P}$ and $\mathbf{p}$ to determine the predicate-adjusted embeddings of entities in different predicate-dependent structures, e.g. multiple hierarchies. The distance between the predicate-adjusted embeddings of e_s and e_o measures the relatedness between them in terms of a predicate p.

4.3 Learning

The genuine quadruples in a temporal KG $\mathcal{G}$ are split into *train*, *validation*, and *test* sets. We add reciprocal relations for every quadruple, which is a standard data augmentation technique commonly used in literature (Balazevic et al., 2019; Goel et al., 2019), i.e. we add (e_o, p^{-1}, e_s, t) for every (e_s, p, e_o, t). Besides, for each fact (e_s, p, e_o, t) in the training set, we generate n negative samples by corrupting either the object (e_s, p, e_o', t) or the subject (e_o, p^{-1}, e_s', t) with a randomly selected entity from $\mathcal{E}$. We use the binary cross-entropy as the loss function, which is defined as

$$\mathcal{L} = \frac{-1}{N} \sum_{m=1}^{N} \left(y_m \log(p_m) + (1 - y_m) \log(1 - p_m) \right),$$

where N is the number of training samples, y_m represents the binary label indicating whether a quadruple q_m is genuine or not, p_m denotes the predicted probability $\sigma(\phi(q_m))$, and $\sigma(\cdot)$ represents the sigmoid function. Model parameters are learned using *Riemannian stochastic gradient descent* (RSGD) (Bonnabel, 2013), where the Riemannian gradient $\Delta_{\mathcal{M}^n} L$ is obtained by multiplying the Euclidean gradient $\Delta_{\mathbb{E}}$ with the inverse of the Riemannian metric tensor.

4.4 Signature Estimation

To better capture a broad range of structures in temporal KGs, we need to choose an appropriate signature of a product manifold $\mathcal{M}^n$, including the number of component spaces, their dimensions, and curvatures. Although we can simultaneously learn embeddings and the curvature of each component during training using gradient-based optimization, we have empirically found that treating curvature as a trainable parameter interferes with the training of other model parameters. Thus, we treat the curvature of each component and the dimension as hyperparameters selected *a priori*. In particular, we use the parallelogram law' deviation (Gu et al., 2018) to estimate both the graph curvature of a given temporal KG and the number of components. Details about this algorithm can be found in Appendix A. Figure 2 shows the curvature histograms on the ICEWS14 and ICEWS05-15 datasets introduced in Section 5.1. It can be noticed that curvatures are mostly non-Euclidean, offering a good motivation to learn embeddings on a product manifold. Taking the ICEWS05-15 dataset as an example, we see that most curvatures are negative. In this case, we can initialize the product manifold consisting of three hyperbolic components with different dimensions. Then we conduct a Bayesian optimization around the initial value of the dimension and the curvature of each component to fine-tune them. Finally, we select the best-performing signature according to performance on the validation set as the final choice.

5 Experiments

5.1 Experimental Set-up

Datasets Global Database of Events, Language, and Tone (GDELT) (Leetaru and Schrodt, 2013) dataset and Integrated Crisis Early Warning System (ICEWS) (Boschee et al., 2015) dataset have established themselves in the research community as representative samples of temporal KGs. The GDELT dataset is derived from an initiative database of all the events across the globe connecting people, organizations, and news sources. We use a subset extracted by Jin et al. (2019), which contains events occurring from 2018-01-01 to 2018-01-31. The ICEWS dataset contains information about political events with specific time annotations, e.g. (Barack Obama, visit, India, 2010-11-06). We apply our model on two subsets of the ICEWS dataset generated by García-Durán et al. (2018): ICEWS14 contains events in 2014, and ICEWS05-15 corresponds to the facts between 2005 to 2015. We compare our approach and baseline methods by performing the link prediction task on the GDELT, ICEWS14 and ICEWS05-15 datasets. The statistics of the datasets are provided in Appendix C.

Baselines Our baselines include both static and temporal KG embedding models. From the static KG embedding models, we use TransE (Bordes et al., 2013), DistMult (Yang et al., 2014), and ComplEx (Trouillon et al., 2016) where we compress temporal knowledge graphs into a static, cumulative graph by ignoring the time information. From the temporal KG embedding models, we compare the performance of our model with several state-of-the-art methods, including TTransE (Leblay and Chekol, 2018), TDistMult/TComplEx (Ma et al., 2018b), and HyTE (Dasgupta et al., 2018).

Evaluation protocol For each quadruple $q = (e_s, p, e_o, t)$ in the test set $\mathcal{G}_{test}$, we create two queries: $(e_s, p, ?, t)$ and $(e_o, p^{-1}, ?, t)$. For each query, the model ranks all possible entities $\mathcal{E}$ according to their scores. Following the commonly filtered setting in the literature (Bordes et al., 2013), we remove all entity candidates that correspond to true triples[1] from the candidate list apart from the current test entity. Let ψ_{e_s} and ψ_{e_o} represent the rank for e_s and e_o of the two queries respectively, we evaluate our models using standard metrics across the link prediction literature: *mean reciprocal rank (MRR)*: $\frac{1}{2\cdot|\mathcal{G}_{test}|}\sum_{q\in\mathcal{G}_{test}}(\frac{1}{\psi_{e_s}}+\frac{1}{\psi_{e_o}})$ and *Hits*$@k (k \in \{1, 3, 10\})$: the percentage of times that the true entity candidate appears in the top k of ranked candidates.

Implementations We implemented our model and all baselines in PyTorch (Paszke et al., 2019). For fairness of comparison, we use Table 2 in supplementary materials to compute the embedding dimension for each (baseline, dataset) pair that matches the number of parameters of our model with an embedding dimension of 100. Taking HyTE as an example, its embedding dimension is 193 and 151 on the ICEWS14 and GDELT dataset, respectively. Also, we use the datasets augmented with reciprocal relations to train all baseline models. We tune hyperparameters of our models using the quasi-random search followed by Bayesian optimization (Ruffinelli et al., 2020) and report the best configuration in Appendix E. We implement TTransE, TComplEx, and TDistMult based on the implementation of TransE, Distmult, and ComplEx respectively. We use the binary cross-entropy loss and RSGD to train these baselines and optimize hyperparameters by early stopping according to MRR on the validation set. Additionally, we use the implementation of HyTE[2]. We provide the detailed

5.2 Comparative Study

Table 2: Filtered MRR for different choices of the distance function with $K = -1$ and $n = 40$ on ICEWS14.

Distance function	MRR
$d(\mathbf{P} \otimes \mathbf{e}_s(t), \mathbf{e}_o(t) \oplus \mathbf{p})$	**55.87**
$\cosh(d(\mathbf{P} \otimes \mathbf{e}_s(t), \mathbf{e}_o(t) \oplus \mathbf{p}))$	54.00
$d(\mathbf{P} \otimes \mathbf{e}_s(t), \mathbf{P} \otimes \mathbf{e}_o(t))$	52.23
$d(\mathbf{P} \otimes \mathbf{e}_s(t), \mathbf{P} \otimes \mathbf{e}_o(t) \oplus \mathbf{p})$	54.55
$d(\mathbf{P} \otimes \mathbf{e}_s(t), \mathbf{e}_o(t))$	47.24
$d(\mathbf{e}_s(t), \mathbf{e}_o(t) \oplus \mathbf{p})$	51.36

Model variants To compare the performance of non-Euclidean embeddings with their Euclidean counterparts, we implement the Euclidean version of Equation 4.2 with $d_{\mathcal{M}}(\mathbf{x}, \mathbf{y}) = d_{\mathbb{E}}(\mathbf{x}, \mathbf{y})$. We refer to it as DyERNIE-Euclid. Besides, we train our model with a single non-Euclidean component to compare embeddings in a product space and in a manifold with a constant curvature. We refer to them as DyERNIE-Prod and DyERNIE-Sgl, respectively. For DyERNIE-Prod, we generate model configurations with different manifold combinations, i.e. $\mathbb{P} \times \mathbb{S} \times \mathbb{E}, \mathbb{P}^3$. Details about the search space are relegated to Appendix E.

Link prediction results We compare the baselines with three variants of our model: DyERNIE-Prod, DyERNIE-Sgl, and DyERNIE-Euclid. We report the best results on the test set among all model configurations in Table 1. Note that the number of parameters of all baselines matches our model's with an embedding dimension of 100. Thus, we see that both DyERNIE-Prod and DyERNIE-Sgl significantly outperform the baselines and DyERNIE-Euclid on all three datasets with the same number of parameters. Even at a low embedding dimension ($n = 10$), our models still have competitive performance, demonstrating the merits of time-dependent non-Euclidean embeddings. Besides, DyERNIE-Prod generally performs better than DyERNIE-Sgl on all three datasets. On the ICEWS14 and ICEWS05-15 datasets, we can observe that the best performing configuration of DyERNIE-Prod at each dimensionality only contains hyperbolic component manifolds. This observation confirms the curvature estimation shown in Figure 2, where most sectional curvatures on the ICEWS14 and ICEWS05-15 datasets are negative.

Table 3: Filtered MRR for different choices of entity representations with $K = -1$ and $n = 40$ on ICEWS14, where $\mathbf{A}_i$ and $\mathbf{w}_i$ represent the amplitude vector and the frequency vector, respectively. ϕ_i denotes the phase shift.

Entity Representations	MRR
$\exp(\log(\bar{\mathbf{e}}_i) + \mathbf{v}_i t)$	**55.87**
$\exp(\log(\bar{\mathbf{e}}_i) + \mathbf{A}_i \sin(\mathbf{w}_i t + \phi_i))$	52.50
$\exp(\log(\bar{\mathbf{e}}_i) + \mathbf{v}_i t + \mathbf{A}_i \sin(\mathbf{w}_i t + \phi_i))$	53.52

Ablation study We show an ablation study of the distance function and the entity representations in Table 2 and 3, respectively. For the distance

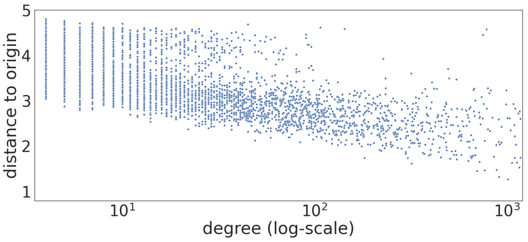

Figure 3: Scatter plot of distances between entity embeddings and the manifold's origin v.s. node degrees on ICEWS05-15. Each point denotes an entity e_j. The x-coordinate gives its degree accumulated over all timestamps, and the y-coordinate represents $d_{\mathcal{M}}(\mathbf{e}_j, \mathbf{0})$.

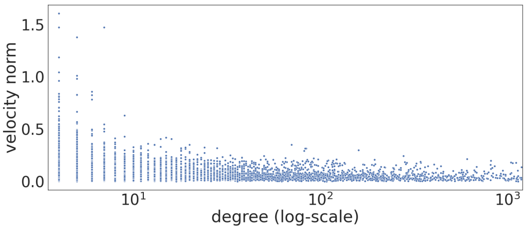

Figure 4: Scatter plot of velocity norms v.s. node degrees on ICEWS05-15. Each point denotes an entity.

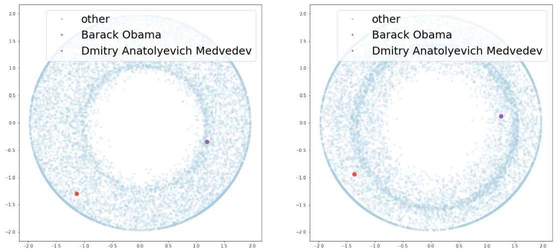

Figure 5: Learned two-dimensional hyperbolic entity embeddings of ICEWS05-15 on the first timestamp 2005-01-01 (left) and the last timestamp 2015-12-31 (right).

function, we use $\mathbf{p}$ and $\mathbf{P}$ to get predicate-adjusted subject and object embeddings and compute the distance between them. We found that any change to distance function causes performance degradation. Especially, removing the translation vector $\mathbf{p}$ most strongly decrease the performance. For the entity representation function, we measure the importance of a linear trend component and a non-linear periodic component. We attempt adding trigonometric functions into entity representations since a combination of trigonometric functions can capture more complicated non-linear dynamics (Rahimi and Recht, 2008). However, experimental results in Table 3 show that using only a linear transformation works the best, which indicates that finding the correct manifold of embedding space is more important than designing complicated non-linear evolution functions of entity embeddings. Additionally, we found the performance degrades significantly if removing the dynamic part of the entity embeddings. For example, on the ICEWS0515 dataset, the Hits@1 metric in the static case is only about half of that in the dynamic case, clearly showing the gain from the dynamism. Details of this ablation study are provided in Appendix G.

Intrinsic hierarchical structures of temporal KGs To illustrate geometric, especially the hierarchical, structures of temporal KGs, we focus on the Poincaré ball model with a dimension of 20 and plot the geodesic distance $d_{\mathcal{M}}(\cdot, \mathbf{0})$ of learned entity embeddings to the origin of the Poincaré ball versus the degree of each entity in Figure 3. Note that the distance is averaged over all timestamps since entity embeddings are time-dependent. We observe that entities with high degrees, which means they got involved in lots of facts, are generally located close to the origin. This makes sense because these entities often lie in the top hierarchical levels. And thus, they should stand close to the root. Under the same settings, we plot the velocity norm of each entity versus the entity degree in Figure 4. Similarly, we see that entities with high degrees have a small velocity norm to stay near the origin of the manifold.

Relative movements between a node pair Figure 5 shows two-dimensional hyperbolic entity embeddings of the ICEWS05-15 dataset on two timestamps, 2005-01-01 and 2015-12-31. Specifically, we highlight a former US president (in orange) and a former prime minister of Russia (in purple). We found that the interaction between these two entities decreased between 2005 and 2015, as shown in Figure 9 in the appendix. Accordingly, we observe that the embeddings of these two entities were moving away from each other. More examples of learned embeddings are relegated to Appendix F.

6 Conclusion

In this paper, we propose an embedding approach for temporal knowledge graphs on a product of Riemannian manifolds with heterogeneous curvatures. To capture the temporal evolution of temporal KGs, we use velocity vectors defined in tangent spaces to learn time-dependent entity representations. We show that our model significantly outperforms its Euclidean counterpart and other state-of-the-art approaches on three benchmark datasets of temporal KGs, which demonstrates the significance of geometrical spaces for the temporal knowledge graph completion task.

Appendices

A Graph Curvature Estimation Algorithm

We use Algorithm 1 to estimate the sectional curvatures of a dataset developed by Bachmann et al. (2019).

B Implementation Details of Baselines

Note that the embedding dimension for each (baseline, dataset) pair matches the number of parameters of our models with an embedding dimension of 100. We use Table 4 and 12 to compute the rank for each (baselines, dataset) pair. Besides, for fairness of results, we use the datasets augmented with reciprocal relations to train all baseline models.

Static knowledge graph embedding models We use TransE (Bordes et al., 2013), DistMult (Yang et al., 2014), and ComplEx (Trouillon et al., 2016) as static baselines, where we compress temporal knowledge graphs into a static, cumulative graph by ignoring the time information. We use the cross-entropy loss and Adam optimizer with a batch size of 128 to train the static baselines. Besides, we use uniform sampling to initialize the embeddings of entities and predicates. Other hyperparameters of the above baselines are shown in Table 5.

Temporal knowledge graph embedding models We compare our model's performance with several state-of-the-art temporal knowledge graph embedding methods, including TTransE (Leblay and Chekol, 2018), TDistMult/TComplEx (Ma et al.,

Table 4: Number of parameters for each model considered when using reciprocal relations: d represent the dimension of embeddings.

Model	# Parameters
ComplEx	$(2\|\mathcal{E}\| + 4\|\mathcal{P}\|) \cdot d$
TransE	$(\|\mathcal{E}\| + 2\|\mathcal{P}\|) \cdot d$
DistMult	$(\|\mathcal{E}\| + 2\|\mathcal{P}\|) \cdot d$
TComplEx	$(2\|\mathcal{E}\| + 4\|\mathcal{P}\| + 2\|\mathcal{T}\|) \cdot d$
TTransE	$(\|\mathcal{E}\| + 2\|\mathcal{P}\| + \|\mathcal{T}\|) \cdot d$
TDistMult	$(\|\mathcal{E}\| + 2\|\mathcal{P}\| + \|\mathcal{T}\|) \cdot d$
HyTE	$(\|\mathcal{E}\| + 2\|\mathcal{P}\| + \|\mathcal{T}\|) \cdot d$
DyERNIE	$2(\|\mathcal{E}\| + 2\|\mathcal{P}\|) \cdot d + 2\|\mathcal{E}\|$

2018b), and HyTE (Dasgupta et al., 2018). We use the ADAM optimizer (Kingma and Ba, 2014) and the cross-entropy loss to train the temporal KG models. We set learning rate = 0.001, negative samples pro fact = 500, number of epochs = 500 , batch size = 256, and validate them every 50 epochs to select the model giving the best validation MRR. For the GDELT dataset, we use a similar setting but with negative samples pro fact = 50 due to the large size of the dataset. The embedding dimensions of the above dynamic baselines on each dataset are shown in Table 6.

Table 5: Hyperparameter settings of static baselines.

Model	TransE	DistMult	ComplEx
Embedding dimension			
ICEWS14	202	202	101
ICEWS05-15	202	202	101
GDELT	202	202	101
Negative Sampling	253	657	1529
Learning rate	3e-4	0.16	0.18

C Datasets

Dataset statistics are described in Table 12. Since the timestamps in the ICEWS dataset are dates rather than numbers, we sort them chronologically and encode them into consecutive numbers.

Table 6: Embedding dimensions of dynamic baselines.

Model	TTransE	TDistMult	TComplEx	HyTE
Embedding dimension				
ICEWS14	193	193	96	193
ICEWS05-15	148	148	74	148
GDELT	151	151	76	151

D Evaluation metrics

Let ψ_{e_s} and ψ_{e_o} represent the rank for e_s and e_o of the two queries, respectively. We evaluate our models using standard metrics across the link prediction literature: *mean reciprocal rank (MRR)*: $\frac{1}{2\cdot|\mathcal{G}_{test}|}\sum_{q\in\mathcal{G}_{test}}(\frac{1}{\psi_{e_s}} + \frac{1}{\psi_{e_o}})$ and *Hits@*$k(k \in \{1, 3, 10\})$: the percentage of times that the true entity candidate appears in the top k of ranked candidates.

E Implementation Details of DyERNIE

Signature search On the ICEWS subsets, we try all manifold combinations with the number of components of $\{1, 2, 3\}$. Due to the large size of data samples on the GDELT dataset, we only try manifold combinations with the number of components of $\{1, 2\}$. Specifically, the candidates are $\{\mathbb{P}^n, \mathbb{S}^n, \mathbb{E}^n\}$ for single manifolds, $\{\mathbb{P}^{n_i} \times \mathbb{S}^{n_i}, \mathbb{P}^{n_i} \times \mathbb{P}^{n_i}, \mathbb{S}^{n_i} \times \mathbb{S}^{n_i}, \mathbb{P}^{n_i} \times \mathbb{E}^{n_i}, \mathbb{S}^{n_i} \times \mathbb{E}^{n_i}\}$ for a product of two component manifolds, and $\{\mathbb{P}^{n_i} \times \mathbb{P}^{n_i} \times \mathbb{P}^{n_i}, \mathbb{P}^{n_i} \times \mathbb{S}^{n_i} \times \mathbb{E}^{n_i}, \mathbb{S}^{n_i} \times \mathbb{S}^{n_i} \times \mathbb{S}^{n_i}, \mathbb{P}^{n_i}, \times \mathbb{P}^{n_i} \times \mathbb{S}^{n_i}, \mathbb{P}^{n_i} \times \mathbb{S}^{n_i} \times \mathbb{S}^{n_i}, \mathbb{P}^{n_i} \times \mathbb{P}^{n_i} \times \mathbb{E}^{n_i}, \mathbb{S}^{n_i} \times \mathbb{S}^{n_i} \times \mathbb{E}^{n_i}\}$ for a product of three component manifold. For each combination, we use the Ax-framework[3] to optimize the assignment of dimensions to each component manifold and the curvatures. The assignment of the best-performing models are shown in Table 9, 10, and 11. We report the best results on each dataset in Table 1 in the main body.

Hyperparameter configurations for best-performing models We select the loss function from binary cross-entropy (BCE), margin ranking loss, and cross-entropy (CE). BCE and CE give a similar performance and outperform the margin ranking loss. However, when using the BCE loss, we could use a large learning rate ($lr > 10$) to speed up the training procedure. In contrast, models with the CE loss incline overfitting by large learning rates. Given the BCE loss, we found the learning rate of 50 works the best for all model configurations. Furthermore, increasing negative samples can improve the performance to some extent, while this impact is weakening gradually as the number of negative samples become larger. However, the number of negative samples largely affect the runtime of the training procedure. We empirically found that the negative sample number of 50 is a good compromise

---

[3] https://ax.dev

between the model performance and the training speed. Besides, there is no statistically significant difference in the model performance when using different optimizers, such as Riemannian Adam (RADAM) and Riemannian stochastic gradient descent (RSGD). Thus, for the model's simplicity, we decide to use RSGD.

Average runtime for each approach $\&$ Number of parameters in each model Table 13 shows the number of parameters and the average runtime for each model.

F Visualization

We plot the geodesic distance $d_{\mathcal{M}}(\mathbf{e}_j, \mathbf{0})$ of learned entity embeddings with a dimension of 20 to the manifold's origin versus the degree of each entity in Figure 6, where $d_{\mathcal{M}}(\mathbf{e}_j, \mathbf{0})$ is averaged over all timestamps since $\mathbf{e}_j$ is time-dependent. Also, the degree of each entity is accumulated over all timestamps. Each point in the upper plot represents an entity where the x-coordinate gives their degree, and the y-coordinate gives their average distance to the origin. The plot clearly shows the tendency that entities with high degrees are more likely to lie close to the origin. The bottom plot shows the same content but with a sampling of 20% points. The gray bar around each point shows the variance of the distance between the entity embedding and the origin over time.

Figure 7 shows two-dimensional hyperbolic entity embeddings of the ICEWS05-15 dataset on four timestamps. We highlight some entities to show the relative movements between them. The number of interactions between the selected entities are depicted in Figure 8 and 9, which evolves over time. Specifically, we highlight Nigerian citizens, the Nigerian government, head of the Nigerian government, other authorities in Nigeria, and Nigerian minister in the first row of subplots. Furthermore, we show the relative movements between the entity embeddings of Barack Obama, Xi Jinping, and Dmitry Anatolyevich Medvedev in the second row of subplots. We can see that two entities are getting closer in the Poincare disc if the number of interactions between them increases.

G Additional Ablation Study

To assess the contribution of the dynamic part of entity embeddings, we remove the dynamic part and run the model variant on static knowledge graphs. Specifically, we compress ICEWS05-15 into a static, cumulative graph by ignoring the time information. As shown in Table 7, the performance degrades significantly if the entity embeddings only have the static part. For example, on the ICEWS0515 dataset, the Hits@1 metric of DyERNIE-Sgl in the static case is less than half of that in the dynamic case, clearly showing the gain from the dynamism.

Table 7: Filtered MRR for dynamic/static entity representations with $dim = 20$ on ICEWS05-15. Note that we run the static model variant on static ICEWS05-15.

Entity Representations	MRR	Hits@1	Hits@3	Hits@10
With dynamic part	63.8	55.9	67.9	78.7
Without dynamic part	38.6	28.3	42.8	59.2

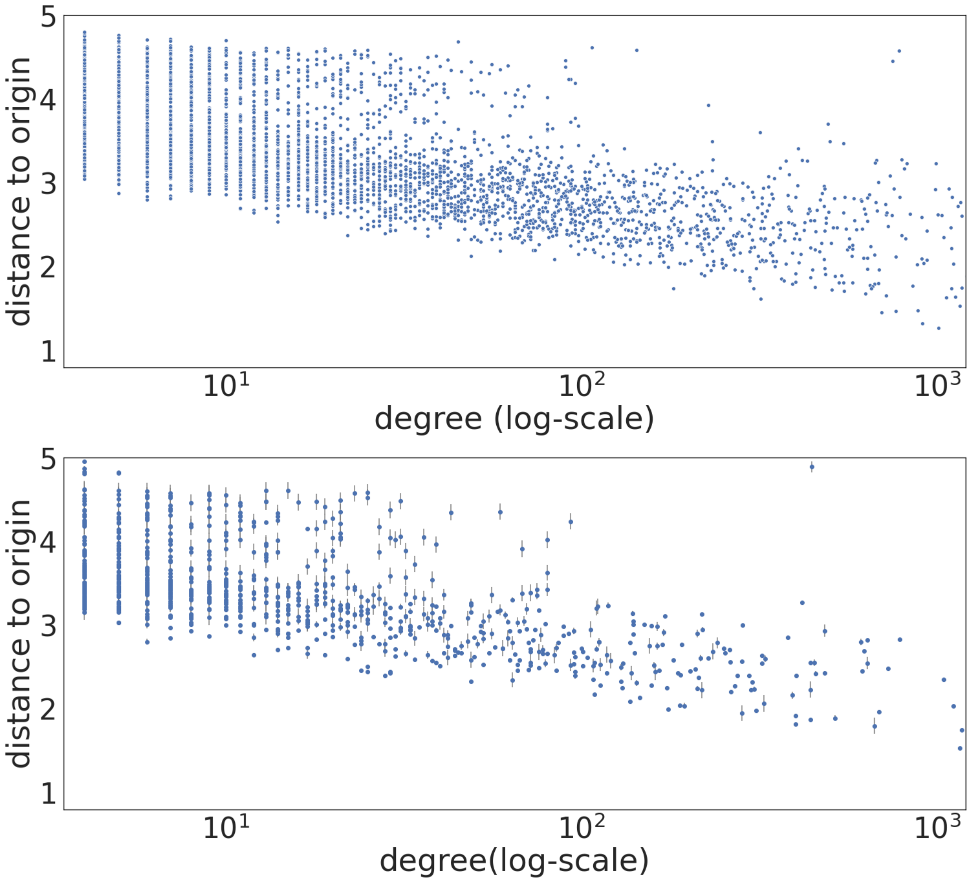

Figure 6: Each point in the upper plot represents an entity whose x-coordinate gives their degree accumulated over all timestamps and y-coordinate gives their distance to the origin averaged over all timestamps. The plot clearly shows the tendency that entities with high degrees are more likely to lie close to the origin. The bottom plot shows the same content but with a sampling of 20% points. The gray bar around each point shows the variance of the distance over all timestamps.

Abstract

It has become a de-facto standard to represent words as elements of a vector space (word2vec, GloVe). While this approach is convenient, it is unnatural for language: words form a graph with a latent hierarchical structure, and this structure has to be revealed and encoded by word embeddings. We introduce Graph-Glove: unsupervised graph word representations which are learned end-to-end. In our setting, each word is a node in a weighted graph and the distance between words is the shortest path distance between the corresponding nodes. We adopt a recent method learning a representation of data in the form of a differentiable weighted graph and use it to modify the GloVe training algorithm. We show that our graph-based representations substantially outperform vector-based methods on word similarity and analogy tasks. Our analysis reveals that the structure of the learned graphs is hierarchical and similar to that of WordNet, the geometry is highly non-trivial and contains subgraphs with different local topology.[1]

1 Introduction

Effective word representations are a key component of machine learning models for most natural language processing tasks. The most popular approach to represent a word is to map it to a low-dimensional vector (Mikolov et al., 2013b; Pennington et al., 2014; Bojanowski et al., 2017; Tifrea et al., 2019). Several algorithms can produce word embedding vectors with distances or dot products capturing semantic relationships between words; the vector representations can be useful for solving numerous NLP tasks such as word analogy (Mikolov et al., 2013b), hypernymy detection (Tifrea et al., 2019) or serving as features for supervised learning problems.

While representing words as vectors may be convenient, it is unnatural for language: words form a graph with a hierarchical structure (Miller, 1995) that has to be revealed and encoded by unsupervised learned word embeddings. A possible step towards this can be made by choosing a vector space more similar to the structure of the data: for example, a space with hyperbolic geometry (Dhingra et al., 2018; Tifrea et al., 2019) instead of commonly used Euclidean (Mikolov et al., 2013b; Pennington et al., 2014; Bojanowski et al., 2017) was shown beneficial for several tasks. However, learning data structure by choosing an appropriate vector space is likely to be neither optimal nor generalizable: Gu et al. (2018) argue that not only are different data better modelled by different spaces, but even for the same dataset the preferable type of space may vary across its parts. It means that the quality of the representations obtained from vector-based embeddings is determined by how well the geometry of the embedding space matches the structure of the data. Therefore, (1) any vector-based word embeddings inherit limitations imposed by the structure of the chosen vector space; (2) the vector space geometry greatly influences the properties of the learned embeddings; (3) these properties may be the ones of a space geometry and not the ones of a language.

In this work, we propose to embed words into a graph, which is more natural for language. In our setting, each word is a node in a weighted undirected graph and the distance between words is the shortest path distance between the corresponding nodes; note that any finite metric space can be represented in such a manner. We adopt a recently introduced method which learns a representation of data as a weighted graph (Mazur et al., 2019) and use it to modify the GloVe algorithm for unsuper-

vised word embeddings (Pennington et al., 2014). The former enables simple end-to-end training by gradient descent, the latter — learning a graph in an unsupervised manner. Using the fixed training regime of GloVe, we vary the choice of a distance: the graph distance we introduced, as well as the ones defined by vector spaces: Euclidean (Pennington et al., 2014) and hyperbolic (Tifrea et al., 2019). This allows for a fair comparison of vector-based and graph-based approaches and analysis of limitations of vector spaces. In addition to improvements on a wide range of word similarity and analogy tasks, analysis of the structure of the learned graphs suggests that graph-based word representations can potentially be used as a tool for language analysis.

Our key contributions are as follows:

- we introduce GraphGlove — graph word embeddings;
- we show that GraphGlove substantially outperforms both Euclidean and Poincaré GloVe on word similarity and word analogy tasks;
- we analyze the learned graph structure and show that GraphGlove has hierarchical, similar to WordNet, structure and highly non-trivial geometry containing subgraphs with different local topology.

2 Graph Word Embeddings

For a vocabulary $\mathbf{V} = \{v_0, v_1, \ldots, v_n\}$, we define *graph word embeddings* as an undirected weighted graph $G(V, E, w)$. In this graph,

- ○ V is a set of vertices corresponding to the vocabulary words;
- ○ $E = \{e_0, e_1, \ldots, e_m\}$ is a set of edges: $e_i = e(v_{src_i}, v_{dst_i})$, $v_{src_i}, v_{dst_i} \in V$;
- ○ $w(e_i)$ are non-negative edge weights.

When embedding words as vectors, the distance between words is defined as the distance between their vectors; the distance function is inherited from the chosen vector space (usually Euclidean). For graph word embeddings, the distance between words is defined as the shortest path distance between the corresponding nodes of the graph:

$$d_G(v_i, v_j) = \min_{\pi \in \Pi_G(v_i, v_j)} \sum_{e_k \in \pi} w(e_k), \qquad (1)$$

where $\Pi_G(v_i, v_j)$ is the set of all paths from v_i to v_j over the edges of G.

To learn graph word embeddings, we use a recently introduced method for learning a representation of data in a form of a weighted graph (Mazur et al., 2019) and modify the training procedure of GloVe (Pennington et al., 2014) for learning unsupervised word embeddings. We give necessary background in Section 2.1 and introduce our method, GraphGlove, in Section 2.2.

2.1 Background

2.1.1 Learning Weighted Graphs

PRODIGE (Mazur et al., 2019) is a method for learning a representation of data in a form of a weighted graph $G(V, E, w)$. The graph requires (i) inducing a set of edges E from the data and (ii) learning edge weights. To induce a set of edges, the method starts from some sufficiently large initial set of edges and, along with edge weights, learns which of the edges can be removed from the graph. Formally, it learns $G(V, E, w, p)$, where in addition to a weight $w(e_i)$, each edge e_i has an associated Bernoulli random variable $b_i \sim Bern(p(e_i))$; this variable indicates whether an edge is present in G or not. For simplicity, all random variables b_i are assumed to be independent and the joint probability of all edges in the graph can be written as $p(G) = \prod_{i=0}^{m} p(e_i)$. Since each edge is present in the graph with some probability, the distance is reformulated as the expected shortest path distance:

$$d(v_i, v_j) = \mathop{\mathbb{E}}_{G \sim p(G)} d_G(v_i, v_j) =$$

$$= \mathop{\mathbb{E}}_{G \sim p(G)} \min_{\pi \in \Pi_G(v_i, v_j)} \sum_{e_i \in \pi} w(e_i), \qquad (2)$$

where $d_G(v_i, v_j)$ is computed efficiently using Dijkstra's algorithm. The probabilities $p(e_i)$ are used only in training; at test time, edges with probabilities less than 0.5 are removed, and the graph $G(V, E, w, p)$ can be treated as a deterministic graph $G(V, E, w)$.

Training. Edge probabilities $p(e_i) = p_\theta(e_i)$ and weights $w(e_i) = w_\theta(e_i)$ are learned by minimizing the following training objective:

$$\mathcal{R}(\theta) = \mathop{\mathbb{E}}_{G \sim p(G)} [L(G, \theta)] + \lambda \cdot \frac{1}{|E|} \sum_{i=1}^{|E|} p_\theta(e_i). \qquad (3)$$

Here $L(G, \theta)$ is a task-specific loss, and $\frac{1}{|E|} \sum_{i=1}^{|E|} p_\theta(e_i)$ is the average probability of an edge being present. The second term is the L_0 regularizer on the number of edges, which penalizes edges for being present in the graph. Training with such regularization results in a graph where an edge becomes either redundant (with probability close to 0) or important (with probability close to 1).

To propagate gradients through the second term in (3), the authors use the log-derivative trick (Glynn, 1990) and Monte-Carlo estimate of the resulting gradient; when sampling, they also apply a heuristic to reduce variance. For more details on the optimization procedure, we refer the reader to the original paper (Mazur et al., 2019).
