Dialectal Arabic Data and Models. Much of the early work on Arabic varieties focused on collecting data for main varieties such as Egyptian and Levantine (Diab et al., 2010; Elfardy and Diab, 2012; Al-Sabbagh and Girju, 2012; Sadat et al., 2014; Zaidan and Callison-Burch, 2011). Many works developed models for detecting 2-3 dialects (Elfardy and Diab, 2013; Zaidan and Callison-Burch, 2011, 2014; Cotterell and Callison-Burch, 2014). Larger datasets, mainly based on Twitter, were recently introduced (Mubarak and Darwish, 2014; Abdul-Mageed et al., 2018; Zaghouani and Charfi, 2018; Bouamor et al., 2019a). Our dataset is orders of magnitude larger than other datasets, more balanced, and more diverse. It is also, by far, the most fine-grained.

Geolocation, Variation, and MTL. Research on geolocation is also relevant, whether based on text (Roller et al., 2012; Graham et al., 2014; Han et al., 2016; Do et al., 2018), user profile (Han et al., 2013), or network-based methods (Miura et al., 2017; Ebrahimi et al., 2018). Models exploiting network information, however, do not scale well to larger datasets (Rahimi et al., 2015). (Eisenstein, 2012) exploit geotagged Twitter data to study how words spread geographically. (Bamman et al., 2014) uses representations based on geolocation to improve semantic similarity. Dunn (2019) studies syntactic variations in 7 languages based on geolocated data. Hovy et al. (2020) visualizes regional variation across Europe using Twitter. Dunn and Adams (2020) find that Twitter data are representative of actual population. MTL has been successfully applied to many NLP problems, including MT and syntactic parsing (Luong et al., 2015), sequence labeling (Søgaard and Goldberg, 2016; Rei, 2017), and text classification (Liu et al., 2016).

11 Conclusion

We introduced the novel task of MDI and offered a large-scale, manually-labeled dataset covering 319 city-based Arabic micro-varieties. We also introduced several novel MTL scenarios for modeling MDs including at hierarchical levels, and with linguistically-motivated auxiliary tasks inspired by diaglossic and code-switching environments. We have also exploited our own data to train MARBERT, a very large and powerful masked language model covering all Arabic varieties. Our models establish new SOTA on a wide range of tasks, thereby demonstrating their value. Ultimately, we hope our work can open up new horizons for studying MDs in various languages.

Acknowledgment

We thank the anonymous reviewers for their valuable feedback, and Hassan Alhuzali for initial help with data. We gratefully acknowledge support from the Natural Sciences and Engineering Research Council of Canada, the Social Sciences Research Council of Canada, Compute Canada (`www.computecanada.ca`), and UBC ARC–Sockeye (`https://doi.org/10.14288/SOCKEYE`).

---

[20] F_1^{PN} was defined by SemEval-2017 as the $macro\ F_1$ over the positive and negative classes only while neglecting the neutral class.

A Data Acquisition and Labeling

A.1 Correction of City and State Tags

City-Level. Investigating examples of the geolocated data, we observed geopy made some mistakes. To solve the issue, we decided to manually verify the information returned from geopy on all the 705 assumed 'cities'. For this purpose of manual verification, we use Wikipedia, Google maps, and web search as sources of information while checking city names. We found that geopy made mistakes in 7 cases as a result of misspelled city names in the queries we sent (as coming from user profiles). We also found that 44 cases were not assigned the correct city name as the first 'solution'. Geopy provided us with a maximum of 7 solutions for a query, with best solutions sometimes being names of hamlets, villages, etc., rather than cities. In many cases, we found the correct solution to fall between the $2nd$ and $4th$ solutions. A third problem was that some city names (as coming from user profiles) were written in non-Arabic (e.g., English or French). We solved this issue by requiring geopy to also return the English version of a city name, and *exclusively* using that English version. Ultimately, we acquired a total of 646 cities.

State-Level. As explained, geopy returned to us a total of 235 states/provinces that correspond to the 646 identified (manually fixed) cities. We also manually verified all the state names and their correspondence to the cities and countries. We found no issues with state tags.

A.2 Validation of User Location

We trained the two annotators and instructed them to examine the profile information of each user on Twitter, providing a link to the profile. We asked them to consider various sources of information as a basis for their decisions, including (1) the profile picture, (2) profile textual description (including user-provided location), (3) the actual name of the user (if available), (4) at least 10 tweets, (5) the followers and followees of the user, and (5) user's network behavior such as the 'likes'.

Each annotator was responsible for $\sim$ 50% of the usernames and was given a random sample of 100 [21] users for each city along with the Twitter handles and the automatically assigned *city* and *country* labels. We asked the users to label the first 10 accounts in each city, and only add more if the city proves specially challenging (as we observed to be the case in a pilot analysis of a few cities). Annotators ended up labeling a total of 4,953 accounts ($\sim$ 11.88 users per city), of whom 4,012 users were verified for country and 3,085 for *both* country and city locations. We found that 81.00% of geopy tags for country are correct, but only 62.29% for city (which reduced our final city count to 319). As a final sanity check, a third annotator reviewed the labels for a random sample of 20 users from each annotator and agreed fully.

B Datasets

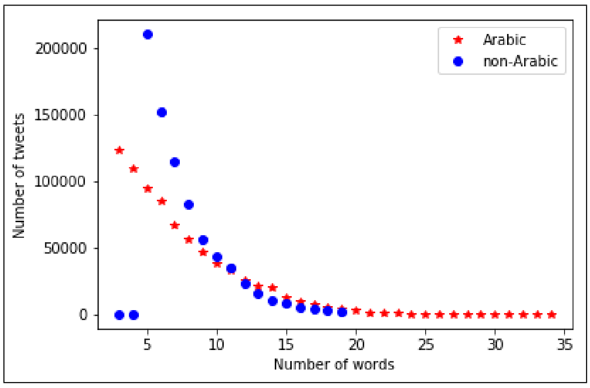

Figure B.1: Word frequency distribution in our CS-21 (code-switching) dataset.

Country	%vld_cntry	%vld_city	#tweets
Algeria	77.49	69.74	185,854
Bahrain	83.95	39.51	25,495
Djibouti	68.42	68.42	3,939
Egypt	92.66	64.02	463,695
Iraq	51.50	37.61	59,287

Table B.1: Statistics of our data representing 233,105 users from 664 cities and 21 countries. We process more than half a billion tweets, from a larger pool of ∼6 billion tweets, to acquire our final dataset. Note that the number of states and cities is further reduced after our manual user verification. Eventually, we acquire data for 319 cities, belonging to 192. The data represent all 21 Arab countries.

Table B.3: Distribution of classes in our data splits.

C Models

C.1 Single Task BiGRUs (Second Baseline)

As mentioned in Section 4.1, our a *second baseline* (Baseline II), is comprised of 3 independent networks (each for one of the 3 tasks) using the same architecture and model capacity. Each network has 3 hidden BiGRU layers, [22] with 1,000 units each (500 units from left to right and 500 units from right to left). We add dot-product attention *only* to the third hidden layer. We trim each sequence at 50 words, [23] and use a batch size of 8. Each word in the input sequence is represented as a vector of 300 dimensions that are learned directly from the data. Word vectors weights W are initialized with a normal distribution, with $\mu = 0$, and $\sigma = 0.05$, i.e., $W \sim N(0, 0.05)$. For optimization, we use Adam (Kingma and Ba, 2014) with a fixed learning rate of $1e-3$. For regularization, we use dropout (Srivastava et al., 2014) with a value of 0.5 on each of the 3 hidden layers.

C.2 Distill BERT

We distill mBERT knowledge in out HA-MTL BiGRUs. In other words, we use the output of the mBERT logit layer as input to our city-first and country-first HA-MTL BiGRUs to optimize a mean-squared error objective function, but not a cross-entropy function (following equation 3 in

---

[22] We also ran single-task networks with 4 hidden layers, but we find them to overfit quickly even when we regularize with dropout at 0.7 on all layers.

[23] In initial experiments, we found a maximum sequence of 30 words to perform slightly worse.

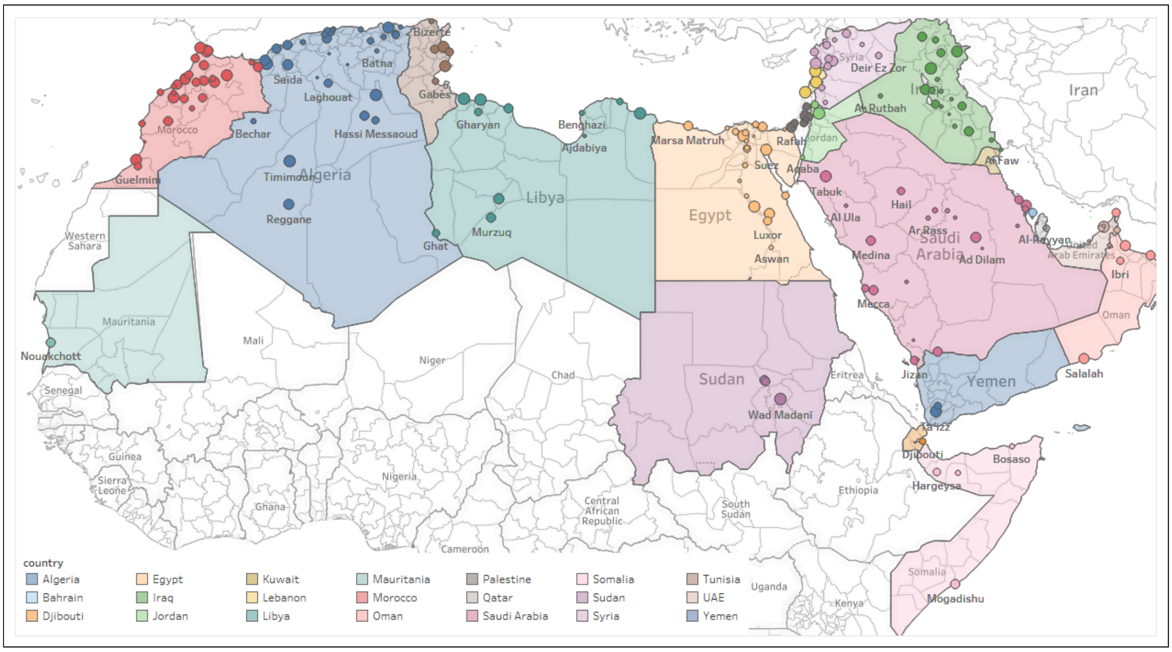

Figure B.2: A bigger-sized map of all 21 Arab countries. States are demarcated in thin black lines within each country. A total of 319 cities (from our user location validation study, in colored circles) are overlayed within corresponding countries.

Tang et al. (2019)). [24] As Table C.1, both of these networks (HA-MTL-Dist-city 1^{st} and HA-MTL-Dist-country 1^{st} in the table) acquire sizeable improvements over the equivalent, non-distilled BiGRUs. Although these distillation models are still less than BERT, the goal behind them is to yield as closer-as-possible performance to BERT albeit with a smaller network that can be deployed in machines with limited capacity and offer quicker inference. Concretely, a HA-MTL-BiGRU model learns the 3 tasks of city, state, and country together compared to the single task BERT where 3 different models are needed for these 3 tasks. In terms of the number of parameters, this means the multi-task BiGRU distillation model has 11.6× *fewer parameters*. HA-MTL-BiGRU is also *1.7 times faster* at inference. [25]

C.3 Multi-Task BiGRUs

D Model Generalization

D.1 Different Data Splits

Narrow, Medium, and Wide Settings. For **(1) narrow**, we select data from cities where we have at least 16 users, dividing users randomly into 3 in

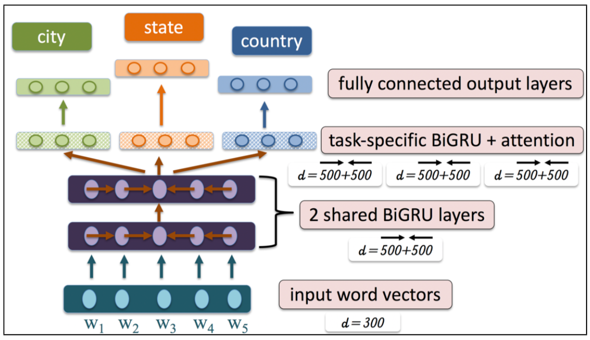

Figure C.1: Illustration of MTL (spec-attn) network for city, state, and country. The three tasks share 2 hidden layers, with each task having its independent attention layer.

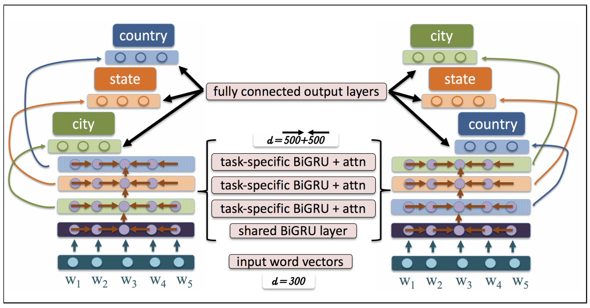

Figure C.2: Hierarchical Attention MTL of city, state, and country. All models share one BiGRU layer of 1,000 units. Layers 2-4 are also BiGRU layers, with dot-product attention. **Left:** City network supervised at layer 2, state at layer 3, and country at layer 4. **Right:** Supervision is reversed from left network.

---

[24] The network architecture of the HA-MTL BiGRU is otherwise similar as before, but we train them for 20 epochs rather than 15.

[25] We perform model inference on the DEV set with a batch size of 128 on a single NVIDIA V100 GPU.

TEST and the rest (13 or more) in TRAIN. This gives us 61 cities, 48 states, and 11 countries. Our **(2) medium** setting is similar to *narrow*, but we sample from cities with at least 13 users instead of 16. We use 3 users for TEST and the rest (10 users or more) for TRAIN. This results in 116 cities, 90 states, and 17 countries. **(3) Wide** has data from a single user from a given city in TEST and the rest of users from the same city in TRAIN. This setting allows more coverage (240 cities, 158 states, and all the 21 countries), at the cost of having as few as only two users for a given city in TRAIN. Figure D.1 shows the distribution of users over the 3 data settings. In addition, Table D.2 shows the data sizes of the TRAIN and TEST sets in each of the 3 runs, across each of the 3 settings.

D.2 Comparison of Models on a Completely New TEST Set.

As mentioned in Section 6, we evaluate our models from the narrow, medium and wide settings *and* our single task MARBERT model (shown in Ta-

Model	DEV						TEST					
	acc	F1	acc@161	acc@80.5	mean(K)	median(K)	acc	F1	acc@161	acc@80.5	mean(K)	median(K)
MARB-319	3.23	2.88	12.32	7.07	1,509.41	1,140.17	3.12	2.53	15.11	7.83	1,446.83	1,022.29
Wide	3.90	3.70	12.71	7.50	1,438.68	1,070.05	3.49	2.97	15.27	7.91	1,370.23	936.60
Medium	5.24	4.69	15.85	9.70	1,171.39	734.98	5.43	4.56	19.91	10.58	1,151.77	652.06

Table D.1: Evaluation of our MARBERT-based models on a new TEST set (GeoAra). **MARB-319:** our single task MARBERT model trained on 319 cities (reported on Table 3). **Narrow:** MARBERT-narrow, **Medium:** MARBERT-medium; **Wide:** MARBERT-wide. **Acc@80.5:** Accuracy at 80.5 kilometers (=50 miles). **Acc@161:** Accuracy at 161 kilometers (=100 miles). **Mean(K):** Mean distance in kilometers. **Median(K):** Median distance in kilometers.

ble 3) all on a completely new test set. This allows a more direct comparison between these models, including to test the impact of *sharing users* across the various data splits (as is the case of single task MARBERT) or *lack thereof* (as is the case for the narrow, medium and wide settings models). We now introduce GeoAra, our new evaluation dataset.

GeoAra Dataset. GeoAra is a dataset of tweets with city labels from 20 Arab countries. [26] To build GeoAra, we run a crawler on each of the 319 cities in our gold data for a total of 10 month (Jan. 2019 - Oct. 2019). We acquire a total of 4.7M tweets from all the cities. We collect Twitter user ids from users who posted consistently from a single location over the whole 10 months (n= 390,396), and crawl the timeline of 148K users. [27] Note that MicroAra (our monolingual dataset) is collected in 2016 and 2017. This means GeoAra involves data from a period significantly different (more recent) than MicroAra (2 years later). We then *only* keep users who posted at least 10 tweets. This leaves us with 101,960 users from 147 cities. From GeoAra, we create a DEV set from a random sample of 100K tweets (908 from users) and a TEST set from a random sample of 97,834 tweets (from 1,053 users). [28] We *do not* share users between the TRAIN, DEV, and TEST splits.

As Table D.1 shows, although all the 4 models degrade on GeoAra, single task MARBERT (MARB-319 in the table) suffers most. This further suggests, that this particular model has captured user-level knowledge that may have allowed it to perform much higher on the TEST set in Table 3 than what it would if user data were not shared across the various splits. In addition, even though our *narrow setting* model covers only 61 cities, it is the one that performs best on both the DEV and TEST GeoAra splits. This might be the case because this model is trained on the most number of users (at least 13 users for each city), which allows it to generalize well on these cities. An error analysis may reveal more information on performance of these particular models on GeoAra. We cast further investigation of this issue as future research.

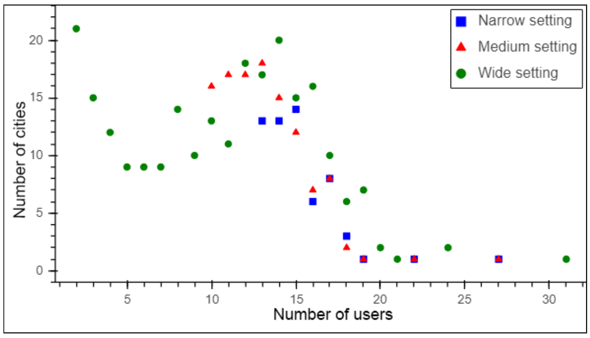

Figure D.1: Distribution of users over cities across our 3 model generalization settings.

	split	TRAIN	TEST	#cities	#states	#countries
Narrow	A	444,838	87,540	61	48	11
	B	445,297	87,081			
	C	453,451	78,927			
Medium	A	807,590	176,337	116	90	17
	B	808,667	175,260			
	C	810,471	173,456			
Wide	A	1,308,640	124,834	240	158	21
	B	1,309,705	123,769			
	C	1,305,098	128,376			

Table D.2: TRAIN and TEST data sizes and label distribution (in city, state, and country) across the 3 splits for each of the *narrow*, *medium*, and *wide* settings.

D.3 MSA vs. Dialect Classifier

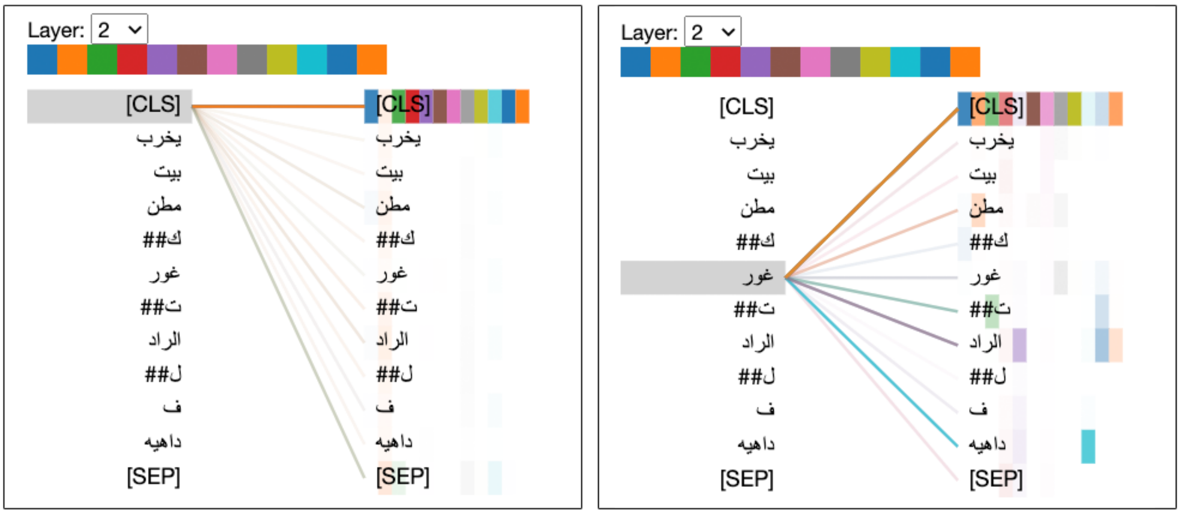
As described in Section 7, we apply an MSA vs. dialect in-house classifier on our *narrow* data setting, to remove MSA. Our in-house classifier fine-tuned MARBERT on the MSA-dialect TRAIN split described in Elaraby and Abdul-Mageed (2018). This

---

[26] These are the same countries as in our MicroAra, with the exception of Djibouti.

[27] We note that this is more conservative than previous geolocation works (e.g., (Han et al., 2012)) that take the majority class city of a user who posted 10 tweets as the label.

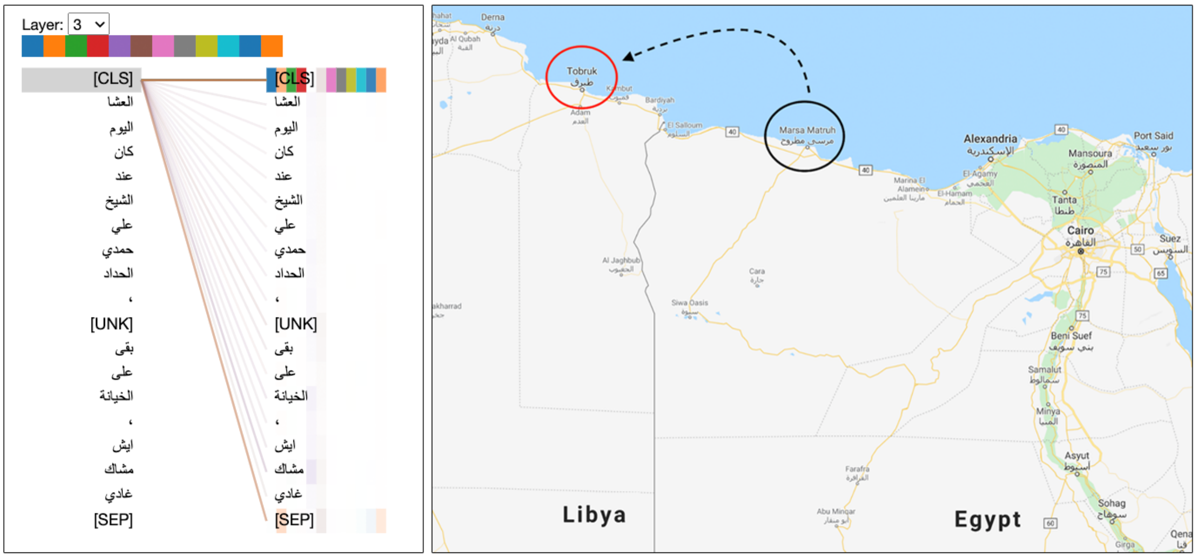
[28] The two splits do not identically match since we also needed to create a specific TRAIN split from the same dataset. The TRAIN split is not part of the current work and so we leave it out.



Gold label: Asuit (Egypt)
Predicted label: Asuit (Egypt)

Sentence: يخرب بيت مطنك. غورت الرادل في داهية
Eng: What a devil! You screwed the guy

Figure D.2: An example sentence where the model correctly predicted the gold city (Asuit, Egypt), clearly laying attention on relevant micro-dialectal tokens.



Gold label: Marsa_Matrouh (Egypt)
Predicted label: Tobruq (Libya)

Sentence: العشا اليوم كان عند الشيخ علي حمدي الحداد ، لمؤخذة بقى على الخيانة ، ايش مشاك غادي
Eng: Dinner tonight was at Shaikh Ali Hamdi Al-Haddad. Why on earth did you leave[?]

Figure D.3: An example of model error. The model confuses the city of Marsa Matrouh (Egypt, black circled) with that of Tobruq (Libya, red circled). The visualization illustrates how the model is capable of relating language across country boundaries, suggesting it does posses micro-dialectal predictive power.

	Dialect		**MSA**	
split	**TRAIN**	**TEST**	**TRAIN**	**TEST**
A	218,231	44,641	226,607	42,899
B	220,697	42,175	224,600	44,906
C	225,737	37,135	227,714	41,792

Table D.3: Distribution of MSA and DA over TRAIN and TEST of *narrow* setting.

binary classifier performs at 89.1% accuracy, and 88.6% F_1 on Elaraby and Abdul-Mageed (2018) MSA-dialect TEST set. Running this model on our *narrow* setting data, gives us the TRAIN and TEST splits with predicted labels described in Table D.3.

E Discussion

As discussed in Section 8, we visualize attention in $\sim$ 250 examples from our TEST set using our MARBERT-narrow model fine-tuned in split B in Table D.2. We provide visualizations from two examples here.

Example 1: Figure D.2 shows a visualization of a sentence from the city of Asuit, Egypt, that the model correctly predicted. **Left:** Attention layer #3 of the model[29] has several heads attending to lexical micro-dialectal cues related to Asuit. Most notably, tokens characteristic of the language of the correct city are attended to. Namely, the word مطنك (part of the metaphorical expression meaning "what a devil") recieves attention in heads 1-3, and the word الرادل "man" in city of Asuit) receives attention in head 2. These cues usually co-occur with the token غور ("you screwed [somebody]"), which is also characteristic of the Southern Egyptian region, and the city of Asuit. This is clear in the image in the **right** where the token غور attends to other micro-dialectal cues in the sequence.

Example 2: Figure D.3 shows a visualization of a sentence from the city of Marsa Matrouh, Egypt, that was incorrectly predicted as Tobruq, Libya. Even though the model makes a prediction error here, its error is meaningful in that it chooses a city that is located in the vicinity of that of the gold city. This means, interestingly, that the city-level model can pick a city close-by to gold in a different country rather than a far city in the same country. This reflects how micro-dialects paint a more nuanced (and linguistically plausible) picture. This also suggests that country-level dialect models are based on arbitrary assumptions, by virtue of being dependent on political boundaries which are not always what defines language variation.

E.1 Brief Error Analysis

We provide a brief error analysis of single Task MARBERT (described in Table 3 of the paper) in Table E.1.

Abstract

The growth of social media has encouraged the written use of African American Vernacular English (AAVE), which has traditionally been used only in oral contexts. However, NLP models have historically been developed using dominant English varieties, such as Standard American English (SAE), due to text corpora availability. We investigate the performance of GPT-2 on AAVE text by creating a dataset of intent-equivalent parallel AAVE/SAE tweet pairs, thereby isolating syntactic structure and AAVE- or SAE-specific language for each pair. We evaluate each sample and its GPT-2 generated text with pretrained sentiment classifiers and find that while AAVE text results in more classifications of negative sentiment than SAE, the use of GPT-2 generally increases occurrences of positive sentiment for both. Additionally, we conduct human evaluation of AAVE and SAE text generated with GPT-2 to compare contextual rigor and overall quality.

1 Introduction

African American Vernacular English (AAVE) is a sociolinguistic variety of American English distinct from Standard American English (SAE) with unique syntactic, semantic, and lexical patterns (Green, 2002; Jones, 2015). Millions of people from predominately Black communities in the United States and Canada use variants of AAVE on a daily basis. Although AAVE has historically been used in spoken contexts, the growing use of social media has encouraged AAVE in written media for which NLP models are increasingly being used.

Recent work in Natural Language Generation (NLG) has introduced GPT-2, a Transformer-based language model that generates high-quality, coherent text when prompted by arbitrary input (Radford et al., 2019). However, GPT-2 displays bias towards particular social groups (Solaiman et al., 2019). Sheng et al. (2019) shows that NLG tools are biased with regard to the subject of a sentence when that subject belongs to an underprivileged group, and Shen et al. (2018) tests sentiment analysis tools with intent-controlled pairs with varying stylistic inclinations. Studies regarding AAVE have analyzed tasks such as POS tagging (Jørgensen et al., 2016), detecting AAVE syntax (Stewart, 2014), voice recognition and transcription (Dorn, 2019), dependency parsing (Blodgett et al., 2016), and hate speech detection (Sap et al., 2019), but not language generation. Coupled with concerns that NLG tools can be used for generating fake news (Gehrmann et al., 2019) or impersonating internet users (Zellers et al., 2019), it is important that current work investigates the contexts in which NLG models display bias against certain demographics.

In this paper, we examine the bias of GPT-2 text generation against AAVE features. We create a new dataset of AAVE/SAE content-controlled pairs by retrieving AAVE tweets and employing human translators to obtain their SAE counterparts. By doing so, we isolate AAVE syntactic structures and lexical items. We then prompt GPT-2 with the first segments of each AAVE/SAE pair. The generated text is compared to its corresponding original second segment by BLEU, ROUGE, and sentiment scores. Additionally, we provide human evaluation for the generated text based on context and quality.

Thus, our contributions include:

- An intent-equivalent dataset of AAVE/SAE pairs with differences only in syntactic structure and dialect-specific vocabulary.
- New evaluation of GPT-2 using sentiment analysis, BLEU, and ROUGE scores of its generated text and the original SAE and AAVE segments.

… piece of food for five days.

Figure 1: Terms used to refer to segments of each AAVE/SAE pairwise sample. Each first segment is used to prompt its respective generated segment and sentiments are taken of the second and generated segments.

- Human evaluation of GPT-2 generated text for each AAVE/SAE pair, where evaluation is conducted to identify contextual accuracy, quality, and likelihood of being categorized as machine-generated.

2 Dataset

Our dataset consists of tweets identified as having at least 99.9% confidence of using AAVE lexical items by the TwitterAAE dataset (Blodgett et al., 2016). We then obtain the SAE equivalent of each of these tweets by employing Amazon Mechanical Turk (AMT) annotators for a total of $n = 2019$ AAVE/SAE pairs. The average length of the original AAVE tweets is about 21 words, and the average length of the SAE counterparts is about 22 words. These samples are intended to be used as a test set for probing neural language model-based text generation.

We use the terms "first segment," "second segment," and "generated segment" to refer to the different sections of each AAVE/SAE sample throughout this paper. A visualization of these partitions can be seen in Figure 1.

Sample Identification TwitterAAE (Blodgett et al., 2016) collects AAVE tweets by using a distantly supervised mixed-membership model on samples that are geolocated to African-American blockgroups, as defined by the U.S. Census data. The tweets have been filtered to ensure conversational language and verified as AAVE on the basis of AAVE-specific lexical item inclusion, phonological phenomena in orthographic variation, and syntactic construction. From TwitterAAE, we randomly sample tweets that contain at least 15 words and have a posterior probability of being demographically-aligned to AAVE of at least 99.9%. We remove hashtags as they are social media-specific occurrences and emoji since we expect them to have disproportionate influence on sentiment scores.

Pairwise Sample Collection To investigate GPT-2 generated text on AAVE versus SAE, we use (small) GPT-2 (Radford et al., 2019) from OpenAI for text generation, which is pretrained on outbound sources from Reddit comments with at least three karma.

Although prior work exists in using unsupervised word embeddings to create vector space-aligned demographic translations (Shen et al., 2018; Lample et al., 2018), we instead use human translation for accuracy purposes. We therefore employed AMT annotators to obtain the SAE equivalents of our AAVE samples.

Each AMT worker was given an AAVE tweet sample, first as a whole for context and then split into a first segment and a second segment. The latter consisted of the last five words of the sample, so as to take approximately a third of the full sample (see Figure 1). We asked annotators to translate the first and second segments individually into SAE; this partition was necessary for use with GPT-2, BLEU, and ROUGE. We provided example translations, and the full instructions can be seen in the AAVE to SAE protocol annotation guidelines. Annotators were filtered by HIT approval rate (higher than 97%) and location (within the United States). Additional instructions included either expanding or providing a contextual equivalent for acronyms, insertion of SAE-appropriate grammar, and preservation of overall structure and intent of the AAVE sample. Annotators were also told to translate the n-word, but to retain non-AAVE-specific explicit language.

	SAE				AAVE			
DistilBERT Classifier	*positive*	*negative*	*neutral*	*average*	*positive*	*negative*	*neutral*	*average*
Original Second Sentiment	50.12%	49.88%	N/A	0.0066	42.35%	57.65%	N/A	-0.1436
GPT-2 Generated Sentiment	47.75%	52.25%	N/A	-0.0399	46.16%	53.84%	N/A	-0.0769
VADER & TextBlob Average	*positive*	*negative*	*neutral*	*average*	*positive*	*negative*	*neutral*	*average*
Original Second Sentiment	24.67%	20.28%	55.05%	0.0779	25.06%	19.71%	55.23%	0.0325
GPT-2 Generated Sentiment	66.02%	25.73%	8.25%	0.1909	62.43%	32.66%	4.85%	0.1443

Table 1: Sentiment scores and averages for the SAE and AAVE samples in our dataset, using pretrained DistilBERT, VADER, and TextBlob sentiment classifiers.

Dataset Viability We test the variability of our dataset's results by taking 1000 random partitions of size 1500 and use DistilBERT (Sanh et al., 2019) to find the average sentiment score. For each partition of our data (both SAE and AAVE with and without generation by GPT-2), the sample variance is under 0.02%.

Semantic Evaluation Previous work has shown that non-AAVE speakers often fail to demonstrate comprehension of AAVE speech, and we acknowledge that such misunderstandings may influence the intent-equivalence of our dataset (Jones et al., 2019). Thus, to determine the semantic validity of the translations, we asked annotators who self-identified as native AAVE speakers and/or code-switchers to verify whether translated SAE phrases preserved the meaning of original AAVE phrases. Of 156 randomly sampled AAVE/SAE pairs, 90% are intent-equivalent according to native AAVE speakers, and 95% according to code-switchers. This confirms that the majority of our pairs have semantic equivalence. We have included the instructions for this validity check in the Semantic equivalence protocol.

3 Sentiment Analysis

We use a sentiment analysis pipeline from Huggingface[1] to evaluate the sentiment of our samples. The pipeline uses distilbert-base-uncased-finetuned-sst-2-english[2], which is pretrained on movie reviews from the Stanford Sentiment Treebank (Socher et al., 2013). In addition to the DistilBERT sentiment classifier, we use VADER, which is a lexicon and rule-based sentiment analysis tool that is attuned to social-media specific sentiment intensity (Hutto and Gilbert, 2015), and TextBlob[3], which does not have documentation on its implementation. However, we justify our use of the latter through its widespread use as an off-the-shelf sentiment classifier, such as in Sheng et al. (2019).

The DistilBERT sentiment classifier restricts classifications to either positive or negative, with degrees of confidence ranging from 0 to 1; we translate this to a -1 to 1 negative-to-positive scale. From VADER we use the compound score, and from TextBlob the polarity; both metrics are normalized and weighted and thus also range from -1 to 1. VADER and TextBlob scores include 0.0, or neutral, while the DistilBERT sentiment classifier does not. We average the latter two in Table 1 to account for model variability in the sentiment classifiers, but keep the DistilBERT scores separate because it does not include neutral classifications.

Baseline As a baseline, we compare the sentiment of each AAVE original second segment to its respective SAE original second segment. We observe that the pretrained sentiment analysis models categorize AAVE as more negative than SAE, despite having the same intent. AAVE has 157 (7.7 % percent) more negative instances than it does positive when using DistilBERT and 37 (1.8 % percent) more negative and neutral instances when using the VADER-TextBlob average. The VADER-TextBlob averages appear to be less biased against AAVE than DistilBERT.

Sentiment Comparison of Generated Text To determine whether GPT-2 generates more negative phrases when provided AAVE text, we compare the sentiment of the generated segment for AAVE to its corresponding generated segment for SAE. For DistilBERT we see that the average for AAVE generated segments is -0.0769, while its SAE counterpart is -0.0399 (see Table 1). This indicates that the AAVE GPT-2 generated segments are more negative than their corresponding SAE segments. We see the same trend for the VADER and TextBlob averages, where the AAVE generated segment has a more negative sentiment score than its corresponding SAE segment. Additionally, in the case of the VADER-TextBlob average, the negative senti-

[2] https://huggingface.co/distilbert-base-uncased-finetuned-sst-2-english

[3] https://textblob.readthedocs.io/en/dev

ments of the original second segments for SAE and AAVE differ by a margin of 0.57%, whereas the difference between the generated negative sentiments is 6.93%, with AAVE being more negative. This shows that even though AAVE has more positive instances than SAE for its original second segment, the use of GPT-2 increases negative sentiment more for AAVE than for SAE.

We also perform a McNemar-Bowker significance test on the results from Table 1 and find a significant difference between the original and generated sentiments for DistilBERT AAVE, VADER AAVE and SAE, and TextBlob AAVE and SAE with $\alpha = 0.05$. VADER and Textblob for both AAVE and SAE had $p < 0.01$. DistilBERT for AAVE had $p = 0.012$ and DistilBERT for SAE had $p = 0.11$.

Flipped Sentiment We compare the sentiment of the second segment of each AAVE phrase to the sentiment of its generated segment and do the same for each corresponding SAE sample. This allows us to observe the extent to which GPT-2 flips the sentiment from positive to negative and vice versa, and whether flipping from positive to negative sentiment is more prevalent in AAVE.

We find that AAVE samples have lower sentiment scores than their SAE equivalents with the classifiers we utilized. However, the AAVE generated segments increase in DistilBERT sentiment score going from -0.1436 to -0.0769 on the -1 to 1 scale, while SAE generated segments decrease from 0.0066 to -0.0399 (see Table 1). However, this is not the case with the VADER-TextBlob average, as the sentiment scores increase for both AAVE and SAE generated segments when compared to their respective second segments.

For the VADER-Textblob average in Table 1, AAVE generated segments are 50.38% less neutral than their original second segments, and SAE generated segments are 46.8% less neutral. While the majority of the original second segments are classified as neutral, the majority of the generated segments are instead classified as positive. However, SAE has a larger increase in positive sentiment scores than AAVE, even though its original positive sentiment was lower than AAVE's corresponding original sentiment.

4 Quality of Generated Text

We use BLEU, ROUGE, and human evaluation scores to determine the difference in the quality of GPT-2 generated text for SAE and AAVE samples.

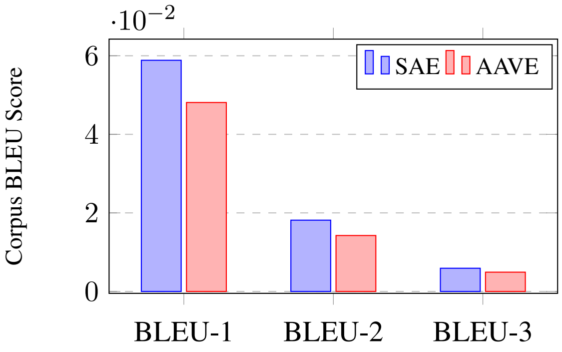

Figure 2: BLEU scores for text generated by GPT-2.

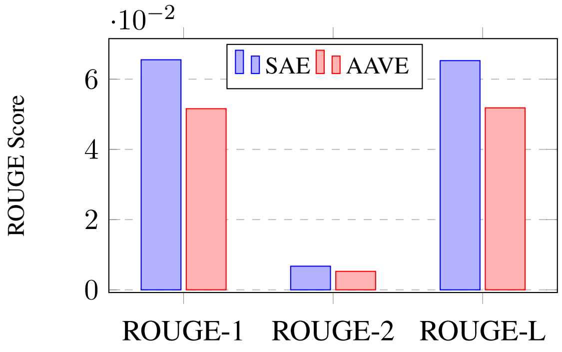

Figure 3: ROUGE scores for text generated by GPT-2.

BLEU and ROUGE For all SAE and AAVE samples, we isolate the second segment of the original sample, for which we take the last five words, and the first five words generated by GPT-2. We then compare the generated segment to the original second segment by calculating their BLEU and ROUGE scores. Specifically, ROUGE-1 and ROUGE-2 measure the overlap of unigrams and bigrams respectively, and ROUGE-L identifies the longest co-occurring sequence between a generated phrase and a reference phrase. BLEU-1, 2, and 3 are the cumulative 1-gram, 2-gram, and 3-gram scores for these pairs of phrases.

Both BLEU and ROUGE results indicate that GPT-2 typically generates more accurate sentences for SAE than for AAVE (see Figures 2 and 3). We note that the BLEU and ROUGE scores are relatively low since the comparison is between incomplete sentences of only five words.

We use a Wilcoxon rank-sum test to determine the significance of our BLEU and ROUGE results. With $\alpha = 0.05$, ROUGE-1 and ROUGE-L are significant. Additional p-values can be found in Table 2.

	B-1	B-2	B-3	R-1	R-2	R-L
p	0.256	0.095	0.097	**0.001**	0.811	**0.003**

Table 2: Wilcoxon rank-sum test p-values for each of our BLEU (B) and ROUGE (R) results. P-values that are significant with $\alpha = 0.05$ are in bold.

Human Evaluation We also conduct human evaluation using AMT to assess the quality of the text generated by GPT-2. Annotators were filtered by HIT approval rate (higher than 95%) and location (within the United States). They were given the first segment of an SAE phrase for context, followed by its corresponding GPT-2 generated segment. We did the same with each corresponding AAVE phrase. Annotators were asked to choose which one of the two generated phrases better fits the context of the respective first segment, which one has better quality, and which one is most likely machine-generated. Ties were allowed for this task. The annotator instructions for this task can be found in the Human evaluation protocol.

Results show that 21.7% more annotators indicate that SAE generated segments have better quality than their corresponding AAVE generated segments, and 12% more annotators indicate that SAE generated segments fit the context better than their AAVE generated segment counterparts (see Table 3). To determine existing bias in human evaluation, we perform the same evaluation on the original second segments of AAVE/SAE pairs and find that 48% choose the SAE original second segments as likely machine-generated, while 31% choose the AAVE original second segments. Looking at 3, the proportion of annotators who select SAE as machine generated decreases to 37.3%, whereas the proportion for AAVE increases to 42.1%. This indicates that GPT-2 worsens the quality of AAVE segments while improving the quality of SAE segments. These findings support our results from BLEU and ROUGE in demonstrating the unequal quality of GPT-2's text generation for SAE and AAVE, thus signifying a bias against AAVE.

5 Conclusion

Through this work, we highlight the need for AAVE-inclusivity in NLG models, especially those perceived as state-of-the-art. To this end, we provide a new evaluation of NLG models by comparing GPT-2's behavior on SAE and AAVE. In addition, we present a new dataset consisting of intent-parallel AAVE/SAE tweet pairs, which can be used in future works studying SAE and AAVE in NLP models. Our sentiment analysis experiments indicate that GPT-2 produces more negative instances when prompted with AAVE text. Moreover, our BLEU, ROUGE, and human evaluation results reveal a disparity in the quality of GPT-2's text generation between AAVE and SAE. We hope our findings can pave the way for further inclusion of diverse language in future NLG models.

	Context	*Quality*	*Likely MG*
SAE	48.7%	54.5%	37.3%
AAVE	36.7%	32.8%	42.1%
TIE	14.6%	12.7%	20.6%

Table 3: Human evaluation results, where "MG" refers to "Machine Generated." Tests are conducted pairwise between generated SAE and AAVE phrases.

A Annotation Guidelines

A.1 AAVE to SAE protocol

You will be given a phrase that is written in African American Vernacular English, which we then split into two parts. Your task is to translate these parts one at a time into Standard American English so that your translations combine to form a coherent phrase.

Standard American English is used in a formal context, such as in professional communication. Although many of these phrases would not be used in professional communication, translate their vocabulary to SAE while maintaining their intent.

Specific cases:

1. Acronyms: translate to its formal SAE equivalent (e.g. “lol” “That’s funny,” “I’m laughing,”) or another equivalent for the given context. If the acronym expands to a valid SAE phrase, you can expand instead of providing a translation (e.g. “ily” “I love you”).
2. Punctuation: translated phrases should have proper punctuation. Insert or fix capitalization, commas, periods, or other appropriate punctuation as necessary.
3. Emoticons: remove emoticons from the translated phrase. For example, “:)”, “:(”, “:/”, and “8)” should be removed.
4. Phrase structure: translated phrases should maintain the structure as well as the intent of their original phrases. Keep general patterns, such as dependent or independent clauses. Try to keep the number of words in the translation about the same as the number of words in the original phrase.
5. Translate the n-word to an appropriate equivalent.
6. Keep swear words as is (the exception is the n-word. It needs to be translated as previously stated).

Example phrase: So the hubby is out kickin it for him and his brutha bday so I guess i ’m going to bed alone tonight :(

- **First part**: So the hubby is out kickin it for him and his brutha bday so I guess i ’m going
- **First part translated:** my husband is celebrating for his and his brother’s birthday, so I guess I’m going
- **Second part:** to bed alone tonight :(
- **Second part translated:** to bed alone tonight.

A.2 Semantic equivalence protocol

Given two phrases, determine whether or not their semantics (meanings) are the same.

- Are you a native or fluent AAVE speaker?
- If you responded ‘Yes’ above, are you able to code switch?
- Are Phrase 1 and Phrase 2 semantically equivalent?

A.3 Human evaluation protocol

You will be given two long phrases. Each one will be split into two parts. Your task is to evaluate the quality of the second part of each phrase and determine which one you prefer.

Looking at the second part of both phrases:

- Which one has better quality?
- Which one fits the context of its respective first part better?
- Which one is more likely generated by machines?

Iterative Domain-Repaired Back-Translation

Abstract

In this paper, we focus on the domain-specific translation with low resources, where in-domain parallel corpora are scarce or nonexistent. One common and effective strategy for this case is exploiting in-domain monolingual data with the back-translation method. However, the synthetic parallel data is very noisy because they are generated by imperfect out-of-domain systems, resulting in the poor performance of domain adaptation. To address this issue, we propose a novel iterative domain-repaired back-translation framework, which introduces the Domain-Repair (DR) model to refine translations in synthetic bilingual data. To this end, we construct corresponding data for the DR model training by round-trip translating the monolingual sentences, and then design the unified training framework to optimize paired DR and NMT models jointly. Experiments on adapting NMT models between specific domains and from the general domain to specific domains demonstrate the effectiveness of our proposed approach, achieving 15.79 and 4.47 BLEU improvements on average over unadapted models and back-translation.[1]

1 Introduction

Neural Machine Translation (NMT) has achieved impressive performance when large amounts of parallel sentences are available (Wu et al., 2016; Vaswani et al., 2017; Hassan et al., 2018). However, some previous works have shown that NMT models perform poorly in specific domains, especially when they are trained on the corpora from very distinct domains (Koehn and Knowles, 2017; Chu and Wang, 2018). The fine-tuning method (Luong and Manning, 2015) is a popular way to mitigate the effect of domain drift. However, it is not realistic to collect large amounts of high-quality parallel data in every domain we are interested in. Since monolingual in-domain data are usually abundant and easy to obtain, it is essential to explore the unsupervised domain adaptation scenario that utilizes large amounts of out-of-domain bilingual data and in-domain monolingual data.

One straightforward and effective solution for unsupervised domain adaptation is to build in-domain synthetic parallel data, including copying monolingual target sentences to the source side (Currey et al., 2017) or back-translation of in-domain monolingual target sentences (Sennrich et al., 2016; Dou et al., 2019). Although the back-translation approach has proven the superior effectiveness in exploiting monolingual data, directly applying this method in this scenario brings low-quality in-domain synthetic data. Table 1 gives two incorrect translation sentences generated by back-translation method. The main reason for this situation is that the synthetic parallel data is built by imperfect out-of-domain NMT systems, which leads to inappropriate word expressions or wrong translations. Fine-tuning on such synthetic data is very likely to hurt the performance of domain adaptation.

In this paper, we extend back-translation by a Domain-Repair (DR) model to explicitly remedy this issue. Specifically, the DR model is designed to re-generate in-domain source sentences given the synthetic data. In this way, the pseudo parallel data's source side can be re-written with the in-domain style, and some wrong translations are fixed. To optimize the DR model, we use the round-trip translation of monolingual source sentences to construct the corresponding training data.

Since source monolingual data is involved, it is natural to extend the back-translation method to bidirectional setting (Zhang et al., 2018), which

Table 1: Two incorrect medical translations caused by the law-domain NMT model in German-English multi-domain datasets (Tiedemann, 2012), in which "*Markteinführung*" and "*in den Verkehr gebracht*" are translated to "after market introduction" and "added to the pack" respectively.

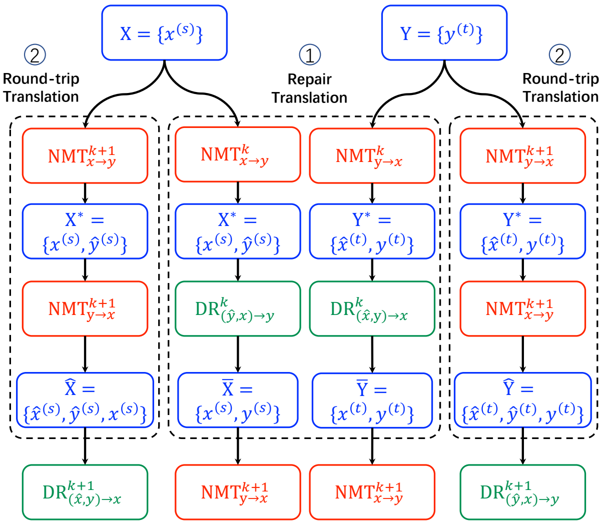

Figure 1: The training process of the iterative domain-repaired back-translation (iter-DRBT) framework at epoch k, where x and y represent the source and target sentences respectively, $\widehat{x}$ and $\widehat{y}$ denote the translation generated by NMT models. The whole framework consists of translation repair and round-trip translation procedures, which are used to generate corresponding training data for NMT and DR models respectively.

jointly optimizes source-to-target and target-to-source NMT models. Based on this setting, we propose the iterative domain-repaired back-translation (iter-DRBT) framework to fully exploit both source and target in-domain monolingual data. The whole framework starts with pre-trained out-of-domain bidirectional NMT models, and then these models are adopted to perform round-trip translation on monolingual data to obtain initial bidirectional DR models. Next, as illustrated in Figure 1, we design a unified training algorithm consisting of translation repair and round-trip translation procedures to jointly update DR and NMT models. More particularly, in the translation repair stage, the back-translated synthetic data can be well re-written as in-domain sentences by the well-trained DR models to further improve NMT models. Then enhanced NMT models run the round-trip translation on monolingual data to build domain-mapping data, which helps DR models better identify mistakes made by the latest NMT models. This training process is iteratively carried out to make full use of the advantage of DR models to improve NMT models.

We evaluate our proposed method on German-English multi-domain datasets (Tiedemann, 2012). Experimental results on adapting NMT models between specific domains and from the general domain to specific domains show that our proposed method obtains 15.79 and 4.47 BLEU improvements on average over unadapted models and back-translation, respectively. Further analysis demonstrates the ability of DR models to repair the synthetic parallel data.

2 Related Work

Since in-domain parallel corpora are usually hard to obtain, many studies attempt to improve the performance of NMT models without any in-domain parallel sentences. One research line is to extract pseudo in-domain data from large amounts of out-domain parallel data. Biçici and Yuret (2011) use an in-domain held-out set to obtain parallel sentences from out-domain parallel sentences by computing n-gram overlaps. Instead, Moore and Lewis (2010), Axelrod et al. (2011) and Duh et al. (2013) use LMs score to select data similar to in-domain text. Recently, Chen et al. (2017) train a domain classifier to weight the out-domain training samples. There are also work on adaptation via retrieving sentences or n-grams in the training data similar to the test set (Farajian et al., 2017; Bapna and Firat, 2019). However, these methods cannot always guarantee to find domain-specific samples from out-domain data.

Another research direction is to exploit plenty of in-domain monolingual data, e.g., integrating a language model during decoding (Çaglar Gülçehre et al., 2015), copy method (Currey et al., 2017), back-translation (Sennrich et al., 2016) or obtaining domain-aware feature embedding via an auxiliary language modeling (Dou et al., 2019). Among these approaches, back-translation is a widely used and effective method in exploiting monolingual data. Our proposed method is also based on back-translation and makes the most of it by improving the data quality with the DR model.

The methods of exploiting monolingual data in NMT can be naturally applied in unsupervised domain adaptation. Some studies are working on exploiting source-side monolingual data by self-training (Zhang and Zong, 2016; Chinea-Ríos et al., 2017) or pre-training (Yang et al., 2019; Weng et al., 2020; Ji et al., 2020), and leveraging both source and target monolingual data simultaneously by semi-supervised learning (Cheng et al., 2016), dual learning (He et al., 2016) and joint training (Zhang et al., 2018; Hoang et al., 2018). Our method utilizes both source and target data as well, with different that we use monolingual data to train bidirectional DR models, and then these models are used to fix pseudo data.

As back-translation is widely considered more effective than the self-training method, several works find that performance of back-translation degrades due to the less rich translation or domain mismatch at the source side of the synthetic data (Edunov et al., 2018; Caswell et al., 2019). Edunov et al. (2018) attempt to use sampling instead of maximum a-posterior when decoding with the reverse direction model. Imamura et al. (2018) add noises to the results of beam search. Caswell et al. (2019) propose to add a tag token at the source side of the synthetic data. Unlike their methods, our method leverages the DR model to re-generate the source side of the synthetic data, which can also increase translation diversity and mitigate the effect of different domains.

3 Iterative Domain-Repaired Back-Translation

In this section, we first illustrate the overview of iter-DRBT framework, then describe the architecture of DR model and the joint training strategy.

3.1 Overview

Suppose that we have non-parallel in-domain monolingual sentences $X = \{x^{(s)}\}$ and $Y = \{y^{(t)}\}$ in two languages respectively, as well as two pre-trained out-of-domain translation models $\text{NMT}^0_{x\to y}$ and $\text{NMT}^0_{y\to x}$, where x and y denote the source and target sentences respectively. The purpose of unsupervised domain adaptation is to train in-domain models $\text{NMT}_{x\to y}$ and $\text{NMT}_{y\to x}$.

In this work, we incorporate a Domain-Repair (DR) model in the iterative back-translation process to fully exploit in-domain monolingual data, in which the DR model is used to refine translation sentences given the synthetic bilingual sentences. The whole framework consists of translation repair and round-trip translation procedures, which are used to generate corresponding training data for NMT and DR models, respectively. For convenience, we take source-to-target translation ($x \to y$) as an example to explain the usage of our proposed method.

Translation Repair Stage. The basic process of back-translation method is to first translate $y^{(t)}$ into $\widehat{x}^{(t)}$ with $\text{NMT}^0_{y\to x}$, and then fine-tune $\text{NMT}^0_{x\to y}$ on the synthetic parallel data $Y^* = \{\widehat{x}^{(t)}, y^{(t)}\}$. As the model $\text{NMT}^0_{y\to x}$ is not trained on truly in-domain bilingual data, there exists domain mismatch between $\widehat{x}^{(t)}$ and the genuine in-domain sentences x. Given the synthetic parallel data $Y^* = \{\widehat{x}^{(t)}, y^{(t)}\}$, we apply the corresponding DR model ($\text{DR}_{(\widehat{x},y)\to x}$) to repair errors in translated sentences, e.g. wrong translations of in-domain phrases or domain-inconsistent expressions, and then obtain the new synthetic parallel data $\overline{Y} = \{x^{(t)}, y^{(t)}\}$ to train $\text{NMT}_{x\to y}$ initialized with $\text{NMT}^0_{x\to y}$.

Round-Trip Translation Stage. In order to optimize $\text{DR}_{(\widehat{x},y)\to x}$, we use the round-trip translation of monolingual source sentences $X = \{x^{(s)}\}$ to construct the corresponding training data $\widehat{X} = \{\widehat{x}^{(s)}, \widehat{y}^{(s)}, x^{(s)}\}$, where $\widehat{y}^{(s)}$ and $\widehat{x}^{(s)}$ are generated by $\text{NMT}^0_{x\to y}$ and $\text{NMT}^0_{y\to x}$ respectively ($x^{(s)} \to \widehat{y}^{(s)} \to \widehat{x}^{(s)}$). In this way, $\text{DR}_{(\widehat{x},y)\to x}$ learns to identify mistakes made by $\text{NMT}^0_{y\to x}$ and corresponding mapping rules, which helps to better fix the errors in synthetic parallel data.

Similarly, these two stages are also applied in the reverse translation direction to train target-to-source NMT model ($\text{NMT}_{y\to x}$) and corresponding DR model ($\text{DR}_{(\widehat{y},x)\to y}$). As illustrated in Figure 1, it is natural to extend such a training process to a joint training framework, which alternately carries out the translation repair and round-trip translation procedures to make full use of the advantage of DR models to improve NMT models.

3.2 Domain-Repair Model

Since the DR model takes the synthetic bilingual sentences as input to produce the in-domain sen-

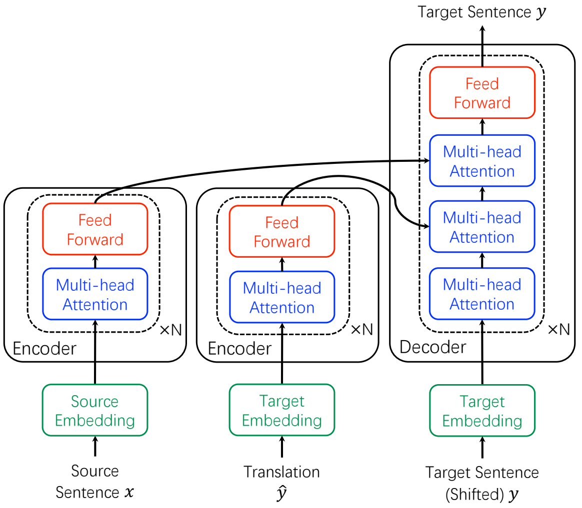

Figure 2: The dual-source transformer architecture of the Domain-Repair model ($\text{DR}_{(\widehat{y},x)\to y}$). For simplicity, we omit some architecture details such as layer normalization and residual connection.

tences, we parameterize the DR model as a dual-source sequence-to-sequence model. As illustrated in Figure 2, the dual-source transformer model naturally extends the original architecture from Vaswani et al. (2017) by adding another encoder for translated sentences and stacking an additional multi-head attention component above the multi-head self-attention component. As usual for the transformer architecture, each block is followed by a skip connection from the previous input and layer normalization. For simplicity, we omit these architecture details in Figure 2.

Our proposed framework involves two DR models ($\text{DR}_{(\widehat{x},y)\to x}$ and $\text{DR}_{(\widehat{y},x)\to y}$), both of which are optimized by maximizing the conditional log likelihood on the training corpus $\widehat{X} = \{\widehat{x}^{(s)}, \widehat{y}^{(s)}, x^{(s)}\}$ and $\widehat{Y} = \{\widehat{x}^{(t)}, \widehat{y}^{(t)}, y^{(t)}\}$ built by round-trip translation respectively:

$$\mathcal{L}_1(\theta_1) = \sum_{s=1}^{|\widehat{X}|} \log P(x^{(s)}|\widehat{y}^{(s)}, \widehat{x}^{(s)}; \theta_1) \tag{1}$$

$$\mathcal{L}_2(\theta_2) = \sum_{t=1}^{|\widehat{Y}|} \log P(y^{(t)}|\widehat{x}^{(t)}, \widehat{y}^{(t)}; \theta_2) \tag{2}$$

where θ_1 and θ_2 denote the model parameters of $\text{DR}_{(\widehat{x},y)\to x}$ and $\text{DR}_{(\widehat{y},x)\to y}$ respectively.

3.3 Joint Training Strategy

```
Algorithm 1: Joint Training Algorithm for NMT and DR Models
Input: pre-trained out-of-domain models $\text{NMT}^0_{x\to y}$
    and $\text{NMT}^0_{y\to x}$, in-domain monolingual sentences
    $X = \{x^{(s)}\}$ and $Y = \{y^{(t)}\}$, maximum iteration
    number $T$
Use $\text{NMT}^0_{x\to y}$ and $\text{NMT}^0_{y\to x}$ to perform round-trip
    translation on $X$ and $Y$ to construct dataset
    $\widehat{X} = \{\widehat{x}^{(s)}, \widehat{y}^{(s)}, x^{(s)}\}$ and $\widehat{Y} = \{\widehat{x}^{(t)}, \widehat{y}^{(t)}, y^{(t)}\}$;
Train $\text{DR}^0_{(\widehat{x},y)\to x}$ and $\text{DR}^0_{(\widehat{y},x)\to y}$ with $\widehat{X}$ and $\widehat{Y}$;
$k = 0$;
for $k \le T$ do
    Translation Repair Stage:
    Use $\text{NMT}^k_{x\to y}$ and $\text{NMT}^k_{y\to x}$ to build synthetic
        data $X^* = \{x^{(s)}, \widehat{y}^{(s)}\}$ and $Y^* = \{\widehat{x}^{(t)}, y^{(t)}\}$
        for $X$ and $Y$ respectively;
    Use $\text{DR}^k_{(\widehat{y},x)\to y}$ and $\text{DR}^k_{(\widehat{x},y)\to x}$ to repair $X^*$
        and $Y^*$ to construct in-domain synthetic data
        $\overline{X} = \{x^{(s)}, y^{(s)}\}$ and $\overline{Y} = \{x^{(t)}, y^{(t)}\}$;
    Update NMT Models:
    $\text{NMT}^{k+1}_{x\to y} \leftarrow$ Fine-tune $\text{NMT}^k_{x\to y}$ with $\overline{Y}$;
    $\text{NMT}^{k+1}_{y\to x} \leftarrow$ Fine-tune $\text{NMT}^k_{y\to x}$ with $\overline{X}$;
    Round-Trip Translation Stage:
    Use $\text{NMT}^{k+1}_{x\to y}$ and $\text{NMT}^{k+1}_{y\to x}$ to perform
        round-trip translation on $X$ and $Y$ to construct
        corresponding dataset $\widehat{X} = \{\widehat{x}^{(s)}, \widehat{y}^{(s)}, x^{(s)}\}$
        and $\widehat{Y} = \{\widehat{x}^{(t)}, \widehat{y}^{(t)}, y^{(t)}\}$;
    Update DR Models:
    $\text{DR}^{k+1}_{(\widehat{x},y)\to x} \leftarrow$ Fine-tune $\text{DR}^k_{(\widehat{x},y)\to x}$ with $\widehat{X}$;
    $\text{DR}^{k+1}_{(\widehat{y},x)\to y} \leftarrow$ Fine-tune $\text{DR}^k_{(\widehat{y},x)\to y}$ with $\widehat{Y}$;
    $k = k + 1$
```

We design the iterative training framework to jointly optimize DR and NMT models, as illustrated in Algorithm 1. The whole training framework starts with pre-trained out-of-domain bidirectional NMT models ($\text{NMT}^0_{x\to y}$ and $\text{NMT}^0_{y\to x}$) and in-domain monolingual data ($X = \{x^{(s)}\}$ and $Y = \{y^{(t)}\}$). To train initial DR models, we use $\text{NMT}^0_{x\to y}$ and $\text{NMT}^0_{y\to x}$ to run round-trip translation on X and Y to construct dataset $\widehat{X} = \{\widehat{x}^{(s)}, \widehat{y}^{(s)}, x^{(s)}\}$ and $\widehat{Y} = \{\widehat{x}^{(t)}, \widehat{y}^{(t)}, y^{(t)}\}$;

Based on initial NMT and DR models, a joint training process is iteratively carried out to further optimize these models. This process consists of translation repair and round-trip translation stages. In the translation repair stage, we first adopt NMT models to translate monolingual data, based on which the DR models are used to further re-write the translated sentences as in-domain sentences. In this way, we can obtain better in-domain synthetic data to further improve NMT models. Next, in the round-trip translation stage, we perform round-trip translation on monolingual data with enhanced NMT models to re-build training data for DR models. The DR models trained on such datasets can better identify mistakes made by latest NMT models ($\text{NMT}^{k+1}_{x\to y}$ and $\text{NMT}^{k+1}_{y\to x}$) and learn correspond-

ing mapping rules, which helps to better fix the synthetic parallel data in the next iteration. Note that we fine-tune the NMT and DR models in each iteration to speed up the whole training process.

4 Experiments

4.1 Setup

Datasets. To evaluate the performance of our proposed method, we adopt a multi-domain dataset released by Koehn and Knowles (2017), which is further built as an unaligned monolingual corpus in Hu et al. (2019). However, there are two issues in the train/dev/test splits used in Hu et al. (2019). First, Ma et al. (2019) and Dou et al. (2020) find that some same sentence pairs exist between the training and test data. Second, Hu et al. (2019) randomly shuffle the bi-text data and split it into halves, which may bring more overlap than in natural monolingual data, i.e., bilingual sentences from a document are probably selected into monolingual data (e.g., one sentence on the source split and its translation on the target split).

To address the impact of the above two issues, we re-collect in-domain monolingual data and test sets in the following steps:

- Download the XML files from OPUS[2], extract parallel corpus from each documents and record the document boundaries.
- Randomly take some documents as dev/test sets and use the rest as training data.
- Divide the training set into two parts, where the number of sentences in the two parts is similar. Then the source and target sentences of the first and second halves are chosen as monolingual data, respectively.
- De-duplicate all overlap sentences within train/dev/test sets.

We choose medical (EMEA) and law (JRC-Acquis) domains for our experiments. All the data statistics are illustrated in Table 2.

Experimental Details. We implement all NMT models with *Transformer_base* (Vaswani et al., 2017). More specifically, the number of layers in the encoder and decoder is set to 6, with 8 attention heads in each layer. Each layer in both encoder and decoder has the same dimension of input and output $d_{\text{model}} = 512$, dimension of feed-forward layer's inner-layer $d_{\text{hidden}} = 2048$. Besides, DR models follow the same setting as the NMT model.

The Adam (Kingma and Ba, 2014) algorithm is used to update DR and NMT models. For training initial NMT and DR models, following the setting of Hu et al. (2019), we set the dropout as 0.1 and the label smoothing coefficient as 0.2. Besides, we adopt the setting of *Fairseq* (Ott et al., 2019) on IWSLT'14 German to English to fine-tune NMT and DR models. During training, we schedule the learning rate with the inverse square root decay scheme, in which the warm-up step is set as 4000, and the maximum learning rate is set as 1e-3 and 5e-4 for pre-training and fine-tuning, respectively.

For the joint training strategy, we set the maximum iteration number T in Algorithm 1 as 2 for balancing speed and performance. In practice, we train our framework on 2 Tesla P100 GPUs for all tasks, and it takes 2 days to finish the whole training.

Methods. We compare our approach with several baseline methods in our experiment:

- **Base:** Directly use out-of-domain NMT models to evaluate on in-domain test sets.
- **Copy:** Copy the target in-domain monolingual data to the source side as parallel data.
- **BT:** Back-translation method, which fine-tunes the out-domain model on synthetic training data generated by a target-to-source out-domain NMT model.
- **DALI-BT:** Using word translation instead of back-translation to generate synthetic parallel data. Such data can be mixed with common back-translation for domain adaptation (Hu et al., 2019).
- **iter-BT:** Iterative back-translation, which alternatively generates synthetic data and optimizes NMT models at both side (Hoang et al., 2018). We adopt the same iteration number as iter-DRBT.
- **DRBT:** The simplified version of our proposed method, in which we only use the DR model to repair synthetic data once.

All experimental results are evaluated by *Sacre-*

Table 3: BLEU scores(%) under different settings. The left four columns are results of adapting between two distinct domains, while the right four domains are results of adapting from the general domain (WMT) to specific domains.

BLEU (Post, 2018) in terms of case-sensitive tokenized BLEU (Papineni et al., 2002).

4.2 Main Results

Adapting between Specific Domains. We verify our approach by adapting NMT models from one distinct domain to another. As illustrated in the left four columns of Table 3, the unadapted models perform poorly on the out-of-domain test sets. Besides, the Copy and BT can improve the performance on target domains, in which the back-translation method achieving more improvements consistently. We reproduce Hu et al. (2019)'s work, and their method combined with back-translation (DALI-BT) gains better performance. Our proposed method (DRBT) significantly outperforms all previous methods on all four translation tasks, achieving up to average 17.40 and 2.08 BLEU improvements compared to Base and DALI-BT, respectively. It demonstrates that the DR model effectively repairs the errors occurred by out-of-domain models, improving the performance of unsupervised domain adaptation.

As the back-translation method suffers from low-quality synthetic data, iter-BT is used to improve the quality of synthetic data and achieves 2.73 BLEU improvements on average, but it still has 0.46 BLEU behind DRBT. This result indicates that the DR model shows a better ability to repair the imperfections of synthetic data. The joint training of DR and NMT models (iter-DRBT) can further obtain 3.15 BLEU improvements compared to DRBT. It also proves that the joint training process helps DR models to better identify mistakes made by the latest NMT models and fix the synthetic parallel data in the following iteration.

#Para.	BT	DRBT	iter-DRBT	Sup.
1K	46.03	48.98	51.30	61.56
5K	49.30	53.59	54.93	61.74
10K	51.32	54.30	56.04	62.07
50K	57.99	59.29	60.03	62.81

Table 4: BLEU scores(%) of DRBT and iter-DRBT under semi-supervised scenario with varied size of in-domain parallel data. We also report supervised results with all the in-domain parallel (Sup.) as upper bound.

Adapting from General to Specific Domains. We further evaluate our method when adapting a model trained on large amounts of general domain data. We use out-of-domain models trained on the WMT14 German-English dataset and adapt them to the Medical and Law domains, respectively. All results are shown in the right half of Table 3.

These results show a similar pattern as previous experiments, except that the gap between our method and BT/iter-BT is reduced. We attribute this reduction to the improvements of general models on in-domain translation. Even so, the iter-DRBT yields the best performance on all test sets, with 11.03 and 0.79 BLEU improvements on average compared to Base and iter-BT, respectively.

Semi-supervised Adaptation. Our method can be easily applied in semi-supervised domain adaptation, with a limited number of in-domain parallel data available. The implementation in this setting is to mix the in-domain parallel data with the generated synthetic data for NMT models training. In addition to the round-translation on monolingual data, we conduct back-translation on parallel data to construct corresponding training data for DR models training.

We conduct experiments on adapting German-to-English NMT models from the Law domain to

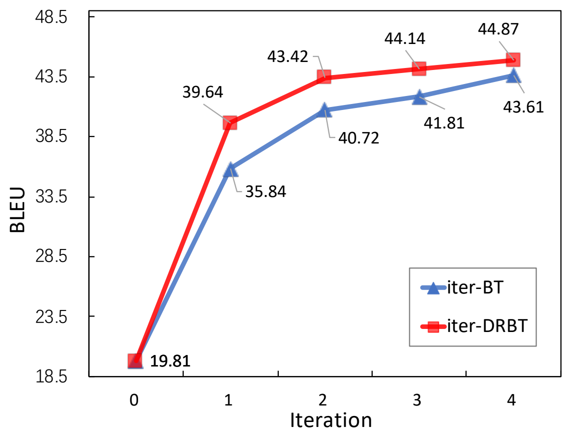

Figure 3: BLEU scores(%) at different iterations of joint training. The model at '0'-th iteration is the unadapted model.

the Medical domain. To assess performance under different scales of in-domain parallel data, we fix the number of monolingual in-domain sentences and vary the number of in-domain parallel sentences in 1K, 5K, 10K, and 50K. We also report the results of fine-tuning on full in-domain parallel data, including additional in-domain parallel data and monolingual data paired with its original translations, to indicate the upper bound of semi-supervised training. All the results are listed in Table 4. We observe the consistent improvement of our proposed method. It is worth noting that given 50K in-domain parallel data, the gap between using repaired synthetic data and using the actual parallel data is rapidly reduced from 12.58 to 3.52 BLEU, and further decreased to only 2.78 by joint-training with one more iteration, demonstrating the effectiveness of our method in the semi-supervised scenario.

4.3 Effect of Joint Training

We further investigate the effect of joint training with more iterations. Specifically, we conduct experiments on adapting from the Medical domain to the LAW domain from German to English, in which iterative back-translation is used for comparison.

We plot the BLEU curve of these two methods over the number of iterations. From Figure 3, we can observe that our proposed method (iter-DRBT) consistently outperforms iterative back-translation (iter-BT) under the same number of iterations. As the number of iterations increases, BLEU improvement achieved by iter-DRBT and iter-BT gradually decreases, but the gap remains.

Table 5: BLEU scores(%) (German/English) on development sets before and after applying DR models.

4.4 Analysis of Domain Repair Models

In this section, we mainly discuss how DR models repair the source side of synthetic data to improve its quality. Compared to the original back-translation data, we find that the change comes from three main points: an improvement in the overall quality of the source side, an improvement in the accuracy of the in-domain lexical translation, and a closer in-domain style of the source side.

Improvement of Translation Quality. We first assess the change in translation quality at the source side of back-translation data. We report the BLEU changes on all the development sets before and after using the DR model. All the results are listed in Table 5. We can see that the source side of the back translation data generated by the out domain model is inferior at the initial stage. The DR model significantly improves its quality, which improves the effectiveness of back-translation.

Improvement of Lexical Translation. We then assess the change in lexical translation at the source side of synthetic data before and after domain repair. Based on the frequency of words that appear in the out-of-domain training data, we allocate target side words of development sets into three buckets (< 1, $[1, 20)$ and ≥ 20, which represent zero-shot words, few-shot words, and frequent words, respectively), and compute the word translation f-scores within each bucket. We use *compare-mt* (Neubig et al., 2019) to do all the analysis and plot the results in Figure 4. We can see that the synthetic data repaired by DR models show better word translation in all the buckets. It is worth noting that the improvement of word translation f-scores on zero/few-shot (< 20) words dramatically exceeds that on frequent words, which shows that DR models are especially good at repairing in-domain lexical mistranslations.

Improvement of Domain Consistent Style. We further evaluate how can DR models remedy the domain mismatch issue at the source side of back-

translated data, including domain inconsistent word selection and language style. We evaluate them by observing the perplexity change measured by in-domain and out-of-domain language models before and after being repaired, in which all the language models are trained with *KenLM* (Heafield, 2011). The out-of-domain language models are trained on out-of-domain training data, while in-domain language models are trained on the original translations of in-domain monolingual data. We list all the perplexity scores in Table 7. On both MED2LAW and WMT2LAW, we observe a consistent bias of perplexity scores towards in-domain language models, which demonstrates that DR models correct the expression of the source side of synthetic data to be more domain consistent.

Table 7: Perplexity of synthetic data's source side scores by both in/out domain language models before and after domain repair.

Case Study. We provide some examples to display how DR models improve the synthetic data. As shown in Table 6, the DR model can reduce some mistranslation, such as correcting the translation of "Johanniskraut" into "St John's wort", as well as generating more domain-related expressions, like "co-administered" and "concomitant use of herbal preparations". This shows the ability of domain repair models to improve the quality and domain consistency of synthetic data generated by imperfect out-of-domain NMT models.

5 Conclusion

In this paper, we argue that back-translation, the predominant unsupervised domain adaptation method in neural machine translation, suffers from the domain shift, restricting the performance of unsupervised domain adaptation. We propose to remedy this mismatch by leveraging a domain repair model that corrects the errors in back-translation sentences. Then the iterative domain-repaired back-translation framework is designed to make full use of the advantage of the domain repair model. Experiments on adapting translation models between specific domains and from general domain to specific domains demonstrate the effectiveness of our method, achieving significant improvements over strong back-translation baselines.

In the future, we would like to extend our method to enhance the back-translation method in multi-domain settings.

Abstract

Back-translation has proven to be an effective method to utilize monolingual data in neural machine translation (NMT), and iteratively conducting back-translation can further improve the model performance. Selecting which monolingual data to back-translate is crucial, as we require that the resulting synthetic data are of high quality *and* reflect the target domain. To achieve these two goals, data selection and weighting strategies have been proposed, with a common practice being to select samples close to the target domain but also dissimilar to the average general-domain text. In this paper, we provide insights into this commonly used approach and generalize it to a dynamic curriculum learning strategy, which is applied to iterative back-translation models. In addition, we propose weighting strategies based on both the current quality of the sentence and its improvement over the previous iteration. We evaluate our models on domain adaptation, low-resource, and high-resource MT settings and on two language pairs. Experimental results demonstrate that our methods achieve improvements of up to 1.8 BLEU points over competitive baselines.[1]

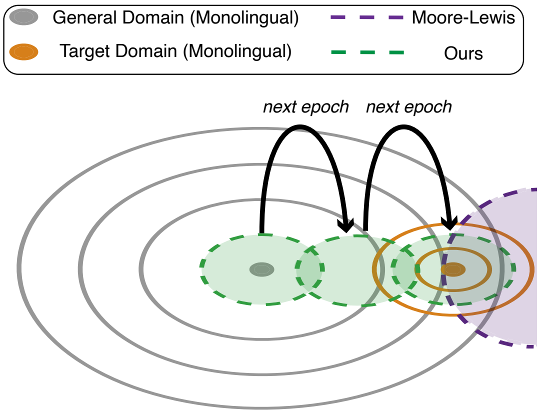

Figure 1: The Moore and Lewis (2010) data selection strategy for domain adaptation constantly selects the same set of sentences which cannot well represent the target domain. Our approach, instead, selects different subsets of sentences at each epoch and we gradually shift from selecting samples from the general-domain distribution to samples from the target distribution.

1 Introduction

Back-translation (Sennrich et al., 2016b) is an effective strategy for improving the performance of neural machine translation (NMT) using monolingual data, delivering impressive gains over already competitive NMT models (Edunov et al., 2018). The strategy is simple: given monolingual data in the target language, one can use a translation model in the opposite of the desired translation direction to *back-translate* the monolingual data, effectively synthesizing a parallel dataset, which is in turn used to train the final translation model. Further improvements can be obtained by iteratively repeating this process (Hoang et al., 2018) in both directions.

However, not all monolingual data are equally important. An envisioned downstream application is very often characterized by a unique data distribution. In such cases of domain shift, back-translating target domain data can be an effective strategy (Hu et al., 2019) for obtaining a better in-domain translation model. One common strategy is to select samples that are both (1) close to the target distribution and (2) dissimilar to the average general-domain text (Moore and Lewis, 2010). However, as depicted in Figure 1, this method is not ideal because the second objective could bias towards the selection of sentences far from the center of the target distribution, potentially leading to selecting a non-representative set of sentences.

Even if we could select all in-domain monolin-

gual data, the back-translation model has not been trained on in-domain parallel data and thus the back-translated data will be of poor quality. As we demonstrate in the experiments, the quality of the back-translated data can have a large influence on the final model performance.

To achieve the two goals of both selecting target-domain data and back-translating them with high quality, in this paper, we propose a method to combine dynamic data selection with weighting strategies for iterative back-translation. Specifically, the dynamic data selection selects subsets of sentences from a monolingual corpus *at each training epoch*, gradually transitioning from selecting general-domain data to choosing target-domain sentences. The gradual transition ensures that the back-translation model of each iteration can adequately translate the selected sentences, as they are close to the distribution of its current training data. We also assign weights to the back-translated data that reflect their quality, which further reduces the effect of potential noise due to low quality translations. The proposed data selection and weighting strategies are complementary to each other, as the former focuses on domain information while the latter emphasizes the quality of sentences.

We investigate the performance of our methods in domain adaptation, low-resource and high-resource MT settings and on German-English and Lithuanian-English datasets. Our strategies demonstrate improvements of up to 1.8 BLEU points over a competitive iterative back-translation baseline and up to 1.2 BLEU points over the best static data selection strategies. In addition, our analysis reveals that the selected samples can represent the target distribution well and that the weighting strategies are effective in noisy settings.

2 Background: Back-Translation

Back-translation (Sennrich et al., 2016a) has proven to be an effective way of utilizing monolingual data for machine translation. Given a parallel training corpus $\mathbf{D}_{FE}$, we first train a target-to-source machine translation model $\mathbf{M}_{EF}$. Then, we use the pre-trained model $\mathbf{M}_{EF}$ to translate a target language monolingual corpus $\mathbf{D}_E$ to the source language and obtain a synthetic parallel corpus $(\mathbf{D}'_F, \mathbf{D}_E)$. Last, we concatenate back-translated data $(\mathbf{D}'_F, \mathbf{D}_E)$ with the original parallel corpus $\mathbf{D}_{FE}$ to train a source-to-target model $\mathbf{M}_{FE}$.

The success of back-translation has motivated researchers to investigate and extend the method (He et al., 2016; Zheng et al., 2020). Hoang et al. (2018) propose to use iterative back-translation and achieve improvements over previous state-of-the-art models. As shown in Algorithm 1, at each training step, a batch of monolingual sentences is sampled from one language and back-translated to the other language. The back-translated data is utilized to train the model in the other direction. The process is repeated in both directions.

Algorithm 1 Iterative Back-Translation

```
Input: Monolingual corpora $\mathbf{D}_F$ and $\mathbf{D}_E$
Output: Translation models $\mathbf{M}_{FE}$ and $\mathbf{M}_{EF}$
  while $\mathbf{M}_{FE}$ and $\mathbf{M}_{EF}$ have not converged do
    for all batches $(\mathbf{B}_F, \mathbf{B}_E)$ in $(\mathbf{D}_F, \mathbf{D}_E)$ do
      Translate $\mathbf{B}_F$ into $\mathbf{B}'_E$ using $\mathbf{M}_{FE}$
      Translate $\mathbf{B}_E$ into $\mathbf{B}'_F$ using $\mathbf{M}_{EF}$
      Train $\mathbf{M}_{FE}$ with $(\mathbf{B}'_F, \mathbf{B}_E)$
      Train $\mathbf{M}_{EF}$ with $(\mathbf{B}'_E, \mathbf{B}_F)$
    end for
  end while
```

3 Methods

In our setting, we are given two MT models $\mathbf{M}_{FE}$ and $\mathbf{M}_{EF}$ pretrained on parallel data $\mathbf{D}_{FE}$, and both source and target monolingual corpora $\mathbf{D}_F$ and $\mathbf{D}_E$. The goal is to select and weight samples from the two monolingual corpora for back-translation, in order to best improve the performance of the two translation models.

3.1 Data Selection Strategies

We first describe a commonly used *static* selection strategy, and then illustrate our *dynamic* approach.

3.1.1 The Moore and Lewis (2010) Method

A common approach for data selection is the Moore and Lewis (2010) method (and extensions, e.g. Axelrod et al. (2011); Duh et al. (2013); Santamaría and Axelrod (2019)), which computes the language model cross-entropy difference for each sentence s in a monolingual corpus:

$$score(\mathbf{s}) = H_{LM_{in}}(\mathbf{s}) - H_{LM_{gen}}(\mathbf{s}), \quad (1)$$

where $H_{LM_{in}}(\mathbf{s})$ and $H_{LM_{gen}}(\mathbf{s})$ represent the cross-entropy scores of s measured with an in-domain and a general-domain language model (LM) respectively. Sentences with the highest scores will be selected for training. Typically, the in-domain language model LM_{in} is trained with

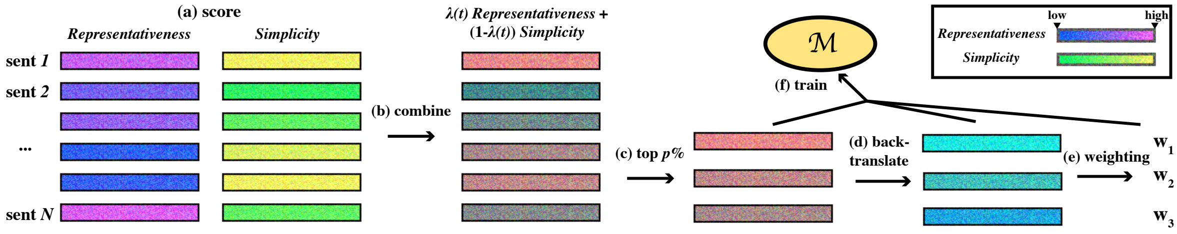

Figure 2: Main procedure of our algorithm. We first compute the representative and simplicity scores for all the monolingual sentences (a). At each training epoch t, we combine the two scores (b) and select the top $p\%$ monolingual sentences (c). After back-translating the selected sentences from the source side to the target side (d), we then perform data weighting on the back-translated samples (e) and train the model with the weighted back-translated sentences (f).

a small set of sentences in the target domain and LM_{gen} is trained with all data available.

3.1.2 Our Two Scoring Criteria

Instead of static data selection, we propose a new curriculum strategy for iterative back-translation. Specifically, we measure both **representativeness**, *i.e.* how well the sentence represents the target distribution, and **simplicity**, *i.e.* how well the MT models can translate the sentence, of each sentence $\mathbf{s}$ in the monolingual corpus. First, we select the most simple samples for back-translation to ensure the quality of the back-translated data. As the training progresses, the model will become better at translating in-domain sentences, and we will then shift to choosing more representative examples.

Formally, at each epoch t, we rank the corpus according to

$$\text{score}(\mathbf{s}) = \lambda(t)\text{repr}(\mathbf{s}) + (1-\lambda(t))\text{simp}(\mathbf{s}), \quad (2)$$

where $\text{repr}(\mathbf{s})$ and $\text{simp}(\mathbf{s})$ denote the representativeness and simplicity of sentence s respectively, which will be dicussed in the following sections. The term $\lambda(t)$ balances between the two criteria and is a function of the current epoch t.

We adopt the square-root growing function for λ (Platanios et al., 2019) and set

$$\lambda(t) = \min(1, \sqrt{t\frac{1-c_0^2}{T} + c_0^2}), \quad (3)$$

where c_0 is the initial value and T denotes the time after which we solely select representative samples. λ increases relatively quickly at first and then its acceleration will be gradually decreased as the training progresses, which is suitable for our task as at first the sentences are relatively simple and thus we will not need much time on those sentences.

Connections to Moore and Lewis (2010). Our proposed criteria generalize Moore and Lewis (2010). The first term of Equation 1, namely $H_{LM_{in}}(\mathbf{s})$, measures the **representativeness** of data because the in-domain LM assigns low entropy to sentences that appear frequently in the target domain. The second term $H_{LM_{gen}}(\mathbf{s})$, on the other hand, measures the **simplicity** of the sentences. If $H_{LM_{gen}}(\mathbf{s})$ is high, it is likely that some n-grams of the sentence $\mathbf{s}$ appear frequently in the parallel training data $\mathbf{D}_{FE}$, indicating that the MT models will likely translate the sentence well. In other words, the sentence s can provide limited additional information if $H_{LM_{gen}}(\mathbf{s})$ is high. Therefore, one can view Moore and Lewis (2010) as selecting the most representative and difficult sentences.

3.1.3 Representativeness Metrics

We propose three approaches to measure the sentence representativeness.

In-Domain Language Model Cross-Entropy (LM-in). As in Axelrod et al. (2011); Duh et al. (2013), we can use $H_{LM_{in}}$ to measure the representativeness of the instances. Concretely, we train a language model LM_{in} with in-domain monolingual data and compute the score $\frac{1}{|\mathbf{s}|}\sum_{t=1}^{|\mathbf{s}|} \log P_{LM_{in}}(s_t|s_{<t})$ for each sentence $\mathbf{s}$.

TF-IDF Scores (TF-IDF). TF-IDF score is another criterion for data selection (Kirchhoff and Bilmes, 2014). For each sentence $\mathbf{s}$, one can compute its term frequency and inverse document frequency for each word. We can thus obtain the TF-IDF vector and calculate the cosine similarity between the TF-IDF vectors of $\mathbf{s}$ and each sentence $\mathbf{s}_{in}$ in a small in-domain dataset, and treat the maximum value as its representativeness score.

BERT Representation Similarities (BERT). BERT (Devlin et al., 2019) has proven to be effective for sentence representation learning. Following the conclusion of Pires et al. (2019), we feed each sentence to the multilingual BERT model and average the hidden states for all the input tokens except [CLS] and [SEP] at the eighth layer to obtain the sentence representation. We then compute the cosine similarity between representations of sentence $\mathbf{s}$ in the monolingual corpus and each sentence $\mathbf{s}_{in}$ in a small in-domain set, and the maximum value is treated as the representativeness score.

3.1.4 Simplicity Metrics

In our experiments, we study two metrics for measuring the simplicity of sentences. Note that in the field of quality estimation for MT (Specia et al., 2010; Fonseca et al., 2019), researchers have proposed several existing techniques to estimate the simplicity of sentences (Turchi et al., 2014; Specia et al., 2015; Shah et al., 2015; Kim and Lee, 2016; Kepler et al., 2019; Zhou et al., 2019; Hou et al., 2019), and here we select a few representative approaches.

General-Domain Language Model Cross-Entropy (LM-gen). We train a language model LM_{gen} with the one side of the parallel training data $\mathbf{D}_{FE}$. Then, for each sentence $\mathbf{s}$ we compute the score $\frac{1}{|\mathbf{s}|}\sum_{t=1}^{|\mathbf{s}|}\log P_{LM_{gen}}(s_t|s_{<t})$.

Round-Trip BLEU (R-BLEU). Given two pretrained MT models $\mathbf{M}_{FE}$ and $\mathbf{M}_{EF}$, round-trip translation first translates a sentence $\mathbf{s}$ into another language using $\mathbf{M}_{FE}$ and then back-translates the result using $\mathbf{M}_{EF}$, obtaining the reconstructed sentence $\mathbf{s}'$. The BLEU score between $\mathbf{s}$ and $\mathbf{s}'$ is treated as our simplicity metric. Similar ideas have been applied to filter sentences of low quality (Imankulova et al., 2017).

For both the representativeness and simplicity scores, it should be noted that they are separately normalized to [0, 1], using the equation $\frac{score(\mathbf{s})-score_{min}}{score_{max}-score_{min}}$, where $score_{max}$ and $score_{min}$ are the maximum and minimum scores.

3.2 Weighting Strategies

Next, we illustrate how we perform data weighting on the back-translated data.

3.2.1 Measuring the Current Quality

As general translation models could perform poorly on the in-domain data, we need ways to measure the current quality of the back-translated sentences in order to down-weight examples of poor quality.

Encoder Representation Similarities (Enc). We feed the source sentence $\mathbf{x}$ and the target sentence $\mathbf{y}$ to the encoders of $\mathbf{M}_{FE}$ and $\mathbf{M}_{EF}$ respectively, and average the hidden states at the final layer to obtain the representations $enc_{FE}(\mathbf{x})$ and $enc_{EF}(\mathbf{y})$. The cosine similarity between them is treated as the quality metric.

Agreement Between Forward and Backward Models (Agree). Inspired by Junczys-Dowmunt (2018), the second approach utilizes the agreement of the two translation models. For each sentence pair $(\mathbf{x}, \mathbf{y})$, we compute the conditional probability $H_{FE}(\mathbf{y}|\mathbf{x})$ and $H_{EF}(\mathbf{x}|\mathbf{y})$, then exponentiate the absolute value between them $\exp(-(|H_{FE}(\mathbf{y}|\mathbf{x})-H_{EF}(\mathbf{x}|\mathbf{y})|))$. Intuitively, the back-translated sentences are of poor quality if there are huge disagreements between the two models.

3.2.2 Measuring Quality Improvements

In domain adaptation, it is natural that at first the in-domain sentences are poorly translated. As training progresses, however, the quality should be improved. We therefore propose a metric to measure the improvement in translation quality and combine it with the current quality metric, in order to encourage the inclusion of in-domain sentences where the translation qualities have improved.

Specifically, every time we obtain the quality score of sentence $\mathbf{s}$, we store it, then the next time we come across the same sentence, we can compare the new quality score with the previous one:

$$\text{Imp}(\mathbf{s}) = clip(\frac{\text{current\_quality}(\mathbf{s})}{\text{previous\_quality}(\mathbf{s})}, w_{low}, w_{high}),$$

where the clipping function limits the weights to a reasonable range. We set (w_{low}, w_{high}) to $(\frac{1}{2}, 2)$.

3.3 Overall Algorithm: Combining Curriculum and Weighting Strategies

Our final algorithm is shown in Figure 2. At each epoch, we compute the score for each sentence in monolingual corpora using Equation 2 and select the top $p\%$ of sentences, where p is a hyper-parameter. Afterwards, we perform back-translation and data weighting on the selected data, then use the back-translated data to train the translation model. The process will be repeated iteratively for both directions, with λ increased at each training epoch.

Table 1: Translation accuracy (BLEU (Papineni et al., 2002)) in the domain adaptation setting. The first and second rows list source and target domains respectively. The third row lists the translation directions. We report the best-performing models of only using selection strategies (*"Best Selection")*, only using curriculum strategies (*"Best Curriculum"*), only using weighting strategies (*"Best Weighting"*) and using both the best curriculum and weighting strategies (*"Best Weighting + Best Weighting"*). "Enc-Imp" indicates both the encoder representation similarities and the quality improvement metrics are used for weighting. The highest scores are in **bold** and $*$ indicates statistical significance compared with the best baseline ($p < 0.05$).

4 Experiments on Domain Adaptation

We first conduct experiments in the domain adaptation setting, where we adapt models from a general domain to a specific domain.

4.1 Setup

Datasets. We first train the translation models with (general-domain) WMT-14 German-English dataset, consisting of about 4.5M training sentences, then perform iterative back-translation with (in-domain) law or medical OPUS monolingual data (Tiedemann, 2012). We de-duplicate the law and medical parallel training data, divide them into two halves and obtain 250K and 200K comparable yet non-parallel sentences respectively in both languages to obtain the monolingual corpora. The development and test sets contain 2K sentences in each domain. Byte-pair encoding (Sennrich et al., 2016b) is applied with 32K merge operations. The general-domain and in-domain language models are trained on the WMT training data and the OPUS monolingual data respectively. The OPUS development sets are used to compute the TF-IDF and BERT representativeness scores.

Table 2: Comparisons of different metrics in domain adaptation. The highest scores in each section are in **bold** and the overall highest scores are in ***bold italic***.

Models. We implement our approaches upon the Transformer (Vaswani et al., 2017). Both the encoder and decoder consist of 6 layers and the hidden size is set to 512. For the translation models, weights of the top 4 layers of the encoders and bottom 4 layers of the decoders are shared between forward and backward models. We also tie the source and target word embeddings. We build 5-gram language models with modified Kneser-Ney smoothing using KenLM (Heafield, 2011).

Hyper-Parameters. c_0 and T in Equation 3 are set to 0.1 and 5. We select 30% of the sentences with the highest score at each epoch for our curriculum methods and 50% of the sentences for the static data selection baselines.

4.2 Results

We compare our dynamic curriculum and weighting methods with three baselines: the iterative back-translation baseline, a baseline trained with only data selection strategies, a baseline trained with only data weighting strategies. The results with the best-performing representativeness and simplicity metrics (TF-IDF and R-BLEU, respectively) in the

Table 3: Noise in back-translated data can degrade the model performance and our weighting strategies (Enc) benefit the most in noisy settings.

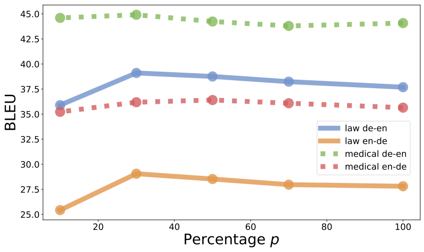

Figure 3: While the model is relatively robust to the number of selected sentences at each epoch, selecting too many or too few sentences can be harmful.

domain adaptation setting are listed in Table 1.

Iterative Back-Translation. The iterative back-translation method is rather competitive, as it improves over the unadapted baseline by 9.6 BLEU and simple back-translation by 1.8 BLEU points.

Selection Strategies. We can see from the table that the best-performing selection strategies, namely selecting sentences with high TF-IDF scores, is generally effective and can improve the baseline by about 0.5 BLEU points.

Curriculum and Weighting Strategies. Both our curriculum and weighting strategies outperform the unadapted and the iterative back-translation models, as well as the curriculum method proposed in Zhang et al. (2019), with our curriculum learning method achieving better performance and improving the strong iterative back-translation baseline by 1.1 BLEU points. Combining curriculum and weighting methods can further improve the performance by up to 0.5 BLEU points, demonstrating the two strategies are complementary to each other.

4.3 Choices of Metrics

We examine different choices of representativeness and simplicity metrics. The performance of different models is listed in Table 2.

Representativeness Metrics. All data selection strategies outperform the baseline, with TF-IDF, LM-diff, and BERT metrics exhibiting fairly robust performance in all settings. Due to its simplicity, we choose TF-IDF for experiments where a good in-domain development set is available.

Data Weighting Strategies. The agreement-based weighting method ("Agree") performs slightly worse than the encoder-similarity weighting strategy ("Enc"), probably because the two languages are similar and thus encoders with shared parameters can accurately measure the data quality.

Curriculum Strategies. Table 2 demonstrates that TF-IDF is a better metric than other representativeness metrics in both static and dynamic data selection settings. Also, the round-trip BLEU score can be better at measuring the simplicity of sentences than LM-gen. Last, by comparing the Moore-Lewis method ("LM-diff") with our curriculum strategy ("LM-in+LM-gen"), we can see that our method outperform Moore-Lewis method in 3 out of 4 settings.

4.4 Analysis

Next, we investigate how noise in the back-translated data impacts the model performance, how many sentences we should select, and if our weighting methods assign weights appropriately.

Effect of Back-Translation Quality. We try to generate the back-translated data using sampling, greedy search and beam search for iterative back-translation and the results are listed in Table 3. We find that the sampling method significantly degrades the model performance, as it introduces more noise than other approaches, demonstrating that noise can have a negative impact in domain adaptation settings. The conclusion is similar to the findings in low-resource settings Edunov et al. (2018). In addition, we find that our weighting strategies are more beneficial in noisy settings.

Effect of the Percentage p. We test how many sentences should be selected at each epoch for our curriculum strategies. As shown in Figure 3, selecting 30% of the monolingual sentences achieves the best performance in general. Selecting fewer samples can discard valuable information whereas choosing more instances can introduce more noise.

	Back-Translated Sentence	Weight	BLEU
Source	- wenn der Viehhalter seinen Betrieb einem Nachfolger bis zum dritten Verwandtschaftsgrad übergibt ;	-	-
Reference	- when the farmer gives over his farm to his family successor up to the third degree of relationship ,	-	-

Table 4: Examples of our weighting strategy (Enc). We use our model (Curri+Enc) at the 5K-, 10K-, 15K-th iterative back-translation step to weight sentences. The assigned weights correlate well with the BLEU scores.

R-BLEU	**TF-IDF**	
	High (≈ 1)	**Low** (≈ 0)
High (≈ 1)	Article 20	(2005 / 686 / EC)
Low (≈ 0)	any Contracting Party may request that a meeting be held .	MS Danuta HÜBNER

Table 5: Example full sentences with different TF-IDF and R-BLEU scores. R-BLEU correlates with the lengths while TF-IDF measures the domain distance.

	train	**dev**	**test**	**mono**
low	WMT en-de (100K)	test2013 (3K) LAW (2K) MED (2K)	test2014 (3K) LAW (2K) MED (2K)	CC (1M) LAW (25K) MED (20K)
high	WMT en-de (4.5M)	test2013 (3K)	test2014 (3K)	CC (10M)
	WMT en-lt (2M)	dev2019 (2K)	test2019 (1K)	News lt (5M) + CC en (5M)

Table 6: Sources and numbers of sentences of the datasets in both low- and high- resource settings. "CC" refers to the CommonCrawl corpus.

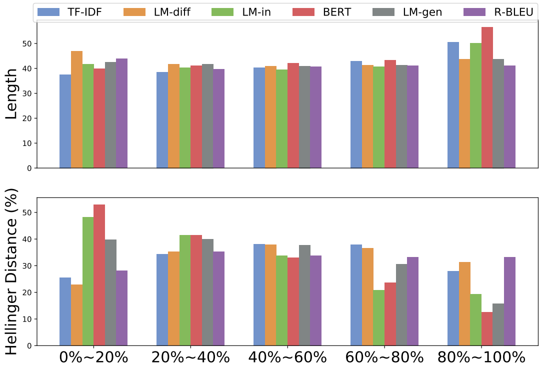

Figure 4: Length and Hellinger distance of sentences in each bucket selected with different metrics.

Weighting Examples. We use our model (Curri+Enc) to back-translate some sentences from the monolingual corpus and Table 4 shows the weights our models assign at different training stages. In this example, the assigned weights correlate well with the BLEU scores, demonstrating our methods can perform weighting appropriately in some cases.

4.5 Characteristics of the Selected Data

In this part, we investigate certain characteristics of the selected samples.

Lengths. Figure 4 shows the average lengths of the selected sentences in each bucket. We can see that 1) both LM-in and BERT favor long sentences, with one possible explanation being that those sentences are more likely to contain in-domain words; 2) TF-IDF does not share this feature, likely due to the IDF term; 3) sentences with high R-BLEU scores are generally short, likely because NMT models are bad at translating long sentences.

Unigram Distribution Distance. We also compute the unigram distribution distance using the Hellinger distance. Concretely, we compute the unigram distribution P and Q for both the selected data and the test set, and calculate

$$\frac{1}{\sqrt{2}}\sqrt{\sum_{i=1}^{V}(\sqrt{p_i}-\sqrt{q_i})^2},$$

where V is the size of the vocabulary. The larger the Hellinger distance is, the more dissimilar the two distributions are. Figure 4 shows that both TF-IDF and BERT match the test distribution well. Also, LM-in performs better than LM-diff, which confirms our hypothesis that the data selected by the Moore-Lewis method cannot adequately represent the target distribution.

Diversity Among Selected Data at Each Epoch. As our curriculum strategies dynamically select different subsets of data, here we examine how many new sentences are actually introduced at each epoch. We find that starting from the second epoch,

Method	WMT-low						WMT-high

Table 7: Translation accuracy (BLEU) in low-resource and high-resource scenarios. The first and second row list the source and target domains. The third row lists the translation directions. The highest scores are in **bold** and $*$ indicates statistical significance compared with the best baseline ($p < 0.05$).

12.5%, 10.4%, 12.5%, 18.3%, 21.5% of the selected sentences will be replaced at each epoch, and 52.5% of the monolingual sentences will be selected at least once in total.

Examples. Table 5 shows examples of the selected sentences. Sentences with both high TF-IDF and R-BLEU scores are typically short and match the target distribution well. Sentences with high TF-IDF but low R-BLEU scores can be long and contain some out-of-vocabulary words, while sentences with low TF-IDF but high R-BLEU scores are generally short and frequently include digits and single characters. Most of the sentences with both low TF-IDF and R-BLEU scores are extremely noisy and can be safely discarded.

5 Experiments on Low-Resource and High-Resource Scenarios

Next, we conduct experiments in both low- and high-resource scenarios over two language pairs: Lithuanian-English and German-English.

5.1 Setup

Data statistics are shown in Table 6. When the target distribution is the news domain, we train the in-domain LMs with 500K sentences from the news monolingual data. The other settings (including hyperparameters) are the same as before.

5.2 Results

The results are reported in Table 7. We find that LM-in and LM-gen is the best metric combination for curriculum strategies when the target distribution is the news domain. TF-IDF and R-BLEU as the representativeness and simplicity metrics are the best in all other settings.

Low-Resource Settings. In low-resource settings, iterative back-translation can improve the baseline model by a large margin, and our curriculum strategies can still outperform the strong baseline by 1.3 BLEU points. Weighting methods also generally help and in the best case scenario, our method can improve iterative back-translation by 1.8 BLEU points.

High-Resource Settings. In high-resource settings, our curriculum strategies improve the iterative back-translation baseline by up to 0.3 BLEU points. Data weighting strategies do not always help, probably because in high-resource settings the back-translated data is already of high quality. In the best case scenario, our method outperforms iterative back-translation by 0.6 BLEU points.

6 Related Work

Back-translation (Sennrich et al., 2016a) has proven to be effective and several extensions of it have been proposed (He et al., 2016; Cheng et al., 2016; Zhang and Zong, 2016; Xia et al., 2019), among which iterative back-translation methods (Cotterell and Kreutzer, 2018; Hoang et al., 2018; Niu et al., 2018; Zheng et al., 2020) have demonstrated strong empirical performance.

For domain adaptation, Moore and Lewis (2010) and Kirchhoff and Bilmes (2014) use language model cross entropy differences and TF-IDF to select data that are similar to in-domain text respectively. van der Wees et al. (2017) propose dynamic data selection strategies for machine translation models, and Zhang et al. (2019) extend the idea to curriculum strategies. As for filtering noisy sentences, Junczys-Dowmunt (2018) propose to utilize the agreement between forward and backward translation models and Wang et al. (2019a) propose uncertainty-based confidence estimation to improve back-translation. Wang et al. (2019b) compose dynamic domain-data selection with dynamic clean-data selection. Our methods generalize previous data selection strategies and our primary focus is to improve iterative back-translation, but our work could be extended to also include training-time dynamic data selection approaches such as the technique of Wang et al. (2020).

7 Conclusion

In this paper, we provide a novel insight into a widely-used data selection method (Moore and Lewis, 2010) and generalize it to a curriculum strategy for iterative back-translation. We also propose data weighting methods to down-weight examples of poor quality. Extensive experiments are performed to evaluate the performance of our methods; analyses reveal the selected samples can represent the target domain well and our weighting strategies benefit noisy settings the most.

A Implementation Details

- We use one 11G NVIDIA GTX 1080 GPUs for each experiment.
- The average training time are: about 30 hours for the baseline models and 40 hours for our models.
- The number of model parameters is 156.81M.
- We use BLEU (Papineni et al., 2002) to evaluate the performance of our models,[2] and *compare-mt* (Neubig et al., 2019) to help with the analysis.[3]
- We manually tune the hyperparameters c_0 in $[0, 0.1, 0.2]$ and T in $[5, 10, 20]$ in Equation 3, and also the percentage of the selected sentences p in each epoch in $[10\%, 20\%, 30\%, 40\%, 50\%]$. We first set c_0 to 0.1, T to 10 and search for the best p, then search for the best T, and finally for c_0, which takes 11 trials in total.
- We follow the instructions on the WMT website to pre-process the data.[4]
- The datasets we use can be downloaded from the WMT website.[5]

Abstract

The complete sharing of parameters for multilingual translation (1-1) has been the mainstream approach in current research. However, degraded performance due to the capacity bottleneck and low maintainability hinders its extensive adoption in industries. In this study, we revisit the multilingual neural machine translation model that only share modules among the same languages (M2) as a practical alternative to 1-1 to satisfy industrial requirements. Through comprehensive experiments, we identify the benefits of multi-way training and demonstrate that the M2 can enjoy these benefits without suffering from the capacity bottleneck. Furthermore, the interlingual space of the M2 allows convenient modification of the model. By leveraging trained modules, we find that incrementally added modules exhibit better performance than singly trained models. The zero-shot performance of the added modules is even comparable to supervised models. Our findings suggest that the M2 can be a competent candidate for multilingual translation in industries.

1 Introduction

With the current increase in the demand for neural machine translation (NMT), serving an increasing number of languages poses a practical problem for the industry. A naive approach for multilingual NMT is to have multiple single-directional models, which is unsustainable owing to the quadratic increase of models as more languages are introduced. A more practical approach is to limit the number of models by sharing the components among the models (Dong et al., 2015; Firat et al., 2016a; Ha et al.; Johnson et al., 2017). In addition to reducing the number of parameters, sharing the components is also regarded as an effective method to enhance the performance. A fully shared model (henceforth 1-1), which only uses one encoder and one decoder to translate all directions (Ha et al.; Johnson et al., 2017), has been the most popular method because of its compactness.

However, introduction of a significant number of tasks into a 1-1 model is known to cause capacity bottleneck. Aharoni et al. (2019) suggested that, given a fixed model capacity, a 1-1 model is bound to the tradeoff between the number of languages and translation accuracy. Zhang et al. (2020) explicitly identified the capacity bottleneck problem of the 1-1 model by showing a clear decrease in performance when translation directions are doubled. Moreover, data unbalance complicates the problem. Arivazhagan et al. (2019b) presented the transfer and interference dilemma among low and high resource languages in an unbalanced environment.

The capacity bottleneck observed in the 1-1 model is particularly undesirable for the industry. Unlimited scaling of the model size (Zhang et al., 2020) is impossible in practice, where inference cost and latency are crucial. With limited capacity, gain from multilingual translation training (henceforth multi-way training) without being subject to the losses of the capacity bottleneck is difficult to achieve. Furthermore, modification of the 1-1 model such as simple addition of a language is troublesome because the entire model must be retrained from the beginning as a single module, thus requiring a considerable amount of time and effort. This low maintainability makes 1-1 less attractable for industrial use. Still, the benefit from multi-way training is difficult to miss.

These problems lead us to revisit the multilingual neural machine translation model that share parameters among the same languages (Firat et al., 2016a). We named this architecture as the *modularized multilingual NMT model* (henthforth M2) since the model share language-specific modules (encoders or decoders) instead of the whole model.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5905–5918,
November 16–20, 2020.

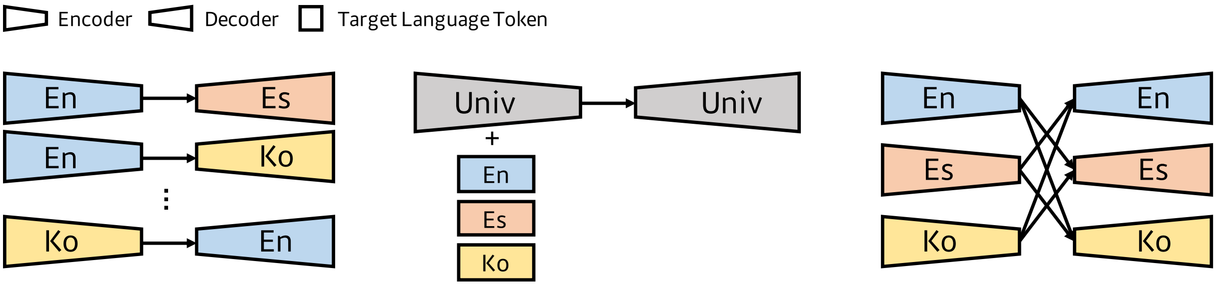

Figure 1: **Model overview** of three different types of multilingual NMT models for three languages: En, Es, Ko. *Left* is a collection of single models for 6 translation directions. *Middle* is the 1-1 model that share the whole parameters of the model for 6 directions. *Right* is the M2 model that only share language-specific modules.

Figure 1 illustrates the architectural overview of multilingual translation using single models, the 1-1 and the M2. Although the M2 has not been given substantial attention owing to the linear increase in its parameters as the number of languages increases, it is relatively free from the capacity bottleneck problem while maintaining a reasonable inference cost. In this study, we explore the possibility of M2 as an alternative to the 1-1 model in industrial settings.

To resolve the capacity bottleneck problem while enjoying the benefits, we identify the effects of multi-way training in a carefully controlled environment. We find that the *data-diversification* and *regularization* of multi-way training enable the M2 to outperform both single and 1-1 models with less suffering from capacity bottlenecks. Additionally, the M2 demonstrates a comparable performance increase to 1-1 for low resource pairs in an unbalanced environment.

Combined with its modularizable architecture, interlingual space learned by the M2 allows convenient and effective modification of the model. The simple addition of language-specific modules to the M2 outperformed an individually trained model. The zero-shot learning of the incremented language module outperforms English pivoted translation and is even comparable to a supervised model. Finally, we show that the language invariance of such space improves with more languages.

In summary, our contribution is threefold. 1) We conceptually specify the effects of multi-way training and verified them with comprehensive experiments. 2) We show that the M2 can leverage those effects as the 1-1 without the constraint of the capacity bottleneck. 3) Finally, we find that multi-way training of the M2 forms interlingual space which allows simple yet effective extension of languages.

2 Related works

2.1 Neural machine translation

The most popular framework for NMT is the encoder-decoder model (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Vaswani et al., 2017). Adopting attention module greatly improved the performance of encoder-decoder model by using context vector instead of fixed length vector (Bahdanau et al., 2014; Luong et al., 2015). By exploiting multiple attentive heads, the Transformer model has become the de-facto standard model in NMT (Vaswani et al., 2017; Ott et al., 2018; So et al., 2019).

2.2 Multilingual neural machine translation

Dabre et al. (2019) categorized the architectures of multilingual NMTs according to their degrees of parameter sharing. We briefly introduce the models under their criteria.

Early multilingual NMT models *minimally shared* the parameters by sharing language-specific encoder (Dong et al., 2015; Lee et al., 2017) or decoder (Zoph and Knight, 2016). Firat et al. (2016a) extended this to sharing both language-specific encoders and decoders with a shared attention module.

The 1-1 model, *fully shared*, uses only one encoder and decoder to translate all directions (Ha et al.; Johnson et al., 2017). The target language is indicated by prepending a reserved target language token to the source text. Being compact, the 1-1 model has become the mainstream of multilingual NMT research (Ha et al.; Johnson et al., 2017; Aharoni et al., 2019; Arivazhagan et al., 2019b; Wang et al., 2019; Liu et al., 2020), However, subsequent studies tried to solve the capacity bottleneck problem of the 1-1 through knowledge compression (Tan et al., 2019b), language clustering (Tan et al., 2019a) or increased capacity (Zhang et al., 2020).

Partially shared models are extensively studied to compromise the capacity bottleneck and model size (Blackwood et al., 2018; Sachan and Neubig, 2018; Platanios et al., 2018; Zaremoodi et al., 2018; Bapna and Firat, 2019). Despite their popularity, we do not compare them in this work because *partially sharing* is essentially relaxing the capacity constraint of *fully sharing*. Also, Sachan and Neubig (2018) reported that the performance of *partially shared* models is language-specific, which is not the focus of our study. Instead, we focus on the general trade off of parameter sharing.

2.3 Interlingual representation

Building interlingual[1] representation is another interest in multilingual language modeling (Schwenk and Douze, 2017). Interlingual space is the ground for zero-shot translation (Johnson et al., 2017; Arivazhagan et al., 2019a; Al-Shedivat and Parikh, 2019) and incremental training (Escolano et al., 2019). Several explicit methods were suggested to build interlingual space including shared attention (Firat et al., 2016a), neural interlingua module (Lu et al., 2018), attention bridge (Vázquez et al., 2019), auxiliary loss (Arivazhagan et al., 2019a) and shared encoder (Sen et al., 2019).

We further extend the study of Firat et al. (2016a) which inspired our M2. Firat et al. (2016a) only shared English encoder and decoder as they used English-centered data (parallel corpus that include English). Instead we show that sharing modules of all languages using diverse directions of data further increases the performance and is the key to build interlingual representation without any explicit regularization.

Our motivation to rediscover the M2 is concurrently shared with Escolano et al. (2020). Escolano et al. (2020) empirically show that M2 is capable of quickly deploying new languages with incrementally added modules, and found it outperforms 1-1. We also experiment on incremental learning and get a similar conclusion, and further interpret the results as an indication that M2 effectively forms an interlingual space. Regarding comparison of M2 and 1-1 in general, we deliver an in-depth understanding of a less-studied model M2 focusing on how to maximize its utility in industry. Experiments on incremental learning are to check whether M2 is a maintainable alternative to 1-1 (which requires expensive re-training from scratch).

3 Effects of multi-way training

Because of its complexity, the effects of multi-way training are yet to be identified. Various factors may affect the performance of multilingual translation: model size compared to the amount of data, the number of training directions, the degree of data imbalance among different directions, and the portion of multi-parallel data. In this section, we discuss the possible effects on performance resulting from these factors.

Capacity bottleneck A capacity bottleneck is the most plausible cause of performance degradation in multi-way training. For a fixed size model, the capacity bottleneck is more prominent with the increase in training directions (especially target languages) and the amount of data (Johnson et al., 2017; Aharoni et al., 2019; Arivazhagan et al., 2019b; Zhang et al., 2020).

Cross-language effect Cross-language effect occurs when multiple languages are shared in a module. Low resource languages reportedly benefit from multi-way training when trained along with high resource pairs (Zoph et al., 2016; Nguyen and Chiang, 2017; Neubig and Hu, 2018). The interaction among languages in a module can either be positive (transfer) or negative (interference) on the performance according to their similarity in linguistic patterns.

Data-diversification Data-diversification is associated with the portion of multi-parallel among multi-way data. If either the source-side or the target-side language is shared across two directions and data of the directions is not multi-parallel, the shared module learns more diverse samples of the language. For example, if an English encoder is shared between En-De and En-Fr directions (and English sentences of two are not completely shared), the encoder learns more diverse English sentences from both pairs. Few studies distinguished this effect (Firat et al., 2016a,b). We refer to the improvement resulting from this factor as the *data-diversification* effect.

Regularization Learning to encode or decode the same language in various directions may result

---

[1] We prefer the term 'interlingual' to 'language-agnostic' because we expect it to be better if the space is shared while maintaining the language-specific features instead of removing them.

in better representation learning and less overfitting in a single direction. This effect has already been observed by Firat et al. (2016a) as the benefit of generalization and suggested by Aharoni et al. (2019) to benefit many-to-many models compared to many-to-one models.

4 Comparison of single models, 1-1 and M2

We compared the models with the same inference capacity in a series of conditions. Note that most of the multilingual NMT research was conducted in a joint one-to-many and many-to-one environment (JM2M): collected data are English-centered. Despite its simplicity, observations under such setting may be unreliable to speak for many-to-many (M2M) environment, which is also clearly in demand in the industry. Therefore, we set M2M training as the default.

We also distinguish between two different dataset compositions: the *sharing* case where all language pairs share the same sentence set, and the *non-sharing* case where there is no overlap between different pairs. To illustrate, a multiparallel set 'En - Es - Ko' can be shared for all possible three pairs (En - Es, En - Ko, Es - Ko) or used only once for one pair. Considering that multiparallel data is rare in practice, we compared the models in a strictly non-sharing environment.

4.1 Settings

Dataset We collected multi-parallel data from Europarl (Koehn, 2005) and selected four languages: German, English, Finnish, and French. To construct a completely balanced environment, we created 500K, 10K, and 10K (train, valid, and test) non-sharing pairs for every twelve possible directions from 1.56M multi-parallel data. For the unbalanced environment, we synthetically reduced the amount of data for some pairs to match a specific ratio of the data amounts for low, medium, and high resource pairs. For further details on data division, see appendix A.

Model For the 1-1 model, we used the model of Aharoni et al. (2019) which is transformer implementation of Johnson et al. (2017). For the M2, we modified Firat et al. (2016a) to not share the attention module. Language-specific embeddings are shared between the encoder and decoder. We implemented all models using transformer (Vaswani et al., 2017). We used the transformer with a hidden dimension of 256 and a feed-forward dimension of 1024 for our base model. The rest of the configuration follows the base model employed by Vaswani et al. (2017) except for the attention dropout and activation dropout of 0.1. The 1-1 model uses a joint vocabulary with 32K tokens, whereas the M2 uses a language-specific vocabulary with 16K tokens each, all processed using the BPE (Kudo, 2018) of the `sentencepiece` package[2] (Kudo and Richardson, 2018).

Pairs	Single	1-1	M2
De-En	33.00	31.04 (-1.96)	33.51 (0.51)
De-Fi	15.20	13.08 (-2.12)	15.93 (0.73)
De-Fr	28.47	25.73 (-2.74)	29.08 (0.61)
En-De	25.87	23.83 (-2.04)	26.46 (0.59)
En-Fi	19.57	16.94 (-2.63)	20.03 (0.46)
En-Fr	35.74	32.99 (-2.75)	36.09 (0.35)
Fi-De	18.97	16.75 (-2.22)	19.51 (0.54)
Fi-En	29.26	27.32 (-1.94)	30.24 (0.98)
Fi-Fr	25.21	22.24 (-2.97)	25.94 (0.73)
Fr-De	22.23	20.09 (-2.14)	22.64 (0.41)
Fr-En	35.49	33.81 (-1.68)	36.18 (0.69)
Fr-Fi	15.42	13.6 (-1.82)	16.15 (0.73)
Avg	25.37	23.12 (-2.25)	**25.98 (0.61)**

Table 1: SacreBLEU test scores of single models, 1-1, and M2 trained using a completely balanced, non-sharing dataset. Values in parentheses indicate the performance difference from single models.

Training We used the `fairseq` framework [3] (Ott et al., 2019) to train and test all models. We set the batch size so that every encoder/decoder module learned at a maximum of 6144 tokens/GPU. All models were trained using 4 NVIDIA Tesla V100 GPUs. We followed the default parameters of the Adam optimizer (Kingma and Ba, 2014). For the learning rate schedule, we used 2K warm-up steps until 1e-3, after which we used the inverse square root learning rate schedule (Vaswani et al., 2017). The best model was selected using the best validation loss within the same maximum number of epochs. All the performance was measured in `sacreBLEU4` (Post, 2018) using a beam size of 4 and a length penalty of 0.6. Appendix B provides more details of training.

ID	Data sharing	Model size	Training pairs	Single	1-1	M2
1	Non-sharing	Base	M2M(12)	25.37	23.12 (-2.25)	**25.98 (0.61)**
2	Sharing	Base	M2M(12)	25.34	23.27 (-2.07)	**25.65 (0.31)**
3	Non-sharing	Large	M2M(12)	25.43	26.90 (1.47)	**27.17 (1.74)**
4*	Non-sharing	Base	JM2M(6)	-	27.50 (-2.32)	29.70 (-0.12)
5*	Non-sharing	Base	M2M(12)	29.82	27.66 (-2.16)	**30.42 (0.6)**

Table 2: Averaged SacreBLEU test scores of single models, 1-1, and M2 trained using a balanced dataset of different configurations. *M2M* indicates the training of full many-to-many directions among languages (12 directions), whereas *JM2M* represents the training of directions that only include English on one side(6 directions). * indicates that the score is averaged only on English-centric.

4.2 Balanced environment

We first compared the performance of multi-way directions in a balanced and non-sharing environment, which is the most strictly controlled.

The results are shown in Table 1. The 1-1 model performed worse than both the single models and the M2 in every direction, clearly indicating a capacity bottleneck. In contrast, **the M2 consistently outperformed not only the 1-1 model but also the single models in all directions**. As the M2 cannot benefit from *cross-language effect* due to the lack of a shared module between any languages, we hypothesize that the following two effects are in charge: *data-diversification* and *regularization*. We verify this hypothesis using ablation studies.

Note that the 1-1 model's variation of degradation is higher with target languages than with source languages, even though all the directions are trained using the same amount. The translation to English (-1.96, -1.94, and -1.68) consistently degraded the least, whereas that to French (-2.74, -2.75, and -2.97) degraded the most, given the same source languages. This finding is consistent with previous observations that the capacity bottleneck is more prominent in the decoders (Johnson et al., 2017; Arivazhagan et al., 2019b).

Ablation We compare models in a series of conditions (see IDs in Table 2). ① We denote the summarized performance demonstrated in Table 1 for reference. ② To establish whether *data-diversification* was responsible for the performance improvement of the M2, we experimented using fully shared data. ③ To observe the behavior under alleviated capacity constraints, we experimented using bigger models. We used a transformer with a hidden dimension of 512 and a feed-forward dimension of 2048 for our large model. The training settings are the same except for a larger batch size (x4). ④ Finally, we compared the models trained using the JM2M (6 directions instead of 12) to observe the behavior of the models with fewer directions. ⑤ We averaged scores of English-centric directions in ① to compare with ④. Appendix C presents the individual score for each direction.

Table 2 shows the results of each environment. When we completely shared the data(②), the performance gain of the M2 versus that of the single models (0.31) decreased. Given that ② eliminates the chance of *data-diversification*, the degraded performance (0.3) can be attributed to it. However, the fact that the M2 still outperforms the single models (0.31) implies that the M2 can still benefit from the *regularization* effect of multi-way training. The minor increase in performance of 1-1 (0.18) seems to imply that *data-diversification* can be detrimental under the severe capacity bottleneck.

③ shows the performance of a larger model trained using the same data. Single models barely improved with the use of larger models, indicating the absence of a capacity bottleneck. On the contrary, the 1-1 model and the M2 both showed an increase in performance. The 1-1 model exhibits a gain from multi-way training only with enough capacity (1.47). This indicates that the benefit of multi-way training can only be achieved with enough capacity for the 1-1 model. Although the M2 is less affected by capacity bottleneck, the larger capacity is also beneficial for the M2 (1.74) to fully leverage the benefits of multi-way training.

To compare the models trained with JM2M (④), ⑤ shows the score averaged only over directions from and to English ①. The JM2M scheme is likely to have mixed results: there is less pressure from the capacity bottleneck due to fewer training directions. However, possible gains from *data-diversification*

	Total Avg	23.12 (-2.25)	25.98 (0.61)	23.29 (0.52)	**25.07 (2.3)**	21.86 (7.17)	**22.44 (7.76)**

Table 3: Test SacreBLEU test scores of single models, 1-1 model, and M2 trained using an unbalanced, completely non-sharing dataset. 1:1:1, 1:2:4, and 1:5:25 represent the ratios of the low, medium, and high resource pairs, respectively. Values in parentheses indicate the performance difference from single models in respective environments.

or *regularization* are also smaller. Both the 1-1 model and the M2 perform better when trained using M2M (⑤) than when trained using JM2M (④). However, the performance difference is more significant in the M2 (0.72) than in the 1-1 model (0.16). We assume that while both models benefit from *data-diversification* and *regularization* accompanied by training using more directions, the capacity bottleneck in 1-1 counterweighs those positive effects.

4.3 Unbalanced environment

We also compared the models with unbalanced training data, which is a natural condition in practice. To synthetically create an unbalanced environment, we first divided the pairs into low (De-En, De-Fi, De-Fr), medium (En-Fr, Fi-Fr), and high (En-Fr) resource pairs. Next, we reduced the amount of data for low and medium pairs, setting the ratio of low:medium:high = 1:2:4, and 1:5:25, respectively. The detailed division of the dataset can be found in appendix A. Note that the models learns with fewer data in the unbalanced environment. We first trained the models without up-sampling.

Table 3 shows the scores of the 1-1 model and the M2 in each setting (1:1:1, 1:2:4, 1:5:25). Both models show similar trends with unbalanced data. Compared to the balanced environment, medium and low resource pairs tend to benefit from multi-way training, with gains more prominent for lower resource pairs as the data get more unbalanced (12.8 by the 1-1 model and 12.85 by the M2). Interestingly, **the M2 exhibits a similar level of improvement to that of the 1-1 model in low and medium resource pairs.** Considering the M2 is not subject to the *cross-language transfer*, the performance increase in lower resource pairs may be better explained by *data-diversification* and *regularization*. This indicates that the *cross-language effect* of the 1-1 model may be more subtle than expected.

M	**US**	**High**	**Medium**	**Low**
1-1	×	23.58 (-0.74)	25.44 (2.7)	18.9 (12.8)
	○	20.5 (-3.83)	24.31 (1.57)	**19.78 (13.68)**
M2	×	**24.86 (0.53)**	**26.46 (3.72)**	18.96 (12.85)
	○	19.64 (-4.69)	23.49 (0.75)	16.88 (10.78)

Table 4: Averaged test SacreBLEU scores of 1-1 and M2 trained with 1:5:25 dataset with and without up-sampling.

On the other hand, M2 barely showed the performance degradation in high resource pairs. This implies that the performance boost of low resource pairs and the drop of high resource pairs may not be necessarily trade-off without a capacity bottleneck.

Ablation The sampling method in an unbalanced setting is known to affect the performance (Arivazhagan et al., 2019b). We compared two models in the most unbalanced environment (1:5:25) with and without up-sampling.

Table 4 shows the results. As previously reported, we confirm that up-sampling makes the results extreme in the 1-1 model: low resource pairs improve more (from 12.8 to 13.68), whereas high resource pairs degrade more (from -0.74 to -3.83). On the other hand, up-sampling in the M2 harmed performance in all the low, medium, and high resource pairs. The difference in converge rates among modules may be the cause; models overfit in low-resource pairs, and underfit in high-resource pairs. This is supported by the changes in the M2's performance with more training epochs (Appendix C).

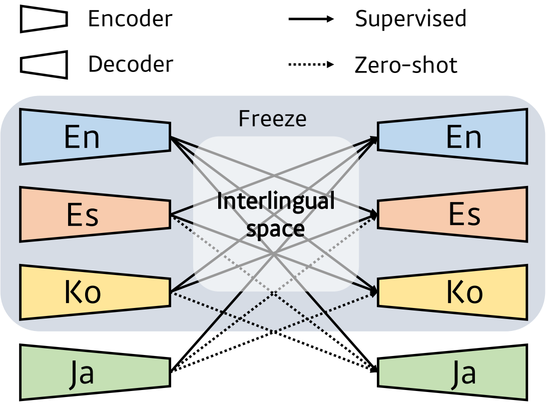

Figure 2: **Interlingual space** formed by the multi-way training of the M2 (En, Es and Ko). While freezing the M2, incrementally training a new language (Ja) with a single parallel corpus (En - Ja) adapt new modules to the interlingual space.

5 Interlingual space of the M2

Creating interlingual space has been an active research area (Lu et al., 2018; Sen et al., 2019; Arivazhagan et al., 2019a; Escolano et al., 2019; Vázquez et al., 2019) because it is critical to scaling out languages, such as incremental learning. Because input of M2 does not contain any information regarding the target language, encoders need to encode it so that any decoder can translate. At the same time, decoders of the M2 should be able to generate from output of any M2 encoder. For this reason, we assume that the output space of M2 encoders is interlingual.

Figure 2 illustrates the interlingual space of a M2. Multi-way training of 3 languages (En, Es and Ko) forms the interlingual space which is shared by 6 modules. This space is preserved as long as the weights of the M2 are frozen. Training a new module (Ja) with a single parallel corpus (En - Ja) using one of the frozen modules (En) adapt the module to the interlingual space. We speculate that the new module (Ja) would be compatible with the other modules (Es and Ko) if the interlingual space is formed well.

ID	Model	En-Fr	Fr-En
1	M2(4) + En-Fr	34.70	34.90
2	M2(4) + En-Fr *with init*	34.88	34.94
3	M2(4) + En,De-Fr	35.40	35.57
4	M2(4) + En,De,Es-Fr	35.41	35.70
5	M2(4) + En,De,Es,Nl-Fr	**35.47**	**35.92**
6*	Single	34.48	34.11
7*	M2(5)	36.24	36.35

Table 5: SacreBLEU test scores of a single model and incremented modules of the M2. Values in parentheses indicate the number of languages involved in the M2 (4: De, En, Es, Nl; 5: 4 + Fr). + indicates incremental training with the former model frozen. *with init* indicates that the incremented module is initialized using the weight of the English module. * represents the model is trained from scratch and not incrementally.

We verify this using incremental zero-shot learning. Additionally, we measure how the language invariance of the space changes as the number of languages involved in the M2 varies. Since maintainability is one of the critical needs in practice, high performance on incremental learning would be a desirable trait in industrial settings.

5.1 Setting

To increase the number of languages, we modified the multi-parallel corpus of Europarl differently. We selected six languages (German, English, Spanish, Finnish, French, and Dutch) and divided a 1.25M multi-parallel corpus into 250K for each direction without sharing. Other details are mostly the same as in former experiments. The detailed division of the dataset and training details can be found in appendix A and B.

5.2 Incremental training

We added French to an M2 model trained using all directions among four languages (German, English, Spanish, and Dutch). An additional French encoder and decoder were trained using English-French pairs while the parameters of English modules remained frozen (①). We also tested two methods to help incremental training as follows. 1) Initialize the new module using one of the modules trained using other languages. In the experiment, we used the weights copied from the English module as the initialization for French (②). Note that the English and French module does not share any information, such as embedding. 2) Train the module with

Model	De-Fr	Fr-De	Es-Fr	Fr-Es	Nl-Fr	Fr-Nl
Pivot	25.42	19.53	30.37	30.87	23.52	22.06
1	26.37	19.08	31.91	32.22	24.31	22.15
2	**26.79**	**19.90**	32.17	32.68	24.64	22.63
3	-	-	**32.91**	**33.34**	25.65	23.44
4	-	-	-	-	**25.82**	**23.55**
6*	26.91	20.86	32.90	33.70	24.81	22.97
7*	28.86	22.70	34.62	35.22	26.58	24.98

Table 6: SacreBLEU zero-shot test scores of the English-pivoted single models and incremented modules from Table 5. * means that the model is trained using the supervision of 250 thousand pairs.

auxiliary directions. We incrementally added auxiliary directions of De-Fr (③), Es-Fr (④), and Nl-Fr (⑤). We compared the models with a singly trained model (⑥), and the M2 models trained using five languages from scratch (⑦). ⑦ worked as an upper bound for the incremental training.

Table 5 shows the performance of En-Fr and Fr-En with incremental training. **The incrementally trained model without any additional method (①) outperformed a single model (⑥) even though half of the model was frozen.** This not only indicates that the language-agnostic space is well-formed but also shows that incremented direction can benefit from a well-trained frozen module.

We also found that our two methods are effective in incremental training. Even though French does not share any information with the trained English module, initializing the French module with the weights learned by the English module benefits the performance marginally. Incrementally training the new module using multiple directions helps as the number of directions increases. Note that the two methods can be applied orthogonally. Although none of the incrementally trained models outperform the M2 model trained from scratch, this still shows that simple incremental training for the M2 can be a good alternative for expensive training from scratch.

We examined whether an incremented module in one direction can generalize to the other directions. We compared the zero-shot performance of the models in Table 5 with the English-pivoted translation performance using two single models. We also denoted the supervised performance of single models, and jointly trained the M2 for reference (250K for each direction).

5.3 Incremental zero-shot learning

Table 6 shows the zero-shot performance of incrementally trained modules. Amazingly, **most of the incremented modules demonstrated better performance than the English-pivoted translation**. The only exception was in the Fr-De direction of the naively incremented module (①), which seemed to be marginal (-0.45). Our methods for incremental training were also effective for zero-shot performance. The results were even comparable to the single supervised models trained with 250K parallel corpus. This shows that multi-way training creates shared (interlingual) space instead of pair specific space.

5.4 The language invariance of the interlingual space

The interlingual space established by the M2 was confounding, considering no additional regularizations or methods were adopted. We measured the language invariance of the interlingual space while the varying the number of languages of the M2 model. We trained a series of M2 models that included 3 - 6 languages (6, 12, 20, and 30 directions) and found that the use of more languages to train the M2 also improved its performance in all directions (appendix D). We investigated with two metrics to measure the language invariance of interlingual space.

Cosine Similarity We measured the representation similarity of parallel sentences from a parallel corpus. To obtain the fixed-size representation, we average pooled the output of encoders through the time steps. We averaged the cosine similarity of 10K pairs from the test set.

Mono-direction translation When training the M2, mono-direction (where source and target languages are the same) is not trained because mod-

Model	Cosine Similarity				BLEU Score
	En-De	En-Nl	De-Nl	Avg	En-En
M2(3)	0.7228	0.7062	0.7043	0.7111	75.55
M2(4)	0.7682	0.7425	0.7635	0.7581	82.55
M2(5)	0.7832	0.7603	0.7827	0.7754	**83.13**
M2(6)	0.8169	0.7905	0.8189	**0.8088**	82.80

Table 7: Cosine text similarity score of encoder outputs and SacreBLEU score of mono-direction translation(En-En). Values in parentheses indicate the number of languages involved in the M2 (3: De, En, Nl; 4: 3 + Es; 5: 4 + Nl; 6: 5 + Fi).

ules tend to learn to simply copy the input, which hinders translation training (Firat et al., 2016a). Meanwhile, interlingual output representation of the encoders should be able to be translated by any decoder, including the decoder of the source language. Therefore, the translation score of mono-direction translation shows how well the information of the source sentence is preserved.

Table 7 shows the cosine similarity and mono-direction translation scores of the M2. As the M2 trains using more languages, the cosine similarity of all three pairs increases, which implies higher language invariance in interlingual space. However, the gain from marginal languages decreases as the number of languages increases. Mono-direction translation scores mostly align with the number of languages except for the M2(6), which degraded a little from M2(5). As a result, we reasonably conclude that the language invariance of the interlingual space improves with more languages.

6 Conclusion

In this study, we re-evaluate the M2 model and suggest it as an appropriate choice for multilingual translation in industries. By extensively comparing the single models, 1-1 model, and M2 in varying conditions, we find that the M2 can benefit from multi-way training through *data-diversification* and *regularization* while suffering less from capacity bottlenecks. Additionally, we demonstrate that the M2 can also benefit low resource pairs in an unbalanced environment as a 1-1 model without being subject to *cross-language effect*. Next, we suggest that the M2 model is easily maintainable because of its interlingual space. The interlingual space not only enables incremental training in a simple manner, but also accompanies competitive incremental zero-shot performance. Furthermore, we validate that the language invariance of the space enhances as the number of languages in the M2 increases. We hope that this study sheds light on the relatively disregarded M2 model and provide a benchmark for selecting a model among varying levels of shared components.

Acknowledgments

The authors of this paper would like to give special thanks to Sang-Woo Lee and Jihyung Moon for their honest and genuine feedback that helped improve the quality of the paper greatly. Also, we are extremely grateful to Jaehyeon Kim, Jaehun Jung and the anonymous reviewers for their suggestions and comments. Finally, we cannot express enough thanks to all of Context Part members of Kakao Enterprise for their continued support and encouragement.

A Dataset

A.1 Division of multi-parallel dataset

In order to create completely non-sharing dataset and make the best use of multi-parallel corpus, we divide the 1.5K multi-parallel corpus into 3

	De	En	Es	Fi	Fr	Nl
De	-	1	2	3	4	5
En	-	-	3	4	5	2
Es	-	-	-	5	1	4
Fi	-	-	-	-	2	1
Fr	-	-	-	-	-	3
Nl	-	-	-	-	-	-

Table 9: Division of multi-parallel parts for each pair in section 5

Resource	**Pairs**	**1:1:1**	**1:2:4**	**1:5:25**
High	En-Fi	500K	500K	500K
Medium	En-Fr	500K	250K	100K
	Fi-Fr	500K	250K	100K
Low	De-En	500K	125K	20K
	De-Fi	500K	125K	20K
	De-Fr	500K	125K	20K

Table 10: The amount of data for each pair in section 4

parts(500K) for section 4 and 5 parts(250K) for section 5. And then, we assigned the parts to pairs so that no two directions of the same side share the same part. The assignment for section 4 and 5 are stated in table 8 and 9 respectively. Validation and test are divided with the same manner. For complete-sharing dataset, training data for all pairs only created from part 1. However, validation and test set remain the same with completely non-sharing dataset.

A.2 Amount of data for each pairs

In order to create unbalanced environment in section 4, we limited the amount of data for some directions. Table 10 shows the amount of the data for each pair in balanced, and unbalanced environments in section 4. For section 5, the amounts of all directions are the same with 250K. All the validation and test set are the same with 10K.

Though our dataset can easily be reconstructed from the open dataset (Europarl) with described process, we also made our dataset available online[4] for convenience of readers. We only uploaded the dataset of the balanced environment since unbalanced environment can be made from them trivially. The dataset is binarized with `fairseq-preprocess` command of `fairseq` framework.

B Training detail

B.1 Batch size

We selected the batch size of 6144 max tokens with the best validation loss of a single model (En-De) among $\{1536, 3072, 6144, 12288, 24576\}$ max tokens per GPU (4 GPUs). While the total number of parameters and the training directions is different among single model, 1-1 and M2, we set the batch size for each direction so that each module learns with the same batch size (6144 tokens). Specifically, one step of a single model includes a single direction, while that of 1-1(4) and M2(4) includes 12 directions. However, training directions per module between 1-1(4) and M2(4) is different with 12 and 3 directions. Therefore, the batch size per direction of 1-1 is 512 (1/12 of 6144) and that of M2 is 1536 (1/4 of 6144). Since we accumulate the gradients of all directions, all the compared modules learn with the same batch size of data.

B.2 Sampling

To train balanced data, we used round robin scheduling of all directions. We compared two sampling methods in ablation of unbalanced environment: up-sampling and proportional sampling. Round robin scheduling is equivalent to up-sampling low-resource data in unbalanced environment. For efficient proportional sampling, we sampled several small batches of pairs proportional to the amount of total pairs. We accumulated gradients of several batches to make expected batch-size of each module to meet the total batch size.

B.3 Early stopping

Since fixing the maximum tokens of a batch per module results in different step size among models, we stopped the training of models based on the maximum number of epochs. All the best models were chosen based on the best validation loss (averaged) within 100 epochs.

C Detailed scores of ablations

This section provides detailed scores of the ablation part of the section 4 and 5.

Table 11 shows detailed scores under complete sharing (② of table 2) and increased capacity (③ of table 2). Table 12 shows detailed scores under JM2M(④ of table 2) and M2M(⑤ of table 2) training.

Table 13 shows detailed scores of the models under proportional sampling and up-sampling in table

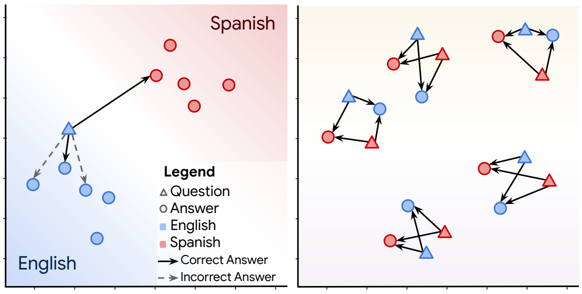
Abstract

We present LAReQA, a challenging new benchmark for language-agnostic answer retrieval from a multilingual candidate pool. Unlike previous cross-lingual tasks, LAReQA tests for "strong" cross-lingual alignment, requiring semantically related *cross*-language pairs to be closer in representation space than unrelated *same*-language pairs. This level of alignment is important for the practical task of cross-lingual information retrieval. Building on multilingual BERT (mBERT), we study different strategies for achieving strong alignment. We find that augmenting training data via machine translation is effective, and improves significantly over using mBERT out-of-the-box. Interestingly, model performance on zero-shot variants of our task that only target "weak" alignment is not predictive of performance on LAReQA. This finding underscores our claim that language-agnostic retrieval is a substantively new kind of cross-lingual evaluation, and suggests that measuring both weak and strong alignment will be important for improving cross-lingual systems going forward. We release our dataset and evaluation code at https://github.com/google-research-datasets/lareqa.

1 Introduction

Recent progress in self-supervised pretraining for language understanding has enabled training large multilingual models on 100+ languages at the same time, as in multilingual BERT (mBERT) and XLM-R (Devlin et al., 2019; Conneau et al., 2019). These models, despite being trained without any explicit objective of cross-lingual alignment, are surprisingly effective for cross-lingual transfer (Pires et al., 2019; Wu and Dredze, 2019; Conneau et al., 2019), suggesting that the models may have learned to "factor out" language and embed inputs into a language-agnostic space.



(a) **Weak Alignment** (b) **Strong Alignment**

Figure 1: A weakly aligned multilingual embedding space enables zero-shot transfer between languages, but incorrect answers in the same language are preferred over correct answers in a different language. A strongly aligned embedding space "factors out" language, so the most semantically relevant pairs are always the closest, regardless of language.

At the same time, Wu and Dredze (2019) observe that mBERT representations at all layers are highly accurate (>96%) at classifying language ID, which the authors find "surprising given the model's zero-shot cross-lingual abilities". This raises an interesting question. To what degree are models like mBERT and XLM-R language agnostic or easily adaptable to be so? Have they effectively disentangled the language-specific signal from the underlying semantic content, with each occupying a separate subspace? Can the learned representations be adapted by a lightweight alignment procedure to be *truly* language agnostic?

To address these questions, we introduce a challenging new task, LAReQA: Language Agnostic Retrieval Question Answering, which requires models to retrieve relevant cross-lingual answers from a multilingual candidate pool. Perform-

---

ing well on this task demands a stronger degree of cross-lingual alignment than previous cross-lingual evaluations like XNLI (Conneau et al., 2018). Concretely, we propose to distinguish "weak" vs. "strong" alignment, defined as follows and illustrated in Figures 1a–1b:

Weak Alignment For any item in language L_1, the nearest neighbor in language L_2 is the most semantically relevant item. (The specific notion of "relevance" may vary across tasks.)

Strong Alignment For any item, all semantically relevant items are closer than all irrelevant items, regardless of their language. Crucially, relevant items in different languages are closer than irrelevant items in the same language.[1]

To our knowledge, LAReQA is the first cross-lingual benchmark to target strong alignment.[2] Building on top of multilingual BERT, we develop and test several baseline models on LAReQA. We find that mBERT already exhibits strong alignment between *some* language pairs, but that this can be improved significantly by leveraging machine translation to extend the set of training examples and encourage cross-lingual alignment.

One observation that emerges from our experiments is that strong alignment comes at a cost. Specifically, our baseline that reaches the best LAReQA performance lags behind other baselines on the narrower task of retrieving relevant answers that match the question language.

Our main contributions are: (1) We propose a new framework for classifying different degrees of cross-lingual alignment. (2) We propose a challenging new benchmark to evaluate language bias in representations, setting stricter notions of cross-lingual embedding space alignment. (3) We investigate the potential for multilingual BERT to achieve "strong" cross-lingual alignment, including various fine-tuning techniques to improve alignment. (4) We publish our trained models and LAReQA benchmarking code for others to reproduce.[3]

2 Looking for Answers across Languages

In this section, we present the practical task of **answer retrieval from a multilingual candidate pool**, and argue that this task goes beyond existing cross-lingual benchmarks in demanding models with strongly aligned multilingual representations. The task can be summarized as: given a question in one language and potential answers in many different languages, retrieve the best answer for the question, *regardless* of language. We begin by describing why this task is both useful and challenging. Subsequently, we compare this task with existing cross-lingual tasks, and show how they differ in their ability to measure "language bias".

2.1 Practical Value of Cross-lingual Retrieval

Finding relevant answers to questions from a large multilingual candidate pool is not a contrived task. User-generated content on the web is increasingly multilingual[4], and the best answer to a given question may be written in a different language than the question. Current information retrieval systems typically do not surface such "cross-lingual" results. This shortcoming is particularly problematic for speakers of languages with a smaller web presence, who may be forced to issue queries in a less familiar language in order to find useful results.

If search engines were language agnostic, retrieved results would come from a wide range of languages. Of course, some results would have to be machine translated to be made interpretable to a given user. But in many cases, even a poorly translated relevant result is more helpful than a less relevant native result.

One domain where cross-lingual retrieval is particularly valuable is in searching over user-generated content such as reviews of products and businesses. For example, suppose a Thai speaker wants to know if a local library offers private meeting rooms, and this question is answered by an existing Arabic user review of the library. Being able to respond to the Thai question by surfacing (a translation of) the relevant Arabic review unlocks content that was previously inaccessible.

There are various options for how to implement such a cross-lingual retrieval system in practice, not all of which require a model to support cross-language matching. One solution would be to store

---

[1] Stricter notions of cross-lingual alignment are possible, such as requiring that model representations remove any trace of the original text language, preventing language ID from being reconstructed. We treat these as sub-types of "strong" alignment, but leave their investigation for future work.

[2] Pires et al. (2019) develop a related heuristic by calculating the average vector delta between two languages, and testing how well translation targets can be retrieved by finding the closest neighbor to the source plus the delta.

[3] Our trained models are available at `https://tfhub.dev/s?q=lareqa`. Our dataset and evaluation code are available at `https://github.com/google-research-datasets/lareqa`.

[4] For example, see `https://en.wikipedia.org/wiki/Wikipedia:Size_of_Wikipedia`.

English translations alongside results in the index, and translate all queries to English before performing search. Alternatively, one could pre-translate results into all languages ahead of time. However as these solutions require extra storage, we believe it is worth considering the simpler approach of retrieving multilingual results directly with a cross-lingual model.

2.2 Language Bias

From the modeling perspective, one of the main challenges in retrieving relevant answers from across languages is avoiding "language bias", where a model prefers one language over another. It's clear why this bias is harmful: if the model prefers answers in a given language, it is prone to retrieve *irrelevant* results in that language over relevant results from another language.

The main type of language bias we observe in our experiments is **same-language bias**—the tendency for models to prefer answers that match the question language. This is illustrated in Figure 1a, where the embeddings cluster primarily by language, and incorrect same-language candidates are preferred over any cross-language candidate. For a multilingual model to avoid same-language bias, it must align text from different languages under a language-agnostic embedding space, as in 1b.

2.3 Taxonomy of Cross-lingual Tasks

Existing cross-lingual tasks—including all tasks in the recent XTREME suite (Hu et al., 2020)—fall into two categories, as described below. Neither type allows us to diagnose language bias and test for language-agnostic embeddings. The key missing piece is that none of these tasks require the model to make a choice among candidates in different languages.

Monolingual Tasks in Many Languages Most existing cross-lingual benchmarks are formed by collecting monolingual tasks across various languages. Often, these evaluations are framed in terms of zero-shot or few-shot transfer learning, with the assumption that a practitioner only has access to task-specific training data in a single language. For instance, XNLI (Conneau et al., 2018) tests how well a model fine-tuned on an English classification task (natural language inference) can generalize to non-English versions of the same task. Similarly, MLDoc (Schwenk and Li, 2018) and PAWS-X (Yang et al., 2019b) test cross-language transfer on document classification and paraphrase identification respectively.

Several recent cross-lingual QA benchmarks can also be described as cross-lingual collections of monolingual tasks. For example, XQuAD (Artetxe et al., 2019) extends the popular SQuAD (Rajpurkar et al., 2016) benchmark to cover QA pairs in 11 languages, but models are only tested on finding answers in contexts that match the question language.[5] TyDi QA (Clark et al., 2020) and MLQA's (Lewis et al., 2019) "cross-lingual transfer" task also fall under this category.

Cross-lingual Tasks with Monolingual Candidates A second class of cross-lingual tasks tests whether a model can, given an input in language X, identify a target in language Y. However, crucially, the set of candidates is restricted to language Y. Thus, while the task is inherently cross-lingual, it does not test for language bias.

BUCC (Zweigenbaum et al., 2017) is a task of this type. Given an English sentence, the task is to retrieve the corresponding translation from a monolingual pool of candidates in another language. Similarly, Tatoeba (Artetxe and Schwenk, 2019) tests retrieval of translation pairs between English and 112 languages, but is restricted to monolingual pools. Bilingual lexicon induction or BLI (Glavaš et al., 2019) is a similar task of cross-lingual retrieval from a monolingual pool, but targeting words rather than sentences.[6]

MLQA (Lewis et al., 2019) is an extractive question answering task, and in one variant of the task, "*generalized* cross-lingual transfer", the question and answer are drawn from different languages. However, even in this case, the candidate answers are restricted to spans within a specific (monolingual) paragraph of context, so there is no way to assess whether the model is biased in preferring answers in one language over another.

3 LAReQA

Having motivated the need for a cross-lingual benchmark that asks models to choose *between*

---

[5] Due to its parallel construction, it is possible to construct "mixed-language" QA pairs from XQuAD. This is the approach we take in Section 3.

[6] One could construct versions of BUCC, Tatoeba and BLI that test for strong alignment, by switching to multilingual candidate pools. It would be interesting to compare these benchmarks to LAReQA in future work. Note, however, that the resulting tasks are somewhat "unnatural", in that there is typically no need to consider same-language candidates when mining for translation pairs or building a bilingual lexicon.

languages, we now present a concrete case of such a cross-lingual evaluation, **LAReQA: Language-Agnostic Retrieval Question Answering**.

3.1 Constructing LAReQA

Our goal is to construct a QA retrieval task over a large multilingual pool where many or most of the target answers are found in a different language than the question itself. To achieve this, we take the existing cross-lingual *extractive* QA tasks XQuAD and MLQA and convert them into *retrieval* tasks: **XQuAD-R** and **MLQA-R**. These sets are designed so as to include parallel QA pairs across languages, allowing us to match questions with answers from different languages. We release XQuAD-R at `https://github.com/google-research-datasets/lareqa`.

XQuAD is constructed by taking 240 paragraphs from the SQuAD v1.1 dev set and professionally translating the questions and contexts into 10 languages. Thus each question appears in 11 different languages and has 11 parallel correct answers. MLQA is constructed by using LASER (Artetxe and Schwenk, 2019) to mine parallel sentences from Wikipedia, which annotators then use to generate questions. Unlike XQuAD, the questions in MLQA have a variable number (2–4) of parallel correct answers across the corpus. Additionally, MLQA only covers 7 of the 11 XQuAD languages, and contexts surrounding the answer are not guaranteed to be parallel. See Artetxe et al. (2019) and Lewis et al. (2019) for more details on these sets.

To convert these span-tagging tasks into retrieval tasks, we follow the procedure from ReQA (Ahmad et al., 2019). Specifically, we break each contextual paragraph into sentences[7], and include all sentences across the dataset as candidate answers. A sentence is considered a correct answer to a question if it contains the target answer span for either that question or an equivalent question in another language (as identified by `qas_id`).[8] Table 1 shows the number of questions and candidates per language in XQuAD-R and MLQA-R. We use the MLQA dev set rather than the larger test set to keep the speed of evaluation reasonable. While the contexts for XQuAD are parallel across languages, differences in sentence breaking lead to variations in the number of candidates per language.[9]

3.2 Evaluation

For our primary evaluation, we use the standard information retrieval metric "mean average precision" (mAP), which measures a model's ability to rank relevant results over irrelevant ones. This metric is suitable when there are multiple relevant results for a given query. In our case, an XQuAD-R question will have 11 relevant answers, while an MLQA-R question will have 2–4 relevant answers.

Formally, given a set of questions Q and a ranking function over all candidates, mean average precision is defined as in Equation 1, where R_i is the number of correct answers for question q_i, $P@j(q_i)$ is the Precision@j for q_i and $\text{rel}(i, j)$ is an "indicator" function with value 1 if the j-th ranked candidate for q_i is correct, 0 otherwise.

$$\text{mAP} = \frac{1}{T} \sum_{q_i \in Q} \frac{1}{R_i} \sum_{j=1}^{K} P@j(q_i) \times \text{rel}(i, j) \quad (1)$$

The mAP metric falls between 0 and 1. Any model that ranks all C correct answers in the top C positions (regardless of order) will achieve a perfect 1.0. Note, such a model cannot have strong language bias, as it needs to rank correct answers

---

[7] Sentence boundaries are generated by an internal sentence breaker. For Thai we use `https://pypi.org/project/thai-segmenter`.

[8] For both XQuAD and MLQA, there were no cases where an answer span crossed a sentence boundary. One sentence can be the correct answer for multiple questions (with different `qas_id`), as long as it contains the relevant target answer spans. We include all sentences from contextual paragraphs as candidates, even those that do not answer any question.

[9] Thai is an outlier, with around 70% the sentences per paragraph as the other languages. This is likely due to erroneous or ambiguous sentence breaking. Note, Thai lacks explicit sentence boundary markers, and human agreement on sentence breaking is much lower than English (Aroonmanakun, 2007).

in *every* language highly. On the other hand, being free from language bias is not sufficient for high mAP. As a trivial example, a model that ranks candidates randomly will have a low mAP. In sum, performing well on LAReQA mAP requires both strong QA retrieval quality, as well as an absence of language bias.

4 Baseline Models

We consider several neural baseline models for evaluation on LAReQA. All our baselines are "dual encoder" models (Gillick et al., 2018), encoding questions and candidate answers separately. Unlike full cross-attention models, this architecture enables retrieval through approximate nearest neighbor search, and thereby scales well to large-scale retrieval problems. For more discussion of dual encoders for deep retrieval, see Gillick et al. (2018) and Ahmad et al. (2019).

Our baselines leverage multilingual BERT (Devlin et al., 2019), or "mBERT", for cross-lingual pretraining. These baselines allow us to test (i) how well mBERT already aligns languages in a language-agnostic space, and (ii) the degree to which it can be adapted to do so.

We initialize each tower of a dual encoder model with pretrained mBERT, sharing weights between the question and answer encoding towers[10], as in Figure 2. To obtain final question and answer encodings, we normalize the BERT CLS token to unit L2 norm. The model score for a QA pair $S(q, a)$ is the dot product of these encodings.

We fine-tune the mBERT towers for QA retrieval on SQuAD training data using an "in-batch sampled softmax" loss (Henderson et al., 2017), as this has been observed to converge quickly and perform well on retrieval tasks (Gillick et al., 2018). The loss, given in Equation 2, encourages the score of a correct answer pair $S(q_i, a_i)$ to be higher than scores for incorrect answer pairings from the mini-batch $S(q_i, a_j)$:[11]

$$-\frac{1}{K}\sum_{i=1}^{K}\left[S(q_i, a_i) - \log\sum_{j=1\, j\neq i}^{K} e^{S(q_i, a_j)}\right] \qquad (2)$$

We train four variants of our mBERT model (110M parameters), using different fine-tuning datasets and batching procedures. Each model is fine-tuned on 32 TPU-v3 cores, with a batch size of 2,048. The in-batch sampled softmax is calculated separately per core, over sub-batches of 64 QA pairs. We use the standard BERT learning rate schedule, with an initial learning rate of 1e-5, which performed the best among {1e-6, 3e-6, 1e-5, 3e-5}. We train all baselines for 100,000 steps and observe no overfitting.

Our first baseline **"En-En"** adapts mBERT to QA retrieval by fine-tuning on the 80,000 English QA pairs from the SQuAD v1.1 train set, with the ranking loss from Equation 2. This baseline tests how well mBERT can perform language-agnostic retrieval when only fine-tuning on English data.

Our second baseline **"X-X"** extends the same SQuAD train set by translating each example into the 11 XQuAD languages using an in-house trans-

---

[10] When feeding inputs to the answer encoding tower, we concatenate the answer sentence and its containing context paragraph ("answer context"), using BERT's segment ids to distinguish between the two.

[11] In practice, we scale the similarity scores by a trainable constant factor before computing the softmax, as we observed this led to faster convergence.

	XQuAD-R	MLQA-R
En-En	0.29	0.36
X-X	0.23	0.26
X-X-mono	0.52	0.49
X-Y	0.66	0.49
Translate-Test	0.72	0.58

Table 2: Mean average precision (mAP) of baseline models on XQuAD-R and MLQA-R.

lation system. Within each example, the question and answer language are the same, giving 880,000 pairs total. If these pairs are shuffled and batched naively, as in Figure 3b, we expect the model to exhibit strong same-language bias, as all positive examples are within-language, while many in-batch negatives are cross-language. To avoid this bias, our third baseline **"X-X-mono"** trains on the same examples, but ensures that each batch is monolingual, as shown in Figure 3c.

Our fourth baseline **"X-Y"** is similar to X-X, but allows a question and answer to be translated into different languages, giving 9,680,000 examples. This setup is the first to directly incentivize the model to treat answers from other languages as correct, which we expect to further reduce same-language bias.

Our final baseline **"Translate-Test"** is not a proper text embedding model, as it relies on an external translation system at test time. Here, we simply translate any test data into English, and then score it with our En-En model.

Additionally, we compare the above baselines with Universal Sentence Encoder Multilingual QA (Yang et al., 2019a), which specifically targets cross-lingual QA retrieval. However, this model only supports 8 of the 11 XQuAD languages, and we found it was not competitive with our mBERT baselines, even when restricting evaluation to the supported languages. See Appendix A for details.

5 Results and Analysis

5.1 LAReQA Performance

We compare our five baseline models on the LAReQA task in Table 2. On both XQuAD-R and MLQA-R, the strongest model is the Translate-Test baseline. This is unsurprising in that LAReQA demands language-agnostic retrieval, and Translate-Test leverages an external machine translation system to actively "remove" the effects of language, by translating all test data to English.

	mAP −rand	mAP −same	% Δ	Rank (% Δ)
En-En	0.29	0.22	0.24	4
X-X	0.23	0.15	0.37	5
X-X-mono	0.52	0.47	0.10	2
X-Y	0.65	0.64	0.02	1
Translate-Test	0.69	0.60	0.13	3

Table 3: Performance on modified versions of XQuAD-R where one target answer is removed, either from the same language as the question (−same) or a random other language (−rand).

Among the pure embedding approaches, X-Y does the best on XQuAD-R, and is tied for best on MLQA-R. The success of X-Y shows that training directly on "mixed-language" QA pairs is helpful for the end task of language-agnostic retrieval from a multilingual pool.

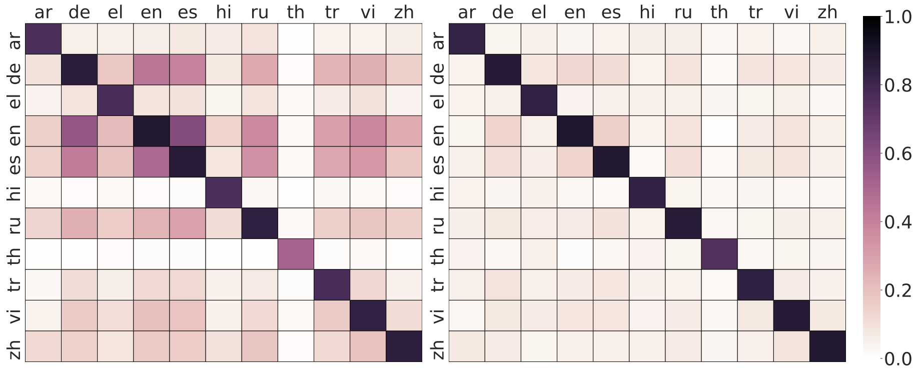
As expected, X-X-mono outperforms X-X, indicating that using a ranking loss with in-batch negatives is problematic when positives are within-language but negatives are mixed-language. Indeed, we will see shortly that X-X exhibits severe same-language bias.

For the remainder of the paper, we focus on XQuAD-R, as it is better balanced across languages than MLQA-R, and the two sets showed similar results.

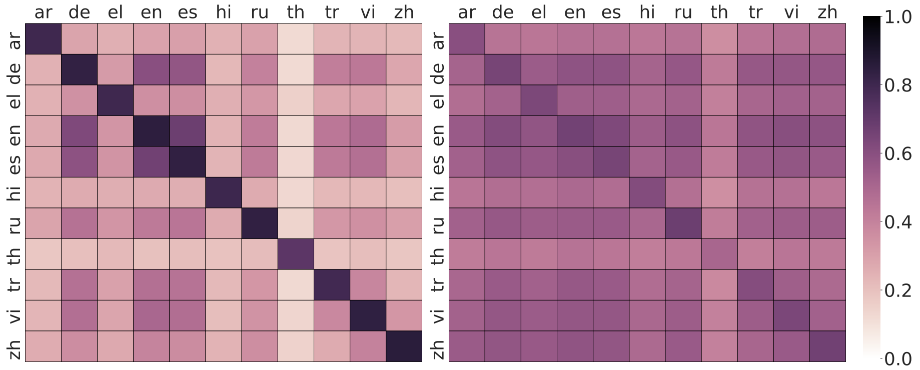
5.2 Language Bias

We offer two additional analyses to more directly illustrate the language biases of our baselines. A third analysis, looking at the language distribution among top retrieved candidates, is given in Appendix B, and is consistent with the results here.

Remove One Target We rerun the XQuAD-R evaluation, but for each question, we remove one of its 11 target answers from the multilingual candidate pool. If a model is free of same-language bias, the effect of removing a single target should be constant, regardless of whether the removed target was in the same language as the question or not. Table 3 shows that in fact all our baselines perform better when a random *cross-language* target is removed (−rand), as compared to the same-language target (−same). Looking at the delta between these conditions, the X-Y baseline only displays a minimal bias, falling from 0.62 to 0.61 mAP. The most affected model is X-X, whose training procedure actively encouraged same-language bias. Interest-



(a) En-En (b) X-X



(c) X-X-mono (d) X-Y

Figure 4: mAP on XQuAD-R broken down by question language (row) and answer language (column), when only one correct answer is included in the multilingual candidate pool.

ingly, even En-En shows a significant delta, indicating that simply fine-tuning mBERT on English QA is not sufficient to produce an embedding space that is strongly language agnostic.

Limit to One Target As a more in-depth analysis of language bias, we evaluate on retrieval from a multilingual pool containing *just one* correct answer. For XQuAD-R, since each question has 11 answers, this means evaluating on each target separately, with the other 10 targets removed from the pool. The heatmaps in Figure 4 show each baseline's mAP on single-answer retrieval, broken down by question language and answer language. Note, in this case mAP is equivalent to mean reciprocal rank (MRR)—the average inverse rank of the target answer. In line with our previous findings, all models display some degree of same-language bias, showing better performance on the diagonal, where Q and A languages match, than off-diagonal. The degree of bias matches the ranking from Table 3. X-Y displays the least bias, with most language pairs reaching over 0.4 mAP. As before, X-X is the most biased, but we also see significant bias in En-En and X-X-mono.

These results also shed light on how well mBERT supports strong cross-lingual alignment "out of the box". Interestingly, even En-En shows fairly strong alignment among typologically related languages (e.g. 0.61 mAP on English-to-German and 0.57 on English-to-Spanish). These findings parallel those of Pires et al. (2019) and Wu and Dredze (2019), who observe that mBERT zero-shot transfer is more effective among related languages. Our retrieval performance is lower between unrelated languages (e.g. 0.06 Arabic-to-Chinese), as well as on pairs where one of the languages is less well represented in mBERT's Wikipedia training data (Greek, Hindi and Thai).

While mBERT exhibits *some* strong cross-lingual alignment out of the box, our results show that this can be improved by using cross-lingual objectives, as in X-X-mono and X-Y. This finding echoes work by Artetxe and Schwenk (2019), Conneau and Lample (2019), Singh et al. (2019) and Siddhant et al. (2020) showing that cross-lingual training can improve zero-shot transfer.

One point worth highlighting is the trade-off between on-diagonal and off-diagonal performance. If we limit attention to the diagonal, the models rank X-X > X-X-mono > En-En > X-Y. Thus, it appears there is a "cost" to strong cross-lingual alignment. For a given application, it may be worth sacrificing same-language quality to achieve better cross-language performance. However this raises the question: Is there any training technique that can achieve strong cross-lingual alignment without degrading within-language performance?

5.3 Comparison to Standard Zero-Shot Cross-Lingual Transfer

To highlight the difference between LAReQA and standard zero-shot cross-lingual evaluations like XNLI, we construct a zero-shot version of our QA retrieval task. We process the XQuAD data as before, but instead of a shared multilingual candidate pool, we restrict candidates to those matching the question language. Thus, like XNLI and the original XQuAD task, we're testing a model's ability to generalize to monolingual tasks in new languages.

The performance of our baselines on this "zero-shot" retrieval from a monolingual pool is shown in Table 4. Remarkably, the model ranking under this task diverges from that under our proposed LAReQA task of retrieval from a *multilingual* pool. In particular, the X-X(-mono) baselines which were only trained on "within-language" examples now perform the best, beating the top LAReQA baselines Translate-Test and X-Y.

This result supports our claim that LAReQA tests for cross-lingual alignment in a way that existing zero-shot evaluations do not. Despite their strong language bias, visible in the dark diagonals in Figure 4, the X-X(-mono) models give excellent performance in the typical zero-shot cross-lingual transfer scenario. Yet, as we saw in in Table 2, these baselines are fundamentally ill-suited for retrieval from a multilingual pool, which demands strongly aligned multilingual embeddings. As an extreme case, X-X scored a mere 0.23 on LAReQA mAP, compared to the best embedding model X-Y and the best overall baseline Translate-Test with 0.63 and 0.70 respectively.

5.4 Embedding Spaces

Figure 5 plots the first two principal components of each baseline's embeddings of all XQuAD-R questions and candidates in English and Chinese (chosen as they are genetically unrelated languages with distinct scripts). The X-X embeddings show a dramatic separation between Chinese and English. This is a clear case of weak alignment, where a model achieves good zero-shot performance (cf. Table 4) despite its embeddings being principally determined by language.

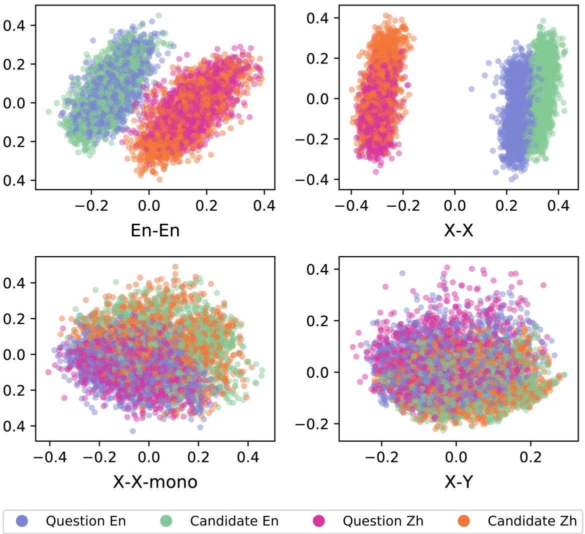


Figure 5: Model embeddings of all English and Chinese questions and candidates from XQuAD-R, visualized under 2D PCA.

More generally, we observe that the more a model separates languages in embedding space, the worse it performs on LAReQA (cf. Table 2). This ordering is also reflected in the degree to which language ID is predictable from the embeddings. When we use a logistic regression to predict language (English vs. Chinese) from the question and candidate embeddings, the accuracies on a one-third holdout are X-X: 99.2%, En-En: 97.7%, X-X-mono: 87.5% and X-Y: 54.0%. This supports the claim that LAReQA is a better test of strong alignment than current zero-shot tasks.

6 Conclusion

LAReQA is a challenging new benchmark testing answer retrieval from a multilingual candidate pool. It goes further than previous cross-lingual benchmarks in requiring "strong" cross-lingual alignment, which is a step closer to truly language-agnostic representations.

We believe there is significant headroom for models to improve on LAReQA. Our best initial baseline sidesteps the alignment problem by simply translating all test data to English. Among embedding-based models, our strongest baseline ("X-Y") actively removes language bias by augmenting training data to include machine-translated cross-lingual examples. However, to achieve strong

alignment, this model sacrifices performance on both retrieval from a monolingual pool (Table 4), as well as retrieval of same-language candidates (Figure 4d diagonal). It is an interesting question for future work whether strong alignment always comes at a cost, or if better training techniques will lead to models that can improve on all these measures simultaneously.

A USE-QA

We test the Universal Sentence Encoder Multilingual QA (Yang et al., 2019a), which specifically targets cross-lingual QA retrieval on our LAReQA benchmark. The architecture and training details of USE-QA are provided in Yang et al. (2019a). We use the USE-QA model out of the box[12] without fine-tuning on any SQuAD data, as it was already trained specifically for retrieval QA. As USE-QA only supports 8 of the 11 XQuAD languages (ar, de, en, es, ru, th, tr, zh), we restrict our evaluation to these languages when comparing USE-QA to other models.

	XQuAD-R_{USE}
En-En	0.33
X-X	0.25
X-X-mono	0.55
X-Y	0.67
Translate-Test	0.73
USE-QA	0.51

Table 5: Mean average precision (mAP) of baseline models on XQuAD-R_{USE}, a version of XQuAD-R restricted to the 8 languages supported by USE-QA.

From Table 5, we can see USE-QA is not competitive with the mBERT baselines, despite being trained specifically for QA retrieval over a large in-house QA dataset. However, it may be possible to improve this performance by fine-tuning for SQuAD retrieval.

B Language Distributions of Top Results

Our core LAReQA mAP metric tests for both question answering (QA) matching ability, as well as absence of language bias. We can factor out QA performance and focus more directly on language bias by simply ignoring which answers are correct, and observing the distribution of languages that a model retrieves among its top-ranked candidates.

The heatmaps in Figure 6 show for each question language (row), the frequency of different answer languages (column) among the top 100 retrieved candidates, for each of our baseline models on the XQuAD-R dataset. The strong diagonal in X-X indicates that when the question is in a given language, nearly all of the top 100 retrieved results are in the same language. Overall, this measure of language bias is consistent with those discussed in Section 5.2, with the models ranking X-Y > X-X-mono > En-En > X-X.

Interestingly, X-Y performs almost perfectly on this "semantics-free" measurement of language bias. This is in contrast to the mAP performance of the same model in Figure 4d, where the retrieval of *correct* answers is somewhat improved when the Q and A languages match. Taken together, we can say that X-Y is nearly perfectly unbiased in which languages it retrieves *on the whole*, but is slightly biased as to which language pairs exhibit the strongest QA matching.

OCR Post Correction for Endangered Language Texts

Shruti Rijhwani,[1] **Antonios Anastasopoulos,**[2,†] **Graham Neubig**[1]

Abstract

There is little to no data available to build natural language processing models for most endangered languages. However, textual data in these languages often exists in formats that are not machine-readable, such as paper books and scanned images. In this work, we address the task of extracting text from these resources. We create a benchmark dataset of transcriptions for scanned books in three critically endangered languages and present a systematic analysis of how general-purpose OCR tools are not robust to the data-scarce setting of endangered languages. We develop an OCR post-correction method tailored to ease training in this data-scarce setting, reducing the recognition error rate by 34% on average across the three languages.[1]

1 Introduction

Natural language processing (NLP) systems exist for a small fraction of the world’s over 6,000 living languages, the primary reason being the lack of resources required to train and evaluate models. Technological advances are concentrated on languages that have readily available data, and most other languages are left behind (Joshi et al., 2020). This is particularly notable in the case of endangered languages, i.e., languages that are in danger of becoming extinct due to dwindling numbers of native speakers and the younger generations shifting to using other languages. For most endangered languages, finding *any* data at all is challenging.

In many cases, natural language text in these languages does exist. However, it is locked away in formats that are not machine-readable — paper books, scanned images, and unstructured web pages. These include books from local publishing houses within the communities that speak endangered languages, such as educational or cultural materials. Additionally, linguists documenting these languages also create data such as word lists and interlinear glosses, often in the form of handwritten notes. Examples from such scanned documents are shown in Figure 1. Digitizing the textual data from these sources will not only enable NLP for endangered languages but also aid linguistic documentation, preservation, and accessibility efforts.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5931–5942,
November 16–20, 2020.

In this work, we create a benchmark dataset and propose a suite of methods to extract data from these resources, focusing on scanned images of paper books containing endangered language text. Typically, this sort of digitization requires an optical character recognition (OCR) system. However, the large amounts of textual data and transcribed images needed to train state-of-the-art OCR models from scratch are unavailable in the endangered language setting. Instead, we focus on *post-correcting* the output of an off-the-shelf OCR tool that can handle a variety of scripts. We show that targeted methods for post-correction can significantly improve performance on endangered languages.

Although OCR post-correction is relatively well-studied, most existing methods rely on considerable resources in the target language, including a substantial amount of textual data to train a language model (Schnober et al., 2016; Dong and Smith, 2018; Rigaud et al., 2019) or to create synthetic data (Krishna et al., 2018). While readily available for high-resource languages, these resources are severely limited in endangered languages, preventing the direct application of existing post-correction methods in our setting.

As an alternative, we present a method that compounds on previous models for OCR post-correction, making three improvements tailored to the data-scarce setting. First, we use a **multi-source model** to incorporate information from the high-resource translations that commonly appear in endangered language books. These translations are usually in the *lingua franca* of the region (e.g., Figure 1 (a,b,c)) or the documentary linguist's primary language (e.g., Figure 1 (d) from Devos (2019)). Next, we introduce **structural biases** to ease learning from small amounts of data. Finally, we add **pretraining methods** to utilize the little unannotated data that exists in endangered languages.

We summarize our main contributions as follows:

- A benchmark dataset for OCR post-correction on three critically endangered languages: Ainu, Griko, and Yakkha.
- A systematic analysis of a general-purpose OCR system, demonstrating that it is not robust to the data-scarce setting of endangered languages.
- An OCR post-correction method that adapts the standard neural encoder-decoder framework to the highly under-resourced endangered language setting, reducing both the character error rate and the word error rate by 34% over a state-of-the-art general-purpose OCR system.

2 Problem Setting

In this section, we first define the task of OCR post-correction and introduce how we incorporate translations into the correction model. Next, we discuss the sources from which we obtain scanned documents containing endangered language texts.

2.1 Formulation

Optical Character Recognition OCR tools are trained to find the best transcription corresponding to the text in an image. The system typically consists of a recognition model that produces candidate text sequences conditioned on the input image and a language model that determines the probability of these sequences in the target language. We use a general-purpose OCR system (detailed in Section 4) to produce a *first pass transcription* of the endangered language text in the image. Let this be a sequence of characters $\boldsymbol{x} = [x_1, \ldots, x_N]$.

OCR post-correction The goal of post-correction is to reduce recognition errors in the first pass transcription — often caused by low quality scanning, physical deterioration of the paper book, or diverse layouts and typefaces (Dong and Smith, 2018). The focus of our work is on using post-correction to counterbalance the lack of OCR training data in the target endangered languages. The correction model takes $\boldsymbol{x}$ as input and produces the *final transcription* of the endangered language document, a sequence of characters $\boldsymbol{y} = [y_1, \ldots, y_K]$.

$$\boldsymbol{y} = \arg\max_{\boldsymbol{y}'} p_{\text{corr}}(\boldsymbol{y}' | \boldsymbol{x})$$

Incorporating translations We use information from high-resource translations of the endangered language text. These translations are commonly found within the same paper book or linguistic archive (e.g., Figure 1). We use an existing OCR system to obtain a transcription of the scanned translation, a sequence of characters $\boldsymbol{t} = [t_1, \ldots, t_M]$. This is used to condition the model:

$$\boldsymbol{y} = \arg\max_{\boldsymbol{y}'} p_{\text{corr}}(\boldsymbol{y}' | \boldsymbol{x}, \boldsymbol{t})$$

2.2 Endangered Language Documents

We explore online archives to determine how many scanned documents in endangered languages exist as potential sources for data extraction (as of this writing, October 2020).

The Internet Archive,[2] a general-purpose archive of web content, has scanned books labeled with the language of their content. We find 11,674 books labeled with languages classified as "endangered" by UNESCO. Additionally, we find that endangered language linguistic archives contain thousands of documents in PDF format — the Archive of the Indigenous Languages of Latin America (AILLA)[3] contains ≈10,000 such documents and the Endangered Languages Archive (ELAR)[4] has ≈7,000.

How common are translations? As described in the introduction, endangered language documents often contain a translation into another (usually high-resource) language. While it is difficult to estimate the number of documents with translations, multilingual documents represent the majority in the archives we examined; AILLA contains 4,383 PDFs with bilingual text and 1,246 PDFs with trilingual text, while ELAR contains ≈5,000 multilingual documents. The structure of translations in these documents is varied, from dictionaries and interlinear glosses to scanned multilingual books.

3 Benchmark Dataset

From the sources described above, we select documents from three critically endangered languages[5] for annotation — Ainu, Griko, and Yakkha. These languages were chosen in an effort to create a geographically, typologically, and orthographically diverse benchmark. We focus this initial study on scanned images of printed books as opposed to handwritten notes, which are a relatively more challenging domain for OCR.

We manually transcribed the text corresponding to the endangered language content. The text corresponding to the translations is not manually transcribed. We also aligned the endangered language text to the OCR output on the translations, per the formulation in Section 2.1. We describe the annotated documents below and example images from our dataset are in Figure 1 (a), (b), (c).

Ainu is a severely endangered indigenous language from northern Japan, typically considered a language isolate. In our dataset, we use a book of Ainu epic poetry (*yukara*), with the "Kutune Shirka" yukara (Kindaichi, 1931) in Ainu transcribed in Latin script.[6] Each page in the book has a two-column structure — the left column has the Ainu text, and the right has its Japanese translation already aligned at the line-level, removing the need for manual alignment (see Figure 1 (a)). The book has 338 pages in total. Given the effort involved in annotation, we transcribe the Ainu text from 33 pages, totaling 816 lines.

Griko is an endangered Greek dialect spoken in southern Italy. The language uses a combination of the Latin alphabet and the Greek alphabet as its writing system. The document we use is a book of Griko folk tales compiled by Stomeo (1980). The book is structured such that in each fold of two pages, the left page has Griko text, and the right page has the corresponding translation in Italian. Of the 175 pages in the book, we annotate the Griko text from 33 pages and manually align it at the sentence-level to the Italian translation. This results in 807 annotated Griko sentences.

Yakkha is an endangered Sino-Tibetan language spoken in Nepal. It uses the Devanagari writing system. We use scanned images of three children's books, each of which has a story written in Yakkha along with its translation in Nepali and English (Schackow, 2012). We manually transcribe the Yakkha text from all three books. We also align the Yakkha text to both the Nepali and the English OCR at the sentence level with the help of an existing Yakkha dictionary (Schackow, 2015). In total, we have 159 annotated Yakkha sentences.

4 OCR Systems: Promises and Pitfalls

As briefly alluded to in the introduction, training an OCR model for each endangered language is challenging, given the limited available data. Instead, we use the general-purpose OCR system from the Google Vision AI toolkit[7] to get the first pass OCR transcription on our data.

The Google Vision OCR system (Fujii et al., 2017; Ingle et al., 2019) is highly performant and supports 60 major languages in 29 scripts. It can transcribe a wide range of higher resource languages with high accuracy, ideal for our proposed method of incorporating high-resource translations

---

[3] `https://ailla.utexas.org`

[4] `https://elar.soas.ac.uk/`

[5] UNESCO defines critically endangered languages as those where the youngest speakers are grandparents and older, and they speak the language partially and infrequently.

[6] Some transcriptions of Ainu also use the Katakana script. See Howell (1951) for a discussion on Ainu folklore.

[7] `https://cloud.google.com/vision`

Language	CER	WER
Ainu	1.34	6.27
Griko	3.27	15.63
Yakkha	8.90	31.64

Table 1: Character error rate and word error rate with the Google Vision OCR system on our dataset.

into the post-correction model. Moreover, it is particularly well-suited to our task because it provides script-specific OCR models in addition to language-specific ones. Per-script models are more robust to unknown languages because they are trained on data from multiple languages and can act as a general character recognizer without relying on a single language's model. Since most endangered languages adopt standard scripts (often from the region's dominant language) as their writing systems, the per-script recognition models can provide a stable starting point for post-correction.

The metrics we use for evaluating performance are character error rate (CER) and word error rate (WER), representing the ratio of erroneous characters or words in the OCR prediction to the total number in the annotated transcription. More details are in Section 6. The CER and WER using the Google Vision OCR on our dataset are in Table 1.

4.1 OCR Performance

Across the three languages, the error rates indicate that we have a first pass transcription that is of reasonable quality, giving our post-correction method a reliable starting point. We note the particularly low CER for the Ainu data, reflecting previous work that has evaluated the Google Vision system to have strong performance on typed Latin script documents (Fujii et al., 2017). However, there remains considerable room for improvement in both CER and WER for all three languages.

Next, we look at the edit distance between the predicted and the gold transcriptions, in terms of insertion, deletion, and replacement operations. Replacement accounts for over 84% of the errors in the Griko and Ainu datasets, and 55% overall. This pattern is expected in the OCR task, as the recognition model uses the image to make predictions and is more likely to confuse a character's shape for another than to hallucinate or erase pixels. However, we observe that the errors in the Yakkha dataset do not follow this pattern. Instead, 87% of the errors for Yakkha occur because of deleted characters.

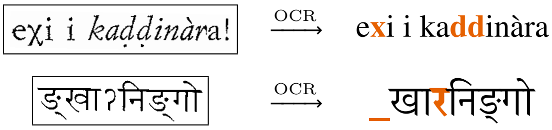

Figure 2: Examples of errors in Griko (top) and Yakkha (bottom) when using the Google Vision OCR.

4.2 Types of Errors

To better understand the challenges posed by the endangered language setting, we manually inspect all the errors made by the OCR system. While some errors are commonly seen in the OCR task, such as misidentified punctuation or incorrect word boundaries, 85% of the total errors occur due to specific characteristics of endangered languages that general-purpose OCR systems do not account for. Broadly, they can be categorized into two types, examples of which are shown in Figure 2:

- **Mixed scripts** The existing scripts that most endangered languages adopt as writing systems are often not ideal for comprehensively representing the language. For example, the Devanagari script does not have a grapheme for the glottal stop — as a solution, printed texts in the Yakkha language use the IPA symbol 'ʔ' (Schackow, 2015). Similarly, both Greek and Latin characters are used to write Griko. The Google Vision OCR is trained to detect script at the line-level and is not equipped to handle multiple scripts within a single word. As seen in Figure 2, the system does not recognize the Cyrillic script character χ in Griko and the IPA symbol **ʔ** in Yakkha. Mixed scripts cause 11% of the OCR errors.

- **Uncommon characters and diacritics** Endangered languages often use graphemes and diacritics that are part of the standard script but are not commonly seen in high-resource languages. Since these are likely rare in the OCR system's training data, they are frequently misidentified, accounting for 74% of the errors. In Figure 2, we see that the OCR system substitutes the uncommon diacritic **ḍ** in Griko. The system also deletes the Yakkha character **ङ्**, which is a 'half form' alphabet that is infrequent in several other Devanagari script languages (such as Hindi).

5 OCR Post-Correction Model

In this section, we describe our proposed OCR post-correction model. The base architecture of the model is a multi-source sequence-to-sequence

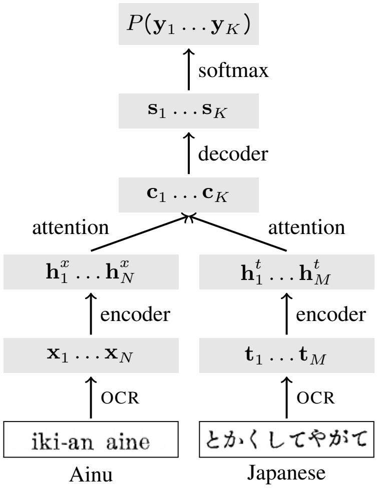

Figure 3: The proposed multi-source architecture with the encoder for an endangered language segment (left) and an encoder for the translated segment (right). The input to the encoders is the first pass OCR over the scanned images of each segment. For example, the OCR on the scanned images of some Ainu text (left) and its Japanese translation (right).

framework (Zoph and Knight, 2016; Libovický and Helcl, 2017) that uses an LSTM encoder-decoder model with attention (Bahdanau et al., 2015). We propose improvements to training and modeling for the multi-source architecture, specifically tailored to ease learning in data-scarce settings.

5.1 Multi-source Architecture

Our post-correction formulation takes as input the first pass OCR of the endangered language segment $\boldsymbol{x}$ and the OCR of the translated segment $\boldsymbol{t}$, to predict an error-free endangered language text $\boldsymbol{y}$. The model architecture is shown in Figure 3.

The model consists of two encoders — one that encodes $\boldsymbol{x}$ and one that encodes $\boldsymbol{t}$. Each encoder is a character-level bidirectional LSTM (Hochreiter and Schmidhuber, 1997) and transforms the input sequence of characters to a sequence of hidden state vectors: $\mathbf{h}^x$ for the endangered language text and $\mathbf{h}^t$ for the translation.

The model uses an attention mechanism during the decoding process to use information from the encoder hidden states. We compute the attention weights over each of the two encoders independently. At the decoding time step k:

$$e^x_{k,i} = \mathbf{v}^x \tanh\left(\mathbf{W}^x_1 \mathbf{s}_{k-1} + \mathbf{W}^x_2 \mathbf{h}^x_i\right) \quad (1)$$

$$\boldsymbol{\alpha}^x_k = \operatorname{softmax}\left(\mathbf{e}^x_k\right)$$

$$\mathbf{c}^x_k = \left[\Sigma_i \alpha^x_{k,i} \mathbf{h}^x_i\right]$$

where $\mathbf{s}_{k-1}$ is the decoder state of the previous time step and $\mathbf{v}^x$, $\mathbf{W}^x_1$ and $\mathbf{W}^x_2$ are trainable parameters. The encoder hidden states $\mathbf{h}^x$ are weighted by the attention distribution $\boldsymbol{\alpha}^x_k$ to produce the context vector $\mathbf{c}^x_k$. We follow a similar procedure for the second encoder to produce $\mathbf{c}^t_k$. We concatenate the context vectors to combine attention from both sources (Zoph and Knight, 2016):

$$\mathbf{c}_k = \left[\mathbf{c}^x_k ; \mathbf{c}^t_k\right]$$

$\mathbf{c}_k$ is used by the decoder LSTM to compute the next hidden state $\mathbf{s}_k$ and subsequently, the probability distribution for predicting the next character $\mathbf{y}_k$ of the target sequence $\boldsymbol{y}$:

$$\mathbf{s}_k = \operatorname{lstm}\left(\mathbf{s}_{k-1}, \mathbf{c}_k, \mathbf{y}_{k-1}\right) \quad (2)$$

$$P\left(\mathbf{y}_k\right) = \operatorname{softmax}\left(\mathbf{W}\mathbf{s}_k + \mathbf{b}\right) \quad (3)$$

Training and Inference The model is trained for each language with the cross-entropy loss ($\mathcal{L}_{\text{ce}}$) on the small amount of transcribed data we have. Beam search is used at inference time.

5.2 Model and Training Improvements

With the minimal annotated data we have, it is challenging for the neural network to learn a good distribution over the target characters. We propose a set of adaptations to the base architecture that improves the post-correction performance without additional annotation. The adaptations are based on characteristics of the OCR task itself and the performance of the upstream OCR tool (Section 4).

Diagonal attention loss As seen in Section 4, substitution errors are more frequent in the OCR task than insertions or deletions; consequently, we expect the source and target to have similar lengths. Moreover, post-correction is a monotonic sequence-to-sequence task, and reordering rarely occurs (Schnober et al., 2016). Hence, we expect attention weights to be higher at characters close to the diagonal for the endangered language encoder.

We modify the model such that all the elements in the attention vector that are not within j steps (we use $j = 3$) of the current time step k are added to the training loss, thereby encouraging elements away from the diagonal to have lower values. The diagonal loss summed over all time steps for a training instance, where N is the length of $\boldsymbol{x}$, is:

$$\mathcal{L}_{\text{diag}} = \sum_k \left(\sum_{i=1}^{k-j} \alpha^x_{k,i} + \sum_{i=k+j}^{N} \alpha^x_{k,i} \right)$$

Copy mechanism Table 1 indicates that the first pass OCR predicts a majority of the characters accurately. In this scenario, enabling the model to directly copy characters from the first pass OCR rather than generate a character at each time step might lead to better performance (Gu et al., 2016).

We incorporate the copy mechanism proposed in See et al. (2017). The mechanism computes a "generation probability" at each time step k, which is used to choose between *generating* a character (Equation 3) or *copying* a character from the source text by sampling from the attention distribution $\boldsymbol{\alpha}_k^x$.

Coverage Given the monotonicity of the post-correction task, the model should not attend to the same character repeatedly. However, repetition is a common problem for neural encoder-decoder models (Mi et al., 2016; Tu et al., 2016). To account for this problem, we adapt the coverage mechanism from See et al. (2017), which keeps track of the attention distribution over past time steps in a coverage vector. For time step k, the coverage vector would be $\mathbf{g}_k = \sum_{k'=0}^{k-1} \boldsymbol{\alpha}_{k'}^x$.

$\mathbf{g}_k$ is used as an extra input to the attention mechanism, ensuring that future attention decisions take the weights from previous time steps into account. Equation 1, with learnable parameter $\mathbf{w}_g$, becomes:

$$e_{k,i}^x = \mathbf{v}^x \tanh\left(\mathbf{W}_1^x \mathbf{s}_{k-1} + \mathbf{W}_2^x \mathbf{h}_i^x + \mathbf{w}_g g_{k,i}\right)$$

$\mathbf{g}_k$ is also used to penalize attending to the same locations repeatedly with a coverage loss. The coverage loss summed over all time steps k is:

$$\mathcal{L}_{\text{cov}} = \sum_k \sum_{i=1}^{n} \min\left(\alpha_{k,i}^x, g_{k,i}\right)$$

Therefore, with our model adaptations, the loss for a single training instance:

$$\mathcal{L} = \mathcal{L}_{\text{ce}} + \mathcal{L}_{\text{diag}} + \mathcal{L}_{\text{cov}} \tag{4}$$

5.3 Utilizing Untranscribed Data

As discussed in Section 3, given the effort involved, we transcribe only a subset of the pages in each scanned book. Nonetheless, we leverage the remaining unannotated pages for pretraining our model. We use the upstream OCR tool to get a first pass transcription on all the unannotated pages.

We then create "pseudo-target" transcriptions for the endangered language text as described below:

- **Denoising rules** Using a small fraction of the available annotated pages, we compute the edit distance operations between the first pass OCR and the gold transcription. The operations of each type (insertion, deletion, and replacement) are counted for each character and divided by the number of times that character appears in the first pass OCR. This forms a probability of how often the operation should be applied to that specific character.

  We use these probabilities to form rules, such as $p($replace d with ḍ$) = 0.4$ for Griko and $p($replace ? with ʔ$) = 0.7$ for Yakkha. These rules are applied to remove errors from, or "denoise", the first pass OCR transcription.

- **Sentence alignment** We use Yet Another Sentence Aligner (Lamraoui and Langlais, 2013) for unsupervised alignment of the endangered language and translation on the unannotated pages.

Given the aligned first pass OCR for the endangered language text and the translation along with the pseudo-target text, $\boldsymbol{x}$, $\boldsymbol{t}$ and $\hat{\boldsymbol{y}}$ respectively, the pretraining steps, in order, are:

- **Pretraining the encoders** We pretrain both the forward and backward LSTMs of each encoder with a character-level language model objective: the endangered language encoder on $\boldsymbol{x}$ and the translation encoder on $\boldsymbol{t}$.

- **Pretraining the decoder** The decoder is pretrained on the pseudo-target $\hat{\boldsymbol{y}}$ with a character-level language model objective.

- **Pretraining the seq-to-seq model** The model is pretrained with $\boldsymbol{x}$ and $\boldsymbol{t}$ as the sources and the pseudo-target $\hat{\boldsymbol{y}}$ as the target transcription, using the post-correction loss function $\mathcal{L}$ as defined in Equation 4.

6 Experiments

This section discusses our experimental setup and the post-correction performance on the three endangered languages on our dataset.

6.1 Experimental Setup

Data Splits We perform 10-fold cross-validation for all experimental settings because of the small size of the datasets. For each language, we divide the transcribed data into 11 segments — we use one segment for creating the *denoising rules* described in the previous section and the remaining ten as the

	Character Error Rate						Word Error Rate					
	Ainu		Griko		Yakkha		Ainu		Griko		Yakkha	
Model	Multi	Single	Multi	Single	Multi	Single	Multi	Single	Multi	Single	Multi	Single
Fp-Ocr	–	1.34	–	3.27	–	8.90	–	6.27	–	15.63	–	31.64
Base	1.56	1.41	6.78	5.95	70.39	71.71	8.56	7.88	15.13	13.67	98.15	99.10
Copy	2.04	1.99	2.54	2.28	14.77	12.30	9.48	8.57	9.33	8.90	30.36	27.81
Ours	0.92	**0.80**	**1.66**	1.70	**7.75**	8.44	5.75	**5.19**	**7.46**	7.51	**20.95**	21.33

Table 2: Our method improves performance over all baselines (10-fold cross-validation averaged over five randomly seeded runs). We present multi- and single-source variants and **highlight** the best model for each language.

folds for cross-validation. In each cross-validation fold, eight segments are used for training, one for validation and one for testing.

We divide the dataset at the page-level for the Ainu and Griko documents, resulting in 11 segments of three pages each. For the Yakkha documents, we divide at the paragraph-level, due to the small size of the dataset. We have 33 paragraphs across the three books in our dataset, resulting in 11 segments that contain three paragraphs each. The multi-source results for Yakkha reported in Table 2 use the English translations. Results with Nepali are similar and are included in Appendix A.

Metrics We use two metrics for evaluating our systems: character error rate (CER) and word error rate (WER). Both metrics are based on edit distance and are standard for evaluating OCR and OCR post-correction (Berg-Kirkpatrick et al., 2013; Schulz and Kuhn, 2017). CER is the edit distance between the predicted and the gold transcriptions of the document, divided by the total number of characters in the gold transcription. WER is similar but is calculated at the word level.

Methods In our experiments, we compare the performance of our proposed method with the first pass OCR and with two systems from recent work in OCR post-correction. All the post-correction methods have two variants – the single-source model with only the endangered language encoder and the multi-source model that additionally uses the high-resource translation encoder.

- Fp-Ocr: The first pass transcription obtained from the Google Vision OCR system.
- Base: This system is the base sequence-to-sequence architecture described in Section 5.1. Both the single-source and multi-source variants of this system are used for English OCR post-correction in Dong and Smith (2018).
- Copy: This system is the base architecture with a copy mechanism as described in Section 5.2. The single-source variant of this model is used for OCR post-correction on Romanized Sanskrit in Krishna et al. (2018).[8]
- Ours: The model with all the adaptations proposed in Section 5.2 and Section 5.3.

Implementation The post-correction models are implemented using the DyNet neural network toolkit (Neubig et al., 2017), and all reported results are the average of five training runs with different random seeds. We assume knowledge of the entire alphabet of the endangered language for all the methods, which is straightforward to obtain for most languages. The decoder's vocabulary contains all these characters, irrespective of their presence in the training data, with corresponding randomly-initialized character embeddings.

6.2 Main Results

Table 2 shows the performance of the baselines and our proposed method for each language. Overall, our method results in an improved CER and WER over existing methods across all three languages.

The Base system does not improve the recognition rate over the first pass transcription, apart from a small decrease in the Griko WER. The performance on Yakkha, particularly, is significantly worse than Fp-Ocr: likely because the data size of Yakkha is much smaller than that of Griko and Ainu, and the model is unable to learn a reasonable distribution. However, on adding a copy mechanism to the base model in the Copy system, the performance is notably better for both Griko and Yakkha. This indicates that adaptations to the base model that cater to specific characteristics of the

---

[8] Although Krishna et al. (2018) use BPE tokenization, preliminary experiments showed that character-level models result in much better performance on our dataset, likely due to the limited data available for training the BPE model.

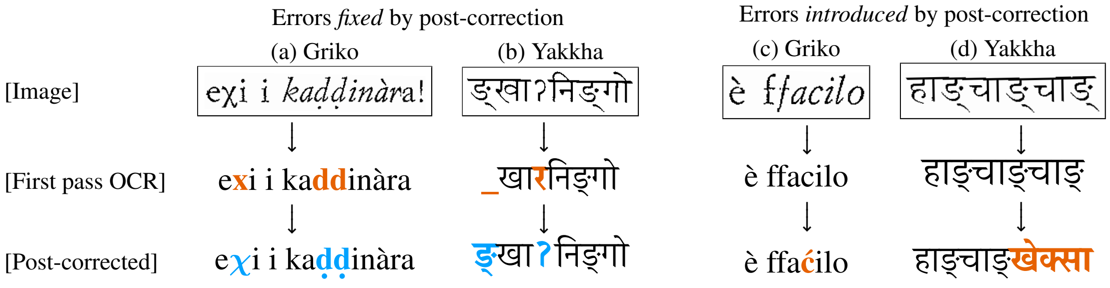

Figure 4: Our model fixes many mixed script and uncommon diacritics errors such as (a) and (b). In rare cases, it "over-corrects" the first pass OCR transcription, introducing errors such as (c) and (d).

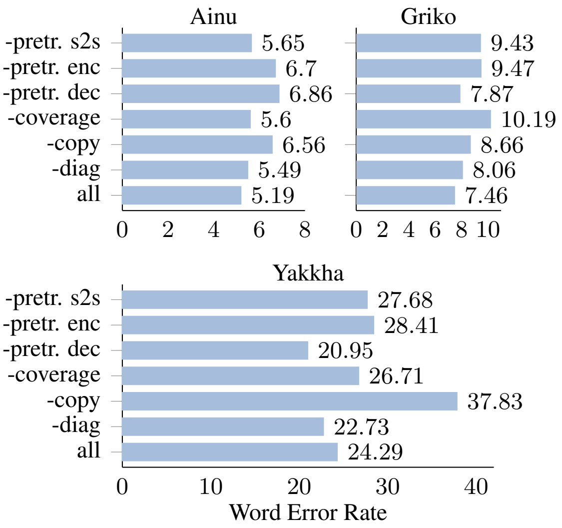

Figure 5: WER with model component ablations on the best model setting in Table 2. "all" includes all the adaptations we propose. Each ablation removes a single component from the "all" model, e.g. "-pretr. s2s" removes the seq-to-seq model pretraining.

post-correction task can alleviate some of the challenges of learning from small amounts of data.

The single-source and the multi-source variants of our proposed method improve over the baselines, demonstrating that our proposed model adaptations can improve recognition even without translations. We see that using the high-resource translations results in better post-correction performance for Griko and Yakkha, but the single-source model achieves better accuracy for Ainu. We attribute this to two factors: the very low error rate of the first pass transcription for Ainu and the relatively high error rate (based on manual inspection) of the OCR on the Japanese translation. Despite being a high-resource language, OCR is difficult due to the complexity of Japanese characters and low scan quality. The noise resulting from the Japanese OCR errors likely hurts the multi-source model.

6.3 Ablation Studies

Next, we study the effect of our proposed adaptations and evaluate their benefit to the performance of each language. Figure 5 shows the word error rate with models that remove one adaptation from the model with all the adaptations ("all").

For Ainu and Griko, removing any single component increases the WER, with the complete ("all") method performing the best. There is little variance in the Ainu ablations, likely due to the high-quality first pass transcription.

Our proposed adaptations add the most benefit for Yakkha, which has the fewest training data and relatively less accurate first pass OCR. The copy mechanism is crucial for good performance, but removing the decoder pretraining ("pretr. dec") leads to the best scores among all the ablations. The denoising rules used to create the pseudo-target data for Yakkha are likely not accurate since they are derived from only three paragraphs of annotated data. Consequently, using it to pretrain the decoder leads to a poor language model.

6.4 Error Analysis

We systematically inspect all the recognition errors in the output of our post-correction model to determine the sources of improvement with respect to the first pass OCR. We also examine the types of errors introduced by the post-correction process.

We observe a *91% reduction* in the number of errors due to mixed scripts and a *58% reduction* in the errors due to uncommon characters and diacritics (as defined in Section 4). Examples of these are shown in Figure 4 (a) and (b): mixed script errors such as the χ character in Griko and the glottal stop **ʔ** in Yakkha are successfully corrected by the model. The model is also able to correct uncommon character errors like **ḍ** in Griko and **ङ्** in Yakkha.

Examples of errors introduced by the model are shown in Figure 4 (c) and (d). Example (c) is in Griko, where the model incorrectly adds a diacritic to a character. We attribute this to the fact that the first pass OCR does not recognize diacritics well; hence, the model learns to add diacritics frequently while generating the output. Example (d) is in Yakkha. The model inserts several incorrect characters, and can likely be attributed to the lack of a good language model due to the relatively smaller amount of training data we have in Yakkha.

7 Related Work

Post-correction for OCR is well-studied for high-resource languages. Early approaches include lexical methods and weighted finite-state methods (see Schulz and Kuhn (2017) for an overview). Recent work has primarily focused on using neural sequence-to-sequence models. Hämäläinen and Hengchen (2019) use a BiLSTM encoder-decoder with attention for historical English post-correction. Similar to our base model, Dong and Smith (2018) use a multi-source model to combine the first pass OCR from duplicate documents in English.

There has been little work on lower-resourced languages. Kolak and Resnik (2005) present a probabilistic edit distance based post-correction model applied to Cebuano and Igbo, and Krishna et al. (2018) show improvements on Romanized Sanksrit OCR by adding a copy mechanism to a neural sequence-to-sequence model.

Multi-source encoder-decoder models have been used for various tasks including machine translation (Zoph and Knight, 2016; Libovický and Helcl, 2017) and morphological inflection (Kann et al., 2017; Anastasopoulos and Neubig, 2019). Perhaps most relevant to our work is the multi-source model presented by Anastasopoulos and Chiang (2018), which uses high-resource translations to improve speech transcription of lower-resourced languages.

Finally, Bustamante et al. (2020) construct corpora for four endangered languages from text-based PDFs using rule-based heuristics. Data creation from such unstructured text files is an important research direction, complementing our method of extracting data from scanned images.

8 Conclusion

This work presents a first step towards extracting textual data in endangered languages from scanned images of paper books. We create a benchmark dataset with transcribed images in three endangered languages: Ainu, Griko, and Yakkha. We propose an OCR post-correction method that facilitates learning from small amounts of data, which results in a 34% average relative error reduction in both the character and word recognition rates.

As future work, we plan to investigate the effect of using other available data for the three languages (for example, word lists collected by documentary linguists or the additional Griko folk tales collected by Anastasopoulos et al. (2018)).

Additionally, it would be valuable to examine whether our method can improve the OCR on high-resource languages, which typically have much better recognition rates in the first pass transcription than the endangered languages in our dataset.

Further, we note our use of the Google Vision OCR system to obtain the first pass OCR for our experiments, primarily because it provides script-specific models as opposed to other general-purpose OCR systems that rely on language-specific models (as discussed in Section 4). Future work that focuses on overcoming the challenges of applying language-specific models to endangered language texts would be needed to confirm our method's applicability to post-correcting the first pass transcriptions from different OCR systems.

Lastly, given the annotation effort involved, this paper explores only a small fraction of the endangered language data available in linguistic and general-purpose archives. Future work will focus on large-scale digitization of scanned documents, aiming to expand our OCR benchmark on as many endangered languages as possible, in the hope of both easing linguistic documentation and preservation efforts and collecting enough data for NLP system development in under-represented languages.

Acknowledgements

We thank David Chiang, Walter Scheirer, and William Theisen for initial discussions on the project, the University of Notre Dame Library for the scanned "Kutune Shirka" Ainu-Japanese book, and Josep Quer for the scanned Griko folktales book. We also thank Taylor Berg-Kirkpatrick, Shuyan Zhou, Zi-Yi Dou, Yansen Wang, Zhen Fan, and Deepak Gopinath for feedback on the paper.

A Appendix

A.1 Implementation Details

The hyperparameters used are:

- Character embedding size = 128
- Number of LSTM layers = 1
- Hidden state size of the LSTM = 256
- Attention size = 256
- Beam size = 4
- For the diagonal loss, $j = 3$
- Minibatch size for training = 1
- Maximum number of epochs = 150
- Patience for early stopping = 10 epochs
- Pretraining epochs for encoder/decoder = 10
- Pretraining epochs for seq-to-seq model = 5

We use the same values of the hyperparameters for each language and all the systems. We select the best model with early stopping on the character error rate of the validation set.

A.2 Additional Experimental Results

Performance on Yakkha with Nepali Table 3 shows the performance for the Yakkha dataset when using Nepali as the high-resource translation input to the multisource model. The performance is similar to those of the experiments using the English translations, as presented in Table 2.

Standard deviation on the main results Table 4 and Table 5 show the character error rate and word error rate respectively including the standard deviation over five randomly seeded runs, corresponding to the systems described in Table 2.

Model	CER	WER
Fp-Ocr	8.90	31.64
Base	70.89	100.00
Copy	11.60	26.74
Ours	7.95	20.83

Table 3: Character error rate (CER) and word error rate (WER) for the Yakkha dataset with the multisource model that uses the OCR on Nepali as the high-resource translation. The table shows the mean over five random runs.

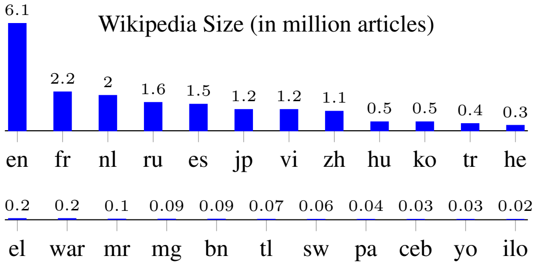
Abstract

Language models (LMs) have proven surprisingly successful at capturing factual knowledge by completing cloze-style fill-in-the-blank questions such as "Punta Cana is located in _." However, while knowledge is both written and queried in many languages, studies on LMs' factual representation ability have almost invariably been performed on English. To assess factual knowledge retrieval in LMs in different languages, we create a multilingual benchmark of cloze-style probes for 23 typologically diverse languages. To properly handle language variations, we expand probing methods from single- to multi-word entities, and develop several decoding algorithms to generate multi-token predictions. Extensive experimental results provide insights about how well (or poorly) current state-of-the-art LMs perform at this task in languages with more or fewer available resources. We further propose a code-switching-based method to improve the ability of multilingual LMs to access knowledge, and verify its effectiveness on several benchmark languages. Benchmark data and code have be released at https://x-factr.github.io.

1 Introduction

Language models (LMs; (Church, 1988; Kneser and Ney, 1995; Bengio et al., 2003)) learn to model the probability distribution of text, and in doing so capture information about various aspects of the syntax or semantics of the language at hand. Recent works have presented intriguing results demonstrating that modern large-scale LMs also capture a significant amount of *factual knowledge* (Petroni et al., 2019; Jiang et al., 2020; Poerner et al., 2019). This knowledge is generally probed by having the LM fill in the blanks of cloze-style prompts such as "Obama is a _ by profession.", where these prompts are invariably written in English. However, it goes without saying that there are many languages of the world other than English, and it is quite conceivable that (1) users may want to query this factual knowledge in other languages, and (2) some facts will be written in non-English languages and thus multilingually trained LMs (hereinafter, M-LMs) may be more equipped to recall these facts in the languages of the original data. In this paper, we study the intersection of *multilinguality and the factual knowledge included in LMs*.



fact	⟨Bloomberg L.P., founded_in, New York⟩		
en prompt	[X] was founded in [Y].		
es prompt	[X] fue [fundar.Gerund;X] en [Y].		
	↓ ↓ ↓

	Chicago, Estados Unidos	4	-3.58
	2012 Bloomberg L.P	5	-3.06

Figure 1: X-FACTR contains 23 languages, for which the data availability varies dramatically. Prompts get instantiated to produce grammatical sentences with different numbers of mask tokens and are used to obtain predictions for [Y]. In this Spanish example, the verb gerund "fundar" *to found* is rendered as "fundada" to agree in gender and number with the subject "Bloomberg L.P.". The final prediction is in bold.

We create a new multilingual benchmark for probing factual knowledge in LMs – the Cross-lingual FACTual Retrieval benchmark (X-FACTR).

X-FACTR shares a similar formulation as the LAMA benchmark of Petroni et al. (2019), which assesses whether LMs have memorized a fact (i.e., a subject-relation-object triple) by having LMs predict the blank (i.e. object) in a cloze-style prompt for each relation after filling in the subject. We manually create such prompts for 23 languages spanning different language families and different levels of data availability (§ 3.1). Because many languages that we handle are morphologically rich, we design a morphology-sensitive annotation schema (see example in Fig. 1) that can properly instantiate prompts using entity metadata (e.g. gender) and a morphological inflection model (§ 3.3).

In addition, while previous works (Petroni et al., 2019; Jiang et al., 2020; Poerner et al., 2019) have limited examination to single-token entities (e.g. "France"), we expand our setting to include multi-token entities (e.g. "United States"), which comprise more than 75% of facts included in our underlying database (Wikidata; § 3.2). We propose several decoding algorithms for prediction of these multi-token entities using masked LMs (§ 4). We discuss the related work in depth in § 7.

We perform experiments on X-FACTR (§ 5), comparing and contrasting across languages and LMs to answer the following research questions: (1) How and why does performance vary across different languages and models? (2) Can multilingual pre-training increase the amount of factual knowledge in LMs over monolingual pre-training? (3) How much does knowledge captured in different languages overlap? We find that the factual knowledge retrieval of M-LMs in high-resource languages is easier than in low-resource languages, but the overall performance is relatively low, indicating that this is a challenging task. We analyze the types of failure cases, shedding light on future directions to improve factual knowledge in M-LMs. In addition, multilingual pre-training does not necessarily lead to a higher recall of facts compared to language-specific monolingual pre-training. The knowledge memorized by M-LMs in fact is largely distinct across languages, with almost 50% of facts being recalled in only one language.

Inspired by the above observations, we propose a code-switching-based objective function to improve the ability of M-LMs to access knowledge using queries from a variety of languages. We replace entities in a sentence from the original language with counterparts in another language, and further fine-tune the LM on these code-switched data (§ 6). We perform experiments on three languages (French, Russian, and Greek, code-switched with English). Results demonstrate that this code-switching-based learning can successfully improve the knowledge retrieval ability with low-resource language prompts.

2 Retrieving Facts from LMs

In this paper we follow the protocol of Petroni et al. (2019)'s English-language LAMA benchmark, which targets factual knowledge expressed in the form of subject-relation-object triples from Wikidata[1] curated in the T-REx dataset (ElSahar et al., 2018). The cloze-style prompts used therein are manually created and consist of a sequence of tokens, where [X] and [Y] are placeholders for subjects and objects (e.g. "[X] is a [Y] by profession."). To assess the existence of a certain fact, [X] is replaced with the actual subject (e.g. "Obama is a $\langle$mask$\rangle$ by profession.") and the model predicts the object in the blank $\hat{y}_i = \mathrm{argmax}_{y_i}\, p(y_i|\boldsymbol{s}_{i:i})$, where $\boldsymbol{s}_{i:i}$ is the sentence with the i-th token masked out. Finally, the predicted fact is compared to the ground truth. In the next section, we extend this setting to more languages and predict multiple tokens instead of a single one.

3 Multilingual Multi-token Factual Retrieval Benchmark

3.1 Languages

In sampling the languages to create our multilingual benchmark, we attempted to create a subset as diverse as possible with regards to data availability, typology, and script – within the constraints of requiring inclusion in Wikidata and standard pre-trained M-LMs. To this end, we created prompts in 23 languages: English, French, Dutch, Spanish, Russian, Japanese, Chinese, Hungarian, Hebrew, Turkish, Korean, Vietnamese, Greek, Cebuano, Marathi, Bengali, Waray, Tagalog, Swahili, Punjabi, Malagasy, Yoruba, and Ilokano.

Our subset includes languages from 11 families (the Indo-European ones include members of the Germanic, Romance, Greek, Slavic, and Indic genera), using 10 different scripts. Our languages display high variance with respect to Wikipedia presence, a proxy for overall data availability, ranging from very large to very small (see Fig. 1).[2]

Table 1: X-FACTR benchmark statistics (in thousands). More details in the Appendix (Tab. 5 and Fig. 6).

3.2 Facts

While Petroni et al. (2019) and follow-up works focus on entities that can be represented by a single token, since many popular entities consist of multiple tokens (e.g. "United States"), we argue that it is crucial to include multi-token entities in the benchmark to make the evaluation unbiased. Similar to Petroni et al. (2019), we use the T-REx dataset to collect facts for our benchmark. Since T-REx aligns facts from Wikidata with sentences in abstract sections from DBpedia, we can estimate the commonality of each fact based on its frequency of being grounded to a sentence in these abstracts.

For each of the 46 relations in T-REx, we sample 1000 subject-object pairs with probability proportional to their frequency. Frequency-proportional sampling makes the distribution of the facts in our benchmark close to real usage and covers facts of different popularity. To keep the benchmark unbiased, we did not constrain the facts with any language-related criteria (e.g., require the entities to have translations in all languages we considered). As a result, some entities (either subjects or objects) might not have translations in all languages. The number of facts in different languages in our multilingual multi-token X-FACTR benchmark is shown in Tab. 1. Because many modern pre-trained M-LMs almost invariably use some variety of subword tokenization, the number of tokens an entity contains will depend on the tokenization method used in the LM. We report the statistics based on the WordPiece tokenization used in multilingual BERT (Devlin et al., 2019). The tokenization scheme statistics for the other M-LMs are similar.

3.3 Prompts

Some languages we include in the benchmark require additional handling of the prompts to account for their grammar or morphology. For example, (some) named entities inflect for case in languages like Greek, Russian, Hebrew, or Marathi. In some languages syntactic subjects and objects need to be in particular cases. Similarly, languages often require that the verb or other parts of the sentence agree with the subject or the object on some morphological features like person, gender, or number.

Our prompts provide the necessary information in order to generate grammatical sentences, given the gender and number of the entities. For example, the Russian prompt for "[X] was born in [Y]" is:

$$\Big[\text{X.Nom}\Big] \quad \Big[\text{родился;X=MASC} \mid \text{родилась;X=FEM} \mid \text{родилось;X=NEUT}\Big] \text{ в } \Big[\text{Y.Ess}\Big].$$

The prompt denotes that the subject ([X]) needs to be in the nominative (`Nom`) case and the object ([Y]) needs to be inflected in the essive case (`Ess`). The prompt also accounts for the variation of the gender of [X] providing options (separated by `|`) for the subject being masculine, feminine, or neuter (`MASC`, `FEM`, `NEUT` respectively).

Everything within square brackets gets concretely instantiated given the subject and object. Grammatical gender is assigned through a combination of Wikidata information and language-specific heuristics, constructed based on feedback from native speakers of each language. When the entity corresponds to a person, we retrieve their "sex_or_gender" properties from Wikidata. In addition, for languages like Greek or French, the gender of an entity can be inferred with fairly high certainty given the form of the word (e.g. looking at the ending). Last, some categories of entities (such as cities, countries, organizations, etc, which can be obtained using the "instance_of" Wikidata property) often get assigned a general grammatical case based on the category.

Once all the morphological features have been specified as detailed above, we use the `unimorph_inflect` package (Anastasopoulos and Neubig, 2019) to generate the appropriately inflected surface form of the bracketed words.[3] We note that the target entity ([Y]) might also need to be inflected, as in the above Russian example, in which case we require the model's predictions to match the inflected target forms.

To verify the quality of the prompts we performed user studies with native speakers, finding that 88% on average were judged as natural and grammatically correct. Details are shown in Appendix B, but it is worth noting that the majority

---

[3] https://github.com/antonisa/unimorph_inflect

of errors are due to prompts being awkward or incorrect for some senses captured by the relation, and not due to our gender heuristics or automatic inflection. This issue is also present in the LAMA English prompts (Jiang et al., 2020).

3.4 Evaluation

As noted in Petroni et al. (2019), because some subject-relation pairs might have multiple correct objects (e.g., America maintains diplomatic relations with multiple countries), we collect all valid objects and judge a prediction as correct if it can match any object (e.g., both France and Canada are correct). Since an entity might have multiple aliases (e.g., “America” and “the US”), we collect all aliases for each entity from Wikidata, and the prediction is marked as correct if it can match any one of them after lowercasing.

4 Multi-token Decoding

As Tab. 1 shows, many facts involve multi-token entities and thus a LM would need to predict these entities in multiple steps. Generating multiple predictions is straightforward for traditional left-to-right LMs (Sundermeyer et al., 2015; Radford et al., 2019), where we can autoregressively decode the next token conditioned on previous tokens. However, many pre-trained LMs such as BERT (Devlin et al., 2019) are *masked* LMs that predict individual words given left and right contexts, and decoding from such masked LMs remains an open problem (Lawrence et al., 2019; Salazar et al., 2020; Ghazvininejad et al., 2019; Wang and Cho, 2019; Cho, 2019). We systematically examined different multi-token decoding algorithms from three orthogonal perspectives: (1) how the initial predictions are produced, (2) how to refine the predictions, and (3) other commonly used components in neural text generation systems. We assume that the following conditional probability distribution is defined by the masked LM for a sentence with n tokens:

$$p(x_k|x'_1, ..., x'_{k-1}, \langle\text{mask}\rangle_k, x'_{k+1}, ..., x'_n), \quad (1)$$

where the subscript of $\langle$mask$\rangle$ indicates its position, and the surrounding token $x'_{\cdot}$ can either be an actual word $x_{\cdot}$ or $\langle$mask$\rangle$. We aim to handle sentences containing multiple mask tokens conditioning on the surrounding actual words:

$$\boldsymbol{s}_{i:j} = x_1, ..., x_{i-1}, \langle\text{mask}\rangle_i, ..., \langle\text{mask}\rangle_j, x_{j+1}, ..., x_n, \quad (2)$$

where $\boldsymbol{s}_{i:j}$ indicates a sentence with the i-th to j-th tokens masked out.[4]

(a) Independent: Barack Obama is a United$_1$ of$_1$ president$_1$ by profession

(b) Order: Barack Obama is a United$_1$ State$_2$ President$_3$ by profession

(c) Confidence: Barack Obama is a minister$_2$ of$_3$ cabinet$_1$ by profession

Figure 2: Illustration of three initial prediction and refinement methods. Green boxes are mask tokens to be filled, and subscripts indicate the prediction order.

4.1 Initial Prediction and Refinement

Given a sentence with multiple mask tokens, e.g., Eq. 2, we can either generate outputs in parallel independently or one at a time conditioned on the previously generated tokens. These methods are similar to the prediction problems that BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019b) perform in their pre-training stages respectively. We define $\boldsymbol{c} \in \mathbb{R}^n$ as the probability of each prediction, with details varying by prediction methods.

After all mask tokens are replaced with the initial predictions, i.e., $\hat{\boldsymbol{s}}_{i:j} = x_1, ..., \hat{y}_i, ..., \hat{y}_j, ..., x_n$, we can further refine the predictions by iteratively modifying one token at a time until convergence or until the maximum number of iterations is reached. Here we outline the algorithms with high-level descriptions, and provide concrete details in Appendix C.

Independent. For independent initial prediction (Fig. 2a), the mask tokens are all predicted in parallel (at once). We also consider two autoregressive methods for initial prediction or refinement.

Order-based. Mask tokens are predicted from left to right, in each step conditioning also on the previously generated tokens (Fig. 2b). In the refinement stage, we modify predictions also from left to right, and convergence is reached when there are no changes in a left-to-right scan.

Confidence-based. In each step, we choose the prediction with the highest probability, so the order of predictions can be arbitrary (Fig. 2c). In the refinement stage, we choose from all predicted tokens the one with the lowest confidence (i.e., the lowest probability) and re-predict it similarly to Ghazvininejad et al. (2019). Convergence is reached when the re-predicted token is the same as the original token.

4.2 Final Prediction

Because we do not know the number of tokens of the ground truth in advance, we enumerate from 1 to M mask tokens and choose the final prediction based on the confidence. Given the prompt in Eq. 2, the simplest way to compute the confidence is pseudo log likelihood, which is the sum

---

[4] We assume that the mask tokens are consecutive for notation simplicity, although all following methods/equations can be easily adapted to non-consecutive cases.

of log probabilities of each predicted token conditioned on the other tokens (Salazar et al., 2020): $v(j-i+1)=\sum_{k=i}^{j}\log c_k$, where c_k is the confidence (probability) of the k-th predicted token, and $v(m)$ is the overall prediction confidence with m initial mask tokens. Among M predictions, we choose the one with the highest confidence.

4.3 Additional Components

We also investigate additional components commonly used in neural generation systems. Specifically, we consider **length normalization** in computing the final confidence (i.e., divide $v(m)$ by the number of mask tokens m) because a simple sum might favor short predictions. In addition, the confidence value $\boldsymbol{c}$ in previous methods contains probabilities when the predictions are first generated, which will become stale once the surrounding tokens change (Ghazvininejad et al., 2019). We consider **re-computing confidence $\boldsymbol{c}$** whenever a change happens. Last, we attempted **beam search** to keep track of the most plausible B predictions at each step. Details of these components can be found in Appendix C, along with a general schema of the overall decoding algorithm in Alg. 1.

5 X-FACTR Benchmark Performance

Implementation Details. We use the implementations of different multilingual/monolingual pre-trained LMs in the Transformers library (Wolf et al., 2019). We examine 3 multilingual pre-trained LMs, M-BERT, XLM, XLM-R (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2019),[5] and 8 monolingual pre-trained LMs, BERT (en), CamemBERT (fr), BERTje (nl), BETO (es), RuBERT (ru), Chinese BERT (zh), BERTurk (tr), and GreekBERT (el) (Martin et al., 2020; de Vries et al., 2019; Cañete et al., 2020; Kuratov and Arkhipov, 2019; Schweter, 2020). Details of these models can be found in Appendix D.

We set the maximal number of mask tokens to $M=5$ for English, French, Dutch, and Spanish. In these languages more than 90% of the entities are split into ≤ 5 tokens. For all other languages we use $M=10$. This is expected because the vocabulary of M-LMs based on WordPiece tokenization is dominated by frequent words and low-resource-language words tend to split into more pieces (Ács, 2019). We set the maximal number of iterations to $T=2M$, so that we can approximately refine all the predicted tokens once for a sentence with M mask tokens (the initial prediction takes exactly M iterations). In our main results, we report results with two decoding algorithms: the simplest independent generation method and the confidence-based method for both initial and refinement predictions. The latter performs better than order-based methods, as we will show in Tab. 3. To save computation time, we only use confidence re-computation for $M=5$. We discuss computation complexity in Appendix C.

Evaluation Metrics. We follow Petroni et al. (2019), computing the accuracy of predicted objects for each relation and macro-average them as final scores. For fine-grained analysis of different decoding methods, pre-trained LMs, and languages, we report results on **all** facts as well as on subsets consisting only of single-token objects (**single**) and multi-token objects (denoted as **multi**).

5.1 Experimental Results

We run both the independent and confidence-based decoding methods with 3 M-LMs, and when available 8 monolingual LMs, across 23 languages,[6] with results shown in Fig. 3. Overall, even in the most favorable settings, the performance of state-of-that-art M-LMs at retrieving factual knowledge in the X-FACTR benchmark is relatively low, achieving less than 15% on high-resource languages (e.g., English and Spanish) and less than 5% for some low-resource languages (e.g., Marathi and Yoruba). This may initially come as a surprise, given the favorable performance reported in previous papers (Petroni et al., 2019; Jiang et al., 2020), which achieved accuracies over 30% on English. We justify this discrepancy in our following analysis. We note that, although we provide baseline results in almost all languages, we perform our extensive analysis on a representative subset, consisting of 13 languages.

Performance on Different Languages. Performance on high-resource languages is usually better than performance on middle- or low-resource languages regardless of the (M-)LMs. This is probably due to high-resource languages having more data in the pre-training stage. It is also possible that even if the fact of low-resource languages is written in the available data for these languages, it is not appropriately memorized due to lack of model capacity or forgetting (Kirkpatrick et al., 2017). It

---

[5] Yoruba is not in the training data of XLM and XLM-R.

[6] Check https://x-factr.github.io for latest results.

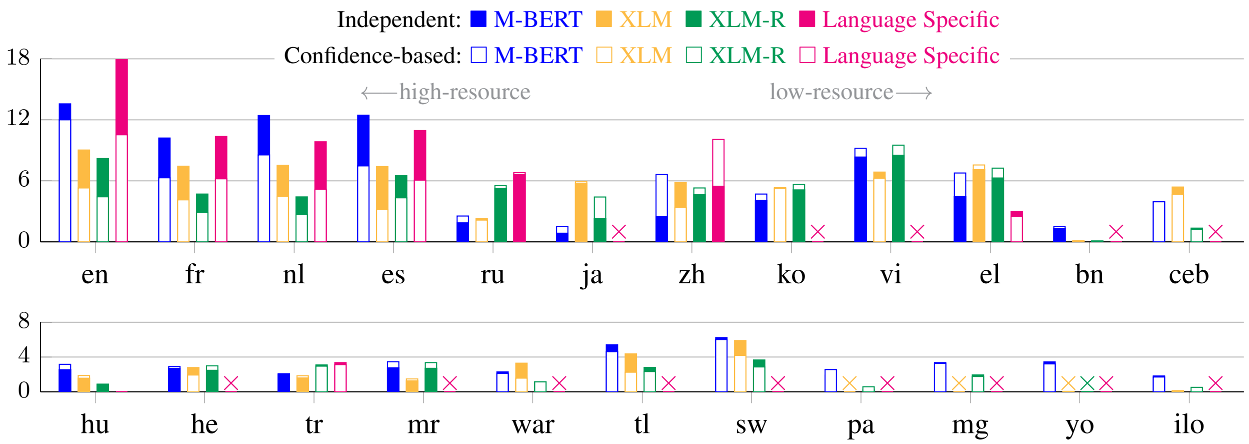

Figure 3: Accuracy on different languages using different LMs (%). Independent prediction (solid bars) outperforms confidence-based prediction (no-fill bars) on high-resource languages but not on low-resource languages. Different models are color-coded, with missing/unsupported models marked with ×. Languages are ranked by the total number of facts in our benchmark. Details in Appendix Tab. 10.

is worth noting that the best results are in Indo-European languages which not only have the most data, but also share the same (Latin) script which could further facilitate cross-lingual learning.

Performance of Different LMs. Comparing the performance of different M-LMs, we found that M-BERT outperforms XLM and XLM-R on high-resource languages, while on low-resource languages performance is similar. This is contradictory to the conclusion on other cross-lingual tasks, such as natural language inference and syntactic prediction, as reported in Hu et al. (2020). Our conjecture is that because factual knowledge probing requires retrieving the identity and relations of individual entities, it is more fine-grained than more coarse-grained understanding of syntactic and semantic classes that are required to solve other tasks. We posit that pre-training methods that show superior performance on inference and syntactic prediction tasks (i.e., XLM-R) might achieve good syntactic/semantic abstraction at the cost of making less concrete lexical distinctions.

Comparing M-BERT with language-specific LMs, we find M-BERT outperforms the monolingual BERT on Dutch, Spanish, and Greek, while underperforming on English, Russian, Chinese, and Turkish. Since most of the LMs follow the architecture and pre-training settings of BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019), we hypothesize that training corpus is the major contributor to the final performance, and summarize those corpora in Tab. 8 in the Appendix. Another potential explanation is that model capacity limitations preclude M-BERT from effectively memorizing entity names/relations in all of the languages.

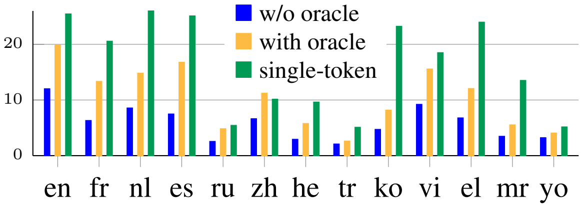

Figure 4: Accuracy of the confidence-based decoding algorithm on different languages using M-BERT w/ and w/o oracle length (%).

Single-token vs Multi-token. Since we choose among M candidate predictions with different numbers of mask tokens based on confidence, it is possible that the prediction with the correct number of mask tokens has lower confidence than the other predictions. To investigate the errors introduced by this step, we conduct an ablation experiment that assumes we know the ground-truth number of mask tokens. As shown in Fig. 4, performance improves significantly by 75% on average across all languages using the oracle mask number, indicating that pre-trained LMs have difficulties in choosing the correct number of mask tokens. The performance on single-token facts (i.e., the setting of previous works that only predicts a single token) is even higher, demonstrating the difficulty of multi-token prediction.[7]

---

[7] The 31.1% accuracy of BERT in Petroni et al. (2019) is over a different set of facts in English, constrained to be in the intersection of vocabularies of several LMs. We have no such constraint, which may explain the slightly lower 25.5% accuracy on the English single-token performance in Fig. 4.

Table 3: Accuracy of different decoding methods using M-BERT on English and Chinese (%).

Error Analysis. Even with access to an oracle for the number of target tokens, though, the performance is still lower than 20%. To understand the types of errors made by the LMs, we sample over 400 error cases in English, Spanish, and Greek, and classify them. The error type distributions along with English examples are outlined in Tab. 2.

The most prominent error type, about one-fourth of mistakes for all LMs, was **repeating subjects**, whereby the prediction repeats either the full or partial subject. Predicting the **wrong entities** is also fairly common, especially in Spanish (29%). Interestingly, we find that wrong predictions are often a language-specific "common" entity such as 'Αϑήνα' (Athens, the capital of Greece) in Greek location prompts, while the Spanish model insisted most musicians play 'flauta' (flute). Another error type, particularly common in Greek (27%), is producing **non-informative** output, where the predictions are function words that could never be an entity. **Type errors** when the semantic type of the prediction is different than expected (e.g. predicting dates instead of locations) are fairly common (English: 8%, Spanish 6%), as are **related concepts** predictions (English: 7%), where the model predicts relevant, possibly factually correct entities (e.g. predicting a country or a state instead of a city). Worryingly, in a fair amount of cases (English: 5%, Spanish: 8%, Greek: 11%) the models output non-existent words (**unk**). Errors of the last 4 types could potentially be avoided by limiting the allowed outputs of the model to specific entity classes; we leave this for future work. Last, we identified around 3% of **false negatives**, where the prediction is actually correct but is not part of our aliases list and less than 1% of **inflection** errors where the prediction is the correct entity but improperly inflected.

Performance of Different Decoding Methods. Overall, the confidence-based decoding method improves the accuracy in middle- and low- resource languages, while it hurts the performance on high-resource languages. To better understand the effect of different components on the final performance, we conduct a comprehensive comparison on English and Chinese. We compare the three initial prediction methods and the three refinement options (including not performing refinement), for a total of nine decoding methods (§ 4.1). We further apply additional improvements (§ 4.3) on the confidence-based decoding method.

By comparing the performance in Tab. 3, we first see advanced decoding methods improve performance on multi-token objects, but hurt performance on single-token ones. The best-performing decoding method on English improves the multi-token accuracy from 5.57% to 11.06%, indicating that advanced decoding methods have a better chance to elicit multi-token facts from M-BERT. Some examples are shown in Tab. 7 in the Appendix. The lower performance on single-token objects is probably caused by the fact that advanced decoding methods discover multi-token predictions that have higher confidence than single-token ones (§ 4.2). For example, the single-token prediction for "Enrique Iglesias used to communicate in _." is "Spanish", while the best decoding method outputs "his own words" with higher confidence. Second, initial prediction methods have a greater effect on the final performance than refinement methods. We

hypothesize that this is because the greedy decoding process heavily depends on previous predictions, and refinement cannot recover from unsatisfactory initial predictions. Third, length normalization was not found useful in either case.

There are also observations not consistent across the two languages. First, since Chinese has a larger portion of multi-token objects than English (as shown in Tab. 1), the overall performance on Chinese increases while it decreases on English, which is consistent with the observation in Fig. 3. Second, confidence re-computation and beam search are not as effective on Chinese, which we conjecture is because that the distribution over English sentences exhibits more multimodality than the distribution over Chinese sentences due to more training data.

6 Improving Multilingual LM Retrieval

As the performance of M-LMs is relatively low, especially on low-resource languages, an obvious endeavor is to refine the model to improve fact retrieval performance in various languages. We analyze how similarly M-BERT performs on queries in different languages. We collect correctly predicted facts across all languages, and count in how many languages each fact was retrieved correctly. As shown in the bottom-left histogram of Fig. 5, half of the correctly predicted facts were correct in a single language, indicating little overlap across languages (Lin et al., 2018). Only 3% of facts were correct in more than 5 languages, and objects in those facts are usually sub-strings of subjects, making them easy to retrieve regardless of the language. This observation is also confirmed by the overlap between pairs of languages in the top-right chart of Fig. 5; even the most similar languages (i.e., English and Dutch) only have 34% of correct predictions in common.

We find that facts retrievable only in a single language tend to be knowledge that is mainly mentioned in a certain language. For example, M-BERT mistakenly predicts “QQ” in the English sentence “Tencent QQ is developed by _.”, while the prediction “腾讯” (Tencent) in the corresponding Chinese sentence “腾讯QQ是由_开发的。” is correct. This is probably because Tencent, a Chinese company, is more frequently mentioned in the Chinese training corpus.

6.1 Methods

Inspired by these observations, we propose to use *code-switching* to create data to fine-tune pretrained LMs, replacing entity mentions in one language (e.g., English/Greek) with their counterparts in another language (e.g., Greek/English). Through this bi-directional code-switching, entity mentions serve as pivots, enabling knowledge that was originally learned in one language to be shared with others. Given a pair of languages, we first identify Wikipedia sentences that mention entities from our benchmark using SLING (Ringgaard et al., 2017). The M-LM is then finetuned on these sentences. Following Wu et al. (2020), with 30% of probability we switch all the entity mentions (can be one or multiple) from the original language to their counterparts in the other language, ending up with sentences like “Ομπάμα later reflected on his years ...", where we substituted “Obama" with a Greek mention of the entity, and vice-versa for Greek-to-English. 70% of the sentences remain the same. If there are multiple mention texts for an entity, we sample proportionally to their frequencies, which we found in our preliminary experiments performed better than using a fixed translation. We fine-tune M-BERT using the masked LM objective on this data, with 15% of non-mention words and 50% of mention words masked out.[8]

6.2 Experimental Results

We choose three languages with different data availability, namely French, Russian, and Greek, and pair them with English, producing 560k, 396k, and 129k code-switched sentences respectively. We compare M-BERT after code-switched fine-tuning (denoted as **cs**) with both the original M-BERT and with fine-tuning only on raw text (**raw**). We vary the evaluation settings to illustrate the effect of code-switching: on top of matching predictions to

---

[8] The larger ratio on entities encourages the model to focus on predicting entities, as in the downstream task.

Lang.	Method	Single-eval All	Single-eval Single	Single-eval Multi	Double-eval All	Double-eval Single	Double-eval Multi

Table 4: Accuracy of M-BERT after fine-tuning on raw and code-switched text (%).

ground truth aliases in the prompt language (**single-eval)**, we evaluate with targets in both languages (**double-eval**; English and prompt).

As shown in Tab. 4, continued fine-tuning on raw text outperforms the original M-BERT, likely due to our fine-tuning on a subset of sentences with mentions of entities from our benchmark. Results on code-switched text are slightly worse when only matching entities in the original target language, but significantly better if we allow matching in both the original language and English. This indicates that code-switched fine-tuning allows M-BERT to retrieve facts, albeit in English rather than in the prompt language. Encouragingly, the increase is larger for low-resource (Greek) and typologically distant-to-English (Russian) languages. For example, the prediction for the Greek prompt "η Θεωρία κατηγοριών είναι μέρος των _." ("Category theory is part of _.") is "mathematics" (in English!), while the prediction without code-switching is the non-informative "οποίων" ("which"). Considering that we have more raw than code-switched sentences in the dataset, this seems to indicate that English entities are easier to predict than their prompt-language counterparts, which might be because facts expressed in English are better learned in the pre-trained model due to training data abundance.

7 Related Work

Factual Knowledge Retrieval from LMs Several works have focused on probing factual knowledge solely from pre-trained LMs without access to external knowledge. They do so by either using prompts and letting the LM fill in the blanks, which assumes that the LM is a static knowledge source (Petroni et al., 2019; Jiang et al., 2020; Poerner et al., 2019; Bouraoui et al., 2020), or fine-tuning the LM on a set of question-answer pairs to directly generate answers, which dynamically adapts the LM to this particular task (Roberts et al., 2020). Impressive results demonstrated by these works indicate that large-scale LMs contain a significant amount of knowledge, in some cases even outperforming competitive question answering systems relying on external resources (Roberts et al., 2020). Petroni et al. (2020) further shows that LMs can generate even more factual knowledge when augmented with retrieved sentences. Our work builds on these works by expanding to multilingual and multi-token evaluation, and also demonstrates the significant challenges posed by this setting.

Multilingual Benchmarks Many multilingual benchmarks have been created to evaluate the performance of multilingual systems on different natural language processing tasks, including question answering (Artetxe et al., 2020; Lewis et al., 2019; Clark et al., 2020), natural language understanding (Conneau et al., 2018; Yang et al., 2019a; Zweigenbaum et al., 2018; Artetxe and Schwenk, 2019), syntactic prediction (Nivre et al., 2018; Pan et al., 2017), and comprehensive benchmarks covering multiple tasks (Hu et al., 2020; Liang et al., 2020). We focus on multilingual factual knowledge retrieval from LMs, which to our knowledge has not been covered by any previous work.

8 Conclusion

We examine the intersection of multilinguality and the factual knowledge included in LMs by creating a multilingual and multi-token benchmark X-FACTR, and performing experiments comparing and contrasting across languages and LMs. The results demonstrate the difficulty of this task, and that knowledge contained in LMs varies across languages. Future directions include other pre-training or fine-tuning methods to improve retrieval performance and methods that encourage the LM to predict entities of the right types.

A Benchmark Details

Tab. 5 shows the detailed number of facts in each language in our X-FACTR benchmark. Fig. 6 demonstrates the ratio of facts with respect to the number of tokens of the object in different languages, where high-resource languages (e.g., English, French, Dutch, and Spanish) have more portion of single-token facts than low-resource languages.

B Benchmark Prompt Quality

The prompts generated in different languages may not be perfectly natural. This could be due to awkwardness of attempting to express relational phrases that were originally devised for English in languages where the semantic distinctions of the underlying words may differ, or due to our errors in our automated approach to grammatical attribute inference and subsequent inflection. To this end, we evaluated our prompts on a sample of languages, providing native speakers with 10 sentences per prompt with the missing slots filled by our inflection models. Our approach produces sentences that are annotated as correct 97.9% of the cases in Spanish, 90.5% in Yoruba, 86.7% in Greek, 82.3% in Marathi, and 81.9% in Russian.

We present an analysis of the annotations on the erroneous prompts in Table 6. The error types differ drastically across languages. Russian and Marathi have comparatively large percentages of inflection-related errors, but for different reasons: the prediction of non-human entity grammatical gender in Russian is difficult and this results in mistakes in the inflection. In Marathi, this issue is also exacerbated by the inflection model, which is of slightly lower quality due to the scarcity of training data availability.

Despite these two outliers, we consider the rest of our prompts to be of high quality. Even if small inflection or grammatical gender assignment mistakes occur (e.g. in Greek) this should not render the prompt unintelligible to native speakers – the burden is on the model to be robust to such slight variations, just as humans are. We point out that the prompts can be awkward or incorrect for some senses captured by the relation, an issue unrelated to our gender heuristics or automatic inflection. This issue, though, is also present in the LAMA English prompts (Petroni et al., 2019; Jiang et al., 2020) and is the result of the original Wikidata annotation.

C Multi-Token Decoding

We outline here the exact concrete formulation of our multi-token decoding algorithms. Given a sentence with multiple mask tokens, e.g., Eq. 2, we can either generate outputs in parallel independently or one at a time conditioned on the previously generated tokens. These methods are similar to the prediction problems that BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019b) perform in their pre-training stages respectively. We define $\boldsymbol{c} \in \mathbb{R}^n$ as the confidence of each prediction, with details varying by prediction method.

C.1 Initial Prediction and Refinement

Independent For independent initial prediction, the mask tokens are all predicted in parallel:

$$\hat{y}_k = \operatorname*{argmax}_{y_k} p(y_k|\boldsymbol{s}_{i:j}), c_k = p(\hat{y}_k|\boldsymbol{s}_{i:j}),$$
$$\forall k \in \{i, ..., j\}.$$

We also consider two autoregressive methods for initial prediction or refinement.

Order-based Mask tokens are predicted from left to right, conditioned on previously generated tokens in each step:

$$\hat{y}_i = \operatorname*{argmax}_{y_i} p(y_i|\boldsymbol{s}_{i:j}), c_i = p(\hat{y}_i|\boldsymbol{s}_{i:j}).$$

In the refinement stage, we modify the predicted tokens from left to right by replacing the token with a ⟨mask⟩ and re-predicting it:

$$\hat{y}_i = \operatorname*{argmax}_{y_i} p(y_i|\hat{\boldsymbol{s}}_{i:j} \setminus i), c_i = p(\hat{y}_i|\hat{\boldsymbol{s}}_{i:j} \setminus i),$$

where $\boldsymbol{s} \setminus i$ means that the i-th token in $\boldsymbol{s}$ is replaced with ⟨mask⟩. Convergence is reached when there are no changes in a left-to-right scan.

Confidence-based Among all the predictions for masked positions, we choose the one with the highest confidence (i.e., the highest probability), so the actual order of predictions can be arbitrary, as shown in Fig. 2:

$$\hat{y}_k = \operatorname*{argmax}_{i \le k \le j, y_k} p(y_k|\boldsymbol{s}_{i:j}), c_k = p(\hat{y}_k|\boldsymbol{s}_{i:j}).$$

In the refinement stage, we choose from all predicted tokens the one with the lowest confidence (i.e., the lowest probability) and re-predict it (Ghazvininejad et al., 2019):

$$\hat{y}_k = \operatorname*{argmax}_{y_k} p(y_k|\hat{\boldsymbol{s}}_{i:j} \setminus k), c_k = p(\hat{y}_k|\hat{\boldsymbol{s}}_{i:j} \setminus k),$$
$$k = \operatorname*{argmin}_{i \le k \le j} c_k.$$

Convergence is reached when the re-predicted token is the same as the original token.

Marathi	82.3	15.1	–	0.2	0	4
Russian	81.9	16.1*	–	–	18.1*	6.7
Yoruba	90.5	–	–	–	4.1	0

Table 6: Error analysis on the prompts after instantiating with actual examples. We note that the error categories are not mutually exclusive. *: The Russian inflection percentage includes gender and number errors, unlike the other languages; the Russian annotator also marked all erroneous sentences as “awkward", skewing the results.

C.2 Additional Decoding Components

Length Normalization Since the sum used in § 4.2 might favor short predictions, we consider normalizing it by the number of the mask tokens:

$$v(j-i+1)=\frac{1}{j-i+1}\sum_{k=i}^{j}\log c_k,$$

Confidence Re-computation Note that the confidence of each predicted token $\boldsymbol{c}$ in previous equations is the probability when the token is predicted. However, the probability will become stale once the surrounding tokens change because of the bidirectional conditional distributions, and this is also noted in (Ghazvininejad et al., 2019). To make the confidence up-to-date, given the prompt in Eq. 2, when a new token is predicted (in the initial stage) or a token is modified (in the refinement stage), we re-compute c_i to c_j. This makes the time complexity quadratic to the number of mask tokens, because every time we make a modification, we have to re-compute the confidence values of all predictions. As a result, the final confidence becomes:

$$c_k = p(\hat{y}_k|\hat{\boldsymbol{s}}_{i:j}\setminus k),$$

where $\hat{\boldsymbol{s}}_{i:j} = x_1, ..., \hat{y}_i, ..., \hat{y}_j, ..., x_n$ contains the final predictions.

Beam Search All of the previous methods use the most plausible prediction at each masked position. We also consider performing beam search that keeps track of the most plausible B predictions. Our beam search algorithm is very similar to the case of conventional left-to-right decoding, except that the decoding order might be arbitrary if we use confidence-based initial or refinement prediction methods. As a result, extending different samples in the beam might lead to the same results so we need an additional deduplication step. The time complexity with all the above components is $\mathcal{O}(M^2BT)$, where M is the maximal number of mask tokens, and T is the maximal number of iteration. Alg. 1 outlines the overall multi-token decoding algorithm. The confidence-based decoding method takes 20 minutes to 2 hours on a Nvidia Geforce RTX 2080 Ti GPU depending on the number of facts of each language.

Algorithm 1: Multi-token decoding.

```
Result: The final sentence $\hat{s}$.
max number of mask tokens $M$, beam size $B$, max
  number of iteration $T$, an initial sentence $s^{(0)}$;
for number of mask tokens $m = 1, ..., M$ do
    $s_m^{(0)} \leftarrow$ insert $m$ $\langle$mask$\rangle$ tokens in $s^{(0)}$;
    $\mathbf{S} \leftarrow \{s_m^{(0)}\}$;
    for iteration $t = 1, ..., T$ do
        $\mathbf{S}' \leftarrow \phi$;
        for each sentence $s_m^{(t-1)} \in \mathbf{S}$ do
            $\{s_m^{(t,b)}\}_{b=1}^{B} \leftarrow$ top $B$ predictions after
              an initial or refinement step;
            $\mathbf{S}' \leftarrow \mathbf{S}' \cup \{s_m^{(t,b)}\}_{b=1}^{B}$
        end
        $\mathbf{S} \leftarrow$ deduplicate and get the top $B$ from $\mathbf{S}'$;
    end
end
$\hat{s} \leftarrow$ top one from $\mathbf{S}$;
```

D Details of Pre-trained LMs

LMs examined in this paper share similar architecture and pre-training setting as BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019), but are trained on different corpora. We provide the shortcut name of each LM in the HuggingFace's Transformer library (https://huggingface.co/transformers/pretrained_models.html) and their training corpora in Tab. 8, from which you can find more information.

E Detailed Experimental Results

Detailed performance across LMs and languages and error cases in Spanish and Greek are shown in Tab. 10 and Tab. 9 respectively.

Abstract

Cross-lingual document alignment aims to identify pairs of documents in two distinct languages that are of comparable content or translations of each other. In this paper, we exploit the signals embedded in URLs to label web documents at scale with an average precision of 94.5% across different language pairs. We mine sixty-eight snapshots of the Common Crawl corpus and identify web document pairs that are translations of each other. We release a new web dataset consisting of over 392 million URL pairs from Common Crawl covering documents in 8144 language pairs of which 137 pairs include English. In addition to curating this massive dataset, we introduce baseline methods that leverage cross-lingual representations to identify aligned documents based on their textual content. Finally, we demonstrate the value of this parallel documents dataset through a downstream task of mining parallel sentences and measuring the quality of machine translations from models trained on this mined data. Our objective in releasing this dataset is to foster new research in cross-lingual NLP across a variety of low, medium, and high-resource languages.

1 Introduction

Cross-lingual document alignment aims to pair documents such that they are translations or near translations of each other. There are a variety of tasks in natural language processing that consume such parallel cross-lingual data. Traditionally, machine translation approaches have leveraged parallel sentences as training data for use with sequence-to-sequence models. Other tasks include cross-lingual information retrieval and cross-lingual document classification. Additionally, cross-lingual data facilitates training cross-lingual representations such as multilingual BERT (Devlin et al., 2019) and XLM (Lample and Conneau, 2019) which are used in many NLP tasks. The availability of high-quality datasets is necessary to both train and evaluate models across these many tasks.

While it is possible to manually label aligned documents across languages, the process is costly and time consuming due to the quadratic search space for document pairs. Additionally, for low-resource languages, identifying these cross-lingual document pairs is more difficult due to their relative scarcity. Furthermore, lack of access to qualified human annotators makes it necessary to have additional quality control in low-resource scenarios (Guzmán et al., 2019).

In this paper, we investigate whether we can rely on weak supervision to generate labels for document pairs. In particular, we focus on the weak signals embedded in the URLs of web documents, that can be used to identify the different translations of a single document across many languages. We preprocess, filter, and apply a set of high-precision hand-crafted rules to automatically sift through a massive collection of 169 billion web documents and identify over a 392 million cross-lingual parallel documents in 8144 language pairs. Of these aligned documents, 292 million are non-English document pairs, and 100 million include English. We evaluate the quality of our automatic-annotation setup by running a manual human evaluation on a diverse sample of positively-labeled documents across six language pairs.

We also introduce a simple baseline that effectively aligns cross-lingual document pairs using solely textual content and in the presence of detractor documents which may not have any parallel counterpart.

Finally, we demonstrate the utility of our parallel corpus by demonstrating how these parallel documents can be mined for training data for a

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5960–5969,
November 16–20, 2020.

downstream machine translation task.

We release the dataset consisting of pairs of translated documents represented by URLs extracted from a massive collection web crawls. We hope that the size, diversity, and quality of this dataset spurs its use not only as a benchmark for document alignment, but also as a parallel corpus for mining parallel sentences and as supervision for a variety of cross-lingual tasks.

2 Related Works

The concept of crawling and mining the web to identify sources of parallel data has been previously explored (Resnik, 1999). A large body of this work has focused on identifying parallel text from multilingual data obtained from a single source: for example the United Nations General Assembly Resolutions (Rafalovitch et al., 2009; Ziemski et al., 2016) or European Parliament parallel corpus (Koehn, 2005). These parallel corpora were curated from specific, homogeneous sources by examining the content and deriving domain-specific rules for aligning documents.

Other approaches have identified parallel documents in unstructured web corpora by relying on metadata (Nie et al., 1999; Espla-Gomis and Forcada, 2010). Some of these methods have focused on publication date and other temporal heuristics to aid in identifying parallel documents (Munteanu and Marcu, 2005, 2006; Udupa et al., 2009; Do et al., 2009; Abdul-Rauf and Schwenk, 2009). However, temporal features can be sparse, noisy, and unreliable. A different class of alignment methods rely on document structure (Resnik and Smith, 2003; Chen and Nie, 2000).

In the WMT-2016 bilingual document alignment shared task (Buck and Koehn, 2016a), many techniques applied retrieval and matching on translated 5-grams (Dara and Lin, 2016) to query, retrieve, and align documents. Similar methods for generating candidates by retrieving matches based on the least frequent bi-lingual 5-grams have been proposed (Gomes and Lopes, 2016) with the insight that rare snippets are more informative. Both of these candidates rely on high-quality translation systems to translate either the source or the target. Such models may not exist, especially for low-resource language directions. The application of alignment to a variety of languages was not explored in WMT-2016 which only considered English to French document alignment – a high-resource direction.

Recently, the use of neural embedding methods has been explored for bilingual alignment of text at the sentence and document level. Guo et al. (2019) propose using hierarchical document embeddings, constructed from sentence embeddings, for bilingual document alignment.

3 Dataset Creation and Description

The Common Crawl corpus is a publicly available crawl of the web. With a new snapshot uploaded each month, and over 2 billion pages released in each snapshot, this data is a vast resource with content across a large number of domains and languages. Previous works have leveraged the data from Common Crawl for mining ngram counts to perform language modeling (Buck et al., 2014). Other works (Smith et al., 2013) have mined Common Crawl for bitexts for machine translation. However, this mining was performed on a small scale. For our dataset, we use 68 snapshots published from 2013 to 2020 which is vastly larger than previous works.

3.1 Preprocessing

The first step in preprocessing the data is deduplication. While investigating combining many Common Crawl snapshots, we found duplicate URLs both within an individual snapshot and almost always across snapshots. As our data curation method relies on unique URLs for each web document, we apply a heuristic to ensure each URL appears once within the final cleaned data. The first step is to normalize each URL; we perform this by simply removing the protocol and host name (e.g., `https://www.aaa.com` → `aaa.com`). Upon normalization, for each URL that appears more than once, we select the instance that possesses the longest document content. This heuristic assumes that occasionally, content is (1) deleted and gets shorter or (2) is amended and gets longer. In this case, it is preferable to operate on the larger content. Starting from 68 Common Crawl snapshots with a raw document count of 169.4 billion documents, upon deduplication, the resultant corpus is approximately 29.6 billion web documents from 107.8 million distinct web domains – a 83% reduction from the raw corpus.

3.2 Language ID & URL Matching

The next step in the pipeline is to tag each document with the dominant language identifier. We utilize a lightweight text classifier such as FastText (Joulin et al., 2017) that has been trained to detect a variety of languages.

To identify pairs of cross-lingual documents, we apply a high-precision, low recall heuristic to assess whether two URLs represent web pages that are translations of each other. This heuristic presumes that two URLs, with high probability, refer to pages that are translations of each other if both can be transformed into the same string after stripping language identifiers. To improve recall, we allow matches where only one of the pair of URLs contain a language identifier e.g., `https://statmt.org` would be a match to `https://fr-fr.statmt.org`. We further ensure that these matches are high-precision by verifying that the language identifier stripped from the URL reflects the language of the web document as predicted by the language identifier; otherwise it is discarded.

Source URL	**Target URL**
eng.`aaa.com`	`aaa.com`
`aaa.com/`**en-gb**`/b`	`aaa.com/`**zh-cn**`/b`
`aaa.com/`**English**`/b`	`aaa.com/`**Yoruba**`/b`
`aaa.com/b/`**en**	`aaa.com/b/`**vi**
`aaa.com/b/`	**thai.**`aaa.com/b/`
`aaa.com/b`**&lang=english**	`aaa.com/b`**&lang=arabic**
`aaa.com/b`**?lang=en**	`aaa.com/b`**?lang=fr**
`aaa.com/b`	`aaa.com/b`**?lang=1**

Table 1: URL matching via language identifiers.

Table 1 shows a few examples of pairs of aligned URLs. Alignment is performed by normalizing each URL by stripping its present language identifiers. Extra care is taken to ensure relevant indicators such as */*, *&*, and *?* are stripped as well to ensure proper alignment between URLs. For reproducibility, we publish an explicit list of patterns used along with the code implementing the pattern matching in the repository alongside the dataset.

Given these rules and restrictions, we mined over 392 million aligned documents (100M with English and 292M without English) across 68 Common Crawl snapshots. We assess the efficacy of this rule-based alignment in the next section.

We select a small subset of the original 68 Common Crawl snapshots to use for evaluating baseline document alignment methods. These 121K documents contain English and non-English documents from 450 web domains. Of these documents, 17.5K pairs are aligned as defined in our URL-aligned dataset. We release this test set as a tractable collection of documents on which to benchmark different alignment methods.

4 Dataset Evaluation

In this section, we analyze the quality of our cross-lingual URL-aligned dataset. We assesses the quality by measuring the precision of a representative sample of the URL-aligned data to human-annotated alignment judgments.

4.1 Dataset Quality Evaluation

To assess the quality of the cross-lingual document pairs obtained by our method, we recruit human annotators to evaluate the alignments and provide an assessment of whether the documents in the pair are total or partial translations of each other. To perform the evaluation, we first selected six languages from various language families, scripts, and levels of resource availability. For each language, we randomly identified 30 pairs of URLs from different web domains aligned into English for a total of 180 pairs. To gather pairs from a diverse set of websites, each URL pair is selected from a distinct web domain.

Then, we tasked twelve human annotators (bilingual or trilingual) to annotate URL pairs. These annotators are fluent in the pairs of languages being assessed and rate the alignment by loading the two web-pages corresponding to each URL in a pair side by side and assessing whether or not the content rendered is both comparable *and* in the correctly tagged language. Each URL pair was evaluated by three human annotators to add a level of redundancy and measure annotator agreement. Note that the evaluation was performed in early November 2019, therefore for some of the pairs in the set, the document content had changed from the time when the Common Crawl snapshot was generated.

In Table 2, we report the precision of our method to generate URL-aligned documents. As individual raters may have differing opinions on what constitutes a cross-lingual comparable document, we report results according to the majority vote. In addition, we report the inter-rating agreement among annotators as measured by the Krip-

	Language	$\mathbf{P}_{maj}$	$\mathbf{K}\boldsymbol{\alpha}$	$\mathbf{P}_{adj}$
High	German	90.0	0.74	96.7
	Chinese	86.7	0.68	93.3
Mid	Arabic	83.3	0.72	90.0
	Romanian	76.7	0.50	96.7
Low	Estonian	83.3	0.68	90.0
	Burmese	86.7	0.88	100.0
	Avg	84.4	0.70	94.5

Table 2: Human evaluation of documents of different languages aligned to English. Languages are classified as high, medium or low resource based on the amount of mined documents. We report the majority-vote precision $\mathbf{P}_{maj}$ and the precision after accounting for experimental error $\mathbf{P}_{adj}$. Additionally, we report $\mathbf{K}\boldsymbol{\alpha}$, a measure of inter-rater agreement.

pendorff Alpha (Krippendorff, 2011) of the annotations. After observing annotator comments and performing a round of error analysis on the pairs identified as misaligned, we identified the following reasons: (1) In 40% of the cases, the content of the rendered web-page has changed since the Common Crawl snapshot was generated or the URL redirects the user to a different page, while the original Common Crawl is a parallel document; (2) In 20% of cases, the content in one of the parallel documents appears to be much shorter than the document in the original (dominant) language but the message is the same, which many annotators didn't consider the document pairs as translations of each other; (3) In 10% of cases the majority of dynamic content within a document pair appears to be in the same language and only boilerplate text such as columns and title are translations; and the remaining 30% are truly non-comparable documents due to a myriad of different reasons. To alleviate the issues introduced by (1) due to experimental setup (i.e. using a freshly rendered web-page) and (2) due to guidelines issues (i.e. partial translations), we sent those cases for an additional round of annotation. The resulting *adjusted* precision after the second round is observed as P_{adj}.

Overall, we observe that the URL pairs in Common Crawl appear to adhere to human-standards of comparability with a majority of measured directions achieving precision of over 90%.

5 Document Alignment Experiments

In Section 4, we verify the quality of the URL-aligned dataset through human-evaluation. In this section, we treat the URL-aligned dataset as a high-precision, low-recall dataset and evaluate baselines that score document pairs based on content rather than URL information. The scored document pairs are then aligned via a greedy bipartite matching algorithm. The resulting alignments are evaluated on a subset of the URL-aligned dataset which is treated as ground truth.

5.1 Problem Definition

Given a set of source documents, D_s and a set of target documents D_t, cross-lingual document alignment aims to find the largest set of pairs of documents from source to target (d_s, d_t) where $d_s \in D_s$ and $d_t \in D_t$ such that each source document and target document can only be used in at most a single pair.

To find the best possible mapping between D_s and D_t we require two components: 1) a similarity function $\phi(d_s, d_t)$ which is used to score a set of candidate documents according to their relatedness; and 2) an alignment or matching algorithm which uses the scores for each of the pairs in $D_s \times D_t$ to produce an alignment of size $min(|D_s|, |D_t|)$ representing the best mapping according to $\phi(d_s, d_t)$.

In the remainder of this section, we introduce our proposed baseline document pair similarity functions and a simple matching algorithm that aligns source and target documents.

5.2 Embedding-Based Document Similarity

To guide the alignment algorithm, a notion of cross-lingual document similarity is necessary. This score should capture the fact that two documents are *semantically* similar despite having some or all of their content in different languages. We describe three simple language-agnostic document embedding methods. These embeddings leverage LASER[1] (Artetxe and Schwenk, 2019), a multilingual sentence representation that uses byte-pair encoding to share the same vocabulary among all languages and trained on parallel sentences pulled from Europarl, United Nations, OpenSubtitles2018, Global Voices, Tanzil and Tatoeba corpus, covering 93 languages.

Direct Embedding The first baseline, Direct Embedding (DE) uses a standard cross-lingual encoder to directly embed each document. Each document d has its dense vector representation

---

[1] `https://github.com/facebookresearch/LASER`

$\mathbf{v}_d$ computed by applying the open-source cross-lingual LASER encoder to its *full textual content*.

Sentence Average Embedding The second baseline, sentence average (SA), performs document embedding by first decomposing each document into sentences, embedding each sentence, then combining these sentence representations. Given a document d, we segment it into a list of sentences $\{s_i\}_{i=1}^{n}$. This time, the LASER encoder is used to encode each sentence s_i into a dense vector $\mathbf{v}_{s_i}$. After embedding each sentence in a document, document embedding is performed by averaging the sentence vectors into a document vector $\mathbf{v}_d$ as follows:

$$\mathbf{v}_d = \frac{1}{n}\sum_{i=1}^{n}\mathbf{v}_{s_i} \tag{1}$$

Weighted Average For the final baseline, we extend the simple sentence averaging to incorporate importance weights for each sentence. To compute this weighted average (WA), we once again embed sentences, however, each sentence's embedding vector is scaled by an importance weight before being averaged to construct the document vector $\mathbf{v}_d$ as follows:

$$\mathbf{v}_d = \frac{1}{n}\sum_{i=1}^{n}\mathbf{w}_{s_i} \times \mathbf{v}_{s_i} \tag{2}$$

We investigate three potential weighting schemes that draw inspiration from tf-idf (Ramos et al., 2003). This weighting scheme is reminiscent of the use of tf-idf to determine word relevance, but instead sentence length and inverse document frequency of a sentence within a web-domain is used. In our experiments we compute w_i for sentence s_i in document d in these three ways.

For the first weighting scheme, we posit that longer sentences should be assigned larger weighting than shorter sentences. To capture this, we weight each sentence by the number of tokens in the sentence relative to the total number of tokens in the entire document. We compute this sentence length (SL) weighting scheme as follows:

$$SL_{s_i} = \frac{|s_i|}{\sum\limits_{s \in d} count(s) \times |s|} \tag{3}$$

Note that this sentence-length weighting is analogous to term-frequency in tf-idf, which is used to assess the importance of a term within a document.

The second insight we investigate is that sentences and text segments that are more frequent in a web-domain are likely boilerplate or less informative segments and should be down-weighted. As such we compute inverse document frequency for each sentence as an alternative weighting scheme. For specific webdomain D we compute IDF as follows:

$$IDF_{s_i} = \log\frac{N+1}{1+|\{d \in D : s \in d\}|} \tag{4}$$

where N is the total number of web-documents in the web domain D, and $|\{d \in D : s \in d\}|$ is the number of documents where the sentence s occurs.

Finally, similarly to combining term-frequency and inverse document frequency in tf-idf, we combine the two sentence-weighting schemes into a third that captures both insights as follows:

$$SLIDF_{s_i} = SL_{s_i} \times IDF_{s_i} \tag{5}$$

Scoring Using the dense document representations for each document from the source and target sets, the next step is to score pairs to evaluate how semantically similar documents are. Given two documents a and b, we compute their semantic similarity using a cosine similarity score:

$$sim(a,b) = \frac{\mathbf{v}_a \cdot \mathbf{v}_b}{||\mathbf{v}_a||\ ||\mathbf{v}_b||} \tag{6}$$

5.3 Competitive Matching Alignment

Using the baseline scoring function, we score all document pairs in the same web domain that belong to the source and target languages respectively. As such, for any given domain, each document in the source document set, D_s is paired with each document in the target set, D_t, yielding $D_s \times D_t$ scored pairs – a fully connected bipartite graph. Just like in (Buck and Koehn, 2016b), the expected output assumes that each page in the non-dominant language has a translated or comparable counterpart. This yields a $min(|D_s|, |D_t|)$ expected number of aligned pairs.

While an optimal matching maximizing scoring can be solved using the Hungarian algorithm (Munkres, 1957), the complexity of this algorithm is $\mathcal{O}(max(|D_s||D_t|)^3)$ which is intractable to even moderately sized web domains. As such, similar to the work in (Buck and Koehn, 2016b), a one-to-one matching between English

Algorithm 1: Competitive Matching

```
Input: $P = \{(d_s, d_t) | d_s \in D_s, d_t \in D_t\}$
Output: $P' = \{(d_{s,i}, d_{t,i}), ...\} \subset P$
$scored \leftarrow \{(p, score(p))$ for $p \in P\}$
$sorted \leftarrow sort(scored)$ in descending order
aligned $\leftarrow \varnothing$
$S_s \leftarrow \varnothing$
$S_t \leftarrow \varnothing$
for $d_s, d_t \in sorted$ do
    if $d_s \notin S_s \wedge d_t \notin S_t$
        $aligned \leftarrow aligned \cup \{(d_s, d_t)\}$
    $S_s \leftarrow S_s \cup d_s$
    $S_t \leftarrow S_t \cup d_t$
end
return aligned
```

and non-English documents is enforced by applying, competitive matching, a greedy bipartite matching algorithm.

In Algorithm 1, each candidate document pair is scored using the document similarity scoring function. These candidates are then sorted in order of most similar to least similar using their numerical score. The algorithm then iteratively chooses a document pair with the highest score as long as the d_s and d_t of each pair have not been used in a previous (higher scoring) pair. The algorithm terminates when $min(|D_s|, |D_t|)$ pairs have been selected. Unlike the Hungarian algorithm, the runtime complexity is a more tractable $\mathcal{O}(|D_s||D_t| \times \log(|D_s||D_t|))$ which is dominated by the cost of sorting all candidate pairs.

5.4 Baseline Results

We evaluate the baseline scoring by aligning the documents from a subset of the 68 Common Crawl snapshots. We score document pairs within the same webdomain using the DE, SA, and WA embedding methods respectively and computing cosine similarity between their representations. For the alignment, we report the performance for each embedding method after applying our competitive matching alignment algorithm as described in Algorithm 1.

Recall (i.e. what percentage of the aligned pages in the test set are found) is computed on a test-set consisting of pairs from the URL-aligned documents, which we verified have high-precision and we treat as the ground-truth test set.

We show the alignment results in Table 3. Comparing DE which directly applies LASER to the entirety of the document content, we see that performance is significantly worse than SA. We suspect this may be the case for two reasons (1) the LSTM-based sentence encoders may suffer at representing the semantic meaning of long documents as the model is originally trained on sentences (2) there may be noisy boiler plate content at the beginning of each web document that is less useful semantically but dominates the representation. Averaging improves the document representation by giving each section of the document equivalent contribution to the final document representation.

When we investigate methods to assign importance weighting to different portions of the document when constructing the document representation, we confirm that importance-weighting segments improves document alignment recall. As seen in Table 3 for SL, weighting longer sentences proportionally more than shorter sentences almost universally outperforms SA; on average weighting by SL improves alignment recall by 17%, 39%, and 10% over SA for low, mid, and high-resource pairs. Similarly down-weighting sentences that occur frequently in the web-domain improves performance by 7%, 39%, and 15% over SA. However combining both weighting schemes (SLIDF) outperforms both yielding a 28%, 57%, and 20% improvement.

Additionally, we observe that as the resource availability increases, the baselines perform better. This may be due to the fact that the LASER embedding models were trained with parallel data and more high-resource parallel sentences were used for training. Finally, it appears that across low, mid, and high-resource directions, European languages appear to be consistently easier to align than non-European languages. For example, Albanian, Serbian, Bosnian, and Belarusian were all aligned with over 0.50 recall despite being low-resource. This may be a by-product of the shared semantic subword vocabulary used by LASER improving performance for low-resource European languages due to their linguistic similarity with the many high-resource European languages.

6 Case Study: MT as an Application

In the Section 4 we did a manual evaluation to gauge the quality of our high-precision alignment method. However, the study is small and does not shed light on the quality of the full dataset.

Therefore, to assess the quality of the aligned document corpus, we propose a downstream task that leverages the aligned document data as a

(c) Low-resource directions.

Table 3: Recall from Common Crawl documents aligned using the baseline content-based alignment methods.

source of supervision for a massively multilingual machine translation task. Our intuition is as follows: cross-lingual document pairs can be used to extract translations that in turn can be used for downstream training of sequence-to-sequence translation systems. Given a set of parallel documents, our expectation is that any reasonable mining algorithm would be able to extract high-quality translations, while the opposite is non-parallel documents. While this is not a standard MT experiment, using MT for downstream evaluation has previously been used to evaluate the quality of sentence filtering and mining approaches. For instance, in the WMT Parallel Corpus Filtering tasks (Koehn et al., 2018, 2019) the downstream performance on a translation task is used as a proxy to determine the quality of a similarity (or filtering) function.

Here, we use MT to evaluate the quality of the mined sentences, and compare it to other independently mined corpora. Our expectation is that, if successful, our approach should be able to mine parallel sentences that are of comparable quality to recent approaches that leverage Wikipedia (Schwenk et al., 2019) and ParaCrawl[2] (Esplà-Gomis et al., 2019), reliable sources of comparable documents.

Sentence mining The first step is to decompose and mine the aligned document corpus for parallel sentences. For simplicity, we segment each document solely on new lines. Given each document pair's decomposition into sentences, we seek to align sentences within each pair of documents. We then aggregate the parallel sentences across all document pairs to form a parallel sentences dataset suitable for training machine translation models.

We use the open-source LASER toolkit (Schwenk, 2018) with the margin-based filtering criterion to mine sentences, as this method has been shown to accurately align sentences for across a variety of low, mid, and high-resource directions (Schwenk et al., 2019; Chaudhary et al., 2019). We use the extracted bitexts for training our NMT systems.

Experimental setup First the data is processed to induce a 5000 subword vocabulary using SentencePiece (Kudo and Richardson, 2018). The model used is a transformer model from fairseq (Ott et al., 2019) with embeddings shared in the encoder and decoder, 5 encoder and decoder layers with dimensionality 512 are used, encoder and decoder FFN with 2 attention heads each with an embedding dimension of 2048 are used along with encoder and decoder normalization. Dropout of 0.4, attention dropout of 0.2 and relu dropout of 0.2 are applied. The adam optimizer is used to train the model for up to 20 epochs by optimizing a smoothed-cross entropy with 0.2 label smoothing.

We decompose the 100-million parallel documents corresponding to the 137 language pairs that include English and mine over 1B unique parallel sentences after filtering. After training models for each direction, we then evaluate the quality of the learned NMT models on a publicly available data set consisting of transcribed and translated TED talks (Qi et al., 2018). Since the development and

Table 4: BLEU scores of NMT models trained on bitext data mined from various web-sources including Wikipedia, ParaCrawl, and our CCAligned document set evaluated on TED Talk test sets.

test sets were already tokenized, we first detokenize them using the Moses de-tokenizer. We performed additional checks to ensure that the TED test set isn't present in mined data.[3]

In Table 4, we report the BLEU scores from the mined bitexts (CCAligned) from our aligned documents on the TED talk dataset. We include test set BLEU scores to a dataset mined from Wikipedia (WikiMatrix) (Schwenk et al., 2019) using LASER sentence embedding and margin-based sentence alignment as well as a cleaned paracrawl dataset (ParaCrawl v6) for comparison. Experimental conditions including model hyper-parameters between these NMT experiments were held constant making the BLEU scores directly comparable. As seen in the table, parallel sentences mined from CCAligned result in comparable BLEU scores to ParaCrawl v6 while yielding higher BLEU scores than WikiMatrix.

While these results do not indicate superiority of one mining method over another (as there are significant differences in the number of mined sentences and nature of the corpus cleaning steps), they indicate that our mined document pairs are a valuable source of parallel data.

Moreover, the resulting corpus can be seen as a significant expansion to the coverage of Paracrawl. For instance, while the ParaCrawl consists of 23 European language pairs (paired with English), our aligned documents cover 8144 language pairs with 137 language pairs that include English. As such, this dataset has the potential to be mined for many low-resource language pairs not available in ParaCrawl. In addition, this dataset can be considered complementary to ParaCrawl as ParaCrawl incorporates techniques to align documents based on content which are then mined for parallel bitexts. Our aligned documents can be a valuable benchmark for ParaCrawl to leverage as they scale to additional, non-European language pairs.

7 Conclusion & Future Works

In this paper, we apply URL-matching to curate a high-quality cross-lingual documents dataset from the CommonCrawl corpus. Our dataset contains over 392 million document pairs from 8144 language pairs covering 138 distinct languages. We first directly evaluate the quality of the URL-aligned pairs using human annotators. We then introduce and evaluate simple embedding-based baseline techniques for aligning documents based on content. Our results indicate there is further work to be done to improve document alignment, especially for low-resource languages and that intelligent alignment schemes can significantly improve alignment performance across many language directions. Finally, we perform a case-study showing that our URL-aligned documents can be mined for high-quality parallel sentences which can be used to train machine translation models. Given the sheer size of this dataset, this has the potential to provide high-quality training data for many low-resource language pairs.

One natural followup to this work is to develop techniques to better mine parallel sentences from these aligned documents – especially for low-resource language pairs. Additional work could also leverage aligned documents as supervision to learn better cross-lingual document representations. Finally, while the aligned dataset is high-precision, leveraging this dataset for supervision in document alignment can potentially yield a larger, high-recall collection. To spur further work, we release the list of aligned URLs as well as code to generate aligned documents given CommonCrawl snapshots[4].

---

[3] Only a handful of high-frequency, short sentences present in the TED dataset were found in the mined data. Upon manual inspection at the source documents, we concluded that these do not constitute data leakage.

Abstract

We propose Semantic Parser Localizer (SPL), a toolkit that leverages Neural Machine Translation (NMT) systems to localize a semantic parser for a new language. Our methodology is to (1) generate training data automatically in the target language by augmenting machine-translated datasets with local entities scraped from public websites, (2) add a few-shot boost of human-translated sentences and train a novel XLMR-LSTM semantic parser, and (3) test the model on natural utterances curated using human translators.

We assess the effectiveness of our approach by extending the current capabilities of Schema2QA, a system for English Question Answering (QA) on the open web, to 10 new languages for the restaurants and hotels domains. Our models achieve an overall test accuracy ranging between 61% and 69% for the hotels domain and between 64% and 78% for restaurants domain, which compares favorably to 69% and 80% obtained for English parser trained on gold English data and a few examples from validation set. We show our approach outperforms the previous state-of-the-art methodology by more than 30% for hotels and 40% for restaurants with localized ontologies for the subset of languages tested.

Our methodology enables any software developer to add a new language capability to a QA system for a new domain, leveraging machine translation, in less than 24 hours. Our code is released open-source.[1]

1 Introduction

Localization is an important step in software or website development for reaching an international audience in their native language. Localization is usually done through professional services that can translate text strings quickly into a wide variety of languages. As conversational agents are increasingly used as the new interface, how do we localize them to other languages efficiently?

The focus of this paper is on question answering systems that use *semantic parsing*, where natural language is translated into a formal, executable representation (such as SQL). Semantic parsing typically requires a large amount of training data, which must be annotated by an expert familiar with both the natural language of interest and the formal language. The cost of acquiring such a dataset is prohibitively expensive.

For English, previous work has shown it is possible to bootstrap a semantic parser without massive amount of manual annotation, by using a large, hand-curated grammar of natural language (Wang et al., 2015; Xu et al., 2020a). This approach is expensive to replicate for all languages, due to the effort and expertise required to build such a grammar. Hence, we investigate the question: *Can we leverage previous work on English semantic parsers for other languages by using machine translation?* And in particular, can we do so without requiring experts in each language?

The challenge is that a semantic parser localized to a new target language must understand questions using an ontology in the target language. For example, whereas a restaurant guide in New York may answer questions about restaurants near Times Square, the one in Italy should answer questions about restaurants near the "Colosseo" or "Fontana di Trevi" in Rome, in Italian. In addition, the parser must be able to generalize beyond a fixed set of ontology where sentences refer to entities in the target language that are unseen during training.

We propose a methodology that leverages machine translation to localize an English semantic parser to a new target language, where the only labor required is manual translation of a few hundreds of annotated sentences to the target language.

November 16–20, 2020.

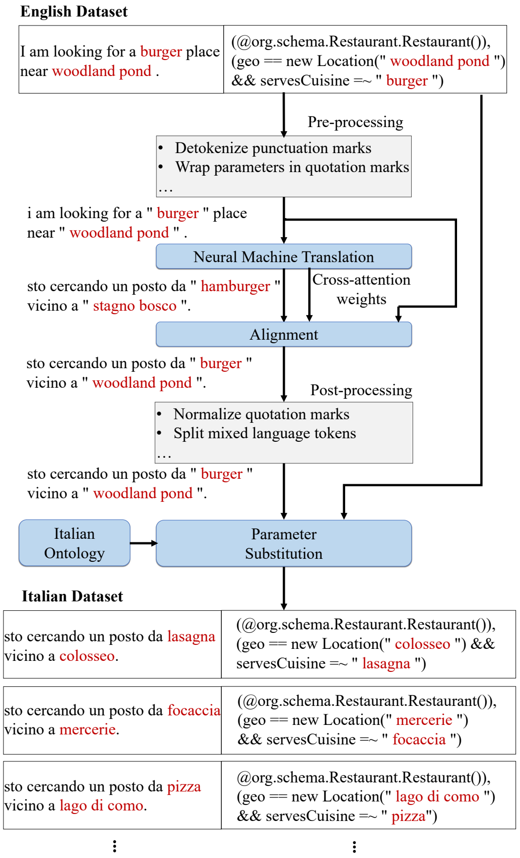

Figure 1: Data generation pipeline used to produce train and validation splits in a new language such as Italian. Given an input sentence in English and its annotation in the formal ThingTalk query language (Xu et al., 2020a), SPL generates multiple examples in the target language with localized entities.

Our approach, shown in Fig. 1, is to convert the English training data into training data in the target language, with all the parameter values in the questions and the logical forms substituted with local entities. Such data trains the parsers to answer questions about local entities. A small sample of the English questions from the evaluation set is translated by native speakers with no technical expertise, as a few-shot boost to the automatic training set. The test data is also manually translated to assess how our model will perform on real examples. We show that this approach can boost the accuracy on the English dataset as well from 64.6% to 71.5% for hotels, and from 68.9% to 81.6% for restaurants.

We apply our approach on the *Restaurants* and *Hotels* datasets introduced by Xu et al. (2020a), which contain complex queries on data scraped from major websites. We demonstrate the efficiency of our methodology by creating neural semantic parsers for 10 languages: Arabic, German, Spanish, Persian, Finnish, Italian, Japanese, Polish, Turkish, Chinese. The models can answer complex questions about hotels and restaurants in the respective languages. An example of a query is shown for each language and domain in Table 1.

Our contributions include the following:

- Semantic Parser Localizer (SPL), a new methodology to localize a semantic parser for any language for which a high-quality neural machine translation (NMT) system is available. To handle an open ontology with entities in the target language, we propose *machine translation with alignment*, which shows the alignment of the translated language to the input language. This enables the substitution of English entities in the translated sentences with localized entities. Only a couple of hundred of sentences need to be translated manually; no manual annotation of sentences is necessary.
- An improved neural semantic parsing model, based on BERT-LSTM (Xu et al., 2020a) but using the XLM-R encoder. Its applicability extends beyond multilingual semantic parsing task, as it can be deployed for any NLP task that can be framed as sequence-to-sequence. Pretrained models are available for download.
- Experimental results of SPL for answering questions on hotels and restaurants in 10 different languages. On average, across the 10 languages, SPL achieves a logical form accuracy of 66.7% for hotels and 71.5% for restaurants, which is comparable to the English parser trained with English synthetic and paraphrased data. Our method outperforms the previous state of the art and two other strong baselines by between 30% and 40%, depending on the language and domain. This result confirms the importance of training with local entities.
- To the best of our knowledge, ours is the first multilingual semantic parsing dataset with localized entities. Our dataset covers 10 linguistically different languages with a wide range of syntax. We hope that releasing our dataset will trigger further work in multilingual semantic parsing.
- SPL has been incorporated into the parser generation toolkit, Schema2QA (Xu et al., 2020a), which generates QA semantic parsers that can answer complex questions of a knowledge base automatically from its schema. With the addition of SPL, developers can easily create multilingual QA agents for new domains cost-effectively.

Language	Country	Examples
		Hotels
English	🇺🇸	I want a hotel near times square that has at least 1000 reviews.
Arabic	🇸🇦	اَنَ أَريد فندق بَالقَرب مِن مسجد الحرَام يحتوي عَلي ١٠٠٠ تعَليق عَلي الأَقل.
German	🇩🇪	Ich möchte ein hotel in der nähe von marienplatz, das mindestens 1000 bewertungen hat.
Spanish	🇪🇸	Busco un hotel cerca de puerto banús que tenga al menos 1000 comentarios.
Farsi	🇮🇷	هتلی در نزدیکی باغ ارم میخواهم که حداقل ۱۰۰۰ نقد داشته باشد.
Finnish	🇫🇮	Haluan paikan helsingin tuomiokirkko läheltä hotellin, jolla on vähintään 1000 arvostelua.
Italian	🇮🇹	Voglio un hotel nei pressi di colosseo che abbia almeno 1000 recensioni.
Japanese	🇯🇵	東京スカイツリー周辺でに1000件以上のレビューがあるホテルを見せて。
Polish	🇵🇱	Potrzebuję hotelu w pobliżu zamek w malborku, który ma co najmniej 1000 ocen.
Turkish	🇹🇷	Kapalı carşı yakınlarında en az 1000 yoruma sahip bir otel istiyorum.
Chinese	🇨🇳	我想在天安门广场附近找一家有至少1000条评论的酒店。
		Restaurants
English	🇺🇸	find me a restaurant that serves burgers and is open at 14:30 .
Arabic	🇸🇦	أَعَثر لي عَلي مطعَم يقدم طعَام الشَاورمَا و يَفتَه بحلول السَاعَت ١٤:٣٠.
German	🇩🇪	Finden sie bitte ein restaurant mit maultaschen essen, das um 14:30 öffnet.
Spanish	🇪🇸	Busque un restaurante que sirva comida paella valenciana y abra a las 14:30.
Farsi	🇮🇷	رستورانی برایم پیدا کن که جوجه کباب داشته باشد و ساعت ۱۴:۳۰ باز باشد.
Finnish	🇫🇮	Etsi minulle ravintola joka tarjoilee karjalanpiirakka ruokaa ja joka aukeaa kello 14:30 mennessä.
Italian	🇮🇹	Trovami un ristorante che serve cibo lasagna e apre alle 14:30.
Japanese	🇯🇵	寿司フードを提供し、14:30までに開店するレストランを見つけてください。
Polish	🇵🇱	Znajdź restaurację, w której podaje się kotlet jedzenie i którą otwierają o 14:30.
Turkish	🇹🇷	Bana köfte yemekleri sunan ve 14:30 zamanına kadar açık olan bir restoran bul..
Chinese	🇨🇳	帮我找一家在14:30营业并供应北京烤鸭菜的餐厅。

Table 1: Example of queries that our multilingual QA system can answer in English and 10 other languages.

2 Related Work

Multi-lingual benchmarks Previous work has shown it is possible to ask non-experts to annotate large datasets for applications such as natural language inference (Conneau et al., 2018) and machine reading (Clark et al., 2020), which has led to large cross-lingual benchmarks (Hu et al., 2020). Their approach is not suitable for semantic parsing, because it requires experts that know both the formal language and the natural language.

Semantic Parsing Semantic parsing is the task of converting natural language utterances into a formal representation of its meaning. Previous work on semantic parsing is abundant, with work dating back to the 70s (Woods, 1977; Zelle and Mooney, 1996; Kate et al., 2005; Berant et al., 2013). State-of-the-art methods, based on sequence-to-sequence neural networks, require large amounts of manually annotated data (Dong and Lapata, 2016; Jia and Liang, 2016). Various methods have been proposed to eliminate manually annotated data for new domains, using synthesis (Wang et al., 2015; Shah et al., 2018; Campagna et al., 2019; Xu et al., 2020a,b), transfer learning (Zhong et al., 2017; Herzig and Berant, 2018; Yu et al., 2018; Moradshahi et al., 2019), or a combination of both (Rastogi et al., 2019; Campagna et al., 2020). All these works focus mainly on the English language, and have not been applied to other languages.

Cross-lingual Transfer of Semantic Parsing Duong et al. (2017) investigate cross-lingual transferability of knowledge from a source language to the target language by employing cross-lingual word embedding. They evaluate their approach on the English and German splits of NLmaps dataset (Haas and Riezler, 2016) and on a code-switching test set that combines English and German words in the same utterance. However, they found that joint training on English and German training data achieves competitive results compared to training multiple encoders and predicting logical form using a shared decoder. This calls for better training strategies and better use of knowledge the model can potentially learn from the dataset.

The closest work to ours is Bootstrap (Sherborne et al., 2020), which explores using public MT systems to generate training data for other languages. They try different training strategies and find that using a shared encoder and training on target language sentences and unmodified logical forms with English entities yields the best result. Their evaluation is done on the ATIS (Dahl et al., 1994) and Overnight (Wang et al., 2015) datasets, in German and Chinese. These two benchmarks have a very small number of entities. As a result, their method is unsuitable for the open ontology setting, where the semantic parser must detect entities not seen during training. To collect real validation and test utterances, Sherborne et al. (2020) use a three-staged process to collect data from Amazon Mechanical Turkers (AMTs). They ask for three translations each per English source sentence with the hypothesis that this will collect at least one adequate translation. We found this approach to be less cost-effective than using professional translators. Since this process is done for the test data, it is important for the translations to be verified and have high quality.

3 Multi-Lingual Parser Generation

Our goal is to localize an English semantic parser for question answering that operates on an open ontology of localized entities, with no manual annotation and a limited amount of human translation.

3.1 Overview

Our methodology is applicable to any semantic parser for which an English dataset is available, and for which the logical form ensures that the parameters appear exactly in the input sentence. We note that many previous techniques can be used to obtain the initial English dataset in a new domain.

Our methodology consists of the following steps:

1. Generate training data in the target language from the English training data and an ontology of localized entities, as discussed below.
2. Translate evaluation and test data in English to the target language. To ensure that our test set is realistic, so high accuracy is indicative of good performance in practice, we engage professional translators, who are native speakers of the target language. We ask them to provide the most natural written form of each sentence in their language, equivalent to how they would type their queries for a text-based virtual assistant.
3. Train a semantic parser to translate sentences in the target language to the logical form using the generated sentences and a few shot of the manually translated sentences. Our semantic parsing model is described in Section 4.2.

3.2 Training Data with Localized Entities

The overall architecture of our approach is illustrated in Fig. 1, which shows how the English query, “I am looking for a burger place near Woodland Pond” is used to generate Italian training samples looking for “lasagna” in “Via Del Corso”, “focaccia” in “Mercerie”, and “pizza” in “Lago di Como”, with the help of an open ontology of Italian entities. Each of the sentences is annotated with their appropriate entities in the native language. This example illustrates why we have to handle the parameters of the queries carefully. While “burger" is translated into “hamburger", “Woodland Pond”, a place in New York, is translated into “laghetto nel bosco”, which is literally a “pond in the woods”; these entities no longer match the entities in the target logical form. In general, during translation, input tokens can be modified, transliterated, omitted, or get mapped to a new token in the target language. If the semantics of the generated utterance in the target language is changed, the original logical form will no longer be the correct annotation of the utterance.

After translation, we substitute the entities with localized ones, and ensure the parameters in the sentences match those in the logical form. To do so, we add a pair of pre- and post-processing steps to the translation to improve the outcome of the translation with public NMT models, based on error analysis. For example, we found that the presence or absence of punctuation marks affect translation results for Persian and Arabic more than other languages. Furthermore, for languages such as Chinese and Japanese, where there is no white space delimitation between words in the sentence, the quotation marks are sometimes omitted during translation, which makes entity tracking difficult. We post-process the sentence using regular expressions to split English parameters from Chinese tokens. For Marian models, we also wrap placeholders for numbers, time, date in quotation marks to ensure they are not translated either.

3.3 Validation and Test Data

As discussed above, a small amount of annotated data in the target language is translated by professional translators. We create sentences with localized entities by showing to the translators English sentences where parameters are replaced with placeholders (numbers, dates) or wrapped in quotation marks (restaurant and hotel names, cuisine types, etc.). We ask the translators to keep the parameters intact and not translate them. The parameters are substituted later with local values in the target language.

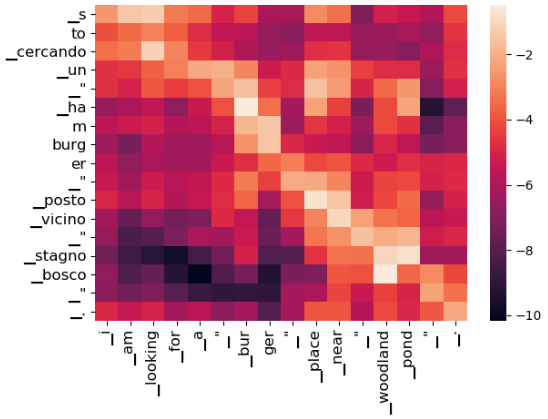

Figure 2: Cross-attention weights are shown for word-pieces in the source (X axis) and target (Y axis) language. Lighter colors correspond to higher weights. The translation is different than the one in Figure 1 as we are using Marian instead of GT.

4 Model Description

This section first describes our translation models, then the neural semantic parser we train with the generated data.

4.1 Machine Translation Models

To translate our training data, we have experimented with both pretrained Marian models (Junczys-Dowmunt et al., 2018) and the Google public NMT system (Wu et al., 2016) (through the Google Translate API). Marian models have an encoder-decoder architecture similar to BART (Lewis et al., 2019) and are available in more than 500 languages and thousands of language pairs. Although Google NMT has generally higher quality than Marian models for different languages pairs and is widely adopted by different systems, Marian is preferred for two reasons. First, Marian provides flexibility, as translation is controlled and can be tuned to generate different translations for the same sentence. Second, the cost of using Google NMT to extend our work to hundreds of languages is prohibitive.

4.1.1 Marian with Alignment

To find the mapping between entities in the source and the translated language, we need to 1) detect entity spans in the output sentence, 2) align those spans with input sentence spans. We have created an alignment module, which uses the cross attention weights between the encoder and the decoder of the Marian model to align the input and output sentences. These weights show the amount of attention given to each input token when an output token is being generated. Figure 2 shows a heatmap of cross-attention weights for an English sentence and its translation in Italian. The cross-attention score for each decoder token is calculated by doing a multi-head attention (Vaswani et al., 2017) over all encoder tokens. For the example shown in Figure 2, each attention vector corresponds to one column in the heatmap.

To simplify the identification of the spans, we mark each entity in the source sentence with quotation marks, using the information in the logical form. We found empirically that the quotation marks do not change the quality of the translation. When all quotation marks are retained in the translated sentences, the spans are the contiguous tokens between quotation marks in the translated sentence. Each quotation mark in the source is aligned with the quotation mark in the target that has the highest cross-attention score between the two. If some quotations marks are not retained, however, we find the positions in the translated sentence that share the highest cross-attention score with the quotation marks surrounding each entity, to determine its span. Once spans are detected, we override target sentence spans with source sentence spans.

4.1.2 Alignment with Google NMT

As we cannot access the internals of Google NMT, we localize the entities by (1) replacing parameter values in the input sentence and logical form pairs with placeholders, (2) translating the sentences, and (3) replacing the placeholders with localized entities. Substituting with placeholders tends to degrade translation quality because the actual parameters provide a better context for translation.

We experimented with other methods such as 1) using a glossary-based approach where parameters are detected and masked during translation and 2) replacing parameters with values from the target language before translation. Both show poorer translation quality. The former technique degrades sentence quality as masking the entity reduces context information the internal transformer model relies upon to generate target sentences. The second approach creates mixed-language sentences, requiring NMT sentences to perform code-switching. It also makes the sentences look less natural and shifts input distribution away from what public NMTs have been trained on.

4.2 Semantic Parsing Model

The neural semantic parser we train using our translated training data is based on the previously proposed BERT-LSTM architecture (Xu et al., 2020a), which we modify to use the XLM-R pretrained model (Conneau et al., 2019) as the encoder instead. Our model is an encoder-decoder neural network that uses the XLM-R model as an encoder and a LSTM decoder with attention and pointer-generator (See et al., 2017). More details are provided in Appendix A. As in previous work (Xu et al., 2020a), we apply rule-based preprocessing to identify times, dates, phone numbers, etc. All other tokens are lower cases and split into subwords according to the pretrained vocabulary. The same subword preprocessing is applied to entity names that are present in the output logical form.

5 Experiments

We have implemented the full SPL methodology in the form of a tool. Developers can use the SPL tool to create a new dataset and semantic parser for their task. We evaluate our models on the Schema2QA dataset (Xu et al., 2020a), translated to other languages using our tool. We first describe our dataset and then show our tool's accuracy, both without any human-produced training data (zero-shot) and if a small amount of human-created data in the target language is available (few-shot). In our experiments, we measure the *logical form exact match* (em) accuracy, which considers the result to be correct only if the output matches the gold logical form token by token. We additionally measure the *structure match* (sm) accuracy, which measures whether the gold and predicted logical forms are identical, ignoring the parameter values. A large difference between exact and structure accuracy indicates that the parameters are poorly handled. We report results on both validation and test sets. We present the results for both restaurants and hotels domain in this paper.

Our toolkit uses the Genie (Campagna et al., 2019) library for synthesis and data augmentation. Our models were implemented using the Huggingface (Wolf et al., 2019) and GenieNLP[2] libraries.

5.1 Dataset

Using our approach, we have constructed a multilingual dataset based on the previously proposed Schema2QA *Restaurants* and *Hotels* datasets (Xu et al., 2020a). These datasets contain questions over scraped Schema.org web data, expressed using the ThingTalk query language. ThingTalk is a subset of SQL in expressiveness, but it is more tailored to natural language translation. The training sets are constructed using template-based synthesis and crowdsourced paraphrasing, while the validation and test sets are crowdsourced and manually annotated by an expert.

We chose these two datasets as a starting point as they require understanding both complex questions and a large number of entities, many of which are not seen in training. Note that the parameters in the logical forms are *aligned* with those in the input utterance: every open-ontology parameter value must appear exactly in the utterance. Table 2 shows the comparison of our dataset with the Overnight (Wang et al., 2015) and ATIS datasets (Dahl et al., 1994), which previous work has translated to other languages (Sherborne et al., 2020). The Schema2QA dataset is larger, has more linguistic variety, and has significantly more possible values for each property. The hotels domain contains 443 and 528 examples, and the restaurants domain contains 528 and 524 examples in the validation and test splits, respectively.

We scrape Yelp, OpenTable, and TripAdvisor websites for localized ontologies on restaurants, and Hotels.com and TripAdvisor for hotels. To ensure that some entities are unseen in validation and test, each ontology is split into two, for (1) training, and (2) validation and test. The two splits overlap between 40% to 50%, depending on the domain and language. We replace the English parameters in the translated sentences with localized entities.

We have translated the Schema2QA dataset to 10 different languages, chosen to be linguistically diverse. To translate the training set, we use Google NMT for Farsi, Japanese, and Turkish. We use Marian for the other seven languages. Marian BLEU scores for all language pairs are available online[3]. In our initial experiments, we found that some of the models with high reported BLEU scores, such as English to Japanese, do not produce correct translations for our dataset. Thus, we perform the following to verify each model's quality: First, we choose a subset of the English evaluation set and translate it with the corresponding Marian model. The results are then back-translated to English using Google NMT. If the meaning is not preserved for at least 90% of the samples, we use Google

Table 2: Statistical analysis of the training set for Overnight, ATIS, and schema2QA datasets. For overnight, the two domains with the lowest reported accuracies are chosen.

NMT for that language.

We chose a subset of the validation set (75% for hotels and 72% for restaurants) to be professionally translated. We use this data to train our parser in a few-shot setting (Section 5.4.4). The full test sets for both domains are professionally translated.

5.2 BackTranslation: Translate at Test Time

As our first baseline, we train an English semantic parser on the English training set; at test time, the sentence (including its entities) is translated on-the-fly from the target language to English and passed to the semantic parser.

The experimental results are shown in Table 3. The results vary from a minimum of 9.7% for Japanese to a maximum of 34.4% for Turkish. Comparing the results to English, we observe about 30% to 50% drop in exact match accuracy. In general, the closer the language is to English in terms of semantics and syntax, the higher the BLEU score will be using NMT. The large difference between em and sm accuracies is caused by the wrong prediction of parameter values. This is expected since the entities translated to English no longer match with the annotations containing localized entities. Note that the English parser has learned to primarily copy those parameters from the sentence.

5.3 Bootstrap: Train with Translated Data

As proposed by Sherborne et al. (2020), we create a new training set by using NMT to directly translate the English sentences into the target language; the logical forms containing English entities are left unmodified. This data is then used to train a semantic parser. The results are shown in Table 3, in the "Bootstrap" column. Overall, the performance of Bootstrap is comparable to the performance of BackTranslation, ranging from 15% on Farsi restaurants to 29% on Finnish hotels.

In a second experiment, we train a semantic parser on a dataset containing both English and translated sentences. Note that the test set is the same and contains only questions in the target language. Training with a mixture of languages has shown improvements over single language training (Liu et al., 2020; Arivazhagan et al., 2019). This experiment (shown as Bootstrap (+English) in Table 3) achieves between 16% to 31% accuracy outperforming BackTranslation for all 5 languages except for Turkish hotels and Turkish and Finnish restaurants.

Overall, these two experiments show that training with translated data can improve over translation at test time, although not by much. Furthermore, as we cannot identify the original parameters in the translated sentences, we cannot augment the training data with localized entities. This step is much needed for the neural model to generalize beyond the fixed set of values it has seen during training. A neural semantic parser trained with Bootstrap learns to translate (or transliterate) the entity names from the foreign language representation in the sentence to the English representation in the logical form. Hence, it cannot predict the localized entities contained in the test set, which are represented in the target language.

5.4 SPL: Semantic Parser Localizer

There are three key components in SPL methodology: 1) Translation with alignment to ensure parameters are preserved, 2) Training with parameter-augmented machine-translated data, and 3) Boosting accuracy by adding human-translated examples to the training data simulating a few-shot setting. Here we describe the experiments we designed to evaluate each component separately.

5.4.1 Test Time Translation with Alignment

In this experiment, we run BackTranslation (BT) with alignment to understand its effect. We translate sentences from the foreign language to English at test time, but we use the entity aligner described in Section 4.1.1 to copy the localized entities in the foreign language to the translated sentence before

Language	**BT**		**Bootstrap**				**Bootstrap (+English)**			
	Test		**Dev**		**Test**		**Dev**		**Test**	
	em	sm	em	sm	em	sm	em	sm	em	sm
Hotels

Finnish	29.2	46.6	27.8	53.4	29.1	52.5	26.9	51.4	**30.2**	57.2
Japanese	15.7	25.2	20.1	29.4	19.9	27.3	21.0	39.3	**20.5**	39.2
Turkish	**32.0**	49.4	18.5	43.6	17.2	40.9	22.6	62.3	25.6	60.2
Restaurants										
German	26.9	51.9	31.3	62.9	25.8	60.1	30.3	61.0	**27.3**	56.9
Farsi	14.5	40.8	20.1	28.2	15.1	26.2	22.0	34.1	**15.5**	28.1
Finnish	**24.0**	55.0	19.9	51.9	18.9	54.4	22.3	53.8	20.8	53.2
Japanese	9.7	29.8	19.2	22.1	18.3	20.6	22.1	31.6	**18.1**	24.3
Turkish	**34.4**	62.6	29.7	54.2	28.4	44.1	33.5	54.7	28.1	45.6

Table 3: Experiment results for hotels (top rows) and restaurants (bottom rows) domain using Bootstrap and BackTranslation methods as our baseline. em and sm indicate exact and structure match accuracy respectively. We chose 5 representative languages for these experiments. Exact match accuracies for the English Test set are 64.6% for hotels, and 68.9% for restaurants.

feeding it into the English semantic parser. The results, as shown in Table 4, improve by 25% to 40% across all languages compared to naive BT. This highlights the importance of having entities that are aligned in the sentence and the logical form, as that enables the semantic parser to copy entities from the localized ontology for correct prediction. This is evident as the exact accuracy result is close to that of structure accuracy.

5.4.2 Training with Machine Translated Data

In the next experiment, we apply the methodology in Section 3 to the English dataset to create localized training data and train one semantic parser per language. We translate a portion of the validation set using human translators and combine it with the machine-translated validation data. For all the following experiments, the model with the highest em accuracy on this set is chosen and tested on human-translated test data.

As shown in Table 4, the results obtained by this methodology outperforms all the baselines. Specifically, we achieve improvements between 33% to 50% over the previous state-of-the-art result, represented by the Bootstrap approach. The neural model trained on SPL data takes advantage of entity alignment in the utterance and logical form and can copy the entities directly. The exact match accuracy ranges from 53% in Chinese to 62% in Spanish for hotels, and from 41% in Japanese to 68% in Spanish for restaurants. Comparing to the accuracy of 65% and 69% for hotels and restaurants in English, respectively, we see a degradation in performance for languages that are very different from English. Languages close to English, such as Spanish, approach the performance of English.

5.4.3 Adding English Training Data

Similar to Bootstrap (+English), we also experimented with combining the original English training set with the training set generated using SPL approach. Except for some drops (0.3%-4%) in accuracy for Spanish and Turkish restaurants and Finnish and Japanese hotels, we observe about 1% to 10% improvement compared to when English training data is not used. As the parser is exposed to a larger vocabulary and two potentially different grammars at once, it must learn to pay more attention to sentence semantics as opposed to individual tokens. Additionally, the English training data contains human-paraphrased sentences, which are more natural compared to synthetic data, and add variety to the training set.

5.4.4 Adding a Few Human Translation to Training Data

In our final experiment, we add the portion of the validation set translated by humans to the training set generated using SPL. Since the validation size is much smaller than the training size (0.03% for hotels and 0.12% for restaurants), this is similar to a few-shot scenario where a small dataset from the test distribution is used for training.

In Table 5 we have computed BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores between machine-translated and human-translated validation data for hotels. One key takeaway is that machine-translated data has quite a different distribution than human-translated data as none of the BLUE scores are higher than 0.45. Adding a few real examples can shrink this gap and yield higher accuracy on natural sentences.

Language	**BT (+Align.)**		**Zero-Shot SPL**				**Zero-Shot SPL (+English)**				**Few-Shot SPL**

Table 4: Experiment results for hotels (top rows) and restaurants (bottom rows) domain using SPL. em and sm indicate exact and structure match accuracy respectively. Zero-shot and few-shot exact match accuracies for English test set are 64.6% and 71.5% for hotels, and 68.9% and 81.6% for restaurants.

As shown in Table 4, the test results are improved significantly across all the languages for both domains. This shows that a small addition of real training data improves the model performance significantly. The exact match accuracy varies across languages, with a low of 61.4% on Arabic and a high of 69.3% on Turkish for hotels, and a low of 64.3% on Polish and a high of 77.1% on Spanish for restaurants. The multilingual results compare favorably with those for English. We show that a few-shot boost of crowdsourced evaluation data in training can also improve the English semantic parser, raising its accuracy from 65% to 72% for hotels, and from 69% to 82% for restaurants. The few-shot approach is particularly helpful when the training and test data are collected using different methods; this can create a new avenue for further research on multilingual tasks.

We have performed an error analysis on the results generated by the parser. At a high level, we found the biggest challenge is in recognizing entities, in particular, when entities are unseen, and when the type of the entities is ambiguous. We also found translation noise would introduce confusion for implicit concepts such as "here". Translation sometimes introduces or removes these concepts from the sentence. Detailed error analysis is provided in Appendix C.

6 Conclusion

This paper presents SPL, a toolkit and methodology to extend and localize semantic parsers to a new language with higher accuracy, yet at a fraction of the cost compared to previous methods. SPL was incorporated into the Schema2QA toolkit (Xu et al., 2020a) to give it a multilingual capability.

SPL can be used by any developer to extend their QA system's current capabilities to a new language in less than 24 hours, leveraging professional services to translate the validation data and mature public NMT systems. We found our approach to be effective on a recently proposed QA semantic parsing dataset, which is significantly more challenging than other available multilingual datasets in terms of sentence complexity and ontology size.

Our generated datasets are automatically annotated using logical forms containing localized entities; we require no human annotations. Our model outperforms the previous state-of-the-art methodology by between 30% and 40% depending on the domain and the language. Our new datasets and resources are released open-source[4]. Our methodology enables further investigation and creation of new benchmarks to trigger more research on this topic.

A Semantic Parser Model

Our neural semantic parser is based on BERT-LSTM model (Xu et al., 2020a), a previously-proposed model that was found effective on semantic parsing. We have modified the model encoder to use XLM-R instead of BERT or LSTM encoder. XLM-R is a Transfomer-based multilingual model trained on CommonCrawl corpus in 100 different languages. Unlike some XLM (Lample and Conneau, 2019) multilingual models, it can

Language	BLEU score (%)	GLEU score (%)	METEOR score (%)	NIST score (%)	TER score (%)

Table 5: Results for different similarity metrics. The results are shown for the hotels validation set.

detect the language from the input ids without requiring additional language-specific tokens. The decoder is an LSTM decoder with attention and a pointer-generator. At each decoding step, the model decides whether to generate a token or copy one from the input context.

We preprocess the input sentences by lowercasing all tokens except for entity placeholders such as TIME_0, DATE_0, etc. and splitting tokens on white space. The formal code tokens are also split on whitespace, but their casing is preserved. XLM-R uses the sentence piece model to tokenize input words into sub-word pieces. For the decoder, to be able to copy tokens from pretrained XLM-R vocabulary, we perform the same sub-word tokenization of parameter values in the input sentence and in the formal language.

The word-pieces are then numericalized using an embedding matrix and fed into a 12-layer pretrained transformer network which outputs contextual representations of each sub-word. The representations are then aggregated using a pooling layer which calculates the final representation of the input sentence:

$$H = \boldsymbol{W}_{agg}\mathrm{ReLU}(\boldsymbol{W}_E\mathrm{mean}(h^0, h^1, ..., h^N))$$

where H is the final sentence embedding, $\boldsymbol{W}_{agg}$ and $\boldsymbol{W}_E$ are learnable weights, relu$(.)$ is the rectified linear unit function, and mean$(.)$ is the average function.[5]

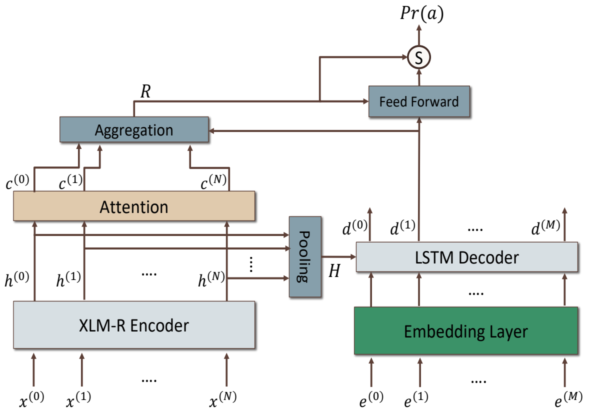

Figure 3: Semantic parser neural model. It has a Seq2Seq architecture with XLM-R encoder and LSTM decoder with attention.

The decoder uses an attention-based pointer-generator to predict the target logical form one token at a time. The tokenized code word-pieces are passed through a randomly initialized embedding layer, which will be learned from scratch. Using pretrained language models instead, did not prove to be useful as none of them are trained on formal languages. Each embedded value is then passed to an LSTM cell. The output is used to calculate the attention scores against each token representation from the encoder (c^t) and produce the final attention context vector (C). The model then produces

---

[5] Bias parameters are omitted for brevity.

two vocabulary distributions: one over the input sentence ($P_c(a^t)$), and one over XLM-R sentence piece model's vocabulary ($P_v(a^t)$). A trainable scalar switch (s) is used to calculate the weighted sum of the two distributions. The final output is the token with the highest probability.

$$\begin{aligned}
&P_c(a^t|C, d^t) = \sum_{a^t=a^{*t}} \text{softmax}(d^t C^\top) \\
&P_v(a^t|C, d^t) = \text{softmax}(\boldsymbol{W}_o C) \\
&P(a^t|C, d^t) = s^t P_c(a^t) + (1 - s^t) P_v(a^t)
\end{aligned}$$

The model is trained autoregressively using teacher forcing, with token-level cross-entropy loss:

$$\mathcal{L} = -\sum_{t=0}^{N} \sum_{a^t \in V} \mathbf{1}[a^t = a^{*t}] \log P(a^t|C, d^t)$$

Here $\mathcal{L}$ indicates the loss value, and $\mathbf{1}[.]$ is the indicator function: it is 1 when the predicted token w matches the gold answer token w^*, and 0 otherwise.

B Implementation Details

Our code implementations are in PyTorch[6] and based on HuggingFace (Wolf et al., 2019). In all of our experiments, we used `xlmr-base` model which is trained on CommonCrawl data in 100 languages with a shared vocabulary size of 250K. The model architecture is similar to BERT and has 12 Transformer Encoder layers with 12 attention heads each and a hidden layer dimension of 768. XLM-R uses sentence-piece model to tokenize the input sentences. We used Adam (Kingma and Ba, 2014) as our optimizer with a learning rate of 1×10^{-4} and used transformer non-linear warm-up schedule (Popel and Bojar, 2018). In all our experiments we used the same value for hidden dimension (768), transformer model dimension (768), the number of transformer heads (12), size of trainable dimensions in decoder embedding matrix (50), and the number of RNN layers for the decoder (1). These parameters were chosen from the best performing model over the English dev set for each domain. Each model has a different number of parameters depending on the language trained on and the number of added vocabulary from the training and validation set. However, this number does not vary much, and the average across languages is about 300M including XLM-R parameters. We batch sentences based on their token count. We set the total number of tokens to be 5K, which would be about 400 examples per batch. Our models were trained on NVIDIA V100 GPU using AWS platform. Single language models were trained for 60K iterations, which takes about 6 hours. For a fair comparison, models trained jointly on English and the target language were trained for 80K iterations.

C Error Analysis

We present an error analysis for 5 languages (Spanish, Persian, Italian, Japanese, and Chinese) for which we have access to native speakers.

- Locations are sometimes parsed incorrectly. In many cases, the model struggles to distinguish an explicit mention of "here" from no mention at all. We suspect this is due to translation noise introducing or omitting a reference to the current location.
- In some examples, the review author's name is being parsed as a location name. The copying mechanism deployed by the neural model decoder relies on the context of the sentence to identify *both* the type and span of the parameter values. Thus if localization is done poorly, the model will not be able to generalize beyond a fixed ontology.
- Occasionally, the parser has difficulty distinguishing between rating value and the number of reviews, especially if the original sentence makes no mention of *starts* or *posts* and instead uses more implicit terms like *top* or *best*.
- In some examples, the input sentence asks for information about "this restaurant" but the program uses the user's home location instead of their current location.
- There are human mistranslations where check-in time has been mislabeled as check-out time. Additionally, sentence ambiguity is exacerbated by the human translation step, for example, between a hotel's official star rating value and the customer's average rating value. In English, this kind of ambiguity is resolved by expert annotation flagging ambiguous sentences.
- Translation noise in some cases, can change the numbers in the sentence. For example, "at least" / "more than" are equivalent in DBTalk language, but it's possible that when the translation occurs

---

[6] `https://pytorch.org/`

the number is changed (“at least 4" → “more than 3").

- In morphologically-rich languages (such as Italian), the entities often are not in grammatical agreement with the rest of the sentence (e.g. a feminine article precedes a masculine entity), which confuses the model on the boundaries of the entity.

Interactive Refinement of Cross-Lingual Word Embeddings

Abstract

Cross-lingual word embeddings transfer knowledge between languages: models trained on high-resource languages can predict in low-resource languages. We introduce CLIME, an interactive system to quickly refine cross-lingual word embeddings for a given classification problem. First, CLIME ranks words by their salience to the downstream task. Then, users mark similarity between keywords and their nearest neighbors in the embedding space. Finally, CLIME updates the embeddings using the annotations. We evaluate CLIME on identifying health-related text in four low-resource languages: Ilocano, Sinhalese, Tigrinya, and Uyghur. Embeddings refined by CLIME capture more *nuanced* word semantics and have higher test accuracy than the original embeddings. CLIME often improves accuracy faster than an active learning baseline and can be easily combined with active learning to improve results.

1 Introduction

Modern text classification requires large labeled datasets and pre-trained word embeddings (Kim, 2014; Iyyer et al., 2015; Joulin et al., 2017). However, scarcity of both labeled and unlabeled data holds back applications in low-resource languages. Cross-lingual word embeddings (Mikolov et al., 2013a, CLWE) can bridge the gap by mapping words from different languages to a shared vector space. Using CLWE features, models trained in a resource-rich language (e.g., English) can predict labels for other languages.

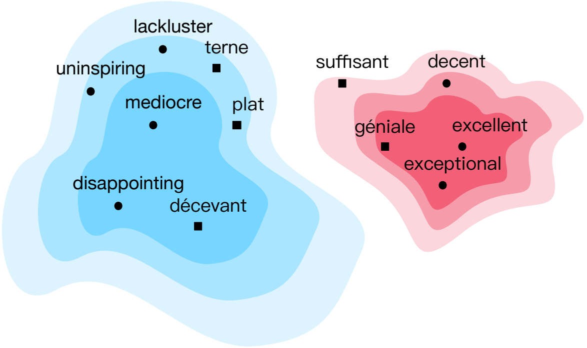

Figure 1: A hypothetical topographic map of an English–French embedding space tailored for sentiment analysis. Dots are English words, and squares are French words. Positive sentiment words are grouped in a clime (red), while negative sentiment words are grouped in another clime (blue). These climes help sentiment analysis.

The success of CLWE relies on the domain and quality of training data (Søgaard et al., 2018). While these methods have impressive word translation accuracy, they are not tailored for downstream tasks such as text classification (Glavas et al., 2019; Zhang et al., 2020a). We develop **CL**assifying **I**nteractively with **M**ultilingual **E**mbeddings (CLIME), that efficiently specializes CLWE with *human interaction*.[1] Given a pre-trained CLWE, a bilingual speaker in the loop reviews the nearest-neighbor words. CLIME capitalizes on the intuition that neighboring words in an ideal embedding space should have similar semantic attributes.

In an analogy to geographic *climes*—zones with distinctive meteorological features—we call areas in the embedding space where words share similar semantic features climes. Our goal is to convert neighborhoods in the embedding space into *classification climes* with words that induce similar labels for a given classification task. For example, in the embedding for English–French sentiment analysis, positive sentiment words such as "excellent", "exceptional", and their French translations are together, while "disappointing", "lackluster", and their translations cluster together elsewhere (Fig-

ure 1). Curating words in the embedding space and refining climes should help downstream classifiers.

First, CLIME uses loss gradients in downstream tasks to find keywords with high salience (Section 2.1). Focusing on these keywords allows the user to most efficiently refine CLWE by marking their similarity or dissimilarity (Section 2.2). After collecting annotations, CLIME pulls similar words closer and pushes dissimilar words apart (Section 3), establishing desired climes (Figure 1).

Quickly deploying cross-lingual NLP systems is particularly important in global public health emergencies, so we evaluate CLIME on a cross-lingual document classification task for four low-resource languages: Ilocano, Sinhalese, Tigrinya, and Uyghur (Section 4). CLIME is effective in this low-resource setting because a bilingual speaker can significantly increase test accuracy on identifying health-related documents in less than an hour.

CLIME is related to active learning (Settles, 2009), which also improves a classifier through user interaction. Therefore, we compare CLIME with an active learning baseline that asks a user to label target language documents. Under the same annotation time constraint, CLIME often has higher accuracy. Furthermore, the two methods are complementary. Combining active learning with CLIME increases accuracy even more, and the user-adapted model is competitive with a large, resource-hungry multilingual transformer (Conneau et al., 2020).

2 Interactive Neighborhood Reshaping

This section introduces the interface designed to solicit human feedback on neighborhoods of CLWE and our keyword selection criterion. Suppose that we have two languages with vocabulary $\mathcal{V}_1$ and $\mathcal{V}_2$. Let $\mathbf{E}$ be a pre-trained CLWE matrix, where $\mathbf{E}_w$ is the vector representation of word type w in the joint vocabulary $\mathcal{V} = \mathcal{V}_1 \cup \mathcal{V}_2$. Our goal is to help a bilingual novice (i.e., not a machine learning expert) improve the CLWE $\mathbf{E}$ for a downstream task through inspection of neighboring words.

2.1 Keyword Selection

With limited annotation time, users cannot vet the entire vocabulary. Instead, we need to find a small salient subset of *keywords* $\mathcal{K} \subseteq \mathcal{V}$ whose embeddings, if vetted, would most improve a downstream task. For example, if the downstream task is sentiment analysis, our keywords set should include sentiment words such as “good” and “bad”. Prior work in active learning solicits keywords using information gain (Raghavan et al., 2006; Druck et al., 2009; Settles, 2011), but this cannot be applied to continuous embeddings. Li et al. (2016) suggest that the contribution of one dimension of a word embedding to the loss function can be approximated by the absolute value of its partial derivative, and therefore they use partial derivatives to visualize the behavior of neural models. However, rather than understanding the importance of individual dimensions, we want to compute the salience of an *entire word vector*. Therefore, we extend their idea by defining the salience of a word embedding as the *magnitude* of the loss function’s gradient. This score summarizes salience of all dimensions from a word embedding. Formally, let $\mathbf{x} = \langle x_1, x_2, \cdots, x_n \rangle$ be a document of n words with label y; let L be the training loss function of the downstream model. We measure the example-level salience of word x_i in document $\mathbf{x}$ as

$$S_{\mathbf{x}}(x_i) = \left\| \nabla_{\mathbf{E}_{x_i}} L(\mathbf{x}, y) \right\|_2 . \quad (1)$$

Equation 1 measures the local contribution of a token in one document, but we are interested in the global importance of a word type across many documents. To compute the global salience score of a word type w, we add example-level salience scores of all token occurrences of a word type w in a large labeled dataset $\mathbf{X}$ and multiply by the inverse document frequency (IDF) of w:

$$S(w) = \text{IDF}(w, \mathbf{X}) \cdot \sum_{\mathbf{x} \in \mathbf{X} : w \in \mathbf{x}} S_{\mathbf{x}}(w). \quad (2)$$

The IDF term is necessary because it discounts *stop words* with high document frequency (e.g., “the” and “of”). These words are often irrelevant to the downstream task and thus have low example-level salience, but they have high total salience because they appear in many examples.

Based on Equation 2, we choose the top-s most salient words as the keyword set $\mathcal{K}$. The hyperparameter s is the number of keywords displayed to the user, which controls the length of a CLIME session. We limit s to fifty in experiments.

2.2 User Interaction

For each keyword k, we want to collect a positive set $\mathcal{P}_k$ with semantically similar words, and a negative set $\mathcal{N}_k$ with unrelated words. To specialize embeddings for a classification task, we ask the user to consider semantic similarity as *inducing a*

Figure 2: The CLIME interface displays a keyword on top while its nearest neighbors in the two languages appear in the two columns below. A user can accept or reject each neighbor, and add new neighbors by typing them in the "add word" textboxes. They may also click on any word to read its context in the training set.

similar label. For example, if the task is English–French sentiment analysis, then "good" should be considered similar to "excellent" and "génial" but dissimilar to "bad" and "décevant". On the interface, the keyword k is displayed on the top, and its nearest neighbors in the two languages are arranged in two columns (Figure 2). The neighbors are the words w with embeddings $\mathbf{E}_w$ closest to $\mathbf{E}_k$ in cosine similarity. The number of displayed nearest neighbors can be adjusted as a hyperparameter, which also controls the session length. For each nearest neighbor, the user can either: (1) press on the green checkmark to add a positive neighbor to $\mathcal{P}_k$, (2) press on the red "X" mark to add a negative neighbor to $\mathcal{N}_k$, or (3) leave an uncertain neighbor alone. The "add word" textbox lets the user add words that are not in the current neighbor list. The added word can then be marked as positive or negative. Section 3 explains how CLIME refines the embeddings with the feedback sets $\mathcal{P}$ and $\mathcal{N}$. The interface also provides a word concordance—a brief overview of the contexts where a word appears—to disambiguate and clarify words. Users can click on any word to find example sentences.

3 Fitting Word Embeddings to Feedback

After receiving user annotations, CLIME updates the embeddings to reflect their feedback. The algorithm reshapes the neighborhood so that words near a keyword share similar semantic attributes. Together, these embeddings form desired task-specific connections between words across languages. Our update equations are inspired by ATTRACT-REPEL (Mrkšić et al., 2017), which fine-tunes word embeddings with synonym and antonym constraints. The objective in ATTRACT-REPEL pulls synonyms closer to and pushes antonyms further away from their nearest neighbors. This objective is useful for large lexical resources like BabelNet (Navigli and Ponzetto, 2010) with hundreds of thousands linguistic constraints, but our pilot experiment suggests that the method is not suitable for smaller constraint sets. Since CLIME is designed for low-resource languages, we optimize an objective that reshapes the neighborhood more drastically than ATTRACT-REPEL.

3.1 Feedback Cost

For each keyword $k \in \mathcal{K}$, we collect a positive set $\mathcal{P}_k$ and a negative set $\mathcal{N}_k$ (Section 2.2). To refine embeddings $\mathbf{E}$ with human feedback, we increase the similarity between k and each positive word $p \in \mathcal{P}_k$, and decrease the similarity between k and each negative word $n \in \mathcal{N}_k$. Formally, we update the embeddings $\mathbf{E}$ to minimize the following:

$$C_f(\mathbf{E}) = \sum_{k \in \mathcal{K}} \left(\sum_{n \in \mathcal{N}_k} \mathbf{E}_k^\top \mathbf{E}_n - \sum_{p \in \mathcal{P}_k} \mathbf{E}_k^\top \mathbf{E}_p \right), \tag{3}$$

where $\mathbf{E}_k^\top \mathbf{E}_n$ measures the similarity between the keyword k and a negative word n, and $\mathbf{E}_k^\top \mathbf{E}_p$ measures the similarity between the keyword k and a positive word p. Minimizing C_f is equivalent to maximizing similarities of positive pairs while minimizing similarities of negative pairs.

3.2 Topology-Preserving Regularization

Prior embedding post-processing methods emphasize regularization to maintain the topology—or properties that should be preserved under transformations—of the embedding space (Mrkšić et al., 2016; Mrkšić et al., 2017; Glavaš and Vulić, 2018). If the original CLWE brings certain translations together, those translated words should remain close after updating the embeddings. The topology also encodes important semantic information that should not be discarded. Therefore, we also include the following regularization term:

$$R(\mathbf{E}) = \sum_{w \in \mathcal{V}} \left\| \hat{\mathbf{E}}_w - \mathbf{E}_w \right\|_2^2. \tag{4}$$

Minimizing $R(\mathbf{E})$ prevents $\mathbf{E}$ from drifting too far away from the original embeddings $\hat{\mathbf{E}}$.

The final cost function combines the feedback cost (Equation 3) and the regularizer (Equation 4):

$$C(\mathbf{E}) = C_f(\mathbf{E}) + \lambda R(\mathbf{E}), \tag{5}$$

where the hyperparameter λ controls the strength of the regularizer. The updated embeddings enforce constraints from user feedback while preserving other structures from the original embeddings. After tuning in a pilot user study, we set λ to one. We use the Adam optimizer (Kingma and Ba, 2015) with default hyperparameters.

4 Cross-Lingual Classification Experiments

We evaluate CLIME on cross-lingual document-classification (Klementiev et al., 2012), where we build a text classifier for a low-resource target language using labeled data in a high-resource source language through CLWE. Our task identifies whether a document describes a medical emergency, useful for planning disaster relief (Strassel and Tracey, 2016). The source language is English and the four low-resource target languages are Ilocano, Sinhalese, Tigrinya, and Uyghur.

Ilocano	... Nagtalinaed dagiti pito a balod ti Bureau of Jail Management and Penology (BJMP) ditoy ciudad ti Laoag iti isolation room gapo iti tuko ...
English	... Seven inmates from the Bureau of Jail Management and Penology (BJMP), Laoag City, have been transferred to the isolation room due to chicken pox ...

Table 1: Excerpt of a positive Ilocano test example (top) and its English translation (bottom) that describes a medical emergency.

Our experiments confirm that a bilingual user can quickly improve the test accuracy of cross-lingual models through CLIME. Alternatively, we can ask an annotator to improve the model by labeling more training documents in the target language. Therefore, we compare CLIME to an active learning baseline that queries the user for document labels; CLIME often improves accuracy faster. Then, we combine CLIME and active learning to show an even faster improvement of test accuracy.

Comparing active learning to CLIME may seem unfair at first glance. In theory, document labeling only requires target language knowledge, while CLIME learns from a bilingual user. In practice, researchers who speak a high-resource language provide instructions to the annotator and answer their questions, so bilingual knowledge is usually required in document labeling for low-resource languages. Moreover, CLIME is complementary to active learning, as combining them gives the highest accuracy across languages.

We also experiment with refining the same set of keywords with multiple rounds of user interaction. The repeated sessions slightly improve test accuracy on average. Finally, we compare with XLM-R (Conneau et al., 2020), a state-of-the-art multilingual transformer. Despite using fewer resources, CLIME has competitive results.

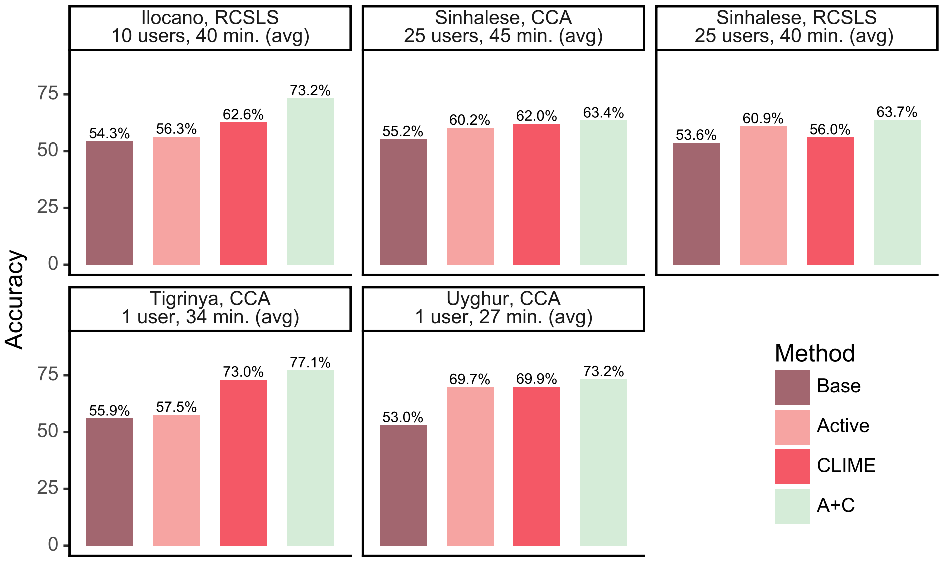

Figure 3: Test accuracy of four methods on four target languages and two CLWE methods. **Base** uses the original CLWE and the original training set. **Active** uses the original CLWE and a training set augmented by active learning. We select and label fifty *target language* documents by uncertainty sampling and combine them with the source language training set. **CLIME** uses the CLWE refined by CLIME and the original training set. **A+C** uses the CLWE refined by CLIME and a training set augmented by active learning. We control the number of user interactions so that **Active**, **CLIME**, and **A+C** require the similar interaction time (Section 4.2). The Sinhalese and Ilocano results are averaged over multiple users, while we only have one user for other languages. Each subcaption indicates the target language, embedding alignment, number of users, and average time per user. **CLIME** has higher accuracy than **Active** on four of the five embeddings, and the combined **A+C** model has the highest.

4.1 Experiment Setup

Labeled Data. We train models on 572 English documents and test on 48 Ilocano documents, 58 Sinhalese documents, 158 Tigrinya documents, and 94 Uyghur documents. The documents are extracted from LORELEI language packs (Strassel and Tracey, 2016), a multilingual collection of documents of emergencies with a public health component.[2] To simplify the task, we consider a binary classification problem of detecting whether the documents are associated with medical needs. Table 1 shows an example document. To balance the label distribution, we sample an equal number of negative examples.

Word Embeddings. To transfer knowledge between languages, we build CLWE between English and each target language. We experiment with two methods to pre-train CLWE: (1) train monolingual embeddings with word2vec (Mikolov et al., 2013b) and align with CCA (Faruqui et al., 2015; Ammar et al., 2016), (2) train monolingual embeddings with fastText (Bojanowski et al., 2017) and align with RCSLS (Joulin et al., 2018). The English embeddings are trained on Wikipedia and the target language embeddings are trained on unlabeled documents from the LORELEI language packs. For alignment, we use the small English dictionary in each pack. Low-resource language speakers are hard to find, so we do not try all combinations of languages and CLWE: we use CCA embeddings for Tigrinya and Uyghur, RCSLS embeddings for Ilocano. Since Sinhalese speakers are easier to find, we experiment with both CLWE for Sinhalese.

Text Classifier. Our classifier is a convolutional neural network (Kim, 2014). Each document is represented as the concatenation of word embeddings and passed through a convolutional layer, followed by max-pooling and a final softmax layer. To preserve cross-lingual alignments, we freeze embeddings during training. This simple model is effective in low-resource cross-lingual settings (Chen et al., 2018; Schwenk and Li, 2018). We minimize cross-entropy on the training set by running Adam (Kingma and Ba, 2015) with default hyperparameters for thirty epochs. All experiments use GeForce GTX 1080 GPU and 2.6 GHz AMD Opteron 4180 processor.

---

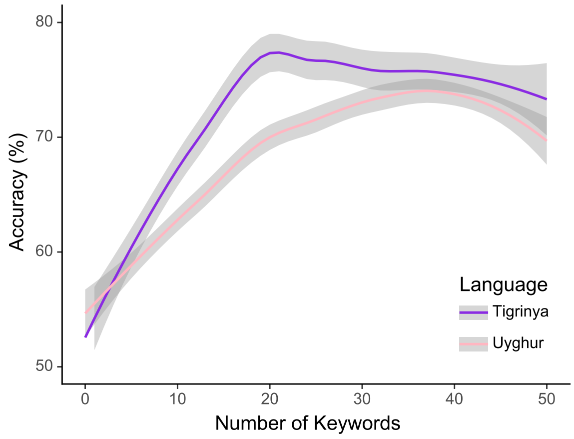

Figure 4: For Uyghur (pink) and Tigrinya (purple), we compare test accuracy between sets of CLWE that differ in the number of keywords used to refine them. The leftmost point corresponds to the **Base** model in Figure 3, while the rightmost point corresponds to the **CLIME** model. Test accuracy generally improves with more feedback at the beginning but slightly drops after reaching an optimal number of keywords.

User Study. We use Upwork to hire participants who are fluent in both English and the target language.[3] Low-resource language speakers are hard to find, so we have a different number of users for each language. We hire ten Ilocano users and twenty-five Sinhalese users. For additional case studies, we hire one Tigrinya user and one Uyghur user. Each user annotates the fifty most salient keywords, which takes less than an hour (Figure 3). For each keyword, we show five nearest neighbors for each language. Each user provides about nine constraints for each keyword.

4.2 Comparisons

After receiving feedback, we update the embeddings (Section 3). We evaluate the new embeddings by retraining a classifier. For each set of embeddings, we train ten models with different random seeds and report average test accuracy.

We compare a classifier trained on the updated embeddings (**CLIME** in Figure 3) against two baselines. The first baseline is a classifier trained on original embeddings (**Base** in Figure 3). If we have access to a bilingual speaker, an alternative to using CLIME is to annotate more training documents in the target language. Therefore, we also compare CLIME to uncertainty sampling (Lewis and Gale, 1994), an active learning method that asks a user to label documents (**Active** in Figure 3). We choose a set of fifty documents where model outputs have the highest entropy from a set of unlabeled *target language* documents and ask an annotator to label them as additional training documents. We then retrain a model on both the English training set and the fifty target language documents, using the original embeddings. For each model, a human annotator labels fifty documents within forty to fifty minutes. This can either be slower or take approximately the same time as an average CLIME session (Figure 3). Thus, any improvements in accuracy using CLIME are even more impressive given that **Active** is no faster than CLIME.

Finally, we explore combining active learning and CLIME (**A+C** in Figure 3). Document-level and word-level interactions are complementary, so using both may lead to higher accuracy. To keep the results comparable, we allocate half of the user interaction time to active learning, and the other half to CLIME. Specifically, we use active learning to expand the training set with twenty-five target language documents and refine the embeddings by running CLIME on only twenty-five keywords. Then, we retrain a model using both the augmented training set and the refined embeddings.

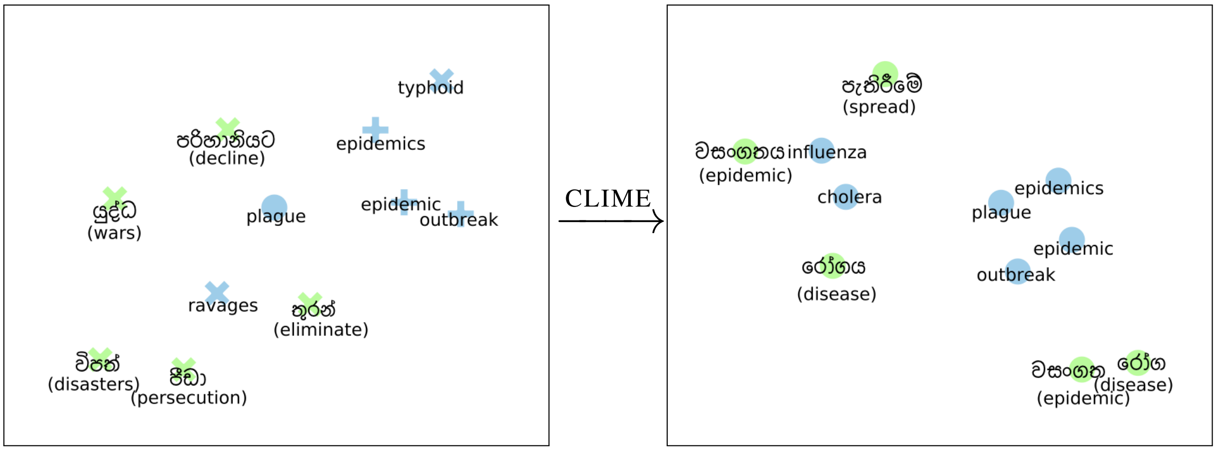
4.3 Results and Analysis

Effectiveness of CLIME. Figure 3 compares the four methods described in the previous section. CLIME is effective in this low-resource setting. On all four target languages, the classifier trained on embeddings refined by CLIME has higher accuracy than the classifier that trains on the original embeddings: CLIME reshapes embeddings in a way that helps classification. CLIME also has higher accuracy than active learning for most users. The combined method has the highest accuracy: active learning and CLIME are complementary. Single-sample t-tests confirm that **CLIME** is significantly better than **Base** and **A+C** is significantly better than **Active** (Appendix A.1).

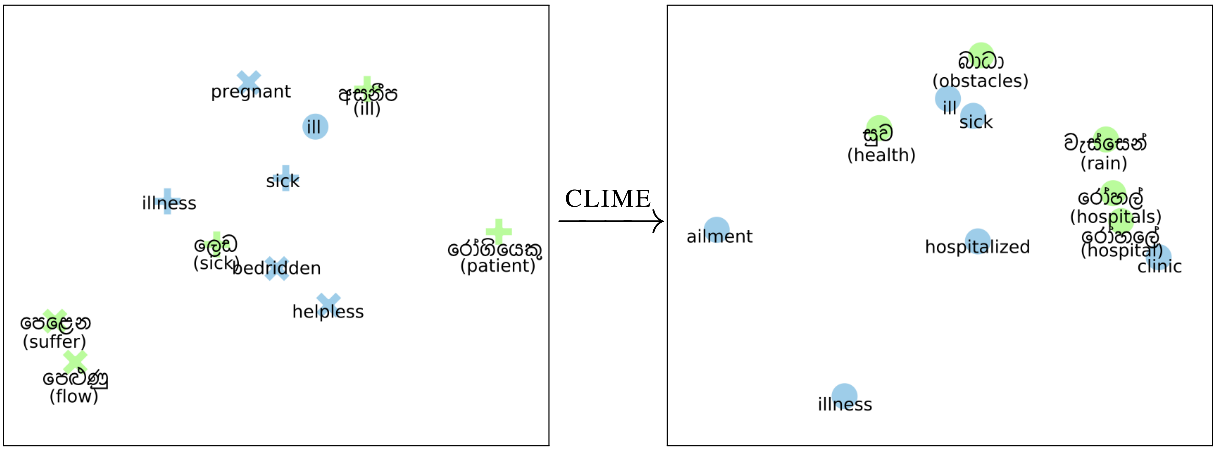
Keyword Detection. We inspect the list of the fifty most salient keywords (Section 2.1). Most keywords have obvious connections to our classification task of detecting medical emergencies, such as “ambulance”, “hospitals”, and “disease”. However, the list also contains some words that are unrelated to a medical emergency, including “over” and “given”. These words may be biases or artifacts from training data (Feng et al., 2018).

---

[3] `https://upwork.com/`



(a) Neighborhood of “plague”



(b) Neighborhood of “ill”

Figure 5: T-SNE visualization of embeddings before (left) and after (right) CLIME updates. From one Sinhalese user study, we inspect two keywords, “ill” and “plague”, and their five closest neighbors in English (blue) and Sinhalese (green). The Sinhalese words are labeled with English translations. Shape denotes the type of feedback: “+” for positive neighbors and “x” for negative neighbors.

Number of Keywords. To evaluate how feedback quantity changes accuracy, we vary the number of keywords and compare test accuracy on Tigrinya and Uyghur datasets (Figure 4). For each keyword s from one to fifty, we update the original embeddings using only the feedback on the top-s keywords and evaluate each set of embeddings with test accuracy. For both languages, test accuracy generally increases with more annotation at the beginning of the session. Interestingly, test accuracy plateaus and slightly drops after reaching an optimal number of keywords, which is around twenty for Tigrinya and about forty for Uyghur. One explanation is that the later keywords are less salient, which causes the feedback to become less relevant. These redundant constraints hamper optimization and slightly hurt test accuracy.

Qualitative Analysis. To understand how CLIME updates the embeddings, we visualize changes in the neighborhoods of keywords with t-SNE (Maaten and Hinton, 2008). All embeddings from before and after the user updates are projected into the same space for fair distance comparison. We inspect the user updates to the Sinhalese CCA embeddings (Figure 5). We confirm that positive neighbors are pulled closer and negative neighbors are pushed further away. The user marks “epidemic” and “outbreak” as similar to the keyword “plague”, and these words are closer after updates (Figure 5a). For the keyword “ill”, the user marks “helpless” as a negative neighbor, because “helpless” can signal other types of situations and is more ambiguous for detecting a medical emergency. After the update, “helpless” is pushed away and disappears from the nearest neighbors of “ill” (Figure 5b). However, a few positive

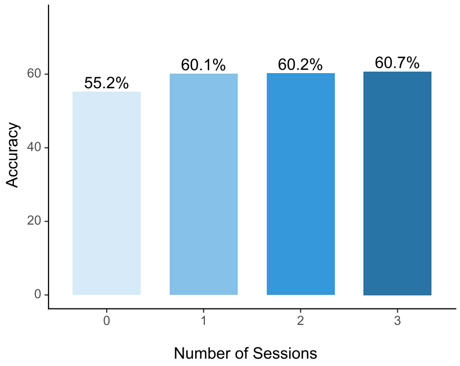


Figure 6: Progress of five Sinhalese users over three CLIME sessions. Largest increase in test accuracy occurs after first session. The leftmost point is the **Base** model from Figure 3. Average accuracy for first session is not the same as Figure 3 because only a subset of users are asked to complete three sessions.

neighbors have inadvertently moved away, such as the Sinhalese translation for "ill". The update algorithm tries to satisfy constraints for multiple keywords, so soft constraints may be overlooked. This motivates repeated CLIME sessions where the user can continue fixing errors.

4.4 Repeating User Sessions

We investigate the effects of having a user complete multiple CLIME sessions. After the user finishes a session, we fit the embeddings to their feedback, produce a new vocabulary ranking, and update the interface for the next session. We experiment on the Sinhalese dataset with CCA embeddings and ask five users to complete three sessions of fifty keywords. Average test accuracy increases with more sessions, but the improvement is marginal after the first session (Figure 6). By the end of the three sessions, one user reaches 65.2% accuracy, a significant improvement from the 55.2% baseline.

4.5 Comparing with Contextual Embeddings

Contextualized embeddings based on multilingual transformers reach state-of-the-art in many tasks, so we compare CLIME with these models. Most existing models (Wu and Dredze, 2019; Lample and Conneau, 2019) do not cover our low-resource languages. The only exception is XLM-R (Conneau et al., 2020), which covers Uyghur and Sinhalese. To compare with CLIME, we fine-tune XLM-R for three epochs with AdamW (Loshchilov and Hutter, 2019), batch size of sixteen, and learning rate of 2e-5. We compute average accuracy over ten runs with different random seeds.

For Uyghur, XLM-R has lower accuracy than our **A+C** approach (71.7% vs. 73.2%). This is impressive given that XLM-R uses much more resources: 270 million parameters, 2.5TB of multilingual Common Crawl data, and 500 GPUs. In contrast, the **A+C** model has 120K parameters and is built in less than two hours with a single GPU (including human interaction and model training).

For Sinhalese, XLM-R has higher accuracy than our **A+C** approach (69.3% vs. 63.7%). Common Crawl has much more Sinhalese words than Uyghur words. This aligns with our intuition: CLIME is more useful in low-resource settings, whereas multilingual transformers are more appropriate for languages with more data. Future work can extend the interactive component of CLIME to multilingual transformers.

5 Related Work

Cross-Lingual Word Embeddings. Ruder et al. (2019) summarize previous CLWE methods. These methods learn from *existing* resources such as dictionaries, parallel text, and monolingual corpora. Therefore, the availability and quality of training data primarily determines the success of these methods (Søgaard et al., 2018). To improve the suitability of CLWE methods in low-resource settings, recent work focuses on learning without cross-lingual supervision (Artetxe et al., 2018; Hoshen and Wolf, 2018) and normalizing monolingual embeddings before alignment (Zhang et al., 2019). In contrast, we design a human-in-the-loop system to efficiently improve CLWE. Moreover, previous CLWE methods are heavily tuned for the intrinsic evaluation task of dictionary induction, sometimes to the detriment of downstream tasks (Glavas et al., 2019; Zhang et al., 2020b). Our method is tailored for downstream tasks such as text classification.

Cross-Lingual Document Classification. Prior approaches transfer knowledge with cross-lingual resources, such as bilingual dictionaries (Wu et al., 2008; Shi et al., 2010), parallel text (Xu and Yang, 2017), labeled data from related languages (Zhang et al., 2020a), structural correspondences (Peter Prettenhofer, 2010), multilingual topic models (Ni et al., 2011; Andrade et al., 2015), machine translation (Wan, 2009; Zhou et al., 2016), and CLWE (Klementiev et al., 2012). Our method instead brings a bilingual speaker in the loop to *actively* provide cross-lingual knowledge, which is more reliable in low-resource settings. Concurrent to our work, Karamanolakis et al. (2020) also show that keyword translation is very useful for cross-lingual document classification.

Human-in-the-Loop Multilingual Systems. CLIME is inspired by human-in-the-loop systems that bridge language gaps. Brown and Grinter (2016) build an interactive translation platform to help refugee resettlement. Yuan et al. (2018) interactively align topic models across languages.

Active Learning. A common solution to data scarcity is active learning, the framework in which the learner iteratively queries an oracle (often a human) to receive annotations on unlabeled data. Settles (2009) summarizes popular active learning methods. Most active learning methods solicit labels for training examples/documents, while CLIME asks for word-level annotation. Previous active learning methods that use feature-level annotation (Raghavan et al., 2006; Zaidan et al., 2007; Druck et al., 2009; Settles, 2011) are not applicable to neural networks and CLWE. Closely related to our work, Yuan et al. (2020) propose an active learning strategy that selects examples based on language modeling pre-training.

Neural Network Interpretation. Our keyword detection algorithm expands upon prior work in interpreting neural networks. Li et al. (2016) uses the gradient of the objective function to linearly approximate salience of one dimension, which helps interpret and visualize word compositionality in neural networks. Their ideas are inspired by visual salience in computer vision (Simonyan et al., 2013; Zeiler and Fergus, 2014). We further extend the idea to compute the global salience of an entire word vector across a labeled dataset.

Specializing Word Embeddings. Our update equations modify prior work on specializing word embeddings that are designed to improve word embeddings with a large lexical knowledge base. Faruqui et al. (2015) *retrofit* word embeddings to synonym constraints. Mrkšić et al. (2016) expand the method by also fitting antonym relations. Mrkšić et al. (2017) includes both monolingual and cross-lingual constraints to improve CLWE. Glavaš and Vulić (2018) use a neural network to learn an specialization function that generalize to words with no lexical constraints. Closest to our work, Zhang et al. (2020b) retrofit CLWE to dictionaries and observe improvement in downstream tasks.

6 Conclusion and Future Work

CLIME is an interactive system that enhances CLWE for a task by asking a bilingual speaker for word-level similarity annotations. We test CLIME on cross-lingual information triage in international health emergencies for four low-resource languages. Bilingual users can quickly improve a model with the help of CLIME at a faster rate than an active learning baseline. Combining active learning with CLIME further improves the system.

CLIME has a modular design with three components: keyword ranking, user interface, and embedding refinement. The keyword ranking and the embedding refinement modules build upon existing methods for interpreting neural networks (Li et al., 2016) and fine-tuning word embeddings (Mrkšić et al., 2017). Therefore, future advances in these areas may also improve CLIME. Another line of future work is to investigate alternative user interfaces. For example, we could ask bilingual users to *rank* nearest neighbors (Sakaguchi and Van Durme, 2018) or provide scalar grades (Hill et al., 2015) instead of accepting/rejecting individual neighbors.

We also explore a simple combination of active learning and CLIME. Simultaneously applying both methods is better than using either alone. In the future, we plan to train a policy that dynamically combines the two interactions with reinforcement learning (Fang et al., 2017).

A Appendices

A.1 Statistical Significance

Comparison	Model	p	t	df
CLIME vs. **Base**	SI(CCA)	<0.01	7.64	24
	SI(RCSLS)	<0.01	3.62	24
	IL(RCSLS)	<0.01	5.16	9
CLIME vs. **Active**	SI(CCA)	0.07	2.00	24
	SI(RCSLS)	<0.01	-7.09	24
	IL(RCSLS)	<0.01	3.96	9
A+C vs. **Active**	SI(CCA)	<0.01	4.297	24
	SI(RCSLS)	<0.01	3.40	24
	IL(RCSLS)	<0.01	13.97	9

Table 2: Results of single-sample t-tests between CLIME and **Base**, CLIME and **Active**, and **A+C** and **Active**, showing the p-value, the t statistic, and the degree of freedoms df. CLIME is significantly better than **Base**, and **A+C** is significantly better than **Active** across different languages and embedding models. The only combination with results that are not significantly different is CLIME and **Active** for Sinhalese (CCA).

We run single-sample t-tests with .05 significance level to see whether adding word-level annotations with CLIME can significally improve classification accuracy. We compare CLIME against **Base**, CLIME against **Active**, and **A+C** against **Active**. We use the user study results from the Sinhalese models (both CCA and RCSLS) and the Ilocano model. Table 2 shows that CLIME is not significantly different from **Active** for the Sinhalese CCA embeddings but does significantly improve accuracy for the Ilocano model. Overall, CLIME is significantly different from **Base** and **A+C** is significiantly different from **Active** across the experiments for all models.

Exploiting Sentence Order in Document Alignment

Brian Thompson

`phi@jhu.edu`

Abstract

We present a simple document alignment method that incorporates sentence order information in both candidate generation and candidate re-scoring. Our method results in 61% relative reduction in error compared to the best previously published result on the WMT16 document alignment shared task. Our method improves downstream MT performance on web-scraped Sinhala–English documents from ParaCrawl, outperforming the document alignment method used in the most recent ParaCrawl release. It also outperforms a comparable corpora method which uses the same multilingual embeddings, demonstrating that exploiting sentence order is beneficial even if the end goal is sentence-level bitext.

1 Introduction

Document alignment is the task of finding parallel document pairs (i.e., documents that are translations of each other) in a large collection of documents, often crawled from the web. Aligned documents have historically been used to produce sentence-level machine translation (MT) data, but there is growing evidence that MT systems should be trained and evaluated using document-level context (Gong et al., 2011; Läubli et al., 2018; Voita et al., 2019; Junczys-Dowmunt, 2019).

We exploit the simple idea that two parallel documents should each contain approximately the same information, *in approximately the same order*. This idea can be traced back at least to the late 1990s, when STRAND (Resnik, 1998) measured how well linearized HTML tags from two documents could be aligned in order to judge whether two web pages were likely parallel. However, more recent work has primarily used unordered representations for documents, including bags of words or n-gram features and averages of sentence embeddings.

Our method consists of two main parts: First, we propose a simple method for candidate generation which embeds documents into a joint semantic embedding space (Berry and Young, 1995; Germann, 2016), in a way that preserves some order information in each document. This enables candidate generation via fast approximate nearest neighbor search. Second, we propose re-scoring those candidate pairs by performing sentence alignment and then scoring that alignment based on (1) the semantic similarity of the resulting aligned sentence pairs; (2) whether the sentence pairs are in the correct languages; and (3) the number of inserted/deleted sentences. Our re-scoring approach seeks to filter out documents pairs that contain similar information, but where the order of that information is not consistent between the two documents.

Our method results in a 61% relative reduction in the false positive rate on the WMT16 document alignment shared task versus the best previously reported method. Applied to web-scraped Sinhala–English data from ParaCrawl (Ban et al., 2020), it improves MT performance by 1.2 BLEU over the document alignment method used in the latest ParaCrawl release (Buck and Koehn, 2016b), when both are used with the Vecalign sentence alignment toolkit (Thompson and Koehn, 2019).

2 Method

We follow a 2-stage approach to consider the $D_S \times D_T$ possible alignments between D_S source documents and D_T target documents:[1]

1. **Candidate Generation**: We first find a fixed number, K, of target documents as potential matches for each source document.
2. **Candidate Re-scoring**: We re-score the $D_S \times K$ document pairs from part 1 using a more accurate but slower scoring method.

---

[1] We define the source/target such that $D_S > D_T$.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5997–6007,
November 16–20, 2020.

Both our candidate generation method and candidate re-scoring method explicitly account for the content of a document as well as the order of that content within the document.

2.1 Candidate Generation

We propose concatenating several sub-vectors—each emphasizing a different section of the document—to form a multilingual document vector. Each sub-vector is the sum of the sentence embeddings for the entire document, after embeddings are weighted to emphasize a given region of the document and to de-emphasize boilerplate text (e.g., from navigational buttons, pull-down menus, or headers).

Let S_n for $n \in \{0, ..., N-1\}$ be the N sentences in a given document. We compute sub-vectors V_j to emphasize uniformly spaced positions $j \in \{0, ..., J-1\}$ in the document:

$$V_j = \sum_{n=0}^{N-1} \mathrm{emb}(S_n)\ H_j(n)\ B(S_n) \qquad (1)$$

where $\mathrm{emb}(S_n)$ is the multilingual embedding of sentence S_n (see §2.1.1), $H_j(n)$ is a windowing function to emphasise the j^{th} region the document (see §2.1.2), and $B(S_n)$ down-weights boilerplate sentences (see §2.1.3).

The final document vector V is a concatenation of normalized position-weighted sub-vectors V_j. Candidate document pairs are found by searching for pairs using cosine distance and approximate nearest neighbor search. We compare all documents from a given webdomain.[2]

2.1.1 Sentence Embeddings

Function $\mathrm{emb}(S_n)$ maps sentence S_n into a multilingual vector space. In this work we use LASER embeddings (Artetxe and Schwenk, 2019b), as the authors provide a pretrained model that works in 93 languages.[3] LASER embeddings require a significant amount of storage space, so for all experiments in this work so we project them from their native size of 1024 down to 128 dimensions using Principal Component Analysis (PCA), as we find this results in a good performance/space trade-off (see Appendix A).

2.1.2 Windowing Function

$H_j(n)$ is a windowing function to emphasize the j^{th} region of a document. If we were to use a simple rectangular window, then our method would be equivalent to splitting the document into sections and computing the average sentence embedding for each section. However, we instead use many smoothed overlapping windows in an effort to encode more fine-grained position information into the final vector document vector, while also making the document alignment process more robust to offsets between parallel sentences, such as in a document pair with a boilerplate header or advertisement present in one document but not the other.

For our windowing function $H_j(n)$ we select a modified PERT distribution (Vose, 2000) with support over $[0, J]$ and mode $\left(\frac{j+0.5}{J}\right)N$. Modified PERT is based on the PERT (Malcolm et al., 1959; Clark, 1962) distribution, but adds a parameter γ to control peakedness of the distribution. PERT is a re-parameterization of the Beta distribution that is defined by the minimum, most likely and maximum values a variable can take.

We select J=16 and γ=20 to produce windows that look reasonable to the authors (see Appendix B). We do not sweep J or γ, as we are concerned about overfitting given our small development set (see Table 1).

2.1.3 Boilerplate Down-weighting

Many 'sentences' in web-crawled data are not true sentences, but boilerplate text such as text of navigational buttons, headers, or pull-down menus. We explore three methods for down-weighting such boilerplate text:

1. Scaling by the inverse of the log of number of the documents containing a given sentence, inspired by IDF (Sparck Jones, 1988; Buck and Koehn, 2016b)
2. A more aggressive variant of IDF which scales sentences by the inverse of the (linear, as opposed to log) number of documents containing a given sentence, which we denote 'LIDF'
3. Scaling each sentence by its length, in characters, as boilerplate lines are often very short (Kohlschütter et al., 2010).

We find that all three boilerplate methods improve candidate generation performance, but select LIDF as it resulted in the best recall performance on our development set in preliminary experiments.

2.2 Candidate Re-scoring

To re-score a document pair proposed by candidate generation, we perform sentence alignment and

---

[2] A webdomain is a top-level website (e.g., acted.org).

[3] github.com/facebookresearch/LASER

score the quality of the resulting sentence alignment in order to judge whether the proposed document pair appears to be a good translation pair. Our goal is to filter out documents pairs that may contain similar information, but where the order of that information is not consistent between the two documents, indicating they are not parallel.

Our proposed document pair scoring function is:

$$S(E,F) = \frac{1}{|a(E,F)|} \sum_{e,f \in a(E,F)} \text{sim}(e,f) p(L_E|e) p(L_F|f) \quad (2)$$

where $a(E,F)$ is the sentence alignment (see §2.2.1) of documents E and F; $\text{sim}(e,f)$ is the cosine similarity between sentences e and f; and $p(L_e|e)$, $p(L_f|f)$ are the probabilities that sentences e, f are in the correct languages L_E, L_F (see §2.2.2). To penalize unaligned sentences, $a(E,F)$ includes insertions/deletions but we define $\text{sim}(e,f)$ to be zero in such cases.

2.2.1 Sentence Alignment

To perform sentence alignment, we use Vecalign (Thompson and Koehn, 2019).[4] Vecalign uses multilingual sentence embeddings to judge sentence similarity, in conjunction with a dynamic programming approximation based on fast dynamic time warping (Salvador and Chan, 2007) to approximate a search over the full space of possible sentence alignments in linear time complexity with respect to document length. We follow Thompson and Koehn (2019) and again use LASER embeddings, except we project all embeddings down to size 128.

2.2.2 Language ID

One artifact of using multilingual sentence embeddings is that they give perfect alignment scores to exact, un-translated sentence copies. Since automatic language identification (LID) of web data is often erroneous and not well defined,[5] this can result in un-translated, (near) duplicate documents being found as document pairs. We propose to use all sentences (regardless of language) in sentence alignment, as we hypothesize that copies provide a strong signal for sentence alignment. However, when scoring the alignment we introduce sentence-level LID probabilities to penalize sentence pairs that are not in the correct languages.

Gold Pairs	1624	2402	0

Table 1: Counts for WMT16 and ParaCrawl data used in this work.

3 Experiments and Results

We evaluate our document alignment method in both high- and low-resource settings. Note that our method is not trained on any parallel documents, and is designed to be as language agnostic as possible. However, it relies on LASER embeddings, which are trained on bitext. Thus we expect performance to be at least partially a function of the quantity of data that LASER is trained on.[6] For high-resource, we use the publicly available French–English data released for the WMT 2016 shared task on document alignment (Buck and Koehn, 2016a) and evaluate document recall following the shared task. The shared task provides a strong set of baselines, as 13 different teams contributed at least one submission. For low-resource, we experiment with Sinhala–English documents extracted from ParaCrawl. In this setting we do not have gold document alignments, so we instead evaluate the quality of MT systems trained on the data extracted via document alignment.

We develop and set all parameters using the training data from WMT16 ('WMT16-train') and then test on the WMT16 test data ('WMT16-test') and the Sinhala–English ParaCrawl data. Basic statistics for each dataset are shown in Table 1.

3.1 Candidate Generation

We find that encoding order in document vectors substantially reduces the number of candidates, K, that must be searched to find the correct document: see Figure 1. The improvement is largest when a small number of candidates are considered—the proposed method approximately halves the num-

---

[4] github.com/thompsonb/vecalign

[5] We observe numerous mixed-language documents (e.g., main body in one language and the boilerplate in another).

[6] For the two languages considered here, LASER was trained on much more French–English data (8.8M) than Sinhala–English data (796k) (Artetxe and Schwenk, 2019b). This comparison is likely complicated by data quality (which we generally expect to be higher in higher-resources languages) and benefits of training in related languages.

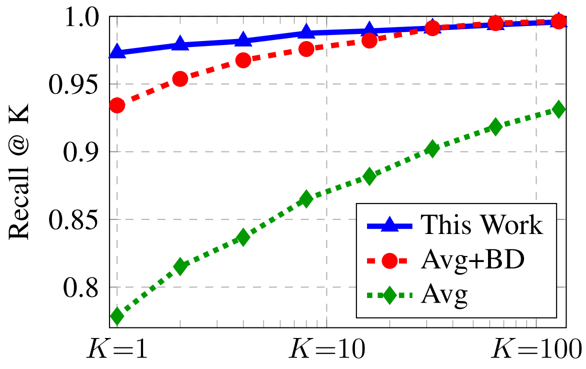

Figure 1: Fraction of the time that a correct document (or near duplicate of it) is found in the top K candidates, as a function of K, found by searching document vectors made from average sentence vectors ('Avg'), average sentence vectors with boilerplate down-weighting ('Avg+BD'), and the proposed method incorporating document order. Results shown on WMT16-test.

ber of false positives between K=1 and K=10 compared to the stronger of the two baselines.

3.2 Document Alignment Recall

Within each webdomain, we embed documents as described in §2.1. For each French document, we find the top K=32 candidate translations via approximate nearest neighbor search using FAISS (Johnson et al., 2017). We then re-score each candidate pair with Equation 2. Language ID probabilities are estimated using fastText (Joulin et al., 2016).[7] We extract the highest scoring document pairs via the greedy search method described in Buck and Koehn (2016b).[8]

We evaluate document pairs following Buck and Koehn (2016a).[9] The proposed method has a recall of 98.5%, compared to the previous best of 96.2% (see Table 2); this corresponds to a 61% relative reduction in false positive rate. We also try our candidate generation method without rescoring (i.e., K=1) and find that it outperforms prior work, but is not as strong as our candidate generation method in conjunction with our candidate re-scoring method. For a description of the contrastive methods, see Buck and Koehn (2016a).

Method	Recall
Azpeitia and Etchegoyhen (2016)	93.1%
Germann (2016)	95.0%
Gomes and Pereira Lopes (2016)	95.9%
Dara and Lin (2016)	96.0%
Buck and Koehn (2016b)	96.2%
This Work: Without Re-Scoring	97.1%
This Work: With Re-Scoring	**98.5%**

Table 2: Document recall on WMT16-test, compared to previous best reported results. The proposed method outperforms prior work, even before re-scoring.

3.3 Impact on Downstream MT

We perform document alignment on Sinhala–English documents web-scraped by ParaCrawl. We apply the same method as in French–English, using the same parameters. We compare to document alignment via Buck and Koehn (2016b), followed by sentence alignment using both Vecalign and Hunalign (Varga et al., 2007), as the latter was used for the most recent ParaCrawl release.

Our document alignment method and Vecalign both use LASER embeddings. The use of LASER embeddings has been proposed for finding parallel sentences in comparable corpora (i.e., without doing document alignment), using a margin-based criterion (Artetxe and Schwenk, 2019a). Since both methods use the same multilingual embeddings (LASER), this allows us to determine whether using document-level information (i.e., performing document alignment and then sentence alignment) provides better data than simply treating the data as comparable corpora and searching for sentence pairs. We refer to this method 'LASER-cc.' For a fair comparison with our document alignment method, we search for sentence pairs within each webdomain.

For each method of finding parallel sentences, evaluation is the same: Since the true amount of parallel data is unknown, we rank the data from highest to lowest quality following Chaudhary et al. (2019) and train systems on a number of different data amounts, as measured by the number of English words. We train NMT systems following the WMT19 sentence filtering shared task (Koehn et al., 2019). Following Thompson and Koehn (2019), we train 5 systems per setting and report both mean and standard deviation BLEU scores. We report BLEU scores using sacreBLEU (Post, 2018).

---

[7] dl.fbaipublicfiles.com/fasttext/supervised-models/lid.176.bin

[8] Buck and Koehn (2016b) found that in practice the greedy search outperformed the theoretically optimal Kuhn–Munkres algorithm (Munkres, 1957).

[9] We use their "soft" recall, which gives credit to document pairs for which the English or French document (but not both) differed from a gold document pair by less than 5%, as measured by text edit distance.

Method	BLEU
Buck + Hunalign	8.74 +/- 0.20
Buck + Vecalign	10.46 +/- 0.13
LASER-cc	10.40 +/- 0.15
This Work + Vecalign	**11.62 +/- 0.09**

Table 3: Downstream BLEU (+/- standard deviation for 5 runs) for the three document alignment + sentence alignment methods compared in this work, plus the comparable corpora method LASER-cc. 'Buck' denotes Buck and Koehn (2016b). BLEU shown for best filtering threshold for each method; see Appendix C for the results over the entire range of threshold values.

Results at the best threshold for each method are shown in Table 3, and results for the full sweep over all thresholds are provided in Appendix C. The proposed method improves downstream MT performance by 1.2 BLEU over Buck and Koehn (2016b), when both are used in conjunction with Vecalign, and 2.9 BLEU over Buck and Koehn (2016b) with Hunalign (used in the most recent Paracrawl release).

The proposed method also outperforms the LASER-cc baseline by 1.2 BLEU. As LASER-cc and the proposed method use the exact same sentence embeddings, this result shows that incorporating sentence order not only produces documents that can be used for document-level MT training, but also results in higher quality sentence pairs.

4 Related Work

There is a large amount of prior work in document alignment. One of the simplest methods is URL similarity (Resnik, 1998; Chen and Nie, 2000), although this has been shown to be brittle (Tiedemann, 2011). HTML structure (Resnik and Smith, 2003; Shi et al., 2006) or metadata such as publication date (Munteanu and Marcu, 2005) is often similar between parallel websites. However, most more recent work has focused on content similarity via bag-of-words or bag-of-ngrams, using bilingual lexicon (Ma and Liberman, 1999; Fung and Cheung, 2004; Ion et al., 2011; Esplà-Gomis et al., 2016; Etchegoyhen and Azpeitia, 2016; Azpeitia and Etchegoyhen, 2019), machine translation (Uszkoreit et al., 2010), or phrase tables (Gomes and Pereira Lopes, 2016).

Some work has considered high-level order as a filtering step after using a unordered representation to generate candidates: Ma and Liberman (1999) and Le et al. (2016) discard n-gram pairs outside a fixed window, while Uszkoreit et al. (2010) filters out documents that have high edit distance between sequences of corresponding n-gram pairs. Utiyama and Isahara (2003) and Zhang et al. (2006) use sentence similarity and/or number of aligned sentences after performing sentence alignment to score candidate documents. Guo et al. (2018) score document pairs using the sentence-level nearest neighbor as well as the absolute difference in sentence position between sentence pairs. In contrast to these methods, our work considers high-level order in both candidate generation and re-scoring.

Guo et al. (2019) demonstrated neural document embeddings are effective representations for document alignment. They trained on millions of document pairs in each specific language pair of interest; in contrast, this work is much simpler and does not require document-level training data.

5 Conclusion

We present a simple but effective method for document alignment. Our method uses multilingual sentence embeddings and explicitly models the *order* of sentences in documents, in both candidate generation and candidate re-scoring. Our method outperforms all published results on the dataset released for the WMT16 shared task on document alignment. It also increases downstream MT performance in a low-resource setting over prior work, including a margin-based comparable corpora method (Artetxe and Schwenk, 2019a). We use the same embeddings as the comparable corpora method, thus the improvement over that method demonstrates the importance of including sentence order in document alignment, even when document-level alignments are not required.

A Vecalign Speed/Space/Accuracy Trade-off

We experiment with projecting the 1028-dimension LASER embeddings into a lower dimensional space using PCA prior to use in Vecalign. We evaluate sentence alignment accuracy following Thompson and Koehn (2019), on the German–French test set released with Bleualign (Sennrich and Volk, 2010), consisting of manually aligned yearbook articles published in both German and French by the Swiss Alpine Club from the Text+Berg corpus (Volk et al., 2010). Accuracy and alignment time for a range of embedding sizes are shown in Figure 2. Timing is measured on a laptop with a 1.80GHz i7-8550 CPU. We see strong performance ($F_1 > 0.85$) for embeddings down to size 32, in conjunction with up to a 70% reduction in runtime and 97% reduction in disk space required to store the embeddings. However, we select a slightly larger dimension of 128 for use in this work. This projection has minimal impact on sentence alignment accuracy, which we expect to have a direct impact on candidate re-scoring performance. We do not explore the relationship between projected size and candidate generation performance in this work.

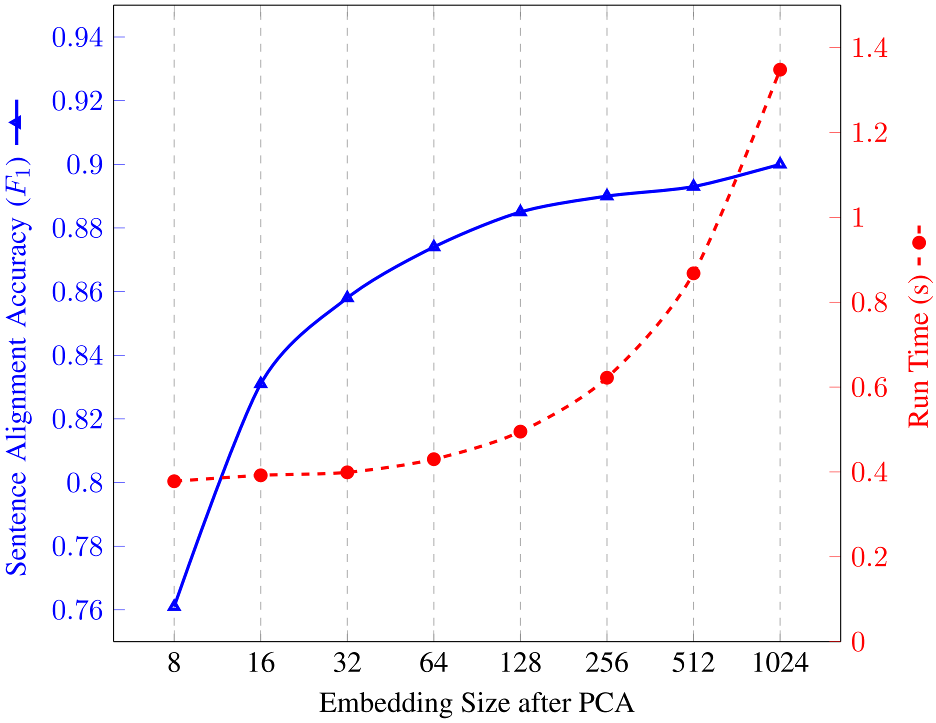

Figure 2: F_1 (solid blue line) vs time to align (dashed red line) the German–French test set after projecting LASER embeddings to various dimensions using PCA.

B Modified PERT Window Illustration

Figure 3 shows the 16 modified PERT windows used in this work, for an example document. We select J=16 and γ=20 to produce windows that look reasonable to the authors, but do not explore sweeping either parameter due to concerns about overfitting on the development set.

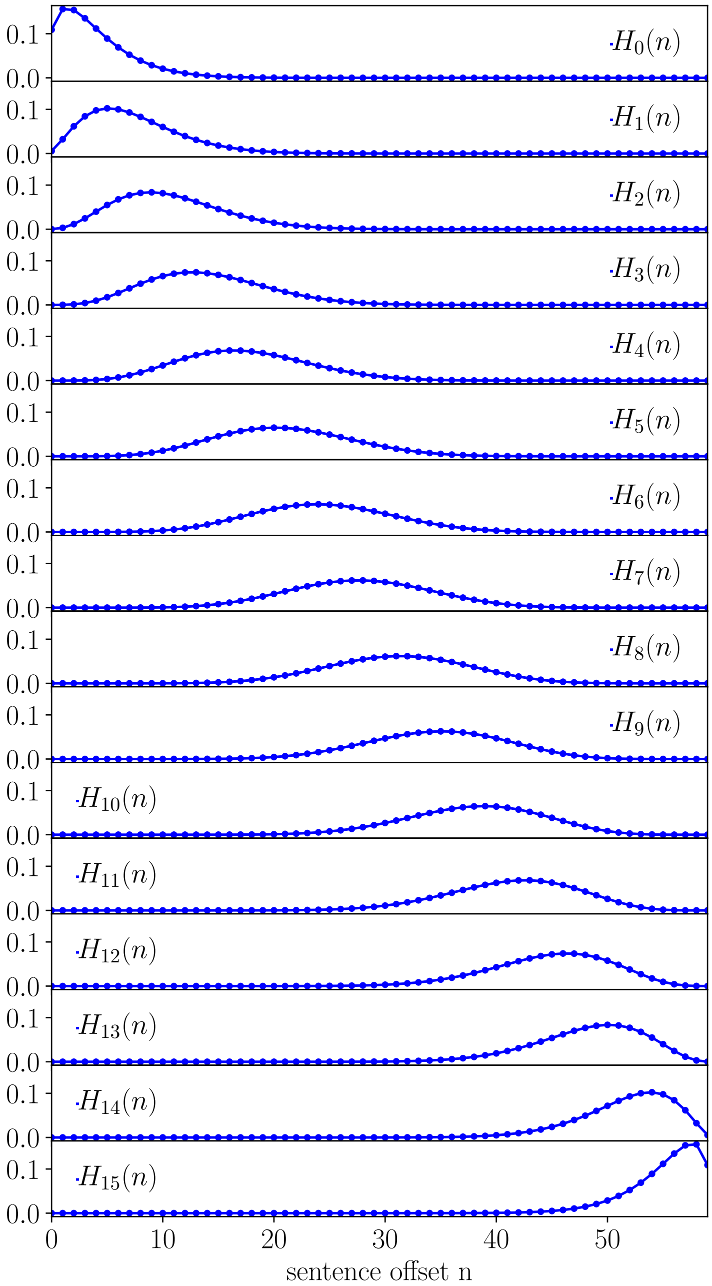

Figure 3: The 16 modified PERT windows used in this work, for an example document containing 60 sentences. Each window emphasizes a different region of the document, but the regions have substantial overlap in an effort to make the final document vector robust to alignment noise, such as offsets caused by a boilerplate header or advertisement present in one document but not the other.

C Downstream MT Performance for All Thresholds

Since the underlying amount of aligned Sinhala–English documents from ParaCrawl is unknown, in order to evaluate downstream MT performance we rank the sentence pairs produced by each method from highest to lowest quality following (Chaudhary et al., 2019) and train each system on many different thresholds. The thresholds for each method are selected to produce different amounts of data, which we measure in English words. Results are shown in Figure 4.

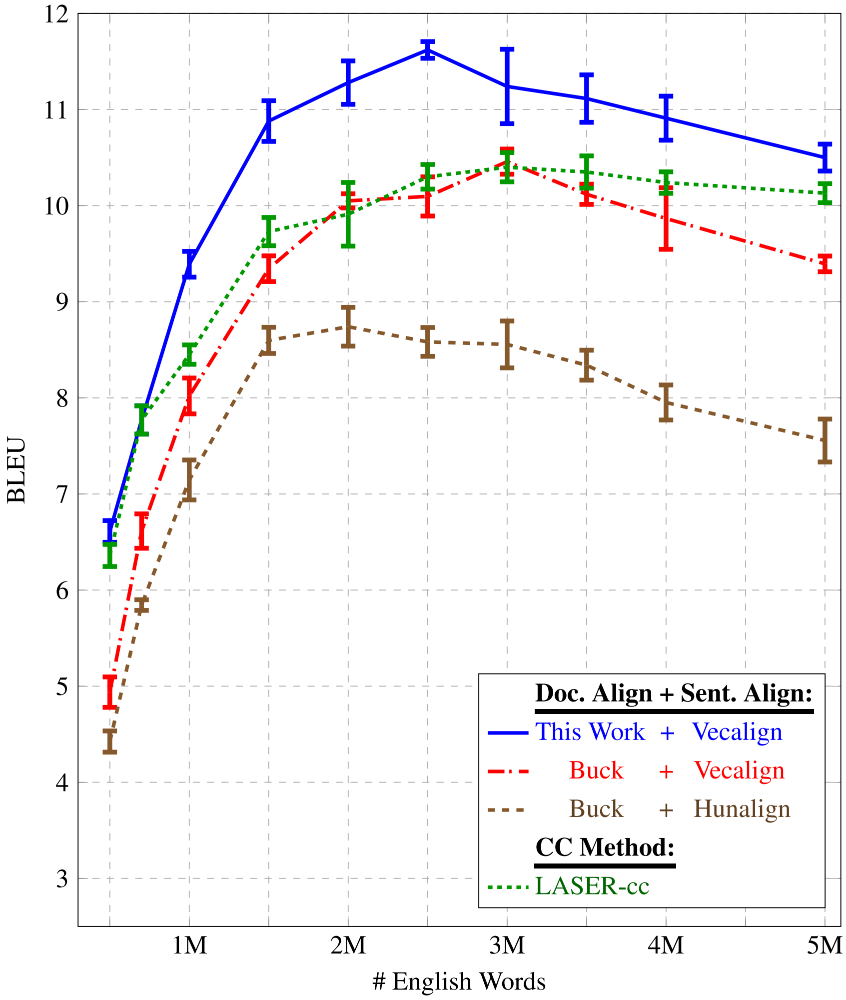

Figure 4: BLEU scores (mean +/- standard deviation for 5 training runs) for systems trained on parallel sentences extracted via several methods, over a range of different filtering thresholds. 'Buck' denotes Buck and Koehn (2016b). LASER-cc denotes the comparable corpora method of Artetxe and Schwenk (2019a).

XGLUE: A New Benchmark Dataset for Cross-lingual Pre-training, Understanding and Generation

Abstract

In this paper, we introduce **XGLUE**, a new benchmark dataset that can be used to train large-scale cross-lingual pre-trained models using multilingual and bilingual corpora and evaluate their performance across a diverse set of cross-lingual tasks. Comparing to GLUE (Wang et al., 2019), which is labeled in English for natural language understanding tasks only, XGLUE has two main advantages: (1) it provides 11 diversified tasks that cover both natural language understanding and generation scenarios; (2) for each task, it provides labeled data in multiple languages. We extend a recent cross-lingual pre-trained model Unicoder (Huang et al., 2019) to cover both understanding and generation tasks, which is evaluated on XGLUE as a strong baseline. We also evaluate the base versions (12-layer) of Multilingual BERT, XLM and XLM-R for comparison. [1]

1 Introduction

Pre-training + Fine-tuning has become a new NLP paradigm, where the general knowledge are firstly learnt from large-scale corpus by self-supervised learning and then transferred to downstream tasks by task-specific fine-tuning. Three different types of pre-trained models are explored recently, including *monolingual pre-trained models* (Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019b; Dong et al., 2019; Lewis et al., 2019a), *multilingual and cross-lingual pre-trained models* (Devlin et al., 2019; Conneau and Lample, 2019; Huang et al., 2019; Conneau et al., 2019) and *multimodal pre-trained models* (Lu et al., 2019; Li et al., 2020; Chen et al., 2019; Zhou et al., 2020). In this paper, we focus on the cross-lingual pre-trained models, due to their importance to alleviating the low-resource issue among languages, where an NLP task often has rich training data in one language (such as English) but has few or no training data in other languages (such as French and German). In order to further advance the development of cross-lingual pre-trained models for various downstream tasks in different languages, this paper introduces **XGLUE**, a new benchmark dataset that can be used to: (i) train large-scale cross-lingual pre-trained models using multilingual and bilingual corpora, (ii) evaluate generalization capabilities of the cross-lingual pre-trained models across a diverse set of cross-lingual tasks.

The contribution of XGLUE is two-fold. First, it provides 11 diversified cross-lingual tasks covering both understanding and generation scenarios. XTREME (Hu et al., 2020) is a concurrent work of XGLUE. But it includes cross-lingual understanding tasks only. Besides, XGLUE introduces 6 new tasks selected from Search, Ads and News scenarios,which makes XGLUE have more practical values. Second, an extended version of Unicoder (Huang et al., 2019) is described and evaluated as a strong cross-lingual pre-trained model baseline on XGLUE for both understanding and generation tasks. We also evaluate the base versions (12-layer) of Multilingual BERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019) and XLM-R (Conneau et al., 2019) for comparison.

2 XGLUE Benchmark

2.1 Pre-training Corpus

We collect two corpora, *Small Corpus* and *Large Corpus*, with different sizes for cross-lingual pre-training. Table 1 lists the data statistics.

2.1.1 Small Corpus (SC)

Multilingual Corpus We extract raw sentences from Wikipedia using *WikiExtractor*. It leads to a 101G multilingual corpus covering 100 languages.

---

[1] The dataset is available at `https://microsoft.github.io/XGLUE/`, The code and model is available at `https://github.com/microsoft/Unicoder`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6008–6018,
November 16–20, 2020.

	Type	# of Languages	Size
Small Corpus	Multilingual	100	101G
	Bilingual	27	146G
Large Corpus	Multilingual	100	2,500G+101G
	Bilingual	27	146G

Table 1: The statistics of two pre-training corpora.

Bilingual Corpus We use an in-house pipeline to extract bilingual sentence pairs from the Web, which leads to a 146G bilingual corpus covering 27 languages, including *Arabic*, *Bulgarian*, *Danish*, *German*, *Greek*, *English*, *Spanish*, *Finnish*, *French*, *Hebrew*, *Hindi*, *Hungarian*, *Indonesian*, *Italian*, *Japanese*, *Korean*, *Dutch*, *Polish*, *Portuguese*, *Russian*, *Swedish*, *Swahili*, *Thai*, *Turkish*, *Urdu*, *Vietnamese* and *Chinese*. All the bilingual pairs are English to another language.

2.1.2 Large Corpus (LC)

Multilingual Corpus Following Wenzek et al. (2019), we construct a clean version of Common Crawl (CC)[2] as the multilingual corpus. First, we use a language identification model trained based on Wikipedia to classify the language of each page in CC. Then, we train a language model for each language using the corresponding part of the Wikipedia corpus, and use it to filter documents as Wenzek et al. (2019) did. We use one CC dump for English and twelve CC dumps for other languages. It leads to a 2,500G multilingual corpus covering 89 languages. We also include the 101G multilingual corpus described in Section 2.1.1.

Bilingual Corpus We reuse the bilingual corpus described in Section 2.1.1. We will add CCMatrix (Schwenk et al., 2019) in the future.

2.2 Downstream Tasks

We select 11 cross-lingual tasks in XGLUE, which are categorized into 3 groups: single-input understanding tasks, pair-input understanding tasks, and generation tasks. For each task, training set is only available in English. In order to obtain a good performance on XGLUE, a model should be able to learn how to do a task well using its English training set, and then transfer this ability to test sets in other languages. Table 2 gives the dataset statistics and Table 3 lists languages covered by all tasks.

2.2.1 Single-input Understanding Tasks

NER We select a subset of the following two NER tasks, CoNLL-2002 NER (Sang, 2002) and CoNLL-2003 NER (Sang and De Meulder, 2003), to form this cross-lingual NER dataset. It covers 4 languages, including *English*, *German*, *Spanish* and *Dutch*, and 4 types of named entities, including *Person*, *Location*, *Organization* and *Miscellaneous* entities that do not belong to the previous three types. F1 score is used as the metric.

POS Tagging (POS) Following (Kim et al., 2017), we select a subset of Universal Dependencies (UD) Treebanks (v2.5) (Zeman et al., 2019), which covers 18 languages. Accuracy (ACC) of the predicted POS tags is used as the metric.

News Classification (NC) This task aims to predict the category given a news article. It covers 5 languages, including *English*, *Spanish*, *French*, *German* and *Russian*. Each labeled instance is a 3-tuple: <news title, news body, category>. The category number is 10. We crawl this dataset from Microsoft News (MSN). Accuracy (ACC) of the multi-class classification is used as the metric.

2.2.2 Pair-input Understanding Tasks

MLQA The MLQA (Lewis et al., 2019b) is a multilingual machine reading comprehension task, which contains QA annotations labeled in 7 languages, including *English*, *Arabic*, *German*, *Spanish*, *Hindi*, *Vietnamese* and *Chinese*. F1 score of the predicted answers is used as the metric.

XNLI We reuse the original XNLI dataset (Conneau et al., 2018) in XGLUE.

PAWS-X The PAWS-X (Yang et al., 2019a) is a paraphrase identification dataset, which extends the Wikipedia portion of the PAWS (Zhang et al., 2019) evaluation to more languages. We select 4 languages, including *English*, *Spanish*, *French* and *German*, from the original dataset and use them in XGLUE. Accuracy (ACC) of the binary classification is used as the metric.

Query-Ad Matching (QADSM) This task aims to predict whether an advertisement (ad) is relevant to an input query. It covers 3 languages, including *English*, *French* and *German*. Each labeled instance is a 4-tuple: <query, ad title, ad description, label>. The label indicates whether the ad is relevant to the query (Good), or not (Bad). We con-

Table 3: The 19 languages covered by the 11 downstream tasks: *Arabic* (ar), *Bulgarian* (bg), *German* (de), *Greek* (el), *English* (en), *Spanish* (es), *French* (fr), *Hindi* (hi), *Italian* (it), *Dutch* (nl), *Polish* (pl), *Portuguese* (pt), *Russian* (ru), *Swahili* (sw), *Thai* (th), *Turkish* (tr), *Urdu* (ur), *Vietnamese* (vi), and *Chinese* (zh). All these 6 new tasks with $*$ are labeled by human, except es, it and pt datasets in QG (80+% accuracy) are obtained by an in-house QA ranker.

struct this dataset based on Bing. Accuracy (ACC) of the binary classification is used as the metric.

Web Page Ranking (WPR) This task aims to predict whether a web page is relevant to an input query. It covers 7 languages, including *English*, *German*, *French*, *Spanish*, *Italian*, *Portuguese* and *Chinese*. Each labeled instance is a 4-tuple: <query, web page title, web page snippet, label>. The relevance label contains 5 ratings: Perfect (4), Excellent (3), Good (2), Fair (1) and Bad (0). We construct this dataset based on Bing. Normalize Discounted Cumulative Gain (nDCG) is used as the metric.

QA Matching (QAM) This task aims to predict whether a <question, passage> pair is a QA pair. It covers 3 languages, including *English*, *French* and *German*. Each labeled instance is a 3-tuple: <question, passage, label>. The label indicates whether the passage is the answer of the question (1), or not (0). We construct this dataset based on Bing. Accuracy (ACC) of the binary classification is used as the metric.

2.2.3 Generation Tasks

Question Generation (QG) This task aims to generate a question for a given passage. We collect <passage, question> pairs from Bing. It covers 6 languages, including *English*, *French*, *German*, *Spanish*, *Italian* and *Portuguese*. BLEU-4 score is used as the metric.

News Title Generation (NTG) This task aims to generate a proper title for a given news body. We collect <news body, news title> pairs from Microsoft News (MSN). It covers 5 languages, including *German*, *English*, *French*, *Spanish* and *Russian*. BLEU-4 score is used as the metric.

3 Pre-train Unicoder for Cross-lingual Understanding Tasks

We select Unicoder (Huang et al., 2019) as the backbone model. Section 3 introduces a simplified version of Unicoder using two pre-training tasks (MLN and TLM) for cross-lingual understanding tasks. Section 4 describes how to extend Unicoder to cover cross-lingual generation tasks.

The original Unicoder (Huang et al., 2019) includes more pre-training tasks besides MLM and TLM. But to keep the baseline pre-trained model simple and to reduce the experimental cost, we just use MLM and TLM in this paper. It means for understanding tasks, Unicoder is almost equal to XLM, except some hyper-parameter differences.

3.1 Masked Language Model (MLM)

Following Devlin et al. (2019), this task extends the masked language model task to multiple languages. At each iteration, a batch is composed of sentences sampled from different languages. The sampling probability of a language l_i is defined as $\lambda_{l_i} = p_{l_i}^{\alpha} / \sum_{l_i} p_{l_i}^{\alpha}$, where p_{l_i} is the percentage of the language l_i in the entire corpus, the smoothing factor α is set to 0.3. For each batch, we randomly sample 15% of the words and replace them with (i) a special symbol [MASK], (ii) a random token or (iii) keep them unchanged with probability 80%, 10% and 10%, respectively. For each token, we only use its token embedding and position embedding, and discard segment embedding and language embedding.

3.2 Translation Language Model (TLM)

Following Conneau and Lample (2019), this task extends the MLM task to bilingual corpus. Given a bilingual sentence pair, TLM first concatenates them into a single sentence, and then masks words using the same strategy of MLM. The pre-trained model learns to recover each masked word based on the bilingual context. We follow MLM to sample language pairs in each batch with $\alpha = 0.3$.

4 Pre-train Unicoder for Cross-lingual Generation Tasks

The encoder-decoder architecture is employed to extend Unicoder to generation tasks, where the BPE embeddings are shared between encoder and decoder. Two separate generative tasks are proposed for Unicoder pre-training: *Multilingual Denoising Auto-Encoding (xDAE)* and *Multilingual Future N-gram Prediction (xFNP)*.

4.1 Multilingual Denoising Auto-Encoding (xDAE)

Motivated by BART (Lewis et al., 2019a), xDAE aims to predict the original text $X = (x_1, x_2, ..., x_{|X|}) \in l_i$ from a language l_i based on its corrupted form $c(X)$, where $c(X)$ is a noising function that corrupts an input text X as its output.

Four different text noising strategies for $c(\cdot)$ are explored in this paper. (1) Shuffle the input text X by adding a noise $\alpha \sim \mathrm{U}(0, 3)$ to the input indices and then re-ordering X based on the rank of the noised indices. (2) Drop words with a probability of 0.1. (3) Replace 10% of the input words in X with the [MASK] symbol. (4) Sample a number of token spans from X with span lengths drawn from a Poisson distribution ($\lambda = 3$), and then replace each token span with a single [MASK] token. Here, 0-length spans correspond to the insertion of [MASK] tokens. Based on the performance of different noising strategies (Table 10), we select (4) and use it in pre-training. We leave finding better text noising strategies for future work.

We train Unicoder using this task by maximizing the following loss function $\mathcal{L}_{xDAE}$:

$$\mathcal{L}_{xDAE} = \sum_{l_i \in L} \sum_{X \in l_i} \sum_{t=1}^{|X|} \log p(x_t | x_{<t}, c(X))$$

where $L = l_1, ..., l_N$ denotes N languages, X is an instance in the i^{th} language l_i, $p(x_t | x_{<t}, c(X))$ denotes the probability of generating a single token x_t at time step t given $c(X)$ and $x_{<t}$.

4.2 Multilingual Future N-gram Prediction (xFNP)

Motivated by ProphetNet (Yan et al., 2020), xFNP introduces a future n-gram prediction mechanism to natural language generation. It encourages the model to plan for the future tokens explicitly and prevents over-fitting on strong local correlations.

Given an input text $X = (x_1, x_2, ..., x_{|X|}) \in l_i$ from a language l_i, we randomly mask k token spans of X to generate the masked text $X^{'}$ as the input, and concatenate all masked token spans into Y as the output. Details of this mask strategy are described in Section 6.1. After this, xFNP first encodes $X^{'}$ to H_{enc} with the encoder:

$$H_{enc} = \mathrm{Encoder}(X^{'})$$

Then, instead of predicting the next token only at each time step, xFNP generates n future tokens simultaneously at time step t with the decoder:

$$\begin{aligned} p(y_t|y_{<t}, X^{'}), ..., p(y_{t+n-1}|y_{<t}, X^{'}) \\ = \text{Decoder}(y_{<t}, H_{enc}) \end{aligned}$$

Following Yan et al. (2020), we set $n = 2$.

We train Unicoder using this task by maximizing the following loss function $\mathcal{L}_{xFNP}$:

$$\begin{aligned} \mathcal{L}_{xFNP} = \sum_{l_i \in L} \sum_{X \in l_i} \{\alpha_0 \cdot \sum_{t=1}^{|Y|} \log p(y_t|y_{<t}, X^{'}) \\ + \alpha_1 \cdot \sum_{t=1}^{|Y|-1} \log p(y_{t+1}|y_{<t}, X^{'})\} \end{aligned}$$

where $X^{'}$ and Y are generated from X based on the method mentioned above. Following Yan et al. (2020), we set $\alpha_0 = \alpha_1 = 1$.

5 Experiments

5.1 Data Labeling

For tasks QADSM, WPR, QAM and QG, we label the data on an Microsoft internal crowdsourcing platform. Each labeler must learn the guideline and pass the labeling test. Each sample is labeled by three labeler. We only keep the samples with two or three labeler have same label.

For tasks NC and NTG, we directly use the category label on MSN website. All the category label on MSN is review by human.

5.2 Experimental Settings

Understanding Tasks The hyper-parameters are set as follows: 768 hidden units, 12 heads, GELU activation, a dropout rate of 0.1, 512 max input length, 12 layers in encoder.

In the pre-training stage, we first initialize Unicoder$_{LC}$ with XLM-R$_{base}$ (Conneau et al., 2019), and then run continue pre-training with the accumulated 8,192 batch size with gradients accumulation. We use Adam Optimizer with a linear warm-up and set the learning rate to 3e-5. We select different understanding tasks randomly in different batches. This costed 12 days on 16 V100.

In the fine-tuning stage, the batch size is set to 32. We use Adam Optimizer (Kingma and Ba, 2014) with warm-up and set the learning rate to 5e-6. For all sentence classification tasks, we fine-tune 10 epochs. For POS Tagging and NER, we fine-tune 20 epochs. And for POS Tagging, we set the learning rate to 2e-5. For MLQA, we set the learning rate to 3e-5, batch size to 12 and train 2 epochs following BERT for SQuAD. After each epoch, we test the fine-tuned model on the dev sets of all languages. We select the model with the best average result on the dev sets of all languages.

Generation Tasks We evaluate Unicoder$_{SC}^{xDAE}$ and Unicoder$_{SC}^{xFNP}$ as two separate models.

For Unicoder$_{SC}^{xDAE}$, the hyper-parameters are set as follows: 768 hidden units, 12 heads, GELU activation, a dropout rate of 0.1, 512 max input length, 12 layers in encoder, 12 layers in decoder.

In the pre-training stage, we first initialize encoder and decoder with XLM-R, and then run continue pre-training with 1,024 batch size. We use Adam optimizer with warm-up and set the learning rate to 2e-4. This costed 10 days on 16 V100.

In the fine-tuning stage, the batch size is 1024. We use Adam Optimizer with learning rate 1e-5 and warm-up steps 2000.

For Unicoder$_{SC}^{xFNP}$, the hyper-parameters are set as follows: 1,024 hidden size, 12 layers in encoder, 12 layers in decoder, 512 max input length.

In the pre-training stage, we pre-train the model from scratch and follow ProphetNet (Yan et al., 2020) to randomly mask a continuous span (with a fixed length 9) in every 64 tokens. About 15% of the tokens in original sequence are masked in this step. We use a special symbol [MASK] to replace 80% of the masked tokens, keep 10% unchanged, and random replace 10% of the masked tokens. We set the batch size to 1,024, training steps to 350,000. The learning rate is set to 1e-4. We set the number of future tokens n to 2.

In the fine-tuning stage, we use Adam Optimizer and set the learning rate to 1e-4. We set the batch size to 64 and the warm-up steps to 1,000.

5.3 Main Result

7 cross-lingual pre-trained models are evaluated on XGLUE and compared in Table 4: 12-layer M-BERT (Devlin et al., 2019) trained on Wikipedia corpus for 102 languages, 12-layer XLM (Conneau and Lample, 2019) trained on Wikipedia and bilingual corpora for 15 languages, 12-layer XLM-R$_{base}$ (Conneau et al., 2019) trained on Common Crawl corpus for 100 languages, 12-layer Unicoder$_{SC}$ trained on small corpus for 100 languages, 12-layer Unicoder$_{LC}$ trained on large corpus for 100 languages, 12-layer Unicoder$_{SC}^{xDAE}$ and

Table 4: The overall evaluation results on XGLUE. We use M-BERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019) and XLM-R$_{base}$ (Conneau et al., 2019) as baselines. Unicoder$_{SC}$ and Unicoder$_{LC}$ are pre-trained using small corpus and large corpus, respectively. Unicoder$_{SC}^{xDAE}$ and Unicoder$_{SC}^{xFNP}$ are pre-trained by xDAE and xFNP for 100 languages, respectively. For the results of M-BERT/XLM-R on generation tasks, we initialize the encoder-decoder model with M-BERT/XLM-R and fine-tune it on each downstream task without pre-training. **All models are (12-layer) based ones.** Given a task, each pre-trained model is fine-tuned using its English training set only, and then applied to all test sets in different languages. AVG$_U^2$ and AVG$_G^2$ denote the average score of the average scores on 9 understanding tasks and 2 generation tasks, respectively.

Table 6: Impacts of different pivot languages on NTG. Unicoder$_{SC}^{xDAE}$/Unicoder$_{SC}^{xFNP}$ evaluated by BLEU-4.

12-layer Unicoder$_{SC}^{xFNP}$ trained on Wikipedia corpus for 100 languages. Given a downstream task, each pre-trained model is fine-tuned using its English training set and then applied to all test sets in different languages. Note that, all results are reproduced by this paper, except the XLM† results on XNLI are from Conneau and Lample (2019).

We find (1) Unicoder$_{LC}$ performs slightly better than M-BERT and XLM-R$_{base}$ on the 9 understanding tasks, as it is pre-trained based on multilingual and bilingual corpora at the same time and uses TLM; (2) Unicoder$_{LC}$ performs better than Unicoder$_{SC}$, as it is pre-trained based on the larger corpus; (3) Unicoder$_{SC}^{xDAE}$ and Unicoder$_{SC}^{xFNP}$ show good cross-lingual transfer capabilities and perform significantly better than M-BERT and XLM-R$_{base}$ on the 2 generation tasks. It proves the importance of introducing generation tasks into pre-training for cross-lingual text generation; (4) Unicoder$_{SC}^{xFNP}$ performs slightly better than Unicoder$_{SC}^{xDAE}$. But it is not a fair comparison, because they use different text denoising tasks (sentence prediction vs. span prediction) and different generation mechanisms (single-token prediction vs. multi-token prediction). We leave combining these two tasks for future work.

5.4 Ablation Study

5.4.1 Pivot-language Fine-tuning

We define pivot-language (*pl*) fine-tuning as fine-tune a pre-trained model for a downstream task using its labeled data in a pivot language (e.g. English) and then apply the fine-tuned model to all languages. Table 4 chooses English as the pivot language, as all tasks in XGLUE have labeled data in English. But is English always the optimal choice? Will the results become better, if we do fine-tuning using other pivot languages?

To answer these questions, we evaluate Unicoder on XNLI and NTG using different pivot languages in fine-tuning and list comparison results in Table 5 and Table 6, respectively. (1) For each test set in language l_i in Table 5 and Table 6, its best result is often achieved when the model is fine-tuned using l_i as the pivot language; (2) For XNLI in Table 5, the best pivot languages are Spanish (es), Greek (el) and Turkish (tr), rather than English (en). For NTG in Table 6, the best pivot language is French (fr) for both Unicoder$_{SC}^{xDAE}$ and Unicoder$_{SC}^{xFNP}$. It means the average quality of a cross-lingual pre-trained model could be further improved on a downstream task, by selecting a specific pivot language in fine-tuning.

5.4.2 Multi-language Fine-tuning

We define multi-language (*ml*) fine-tuning as fine-tune a pre-trained model for a downstream task using all its available labeled data in different languages. We evaluate Unicoder on XNLI and NTG using this fine-tuning method and list evaluation results in Table 7 and Table 8, respectively.

We find multi-language fine-tuning can achieve better results than pivot-language fine-tuning on both XNLI and NTG. It means the average quality of a cross-lingual pre-trained model could be significantly improved on a downstream task, by using combined labeled data in multiple languages.

5.4.3 Multi-task Fine-tuning

We define multi-task (*mt*) fine-tuning as fine-tune a pre-trained model for multiple downstream tasks using their combined labeled data. To reduce the experimental cost, we evaluate Unicoder on 5 understanding tasks: XNLI, PAWS-X, NC, QAM and QADSM, using their merged English labeled data in fine-tuning. Results are listed in Table 9.

We find PAWS-X and QADSM can benefit from the joint fine-tuning strategy, but XNLI, NC and QAM cannot. We leave discovering relationships between different tasks for better downstream task fine-tuning for future work.

5.4.4 Impacts of Text Noising Strategies

We investigate the impacts of different text noising strategies (Section 4.1) in Unicoder$_{SC}^{xDAE}$, and list comparison results in Table 10, where (1)+(2)+(3) denotes the result of using the first three strategies in pre-training, (4) denotes the result of using the last strategy in pre-training, (1)+(2)+(3)+(4) denotes the result of using all strategies in pre-training. To reduce experiment cost, we set max sequence length to 256 and only train 60K steps. We find that (4) can achieve the best average result on NTG. So all results of Unicoder$_{SC}^{xDAE}$ reported in this paper is pre-trained using (4) only.

Unicoder$_{LC}$ (mt)	74.4	**90.2**	83.4	68.7	**69.0**	77.1

Table 9: Impacts of multi-task fine-tuning on XNLI, PAWS-X, NC, QAM and QADSM. pl and mt denote pivot-language fine-tuning (English as pivot) on each task and multi-task fine-tuning, respectively.

We also compare Unicoder$_{SC}^{xDAE}$ with XNLG (Chi et al., 2019) on the Abstractive Summarization task. For fairly comparison, we implement xDAE in same code base and use same pre-training languages as XNLG. The zero-shot comparison results are listed in Table 11. We can see that by using xDAE only in pre-training, Unicoder$_{SC}^{xDAE}$ can outperform XNLG significantly, which is pre-trained using 4 tasks including MLM, DAE, XMLM and XAE. It verifies the effectiveness of the fourth text noising strategy described in Section 4.1 for generation tasks.

6 Related Work

Dataset GLUE (Wang et al., 2019) includes 9 natural language understanding tasks that are labeled in English only. Comparing to GLUE, XGLUE not only expands task annotations to multiple languages, but also includes natural language generation tasks. XNLI (Conneau et al., 2018), NER (Sang, 2002; Sang and De Meulder, 2003), POS Tagging (Kim et al., 2017), MLQA (Lewis et al., 2019b) and PAWS-X (Yang et al., 2019a) are 5 multilingual datasets built for specific tasks.

Table 11: The zero-shot results on Abstractive Summarization. Unicoder$_{SC}^{xDAE}$ and XNLG are fine-tuned using English labeled data. ROUGE-L is the metric.

XGLUE not only includes these 5 existing tasks, but also introduces 6 new tasks selected from real-world scenarios (i.e., Search, Ads and News). This makes XGLUE have more practical values. XTREME (Hu et al., 2020) is a concurrent work of XGLUE. Comparing to it, XGLUE includes both understanding and generation tasks, which, to the best of our knowledge, is the first attempt in the cross-lingual dataset construction efforts.

Cross-lingual Pre-trained Model Multilingual BERT (M-BERT) (Devlin et al., 2019) performs pre-training based on the multilingual corpus with the masked language model task. By sharing the model parameters and the vocabulary for all languages, M-BERT can obtain the cross-lingual capability over 102 languages. XLM (Conneau and Lample, 2019) performs cross-lingual pre-training based on multilingual corpus and bilingual corpus, by introducing the translation language model task into pre-training. Based on XLM, Unicoder (Huang et al., 2019) uses more cross-lingual pre-training tasks and achieves better results on XNLI. XLM-R (Conneau et al., 2019) is a RoBERTa (Liu et al., 2019)-version XLM without using translation language model in pre-training. It is trained based on a much larger multilingual corpus (i.e. Common Crawl) and become the new state-of-the-art on XNLI. In this paper, we use both the Common Crawl corpus and the bilingual corpus, aiming to build a stronger baseline model on XGLUE. BART (Lewis et al., 2019a) and ProphetNet (Yan et al., 2020) are two latest generative pre-trained models. We borrow ideas from these two works and extend Unicoder to cross-lingual generation tasks, which goes a step further to verify and explore different text generation approaches in the cross-lingual scenario.

7 Conclusion

We present XGLUE as a new cross-lingual benchmark and conduct comprehensive evaluations with interesting findings observed. We thank STC-A NLP, Bing Answers, Bing Ads, Bing Relevance and Microsoft News for providing the datasets.

Abstract

The linear-chain Conditional Random Field (CRF) model is one of the most widely-used neural sequence labeling approaches. Exact probabilistic inference algorithms such as the forward-backward and Viterbi algorithms are typically applied in training and prediction stages of the CRF model. However, these algorithms require sequential computation that makes parallelization impossible. In this paper, we propose to employ a parallelizable approximate variational inference algorithm for the CRF model. Based on this algorithm, we design an approximate inference network that can be connected with the encoder of the neural CRF model to form an end-to-end network, which is amenable to parallelization for faster training and prediction. The empirical results show that our proposed approaches achieve a 12.7-fold improvement in decoding speed with long sentences and a competitive accuracy compared with the traditional CRF approach.

1 Introduction

Sequence labeling assigns each token with a label in a sequence. Tasks such as Named Entity Recognition (NER) (Sundheim, 1995), Part-Of-Speech (POS) tagging (DeRose, 1988) and chunking (Tjong Kim Sang and Buchholz, 2000) can all be formulated as sequence labeling tasks. BiLSTM-CRF (Huang et al., 2015; Lample et al., 2016; Ma and Hovy, 2016) is one of the most successful neural sequence labeling architectures. It feeds pretrained (contextual) word representations into a single layer bi-directional LSTM (BiLSTM) encoder to extract contextual features and then feeds these features into a CRF (Lafferty et al., 2001) decoder layer to produce final predictions. The CRF layer is a linear-chain structure that models the relation between neighboring labels. In the traditional CRF approach, exact probabilistic inference algorithms such as the forward-backward and Viterbi algorithms are applied for training and prediction respectively. In many sequence labeling tasks, the CRF layer leads to better results than the simpler method of predicting each label independently.

In practice, we sometimes require very fast sequence labelers for training (e.g., on huge datasets like WikiAnn (Pan et al., 2017)) and prediction (e.g. for low latency online serving). The BiLSTM encoder and the CRF layer both contain sequential computation and require $O(n)$ time over n input words even when parallelized on GPU. A common practice to improve the speed of the encoder is to replace the BiLSTM with a CNN structure (Collobert et al., 2011; Strubell et al., 2017), distill larger encoders into smaller ones (Tsai et al., 2019; Mukherjee and Awadallah, 2020) or in other settings (Tu and Gimpel, 2018; Yang et al., 2018; Tu and Gimpel, 2019; Cui and Zhang, 2019). The CRF layer, however, is more difficult to replace because of its superior accuracy compared with faster alternatives in many tasks.

In order to achieve sublinear time complexity on the CRF layer, we must parallelize the CRF prediction over the tokens. In this paper, we apply Mean-Field Variational Inference (MFVI) to approximately decode the linear-chain CRF. MFVI iteratively passes messages among neighboring labels to update their distributions locally. Unlike the exact probabilistic inference algorithms, MFVI can be parallelized over different positions in the sequence, achieving time complexity that is constant in n with full parallelization. Previous work (Zheng et al., 2015) showed that such an algorithm can be unfolded as an RNN for grid CRF struc-

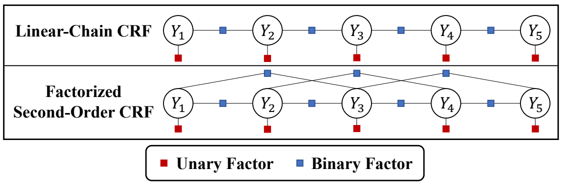

Figure 1: Factor graphs of different CRFs. Y_i is the random variable representing the i-th label.

ture. We expand on the work for the linear-chain CRF structure and unfold the algorithm as an RNN which can be connected with the encoder to form an end-to-end neural network that is amenable to parallelization for both training and prediction. We call the unfolded RNN an approximate inference network (AIN). In addition to linear-chain CRFs, we also apply AIN to factorized second-order CRF models, which consider relations between more neighboring labels. Our empirical results show that AIN significantly improves the speed and achieves competitive accuracy against the traditional CRF approach on 4 tasks with 15 datasets.

2 Approaches

Given an input sequence with n tokens $\mathbf{x} = [x_1, x_2, \dots, x_n]$ and a corresponding label sequence $\mathbf{y} = [y_1, y_2, \dots, y_n]$ with a label set of size L, the conditional probability of $\mathbf{y}$ given $\mathbf{x}$ specified by a CRF with position-wise factorization is:

$$P(\mathbf{y}|\mathbf{x}) = \frac{\exp\{\sum_{i=1}^{n} \psi(\mathbf{x}, \mathbf{y}, i)\}}{\sum_{\mathbf{y}' \in \mathcal{Y}(\mathbf{x})} \exp\{\sum_{i=1}^{n} \psi(\mathbf{x}, \mathbf{y}', i))\}}$$

where $\mathcal{Y}(\mathbf{x})$ is the set of all possible label sequences for $\mathbf{x}$ and $\psi(\mathbf{x}, \mathbf{y}, i)$ is a potential function.

In the simplest case, the potential function is just a softmax function that outputs the distribution of each label independently. We call it the MaxEnt approach. In a typical linear-chain CRF, the potential function is decomposed into a unary potential ψ_u and a binary potential ψ_b (called the emission and transition functions respectively):

$$\psi(\mathbf{x}, \mathbf{y}, i) = \psi_u(\mathbf{x}, y_i) + \psi_b(y_{i-1}, y_i) \quad (1)$$

$$\psi_u(\mathbf{x}, y_i) = \mathbf{r}_i \mathbf{W} \mathbf{v}_{y_i}$$

$$\psi_b(y_{i-1}, y_i) = \mathbf{U}_{y_{i-1}, y_i} \quad (2)$$

where $\mathbf{r}_i$ is the contextual feature of x_i output from the CNN or BiLSTM encoder with dimension d, $\mathbf{v}_{y_i}$ is a one-hot vector for label y_i, $\mathbf{W}$ is a $d \times L$ matrix and $\mathbf{U}$ is an $L \times L$ matrix containing the transition scores between two labels. The factor graph of a linear-chain CRF is shown at the top of Figure 1.

The exact probabilistic inference algorithms (Viterbi and forward-backward) for the CRF layer are significantly slower than the MaxEnt approach. They take $O(nL^2)$ and $O(n \log L)$ time on CPU and GPU[1] respectively, while the decoder in MaxEnt takes $O(nL)$ and $O(\log L)$.

2.1 AIN on Linear-Chain CRF

In order to speed up the training and prediction time of the CRF layer, we propose the approximate inference network (AIN), which is a neural network derived from MFVI for approximate decoding in linear-chain CRF.

MFVI approximates the distribution $P(\mathbf{y}|\mathbf{x})$ with a factorized distribution $Q(\mathbf{y}|\mathbf{x}) = \prod_{i=1}^{n} Q_i(y_i|\mathbf{x})$ and update it iteratively to minimize the KL divergence $KL(Q||P)$. The update formula of $Q_i(y_i|\mathbf{x})$ at iteration m is:

$$s(i,j,k) := \sum_{y_i=1}^{L} Q_i^{k-1}(y_i|\mathbf{x}) \psi_b(y_{\min\{i,j\}}, y_{\max\{i,j\}})$$

$$Q_i^m(y_i|\mathbf{x}) \propto \exp\{\psi_u(\mathbf{x}, y_i) + s(i-1, i, m) + s(i+1, i, m)\}$$

where $s(i,j,k)$ represents the message from node i to node j at time step k. $Q_i^0(y_i|\mathbf{x})$ is set by normalizing the unary potential $\psi_u(\mathbf{x}, y_i)$. Upon convergence, the label sequence with the highest approximate probability $Q(\mathbf{y}|\mathbf{x})$ can be found by optimizing $Q_i(y_i|\mathbf{x})$ at each position i:

$$\hat{y}_i = \operatorname*{argmax}_{y_i \in \{1,\dots,L\}} Q_i(y_i|\mathbf{x})$$

Similar to Zheng et al. (2015), we unfold the MFVI algorithm as a recurrent neural network that is parameterized by the linear-chain CRF potential functions. We fix the number of iterations to M and call the resulting network AIN. AIN can be connected with the encoding network that computes the potential functions and together they form an end-to-end neural network.

Note that, different from previous work (Krähenbühl and Koltun, 2011; Zheng et al., 2015; Baqué

---

[1] We assume that the number of threads is enough for full parallelization on GPU and the parallel reduction (e.g., sum and max) for a L elements vector takes $O(\log L)$ time (Harris et al., 2007).

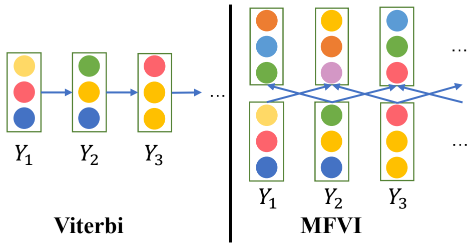

Figure 2: Illustration of the computation graphs for the Viterbi decoding and one iteration of our MFVI inference on the CRF model. Y_i is the random variable representing the i-th label with three possible values. The illustrated vectors represent Viterbi scores and Q_i distributions respectively.

et al., 2016; Chen et al., 2018; Wang et al., 2019) using the MFVI algorithm for solving intractable problems of densely connected probabilistic models to get better accuracy, we propose to employ the MFVI algorithm to accelerate tractable inference of sequence-structured probabilistic models. As far as we know, this is the first attempt of using approximate inference on tractable models for speedup with GPU parallelization.

The time complexity of each iteration of the MFVI algorithm is $O(nL^2)$, which is on par with the time complexity of the exact probabilistic inference algorithms. However, in each iteration, the update of each distribution $Q_i(y_i|\mathbf{x})$ depends only on its two neighboring distributions from the previous iteration, so each iteration can be parallelized over positions. A comparison between the Viterbi algorithm and the MFVI algorithm is shown in Figure 2. The time complexity of our AIN decoder with full GPU parallelization is $O(M \log L)$, while the time complexity of the exact probabilistic inference algorithms with GPU parallelization is $O(n \log L)$. We set the value of M to 3s , which is much smaller than the typical value of sequence length n.

2.2 AIN on Factorized Second-Order CRF

We can extend AIN to the second-order CRF with a ternary potential function over every three consecutive labels. In the second-order CRF, the potential function in Eq. 1 becomes:

$$\psi(\mathbf{x}, \mathbf{y}, i) = \psi_u(\mathbf{x}, y_i) + \psi_t(y_{i-2}, y_{i-1}, y_i)$$

However, the second-order CRF has space and time complexity that is cubic in L. Therefore, we factorize its ternary potential function and reduce its complexity to be quadratic in L:

$$\psi_t(y_{i-2}, y_{i-1}, y_i) = \psi_{b'}(y_{i-2}, y_i) + \psi_b(y_{i-1}, y_i)$$
$$\psi_{b'}(y_{i-2}, y_i) = \tilde{\mathbf{U}}_{y_{i-2}, y_i}$$

where the matrix $\tilde{\mathbf{U}}$ has the same shape as $\mathbf{U}$ in Eq. 2. The factor graph of our factorized second-order CRF is shown at the bottom of Figure 1. The update formula is similar to that of our first-order approach but with more neighbors:

$$Q_i^m(y_i|\mathbf{x}) \propto \exp\{\psi_u(\mathbf{x}, y_i) + s'(i-2, i, m) + s(i-1, i, m) + s(i+1, i, m) + s'(i+2, i, m)\}$$

where $s'(i, j, k)$ has a similar definition as $s(i, j, k)$ by replacing ψ_b with $\psi_{b'}$. The time complexity of this approach is also $O(nL^2)$ for each iteration and $O(M \log L)$ with full GPU parallelization for M iterations. Following the first approach, we also unfold MFVI of this approach as an AIN.

2.3 Learning

Given a sequence $\mathbf{x}$ with corresponding gold labels $\mathbf{y}^* = \{y_1^*, \cdots, y_n^*\}$, the learning objective of our approaches is:

$$\mathcal{L}_{\text{NLL}} = -\sum_{i=1}^{n} \log Q_i^M(y_i^*|\mathbf{x})$$

Since AINs are end-to-end neural networks, the objective function can be optimized by any gradient-based method in an end-to-end manner.

3 Experiments

3.1 Datasets

Named Entity Recognition (NER) We use the corpora from the CoNLL 2002 and CoNLL 2003 shared tasks (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), which contain four languages in total. We use the standard training/development/test split for experiments.[2]

Chunking The chunking datasets are also from the CoNLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003) that contains English and German datasets. We use the same standard split as in NER.

Table 2: Averaged F1 score and accuracy on four tasks. **SF** represents the slot filling task. $\star$: For reference.

Part-Of-Speech (POS) Tagging Universal Dependencies[3] (UD) (Nivre et al., 2018) contains syntactically annotated corpora of over 70 languages. We use universal POS tag annotations with 8 languages for experiments. The list of treebanks is shown in Table 3. We use the standard training/development/test split for experiments.

Slot Filling Slot filling is a task that interprets user commands by extracting relevant slots, which can be formulated as a sequence labeling task. We use the Air Travel Information System (ATIS) (Hemphill et al., 1990) dataset for the task. [4].

3.2 Settings

Embeddings For word embeddings in the NER, chunking and slot filling experiments, we use the same word embedding as in Lample et al. (2016) except that we use *fastText* (Bojanowski et al., 2017) embedding for Dutch which we find significantly improves the accuracy (more than 5 F1 scores on CoNLL NER). We use *fastText* embeddings for all UD tagging experiments. For character embedding, we use a single layer character CNN with a hidden size of 50, because Yang et al. (2018) empirically showed that it has competitive performance with character LSTM. We concatenate the word embedding and character CNN output for the final word representation.

Encoder In our experiments, we use three types of encoders. The first is a BiLSTM fed with word and character embeddings, which captures contextual information globally. The second is a single layer CNN with only word embedding as input, which captures contextual information locally. The third is a single linear layer with word embeddings as input, which does not capture any contextual information. We use these settings for a better understanding of how the decoders perform on each task when the encoders capture different levels of contextual information.

Decoder We use the MaxEnt approach, the traditional CRF approach and AINs with the first-order and factorized second-order CRFs for decoding. We denote these approaches by **MaxEnt**, **CRF**, **AIN-1O** and **AIN-F2O** respectively. We set the iteration number M to 3 in AINs because we find that more iterations do not result in further improvement in accuracy.

Hyper-parameters For the hyper-parameters, we follow the settings of previous work (Akbik et al., 2018). We use Stochastic Gradient Descent for optimization with a fixed learning rate of 0.1 and a batch size of 32. We fix the hidden size of the CNN and BiLSTM layer to 512 and 256 respectively, and the kernel size of CNN to 3. We anneal the learning rate by 0.5 if there is no improvement in the development sets for 10 epochs when training.

Evaluation We use F1 score to evaluate the NER, slot filling and chunking tasks and use accuracy to evaluate the POS tagging task. We convert the BIO

[4] We use the same dataset split as https://github.com/sz128/slot_filling_and_intent_detection_of_SLU/tree/master/data/atis-2

format into BIOES format for NERs, slot filling and chunking datasets and use the official release of CoNLL evaluation script[5] to evaluate the F1 score.

3.3 Results

Speed We report the relative speed improvements over the **CRF** model based on our PyTorch (Paszke et al., 2019) implementation run on a GPU server with Nvidia Tesla V100. Following Tsai et al. (2019), we report the training and prediction speed with 10,000 sentences of 32 and 128 words, respectively. The results (Table 1) show that AINs are significantly faster than **CRF** in terms of both the full model speed and the decoder speed. The speed advantage of AINs is especially prominent with long sentences, suggesting their usefulness in tasks like document-level NER.

Accuracy We run each approach on each dataset for 5 times and compute its average accuracy. Because of space limit, we report the accuracy averaged over all the datasets for each task in Table 2. Please refer to the supplementary material for the complete results. AINs achieve competitive overall accuracy with **CRF**, even though AINs take significantly less time than **CRF**. With the BiLSTM encoder which has the capability to capture global contextual information, AINs achieves almost the same average accuracy as **CRF**, demonstrating that AINs performing approximate inference with local contextual information are competitive with **CRF** with globally exact decoding. With the CNN encoder that encodes local contextual information, AINs are inferior to **CRF** because both the CNN layer and our approaches utilize only local information. Without any contextual encoders (Word Only), the accuracy of these decoders vary significantly over tasks. For NER and chunking, **CRF** is the strongest, but our approaches only marginally underperform **CRF** while significantly outperform **MaxEnt**. For POS tagging and slot filling, our approaches outperform **CRF**, which implies that local information might be more beneficial for these tasks. Comparing **AIN-1O** and **AIN-F2O**, **AIN-F2O** is stronger when the encoder is weak, but their performance gap becomes smaller and eventually disappears when the encoder gets stronger.

3.4 Discussion on Transformers

Recently, the Transformer (Vaswani et al., 2017) encoder has significantly improved the performance of tasks such as neural machine translation. The Transformer can be parallelized over the input words while the BiLSTM layer needs sequential computation. However, the transformer structure is rarely applied in sequence labeling tasks. One possible reason is that the performance of models with Transformers encoders are inferior to the performance of models with the BiLSTM encoders. In our experiments, a six-layer transformer with a MaxEnt decoder achieves an F1 score of only 80.00 on CoNLL English NER, which is significantly lower than the 91.00 F1 score of our BiLSTM+MaxEnt model (Table 5). For the speed, the six-layer transformer model with a MaxEnt decoder is 1.58/1.14 times slower than the single-layer BiLSTM model with a MaxEnt decoder with sentences of 32/128 words respectively. Therefore, we do not include the Transformer encoder in our experiments.

4 Conclusion

In this paper, we propose approximate inference networks (AIN) that use Mean-Field Variational Inference (MFVI) instead of exact probabilistic inference algorithms such as the forward-backward and Viterbi algorithms for training and prediction on the conditional random field for sequence labeling. The MFVI algorithm can be unfolded as a recurrent neural network and connected with the encoder to form an end-to-end neural network. AINs can be parallelized over different positions in the sequence. Empirical results show that AINs are significantly faster than traditional CRF and do very well in tasks that require more local information. Our approaches achieve competitive accuracy on 4 tasks with 15 datasets over three encoder types. Our code is publicly available at https://github.com/Alibaba-NLP/AIN.

Abstract

Named Entity Recognition (NER) is a fundamental task in natural language processing. In order to identify entities with nested structure, many sophisticated methods have been recently developed based on either the traditional sequence labeling approaches or directed hypergraph structures. Despite being successful, these methods often fall short in striking a good balance between the expression power for nested structure and the model complexity. To address this issue, we present a novel nested NER model named HIT. Our proposed HIT model leverages two key properties pertaining to the (nested) named entity, including (1) explicit boundary tokens and (2) tight internal connection between tokens within the boundary. Specifically, we design (1) Head-Tail Detector based on the multi-head self-attention mechanism and bi-affine classifier to detect boundary tokens, and (2) Token Interaction Tagger based on traditional sequence labeling approaches to characterize the internal token connection within the boundary. Experiments on three public NER datasets demonstrate that the proposed HIT achieves state-of-the-art performance.

1 Introduction

Named Entity Recognition (NER) is a fundamental task in natural language processing due to the fact that the named entities often convey the key information of the text (Lample et al., 2016). It is common in many practical scenarios that the named entities have a nested structure (Finkel and Manning, 2009; Silla and Freitas, 2011). That is, an entity could contain other entities or be a part of other entities. As shown in Figure 1, the entity "the western Canadian province of British Columbia" in the first example contains two inner entities, i.e., "western Canadian" and "British Columbia". Traditional methods often treat the NER task as a sequence labeling problem (Lin et al., 2018) and thus are primarily designed to recognize flat entities in the input sentences (as shown in the second example in Figure 1). Due to the nature of the nested entity, a token might belong to different entities. It is difficult to represent such nested structures using a single label accurately. Therefore, the performance of traditional NER methods will dramatically suffer when recognizing nested entities (Katiyar and Cardie, 2018).

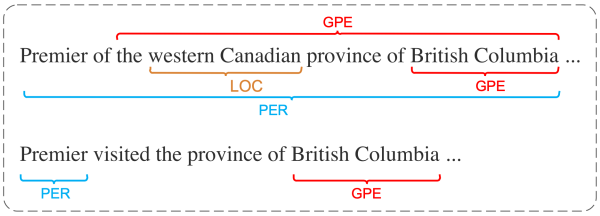

Figure 1: Examples of the named entity. The first example is a sentence with nested named entities, and the second one is a sentence only with flat named entities.

In recent years, more sophisticated methods have been developed for the nested NER task, which are grouped into two categories, including sequence-based method and hypergraph-based method. The sequence-based methods (Sohrab and Miwa, 2018; Ju et al., 2018; Zheng et al., 2019) often utilize the traditional sequence labeling approaches to learn the nested structure. For example, Ju et al., (2018) leverage the hierarchical Long Short Term Memory (LSTM) networks to capture the nested named entities from the inner entity to the outer entity. However, such methods might still suffer from error propagation due to the fundamental limitation of sequence labeling approaches in representing the nested structure. In response, hypergraph-based methods (Lu and Roth, 2015; Wang and Lu, 2018) introduce the hypergraph structure for learning the nested named entity. These methods replace the undirected graph structure, commonly used in the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6027–6036,
November 16–20, 2020.

flat NER task, by the directed hypergraph structure. The advantage lies in that hyperedges can naturally express the nested structure. One issue of their method (Lu and Roth, 2015) is the spurious structure of hypergraphs. Wang and Lu (2018) further propose the neural segmental hypergraphs to address this issue. However, if the input sentence is too long or there exist many entity categories, their hypergraph structure becomes too complicated, which in turn makes the optimization of such models very difficult, if not impossible.

This paper further explores the precise expression of the nested structure with appropriate model complexity to overcome these shortcomings effectively. We observe two key properties pertaining to the named entity, including (1) explicit boundary tokens and (2) tight internal connection between tokens within the boundary. For example, in Figure 1, "Premier" and "Columbia" (in the first example) are explicit boundary tokens, and the tokens within the boundary are closely connected with each other. On the other hand, although the candidate region "Premier visited province of British Columbia" (in the second example) shared the same boundary tokens "Premier" and "Columbia", the tokens within the boundary suggest this region should not be an entity. This indicates that different internal tokens greatly influence whether the region determined by the boundary tokens is a valid entity. In other words, in the NER task, one region should be identified as a named entity if it meets these two properties. More importantly, these properties are sensitive to the entities with the nested structure.

Armed with these observations, we propose a novel neural model named HIT for recognizing the named entities with the nested structure. Our proposed model effectively identifies nested named entities by modeling both the boundary tokens (referred to as "head-tail pair" in this paper) and connection relationship between tokens within the boundary (referred to as "token interaction" in this paper). To be specific, we design a head-tail detector based on the multi-head self-attention mechanism (Vaswani et al., 2017) and the bi-affine classifier (Dozat and Manning, 2016) to detect explicit boundary tokens. The main advantage of the multi-head self-attention mechanism is that it can directly learn the connection between tokens without having to consider token ordering information. Particularly, we adopt Focal Loss (Lin et al., 2017) to address the class imbalance problem in the training process. This is because the head-tail detector aims to detect all candidates of head-tail pairs, only a few of which correspond to valid entities. In addition, we design a token interaction tagger based on traditional sequence labeling approaches (Lample et al., 2016; Shang et al., 2018) to characterize the internal connection between tokens within the boundary through context. Another advantage of the token interaction tagger is that the captured internal connection features contain abundant lexical and semantic information, which can be used to predict the category of entities. By integrating the head-tail detector and token interaction tagger, we apply the region classifier to predict the entity categories. Extensive experiments on three public NER datasets, including GENIA (English) (Kim et al., 2003), GermEval 2014 (German) (Benikova et al., 2014), and JNLPBA (English) (Kim et al., 2004), reveal that our proposed HIT achieves state-of-the-art performance.

The main contributions of this paper are as follows,

- We demonstrate that the head-tail pair can effectively and precisely express the boundary information of entities with nested structure.
- We utilize token interaction tagger to characterize the internal connection between tokens within the boundary, where we reveal that token interaction has a great impact on identifying entities.
- We complete entity classification with head-tail pair and token interaction sequence while introducing a multi-task loss to train our model simultaneously.

The rest of the paper is organized as follows. Section 2 describes the details of our model. Experimental results are reported in Section 3. Section 4 reviews the related work. Section 5 concludes the paper.

2 Model

In this section, we present the HIT model in detail. Figure 2 depicts the overall architecture of our model. The HIT contains three main components, including the head-tail detector, token interaction tagger, and region classifier. For each given sentence $x = \{w_1, w_2, ..., w_m\}$, where m is the length of the sentence, HIT firstly maps the sentence x to a token representation sequence $\mathbf{x} = \{\mathbf{w}_1, \mathbf{w}_2, ..., \mathbf{w}_m\}$. The representation sequence $\mathbf{x}$ is then fed into the head-tail detector to predict whether

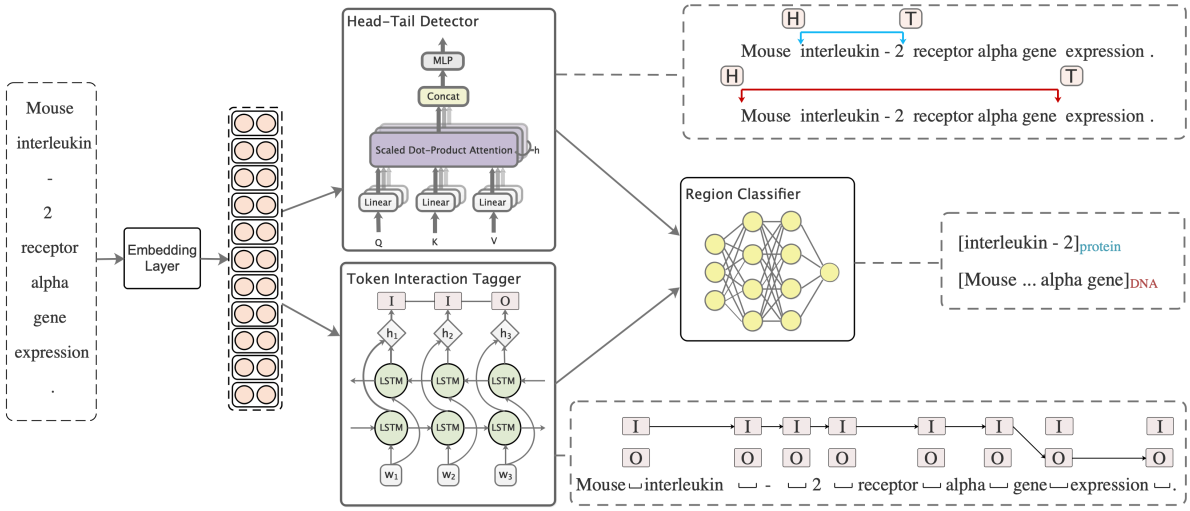

Figure 2: An overview of the proposed HIT model.

each pair-wise tokens is the head-tail of an entity. In the meanwhile, token interaction tagger is used to capture internal connections between adjacent tokens based on context, which indicates if the token before or after the current token belongs to an entity. Finally, the region classifier is employed to integrate the head-tail detector and token interaction tagger to complete the entity recognition. In the following subsections, we will describe each part of our proposed HIT in detail.

2.1 Head-Tail Detector

The head-tail detector is a pair-wise classifier that determines whether each pair of tokens in the sentence is the boundary of an entity. As shown in Figure 2, the "interleukin - 2" and "Mouse interleukin - 2 receptor alpha gene" are both entities. Ideally, our head-tail detector should be able to determine that the head-tail pairs "interleukin-2" and "Mouse-gene" are both boundary tokens of entities.

Formally, given the token representation sequence $\mathbf{x}$, the head-tail detector first generates the boundary representation $\mathbf{b}_i$ of token w_i based on the multi-head self-attention network (Vaswani et al., 2017). For simplicity, we denote the scaled dot-product attention as the following equation,

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\frac{\mathbf{QK}^T}{\sqrt{d_k}})\mathbf{V}, \quad (1)$$

where $\mathbf{Q}$, $\mathbf{K}$, $\mathbf{V}$ are the query matrix, keys matrix, and value matrix, respectively. In our setting, $\mathbf{Q} = \mathbf{K} = \mathbf{V} = \mathbf{x}$, and $1/\sqrt{d_k}$ is the scaling factor. The multi-head attention can learn multiple scaled dot-product attentions by using different linear projections in parallel. Formally, the multi-head attention can be expressed as follows,

$$\text{head}_i = \text{Attention}(\mathbf{QW}_i^Q, \mathbf{KW}_i^K, \mathbf{VW}_i^V), \quad (2)$$

$$\mathbf{b} = \text{Concat}(\text{head}_1, \ldots, \text{head}_h)\mathbf{W}^O, \quad (3)$$

where $\mathbf{W}_i^Q$, $\mathbf{W}_i^K$, $\mathbf{W}_i^V$, and $\mathbf{W}^O$ are trainable projection parameters.

By virtue of the self-attention mechanism, the boundary representation $\mathbf{b}_i$, composed of all the token representations, is immune from the order of tokens in the sentence. In our model, the head-tail detector is designed to detect each pair of tokens in terms of whether it is the head-tail pair of an entity, while filtering out the influence of the distance between two tokens in the sentence. Thus the self-attention mechanism is more suitable for head-tail detector than other architectures, e.g., LSTM (Lample et al., 2016) and Convolutional Neural Network (CNN) (Chiu and Nichols, 2016). It is worth pointing out that we additionally leverage the token interaction tagger (Subsection 2.2) to characterize the internal connection from the context, which takes into account the token order information.

By the generated boundary representation sequence $\mathbf{b} = \{\mathbf{b}_1, \mathbf{b}_2, ..., \mathbf{b}_m\}$, we construct token representation pairs ($\mathbf{b}_i$, $\mathbf{b}_j$) through pairwise combination, where ($\mathbf{b}_i$, $\mathbf{b}_j$) denotes that the token w_i is assumed as the head token of an entity, and w_j is assumed as the tail token. Each token representation pair is finally fed into a bi-affine classifier (Dozat and Manning, 2016) to determine whether it is the head-tail pair of an entity. The predicted head-tail distribution is defined as follow,

$$\mathbf{d}_{ij} = \mathbf{b}_i^\top \mathbf{U}^{(1)} \mathbf{b}_j + (\mathbf{b}_i \oplus \mathbf{b}_j)^\top U^{(2)} + b, \quad (4)$$

where $\oplus$ denotes concatenation operation, $\mathbf{U}^{(1)}$

and $U^{(2)}$ denote weight matrices, and b denotes bias.

In practice, the classifier does not need to consider all token representation pairs due to (Wang and Lu, 2018), which finds that restricting the maximum length of entities to 6 can cover more than 95% of entities. We set the same entity maximum length restriction (6) in our model. In addition, since only a few candidates are the boundaries of valid entities, the head-tail detector might encounter the class imbalance problem during the training process. Accordingly, we employ the Focal Loss (Lin et al., 2017) to optimize the parameters of the head-tail detector,

$$\mathcal{L}_{ht} = \sum_{ij} - \beta^{'}_{ij}(1 - \mathbf{d}^{'}_{ij})^{\gamma}\log(\mathbf{d}^{'}_{ij}),$$
$$(\mathbf{d}^{'}_{ij}, \beta^{'}_{ij}) = \begin{cases} (\mathbf{d}_{ij}, \beta_{ij}), & \text{if } \mathbf{d}_{ij} \text{ is true;} \\ (1 - \mathbf{d}_{ij}, 1 - \beta_{ij}), & \text{otherwise,} \end{cases} \tag{5}$$

where $(1 - \mathbf{d}^{'}_{ij})^{\gamma}$ denotes the modulating factor and γ is the focusing parameter. β_{ij} denotes the weighting factor.

Note that since different entities do not share the same head-tail pair, our head-tail detector can naturally solve the difficulty of expressing nested entities. Moreover, we preserve all the predicted head-tail pairs of each sentence, which are also important features for the subsequent region classification.

2.2 Token Interaction Tagger

Although the head-tail pair is important for recognizing the nested named entity, it still ignores the connection between tokens within the head-tail pair. Inspired by (Muis and Lu, 2017) and (Shang et al., 2018), we construct a token interaction tagger to label the gap between every two adjacent tokens in the sentence. First of all, we define two possible connections of the gap, including the internal connection (I) and others (O). As shown in Figure 2, we use the internal connection (I) to indicate that both of the two adjacent tokens might belong to the same entity. The others (O) means that at least one of these two adjacent tokens do not belong to the same entity.

It is worth mentioning that we encourage the token interaction tagger to label the nested boundary gaps as the internal connection (I) when dealing with the entities with nested structure. Take an example in Figure 2 to illustrate this point, the gap between "2" and "receptor" belongs to the nested boundary gap, because the gap is inside the outer entity "mouse interleukin-2 receptor alpha gene". Such nested boundary gaps should be labeled as "I", and the explicit distinction between outer and inner entities is obtained by the head-tail detector. Therefore, the token interaction tagger is designed to capture the internal connection between adjacent tokens primarily.

Since it is important to learn lexical and semantic information in the context for determining token interaction, we employ BiLSTM to encode the token representation sequence $\mathbf{x}$. For simplicity, we denote the interaction representation extraction as the following equations,

$$\overrightarrow{\mathbf{h}}_i = \mathbf{LSTM}_f(\mathbf{w}_i, \overrightarrow{\mathbf{h}}_{i-1}, \theta_f), \tag{6}$$
$$\overleftarrow{\mathbf{h}}_i = \mathbf{LSTM}_b(\mathbf{w}_i, \overleftarrow{\mathbf{h}}_{i-1}, \theta_b), \tag{7}$$
$$\mathbf{h}_i = \overrightarrow{\mathbf{h}}_i \oplus \overleftarrow{\mathbf{h}}_i, \tag{8}$$

where the θ_f and θ_b denote the parameters of the forward and backward LSTM, respectively. The $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ are the hidden states at the position i of the forward and backward LSTM, respectively.

The interaction representation sequence $\mathbf{h}$ is then fed into a CRF (Lafferty et al., 2001), which can decode these features and tag connections for each gap. The scoring equation defined by CRF is

$$s(\mathbf{h}, y) = \sum_{i=1}^{m} \log \psi_{EMIT}(y_i \rightarrow \mathbf{h}_i) + \log \psi_{TRANS}(y_{i-1} \rightarrow y_i), \tag{9}$$

where y is the target tag sequence corresponding to sentence x. The $\psi_{EMIT}(y_i \rightarrow \mathbf{h}_i)$ represents the emission potential from the token w_i to the tag y_i. The $\psi_{TRANS} \in \mathbb{R}^M$ is a transition matrix that comes from CRF to control the transition probability from y_{i-1} to y_i, where M is the tag size.

We use the following loss function to optimize the parameters of token interaction tagger,

$$\begin{aligned}\mathcal{L}_i &= -\log(p(y|\mathbf{h})) \\ &= -\log(\frac{\exp(s(\mathbf{h}, y))}{\sum_{y' \in Y} \exp(s(\mathbf{h}, y'))}),\end{aligned} \tag{10}$$

where y' is one of the candidate tag sequences in Y. Since lexical and semantic information is beneficial to predict the entity categories, we retain the entire token interaction sequence $\mathbf{h}$ for the region classifier, which will be introduced in the next subsection.

2.3 Region Classifier

With the guidance of the head-tail pairs and token interaction sequence obtained from the above two components, we can establish candidate region representations. Moreover, each candidate region representation should meet the two constraints, including (1) the head-tail pair has been detected by the head-tail detector and (2) the corresponding internal tokens are closely connected (i.e., all of the token gaps within the head-tail pair labeled as internal connection (I)). Therefore, if all of the token gaps corresponding to the detected head-tail pair $(\mathbf{b}_i, \mathbf{b}_j)$ are labeled as the internal connection (I), then we obtain the final region representation $\mathbf{r}_{ij}$ as follows,

$$\mathbf{r}_{ij} = \mathbf{b}_i^h \oplus \mathbf{b}_j^t \oplus \mathbf{c}_{ij}, \tag{11}$$

$$\mathbf{c}_{ij} = \left[\tfrac{1}{j-i}\textstyle\sum_{k=i}^{j} \mathbf{h}_k\right], \tag{12}$$

where $\mathbf{c}_{ij}$ denotes the representation of candidate token interaction, and we average the corresponding token interaction subsequence to treat them equally. The final regional representation $\mathbf{r}_{ij}$ will be sent to a two-layer multilayer perceptron networks (MLP) to predict entity category label. We compute the loss of category label prediction as follows,

$$\mathbf{d}_{ij}^r = \mathrm{softmax}(\mathrm{MLP}(\mathbf{r}_{ij})), \tag{13}$$

$$\mathcal{L}_r = -\textstyle\sum_{ij}(\hat{\mathbf{d}}_{ij}^r)\log(\mathbf{d}_{ij}^r), \tag{14}$$

where $\hat{\mathbf{d}}_{ij}^r$ and $\mathbf{d}_{ij}^r$ denote the true and predicted category distributions, respectively.

2.4 Training

We define the final multi-task loss as follow,

$$\mathcal{L} = \lambda_1\mathcal{L}_{ht} + \lambda_2\mathcal{L}_i + \lambda_3\mathcal{L}_r, \tag{15}$$

where λ_1, λ_2, and λ_3 are hyper-parameters of $\mathcal{L}_{ht}$ in Eq. (5), $\mathcal{L}_i$ in Eq. (10), and $\mathcal{L}_r$ in Eq. (14), respectively. Note that the proposed HIT predicts the category label after all the head-tail pairs and the token interactions have been recognized. We feed all the ground-truth labels during training progress so that all components can be trained jointly. All models are optimized using the Adaptive Moment Estimation (Adam) (Kingma and Ba, 2014) method.

3 Experiments

In this section, we first introduce the datasets, the baseline methods, and implementation details. We then present the experimental results used for evaluations, followed by analyzing two key properties and the ablation study of our HIT model.

Table 1: Statistics of GENIA dataset.

3.1 Datasets

To evaluate our proposed model, we conduct experiments on three public datasets, including GENIA (Kim et al., 2003), GermEval 2014 (Benikova et al., 2014), and JNLPBA (Kim et al., 2004). Among them, both GENIA and GermEval 2014 are commonly used benchmark datasets for nested NER task.

GENIA[1] dataset is English biology nested named entity dataset, which is based on GENIAcorpus3.02p that comes with POS tags for each token. It contains five entity types, including DNA, RNA, protein, cell line, and cell type categories. The dataset contains 18,546 sentences corresponding to 55,740 tokens. Following previous works (Finkel and Manning, 2009; Lu and Roth, 2015), we split the dataset into 8.1:0.9:1 for training, development, and testing. Table 1 shows the statistics of GENIA dataset.

GermEval 2014[2] dataset is a new German nested named entity dataset that contains four entity types. The dataset covers over 31,000 sentences corresponding to over 590,000 tokens. We use this dataset to evaluate the performance of our model in different languages.

JNLPBA[3] dataset is originally from GENIA corpus. It defines a training set and a testing set. Unlike the other two datasets, only the flat top-most entities are present in this dataset. Therefore, we use it to evaluate how well the HIT model performs in recognizing flat entities.

3.2 Baseline Methods

We compare our model with several state-of-the-art models that can be divided into two groups:

---

[1] http://www.geniaproject.org/genia-corpus

[2] https://sites.google.com/site/germeval2014ner/data

[3] http://www.geniaproject.org/shared-tasks/bionlp-jnlpba-shared-task-2004

Sequence-based methods. Muis and Lu (2017) label the gap between tokens by the entity separators, which can capture entities that overlap with one another. Sohrab and Miwa (2018) use the region representation by LSTM to recognize nested entities. Ju et al. (2018) encode sentence with stacking flat LSTM layers and decoding it to different categories by cascaded CRFs. Zheng et al. (2019) use the sequence labeling models to detect the nested entity boundary and merge the corresponding boundary label sequence to complete categorical prediction.

Hypergraph-based methods. Lu and Roth (2015) are the first to use the hypergraph-based method to tackle the problem of entity detection. Katiyar and Cardie (2018) learn the hypergraph representation for nested entities from the multi-layer BiLSTMs. Wang and Lu (2018) use segmental hypergraph representation to capture features and interactions that cannot be captured by previous models for nested entity recognition.

3.3 Implementation Details

For the embedding method, we initialize token vectors with 128-dimension pre-trained token embeddings, which are fine-tuned during training. We conduct hyper-parameter optimization by exploring the range of parameters shown in Table 2 using random search, and we select the set of parameters that achieves the best performance on the GENIA development set. The self-attention in the head-tail detector has a depth of 4 and heads of 4. The BiLSTM in the token interaction tagger has a depth of 2 and a hidden size of 256. The MLP in the region classifier has a depth of 2 and a hidden size of 256. The focusing parameter γ is set to 2, and the β_{ij} is set to 0.7. Moreover, the λ_1, λ_2 and λ_3 are set to 0.4, 0.3 and 0.3, respectively. The initial learning rate is set to 0.008 and decreases as the training step increases. We apply Dropout (Srivastava et al., 2014) to the output of the BiLSTM layer at the rates of 0.5. The batch size is set to 64 at the sentence level. We monitor the training process on the development set and report the final result on the test set. We implement our model under PyTorch[4]. All of our experiments are performed on NVIDIA 1080ti GPU and Intel i7-8700K CPU. The training time for each epoch is 40 min. From the performance on the development set, our model reached the best performance after 20 epochs.

Hyper-parameters	**Range**	**Final**
Self Attention–depth	[1, 4]	4
Self Attention–head	[1, 6]	4
BiLSTM–depth	[1, 4]	2
BiLSTM–hidden size	[128, 512]	256
MLP–depth	[1, 2]	2
MLP–hidden size	[128, 512]	256
Dropout	[0.2, 0.8]	0.5
γ	[0, 5]	2
β_{ij}	[0, 1]	0.7
Batch Size	[16, 64]	64

Table 2: Hyper-parameters used for training the HIT model.

3.4 Main Results

We employ the precision (P), recall (R), and F1-score (F) to evaluate the performance of each method. The experimental results of our HIT on the GENIA dataset are illustrated in Table 3. As we can see, the proposed HIT outperforms all the compared methods in both recall and F1-score, with better or comparable results in precision. For example, our HIT achieves 74.4% recall value, which surpasses Zheng et al. (2019) by 0.8%. From Table 3, we observe that all hypergraph-based methods fall short in the recall value. These results demonstrate that most entities recognized by our HIT are indeed valid entities. The reason is that the region classifier in our HIT can capture the non-entity type for the candidate region, which means that the classifier has the ability to determine whether the candidate region is a valid entity or not. With this ability of region classifier and the two constraints introduced in Section 2.3, our HIT effectively alleviates the error propagation problem. Furthermore, the HIT yields a precision value of 78.1%, which is 1.7% lower than Katiyar and Cardie (2018). On the other hand, the HIT outperforms Katiyar and Cardie (2018) by 6.2% in the recall value. More importantly, HIT outperforms Wang and Lu (2018) by 1.1%, Zheng et al. (2019) by 2.5%, and Katiyar and Cardie (2018) by 2.6% in terms of F1-score, respectively. These results indicate that our HIT is capable of capturing the explicit boundary tokens and the tight internal connection between tokens within the boundary, which precisely captures the nested structure of entities. Specifically, Table 4 shows the performance of each category on GENIA. We observe that the proposed HIT achieves

Our HIT	74.8	**70.5***	**72.6***

Table 5: Main results on GermEval 2014. Significant improvement over baselines is marked with * (p-value < 0.05).

the best performance in recognizing the entities of the RNA category. The reason for the best results obtained for RNA is that the entities pertaining to RNA mainly end up either with “mRNA” or “RNA”. And our HIT yields 77.5% F1-score on the protein category, which covers over half of the named entities in GENIA.

In addition, to evaluate the performance of our proposed HIT in different languages, we conduct additional experiments on the GermEval 2014 dataset, and the experimental results are shown in Table 5. We can first observe that the HIT outperforms all the compared methods both in recall and F1-score. Compare to the suboptimal (Zheng et al., 2019), it still significantly achieves 1.4% and 0.9% relative improvements on recall and F1-score, respectively. Also, compared with Table 3, we found that the overall performance on the GENIA dataset is better than on the GermEval 2014 dataset. One possible reason is that the entities in the GermEval 2014 dataset are much sparser.

Furthermore, we conduct experiments on the JNLPBA dataset to demonstrate the applicability of our proposed HIT on flat entities. Compared with the state-of-the-art method (Gridach, 2017), which achieves 75.8% in F1-score, HIT achieves a competitive performance of 74.9%.

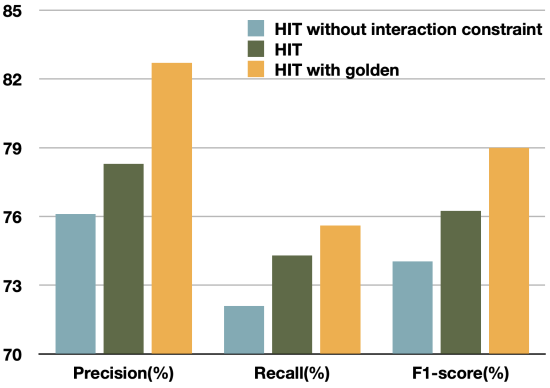

Figure 3: Results on HIT of different structures.

3.5 Analysis of Two Key Properties

Our proposed HIT is designed by leveraging two key properties pertaining to the (nested) named entity, including (1) explicit boundary tokens and (2) tight internal token connection within the boundary. In order to further evaluate the importance of these properties for nested NER, we construct the following two sets of comparative experiments on the GENIA dataset, and the corresponding experimental results are shown in Figure 3.

Analysis of Boundary Tokens. In our model, we use the head-tail pair to represent the boundary tokens of nested entities. To illustrate the importance of capturing entity boundary information in identifying nested entities, we use golden head-tail pairs instead of the results from the head-tail detector to our HIT in this set of experiments[5]. This revised model is denoted as “HIT with golden”, and the golden head-tail pairs are collected from the GENIA dataset. From Figure 3, we can find that HIT with golden achieves additional performance improvement over the proposed HIT in terms of all metrics. These results further corroborate that explicit boundary tokens indeed play an important role in recognizing named entities, and the head-tail pair can effectively and precisely express the boundary of entities with the nested structure.

Analysis of Token Interaction. In order to fur-

---

[5] We do not conduct opposite experiments using golden token interaction tags since our model exploits the token interaction representation to improve the overall performance, rather than the token interaction tag. In addition, it is hard to obtain the golden token interaction representation.

ther explore the effects of token interaction within the boundary, we modify the strategy of generating the candidate region representations in this set of experiments. As we introduced in Section 2.3, the candidate regions are generated under two constraints. We remove the token interaction constraint (i.e., the second constraint), which indicates the candidate region representation is only generated under the detected head-tail pairs (i.e., the first constraint). In other words, all detected head-tail pairs can establish their candidate region representations based on Eq. (11). This means that some adjacent tokens might not be closely connected together in such candidate regions. The revised model denotes as "HIT without interaction constraint". From the results shown in Figure 3, we can see that our HIT outperforms the HIT without interaction constraint by 2.4% on F1-score. The main reason is that the token interaction constraint can mitigate the error propagation caused by the head-tail detector. These results validate that the internal tokens of entity are indeed closely connected with each other, and the token interaction has a great impact on detecting named entities.

3.6 Ablation Study

We choose the GENIA dataset to conduct several ablation experiments to elucidate the main components of our proposed HIT, and the experimental results are shown in Table 6 and Table 7.

Effectiveness of Head-Tail Detector. The head-tail detector in our model consists of a multi-head attention encoder and a bi-affine classifier. To explore the effectiveness of the detector, we examine the head-tail detector based on different structures, including the BiLSTM encoder and linear classifier. In addition, in this set of experiments, we also use the Cross Entropy instead of Focal Loss to the detector. Table 6 shows the results of various head-tail detection methods. From the results, one could observe that the BiLSTM performs worse than the multi-head attention mechanism in this case. One explanation could be that the BiLSTM network learns the token ordering features and considers the distance of the head token and tail token in the sentence, which makes the BiLSTM-based detector suffer from detecting long named entities. Furthermore, we can observe that Focal Loss is more effective for the detector than Cross Entropy, due to the fact that the detector using Cross Entropy overlooks the class imbalance problem. These results validate that the Focal Loss can perform well in NLP tasks. In addition, the detector based on the bi-affine classifier achieves 1.2% improvement on F1-score compared to the detector based on the linear classifier.

Method	P(%)	R(%)	F(%)
HTD with BiLSTM encoder	79.7	77.1	78.4
HTD with linear classifier	81.2	78.9	80.0
HTD with Cross Entropy	79.2	76.7	77.9
Head-Tail Detector	82.1	80.4	81.2

Table 6: Performance of the head-tail pair detection based on the Head-Tail Detector (HTD) of different structures.

Method	P(%)	R(%)	F(%)
TIT with softmax	91.7	88.6	90.1
Token Interaction Tagger	93.5	90.4	91.9

Table 7: Performance of the token interaction tagging based on the token interaction tagger (TIT) of different structures.

Effectiveness of Token Interaction Tagger. We compare the softmax with CRF as the output layer of the token interaction tagger, and the experimental results are shown in Table 7. We can see that the tagger with CRF can effectively recognize the token interaction and surpass the tagger with softmax by 1.8%. The main reason is that the CRF can utilize the connection of the current tag and the previous tag, where the softmax cannot. Therefore, we conclude that the CRF-based model is more suitable for token interaction tagger.

4 Related Work

Many methods have been proposed for nested NER. Early works on dealing with nested entities rely on hand-craft features or rule-based post-processing (Zhang et al., 2004; Zhou et al., 2004). They use the supervised method that combines the Hidden Markov Model with rule-based post-processing to extract both the inner and outer entities. Moreover, Finkel and Manning (2009) propose a chart-based parsing method for handling nested entities. They construct a discriminative constituency tree to represent each sentence, and each entity is represented as one of the subtrees. However, their method has a cubic time complexity.

Traditionally, the conventional NER is considered as a sequence labeling task. Some studies reveal that sequence labeling-based methods can also perform well on the nested NER. Muis and Lu (2017) introduce a novel notion of mention separators that can effectively detect the nested entity mention. Their method labels gaps between words to yield better performance, which relies on hand-crafted features. Ju et al. (2018) propose dynamically stacking flat NER layers, while the number of stacked layers depends on the level of entity nesting. It can recognize entities sequentially from inner to outer. However, their method inevitably suffers from the error propagation since the outer entity detection overly depends on whether the inner entity is correctly recognized or not. Zheng et al. (2019) propose a boundary-aware neural model that leverages entity boundaries to predict entity categorical labels. Their method modifies the BIEO (i.e., Beginning, Internal, End and Other) hypothesis for detecting the boundary of nested entity.

More recently, Lu and Roth (2015) present a novel hypergraph-based method with linear time complexity to tackle the problem of nested entity mention detection. One issue in their approach is the spurious structures of the hypergraph. Wang and Lu (2018) improve the method of Lu and Roth (2015) by modeling arbitrary combinations of mentions with a segmental hypergraph. However, such an architecture leads to a higher time complexity during both training and decoding. Katiyar and Cardie (2018) propose a hypergraph-based representation based on the BILOU tagging scheme. They treat the hypergraph construction procedure as a multi-label assignment process.

5 Conclusions

In this paper, we propose a novel neural model HIT for recognizing nested named entity. It leverages the head-tail pair and token interaction to express the entities with the nested structure. Specifically, the head-tail detector can detect the head-tail pair of named entities. Furthermore, the token interaction tagger captures the internal token connection within the boundary. Experiments on three public datasets show that our model achieves significant improvements over the state-of-the-art models. For future work, we will apply HIT to other languages, and further explore potential cases of overlapping entities in nested NER task.

Abstract

Supertagging is conventionally regarded as an important task for combinatory categorial grammar (CCG) parsing, where effective modeling of contextual information is highly important to this task. However, existing studies have made limited efforts to leverage contextual features except for applying powerful encoders (e.g., bi-LSTM). In this paper, we propose attentive graph convolutional networks to enhance neural CCG supertagging through a novel solution of leveraging contextual information. Specifically, we build the graph from chunks (n-grams) extracted from a lexicon and apply attention over the graph, so that different word pairs from the contexts within and across chunks are weighted in the model and facilitate the supertagging accordingly. The experiments performed on the CCGbank demonstrate that our approach outperforms all previous studies in terms of both supertagging and parsing. Further analyses illustrate the effectiveness of each component in our approach to discriminatively learn from word pairs to enhance CCG supertagging.[1]

1 Introduction

Combinatory categorial grammar (CCG) is a lexicalized grammatical formalism, where the lexical categories (also known as supertags) of the words in a sentence provide informative syntactic and semantic knowledge for text understanding. Therefore, CCG parse often provides useful information for many downstream natural language processing (NLP) tasks such as logical reasoning (Yoshikawa et al., 2018) and semantic parsing (Beschke, 2019). To perform CCG parsing in different languages, most studies conducted a supertagging-parsing pipline (Clark and Curran, 2007; Kummerfeld et al., 2010; Song et al., 2012; Lewis and Steedman, 2014b; Huang and Song, 2015; Xu et al., 2015; Lewis et al., 2016; Vaswani et al., 2016; Yoshikawa et al., 2017), in which their main focus is the first step, and they generated the CCG parse trees directly from supertags with a few rules afterwards.

Building an accurate supertagger in a sequence labeling process requires a good modeling of contextual information. Recent neural approaches to supertagging mainly focused on leveraging powerful encoders with recurrent models (Lewis et al., 2016; Vaswani et al., 2016; Clark et al., 2018), with limited attention paid to modeling extra contextual features such as word pairs with strong relations. Graph convolutional networks (GCN) is demonstrated to be an effective approach to model such contextual information between words in many NLP tasks (Marcheggiani and Titov, 2017; Huang and Carley, 2019; De Cao et al., 2019; Huang et al., 2019); thus we want to determine whether this approach can also help CCG supertagging.

However, we cannot directly apply conventional GCN models to CCG supertagging because in most of the previous studies the GCN models are built over the edges in the dependency tree of an input sentence. As high-quality dependency parsers are not always available, we do not want our CCG supertaggers to rely on the existence of dependency parsers. Thus, we need another way to extract useful word pairs to build GCN models. For that, we propose to obtain word pairs from frequent chunks (n-grams) in the corpus, because those chunks are easy to identify with co-occurrence counts. To appropriately learn from n-grams, one requires the GCN to be able to distinguish different word pairs because such information in n-grams are not explicitly structured as that in dependency parses. Because existing GCN models are limited in treating all word pairs equally, we propose an adaptation of conventional GCN for CCG supertagging.

November 16–20, 2020.

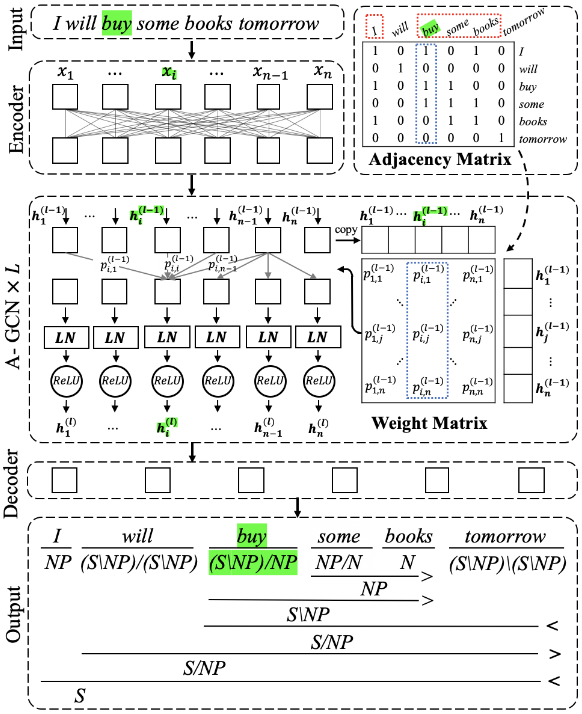

Figure 1: The architecture of our CCG supertagger with A-GCN and an example input sentence with its supertagging and parsing output. The supertagging process for "*buy*" is highlighted in green. The adjacency matrix illustrates the edges of the graph that is built upon the chunks (n-grams) extracted from the lexicon $\mathcal{N}$, with the chunks illustrated in the red boxes.

In this paper, we propose attentive GCN (A-GCN) for CCG supertagging, where its input graph is built based on chunks (n-grams) extracted with unsupervised methods. In detail, two types of edges in the graph are introduced to model word relations within and across chunks and an attention mechanism is applied to GCN to weight those edges. In doing so, different contextual information are discriminatively learned to facilitate CCG supertagging without requiring any external resources. The validity of our approach is demonstrated by experimental results on the CCGbank (Hockenmaier and Steedman, 2007), where state-of-the-art performance is obtained for both tagging and parsing.

2 The Approach

We treat CCG supertagging as a sequence labeling task, where the input is a sentence with n words $\mathcal{X} = x_1 x_2 \cdots x_i \cdots x_n$, and the output is a sequence of supertags $\widehat{\mathcal{Y}} = \widehat{y}_1 \widehat{y}_2 \cdots \widehat{y}_i \cdots \widehat{y}_n$. Our approach uses attentive GCN (A-GCN) to incorporate information of word pairs through a graph; the graph is built based on n-grams in the input sentence that appear in a lexicon $\mathcal{N}$. This lexicon consists of n-grams automatically extracted from raw corpora by unsupervised methods. The overall architecture of our tagger is illustrated in Figure 1, with an input sentence and corresponding supertagging and parsing output. The details of the main components in the architecture are provided below.

2.1 GCN

Normal GCN models with L layers learn from word pairs suggested by the dependency parsing results of the input sentence $\mathcal{X}$, where the edges between all pairs of words x_i and x_j are represented by an adjacency matrix $\mathcal{A} = \{a_{i,j}\}_{n \times n}$. In $\mathcal{A}$, $a_{i,j} = 1$ if there is a dependency edge between x_i and x_j or $i = j$ (the direction of the edge is ignored), and $a_{i,j} = 0$ otherwise. Based on the adjacency matrix, for each x_i, the l-th GCN layer finds all x_j associated with x_i (where $a_{i,j} = 1$), takes their hidden vectors $\mathbf{h}_j^{(l-1)}$ from the $(l-1)$-th layer, and computes the output for x_i by

$$\mathbf{h}_i^{(l)} = \sigma(LN(\sum_{j=1}^{n} a_{i,j}(\mathbf{W}^{(l)} \cdot \mathbf{h}_j^{(l-1)} + \mathbf{b}^{(l)}))) \quad (1)$$

where $\mathbf{W}^{(l)}$ and $\mathbf{b}^{(l)}$ are trainable matrix and bias for the l-th GCN layer, LN refers to layer normalization and σ the $ReLU$ activation function. Therefore, in normal GCN, for each x_i, all the x_j that connect to x_i are treated exactly the same.

2.2 Graph Construction based on Chunks

Since CCG supertagging is also a parsing task, we do not want our approach to rely on the existence of a dependency parser. Without such a parser, we need an alternative for finding good word pairs to build the graph in A-GCN (which is equivalent to build the adjacency matrix $\mathcal{A}$). Inspired by the studies that leverage chunks (n-grams) as effective features to carry contextual information and enhance model performance (Song et al., 2009; Song and Xia, 2012; Ishiwatari et al., 2017; Yoon et al., 2018; Zhang et al., 2019; Tian et al., 2020a,c,b), we propose to construct the graph based on the chunks (n-grams) extracted from a pre-constructed n-gram lexicon $\mathcal{N}$. Specifically, the lexicon is constructed by computing the PMI of any two adjacent words s', s'' in the training set by

$$PMI(s', s'') = log \frac{p(s's'')}{p(s')p(s'')} \quad (2)$$

where p is the probability of an n-gram (i.e., s', s'' and $s's''$) in the training set; then a high PMI

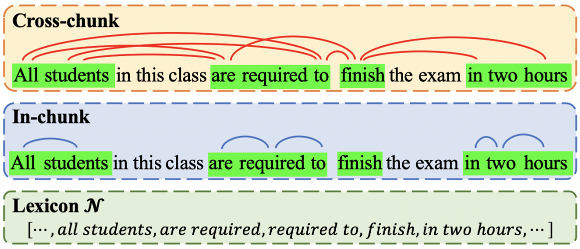

Figure 2: Examples of the two types of edges for building the graph in an input sentence, in which chunks (n-grams) extracted from the lexicon $\mathcal{N}$ are highlighted in green; example in-chunk and cross-chunk edges are marked in blue and red color, respectively.

score suggests that the two words co-occur a lot in the dataset and are more likely to form a n-gram. For each pair of adjacent words s_{i-1}, s_i in a sentence $\mathcal{S} = s_1 s_2 \cdots s_{i-1} s_i \cdots s_n$, we compute the PMI score of the two words and use a threshold to determine whether a delimiter should be inserted between them. As a result, the sentence $\mathcal{S}$ is segmented into pieces of n-grams and we extract all n-grams from all sentences to form the lexicon $\mathcal{N}$.[2]

Then for graph building, given an input sentence $\mathcal{X}$, we find all the n-grams in $\mathcal{X}$ that appear in $\mathcal{N}$. A *chunk* is either a n-gram that does not overlap with other n-grams or a text span that covers multiple overlapping n-grams. For example, in Figure 2, we find four chunks (i.e., "*all students*", "*are required to*", "*finish*", and "*in two hours*") in the example sentence according to the lexicon $\mathcal{N}$ (the chunks are highlighted in green). In these chunks, "*all students*", "*finish*", and "*in two hours*" are non-overlapping n-grams included in the lexicon and "*are required to*" is a text span that covers the overlapping n-grams "*are required*" and "*required to*". In most cases, the adjacent words within the same chunk tend to have a strong word-word relation in terms of co-occurrence, and thus we can build the graph and its adjacency matrix accordingly.

Based on the chunks, we construct the graph by two types of edges, i.e., the in-chunk and cross-chunk ones: the first type is to model local word pairs, and the graph includes edges between any two adjacent words within the same chunk. For example, as shown in Figure 2, the in-chunk edges (blue lines) for the chunk "*in two hours*" are "(*in, two*)" and "(*two hours*)". The second type is to model cross chunk word pairs, which are built from any two adjacent chunks with the starting and ending words in the two chunks connected. The motivation of using the starting and ending words is that English phrases tend to be head-initial (e.g., verb phrase such as "*buy some books*") or head-final (e.g., adjective phrase such as "*red apples*") in many cases. E.g., for the two chunks "*all students*" and "*are required to*" in Figure 2, the corresponding cross-chunk edges (red lines) are "*(all, are)*", "*(all, to)*", "*(students, are)*", and "*(students, to)*". The graph is equivalent to the adjacency matrix $\mathcal{A}$, where $a_{i,j} = 1$ if there is an edge between x_i and x_j in the graph or $i = j$, and $a_{i,j} = 0$ otherwise.[3]

2.3 The Attentive GCN

When learning from a graph, conventional GCN models treat all word pairs from the graph equally, and thus are unable to account for the possibility that the contribution of different x_j on x_i may vary. Particularly for our graph built from chunks, it is important to be able to distinguish different word pairs because all the chunks and the graph are constructed automatically without a dependency parser. Therefore, we apply an attention mechanism to the adjacency matrix and adapt Eq. (1) used in the normal GCN for our A-GCN by replacing the $a_{i,j} \in \{0, 1\}$ by a weight $p^{(l)}_{i,j} \in (0, 1)$. For each x_i and all its associated x_j, the weight $p^{(l)}_{i,j}$ for this word pair is computed by

$$p^{(l)}_{i,j} = \frac{a_{i,j} \cdot exp(\mathbf{h}^{(l-1)}_i \cdot \mathbf{W}^{(l)}_{pos} \cdot \mathbf{h}^{(l-1)}_j)}{\sum_{j=1}^{n} a_{i,j} \cdot exp(\mathbf{h}^{(l-1)}_i \cdot \mathbf{W}^{(l)}_{pos} \cdot \mathbf{h}^{(l-1)}_j)} \tag{3}$$

where $\mathbf{W}^{(l)}_{pos}$ models the positional relation (i.e., *left*, *right*, or *self*) between x_i and x_j and it has three choices, i.e., $\mathbf{W}^{(l)}_{left}$, $\mathbf{W}^{(l)}_{right}$, and $\mathbf{W}^{(l)}_{self}$ for different i and j,[4] with each of them a trainable square matrix in the l-th layer of A-GCN.

2.4 Supertagging with A-GCN

To conduct supertagging with A-GCN, we firstly obtain the hidden vector $\mathbf{h}^{(0)}_i$ for x_i from BERT (Devlin et al., 2019) to feed into the first GCN layer. Upon receiving the encoding results from A-GCN, the following supertagging process is straightforward: each $\mathbf{h}^{(L)}_i$ is obtained from the last A-GCN layer and aligned with the output by $\mathbf{o}_i = \mathbf{W}_d \cdot \mathbf{h}^{(L)}_i$, where $\mathbf{W}_d$ is a trainable matrix

---

[2] For example, a sentence can be segmented into $\mathcal{S} = s_1/s_2 s_3 s_4/s_5$ ("/" refers to a delimiter) if the PMI of s_1, s_2 and s_4, s_5 are lower than the threshold and the PMI of s_2, s_3 and s_3, s_4 are greater than the threshold; we thus obtain three n-grams, i.e., s_1, $s_2 s_3 s_4$, and s_5 from this sentence.

[3] We do not distinguish the two types of edges in $\mathcal{A}$.

[4] For example, $\mathbf{W}^{(l)}_{pos} = \mathbf{W}^{(l)}_{left}$, if $j < i$.

	Train	Dev	Test

+ A-GCN (Full)	345M	96.08	90.13
+ A-GCN (Chunk)	345M	**96.31**	**90.52**

Table 3: Results (supertagging accuracy and labeled F-scores) of different models with BERT-Large encoder on the development set of CCGbank. "PARM" is the number of trainable parameters in the models; "Full" uses the fully connected graph and "Chunk" uses the graph built based on chunks.

for the alignment. Then, a *softmax* decoder is used to predict the supertag $\hat{y}_i$ for x_i:

$$\hat{y}_i = \arg\max \frac{exp(\mathbf{o}_i^t)}{\sum_{t=1}^{|\mathcal{T}|} exp(\mathbf{o}_i^t)} \qquad (4)$$

where $\mathcal{T}$ denotes the set with all CCG categories and o_i^t the value at dimension t in $\mathbf{o}_i$.

3 Experiments

3.1 Settings

We run experiments on the English CCGbank (Hockenmaier and Steedman, 2007)[5] and follow Clark and Curran (2007) to split it into train/dev/test sets, whose statistics (sentence and word numbers) are reported in Table 1. To construct n-gram lexicon $\mathcal{N}$ for building the edges in our graph, we perform PMI on the training set of CCGbank to extract n-grams whose length is between $[1, 5]$, with the threshold of the PMI score set to 0. For the encoder, we try both cased and uncased BERT-Large (Devlin et al., 2019) with their default settings (e.g., 24 layers of self-attentions in 1024 dimensional hidden vectors)[6] and used two layers for A-GCN. To obtain CCG parse from the generated supertags, we adopt the parsing algorithm used in EasyCCG (Lewis and Steedman, 2014a). We follow previous studies (Lewis and Steedman, 2014a; Lewis et al., 2016; Yoshikawa et al., 2017) to evaluate our model on both the tagging accuracy of the most frequent 425 supertags and the labeled F-scores (LF) of the dependencies converted from CCG parse[7].

For other hyper-parameter settings, we test their values as shown in Table 2 when training our models. We tried all combinations of them for each model and use the one achieving the highest supertagging results in our final experiments. Note that, with the best hyper-parameters, the best performance is achieved with warm-up rate 0.1, batch size 16, and learning rate 1e-5.

3.2 Results

To explore the effectiveness of our approach, we run CCG taggers with and without A-GCN, and try two ways to construct the graph: one is a fully connected GCN where edges are built between every two words; the other is our proposed approach with the chunk-based graph. Experimental results on supertagging accuracy (TAG) and labeled F-scores (LF) for parsing on the development set of CCGbank are reported in Table 3, with the number of trainable parameters of all models also presented.

The experiments show that, for both cased and uncased BERT encoders, the proposed chunk A-GCN works the best in terms of both supertagging accuracy and parsing results. In contrast, Full A-GCN has inferior performance to the BERT baselines. This contrast shows the importance of appropriate construction of the graphs fed into A-GCN, since the fully connected graph with all words asso-

Yoshikawa et al. (2017)	-	90.4
Clark et al. (2018)	96.1	-
Stanojević and Steedman (2019)	95.4	90.5
EasyCCG†	-	86.14
BERT†	96.25	90.46
BERT + A-GCN (Full)†	96.10	90.34
BERT + A-GCN (Chunk)†	**96.39**	**90.68**

Table 4: Comparison of our models with uncased BERT encoder and previous studies on the test set of CCGbank. Models with "†" use the EasyCCG parser to generate CCG parse trees from the predicted supertags.

ciated with one another may introduce noise word relations and thus yield bad performance.

Furthermore, we run our models with uncased BERT encoder on the test set and compare the performance with previous studies on both supertagging and parsing. Table 4 shows the results, where the studies marked by † use the same parser (i.e., the EasyCCG parser) to generate CCG trees from supertags. Among the previous studies, Stanojević and Steedman (2019) performed CCG parsing directly without the suppertagging step, whereas the rest all did supertagging first. Regardless of this difference, our approach performs the best on CCGbank in both supertagging accuracy and parsing LF.

3.3 Ablation Study

We conduct an ablation study to explore the effect of the two types of edges and the attention mechanism on our best model. The supertagging and parsing results of models with different configurations are reported in Table 5, where the results are categorized into four groups. The first group (ID 1) is the results of the best performing model where all settings are activated; the second (ID 2-3) is the ablation of either in-chunk or cross-chunk edges with attention; the third (ID 4-6) is the result of using normal GCN without the attention mechanism; and the last group (ID 7) is the baseline model where none of the three settings is activated.

The results show that the model performance drops when either part is ablated (ID 1 vs. ID 2-6). Specifically, removing attention significantly hurts the performance, where all configurations without attention (ID 4-6) shows worse-than-baseline (ID 7) results; this observation confirms the importance of applying attention on GCN. One possible explanation to this phenomenon could be that considerable noises are introduced to the graph because the edges in our graph are derived from chunks and they do not follow syntax in most cases; thus, it is crucial to assign weights to the edges and not treat them with equally. Interestingly, comparing the two types of edges, models with cross-chunk edges yield much higher results than the ones with in-chunk edges only when the attention is not used (ID 5 vs. ID 6), while it is slightly better when attention is applied (ID 2 vs. ID 3). This comparison suggests that in-chunk edges could introduce more noise than cross-chunk edges. So that when the attention is not used (ID 6), the model fails to weight the edges and results in a significant drop on its performance; On the contrary, when the attention is applied (ID 3), our model is able to even the performance of models with in-chunk and cross-chunk edges, which confirms that weighting is essential in selecting useful information for CCG supertagging.

ID	**Settings**			**Tag**	**LF**
	In-chunk	Cross-chunk	Attention		
1	√	√	√	**96.39**	**90.68**
2	×	√	√	96.34	90.58
3	√	×	√	96.30	90.50
4	√	√	×	87.31	82.02
5	×	√	×	95.01	89.84
6	√	×	×	89.83	84.57
7	×	×	×	96.25	90.46

Table 5: Experimental results of models with uncased BERT-Large encoder on the test set of CCGbank, where the in-chunk, cross-chunk edges or the attention mechanism in our A-GCN module is ablated.

4 Conclusion

In this paper, we propose A-GCN for CCG supertagging, with its graph built from chunks extracted from a lexicon. We use two types of edges for the graph, namely, in-chunk and cross-chunk edges for word pairs within and across chunks, respectively, and propose an attention mechanism to distinguish the important word pairs according to their contribution to CCG supertagging. Experimental results and the ablation study on the English CCGbank demonstrate the effectiveness of our approach to CCG supertagging, where state-of-the-art performance is obtained on both CCG supertagging and parsing. Further analysis is performed to investigate using different types of edges, which reveals their quality and confirms the necessity of introducing attention to GCN for CCG supertagging.

Abstract

Data augmentation techniques have been widely used to improve machine learning performance as they enhance the generalization capability of models. In this work, to generate high quality synthetic data for low-resource tagging tasks, we propose a novel augmentation method with language models trained on the linearized labeled sentences. Our method is applicable to both supervised and semi-supervised settings. For the supervised settings, we conduct extensive experiments on named entity recognition (NER), part of speech (POS) tagging and end-to-end target based sentiment analysis (E2E-TBSA) tasks. For the semi-supervised settings, we evaluate our method on the NER task under the conditions of given unlabeled data only and unlabeled data plus a knowledge base. The results show that our method can consistently outperform the baselines, particularly when the given gold training data are less.[1]

1 Introduction

A large amount of training data is often essential for neural model performance, especially, for large networks. Having more training data can help reduce overfitting and improve model robustness. However, preparing a large amount of annotated data is usually costly, labor intensive and time-consuming. Data augmentation (Simard et al., 1998) is a useful technique for synthetic data generation, which is widely used in computer vision (Fawzi et al., 2016; D'Innocente et al., 2017; Wang et al., 2019) and speech (Schlüter and Grill, 2015; Ko et al., 2017).

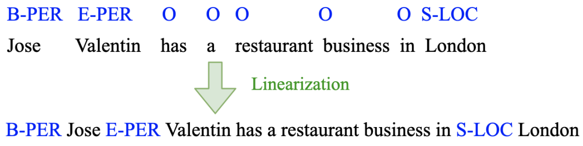

Figure 1: An example of labeled sentence linearization. All words and their tags are paired up by inserting tags before (or after) the words (*O* tags removed).

However, due to the complexity of language, it is more challenging to apply data augmentation techniques to natural language processing (NLP). Unlike computer vision and speech, where handcrafted rules (such as rotation, cropping, masking, etc.) can be easily applied to transform original data, it is difficult to generalize such rules for languages. Although simple distortion usually does not change the semantics of visual information, deleting or replacing a single word could completely change the meaning of the sentence.

One successful method for data augmentation in NLP is *back translation* (Sennrich et al., 2016; Fadaee et al., 2017; Dong et al., 2017; Yu et al., 2018), where a translation model is used to translate monolingual sentences from target language to source language to generate synthetic parallel sentences. Other successful methods include: systematically reordering the dependents of some nodes in gold data to generate synthetic data for dependency parsing (Wang and Eisner, 2016), leveraging knowledge base for question generation (Serban et al., 2016) and using simulation-based approach to generate a set of prerequisite toy tasks for QA (Weston et al., 2015). Besides, synonym replace-

ment, random deletion/swap/insertion, generation with VAE or pre-trained language models are also used in some NLP tasks (Kobayashi, 2018; Wei and Zou, 2019; Anaby-Tavor et al., 2020; Raille et al., 2020; Kumar et al., 2020), but mainly for translation and classification tasks.

Compared with the above-mentioned downstream tasks like translation and classification, sequence tagging is more fragile when it is confronted with data augmentation noises due to the finer granularity of the (token-level) task. Annotating unlabeled data with a weak tagger, leveraging aligned bilingual corpora to induce annotation and synonym replacement are three attempted data augmentation methods for sequence tagging (Shang et al., 2018; Yarowsky et al., 2001; Mathew et al., 2019). Weakly labeled data will inevitably introduce more noise. Note that annotating unlabeled data with a weak tagger requires in-domain data and in-domain knowledge, otherwise it may suffer from domain-shift problem (Bari et al., 2020). Leveraging aligned bilingual corpora requires additional resources, which may not be available for low resource languages. Synonym replacement often relies on additional knowledge, e.g., WordNet (Miller, 1995), which is a manually designed dictionary that may have low coverage (or not available) for low-resource languages.

In this work, we investigate data augmentation with a generation approach for sequence tagging tasks. We first linearize the labeled sentences as shown with an example in Figure 1. Then a language model (LM) is trained on the linearized data and used to generate synthetic labeled data. Unlike employing weak taggers to label unseen data, our method unifies the processes of sentence generation and labeling using a LM. Concretely, a word and its tag in a pair (e.g., "B-PER Jose") are trained to be generated together, in which the tag-word pairs with high probability will be chosen by the LM during generation (§3.2). Our method does not require additional resources like WordNet. Nevertheless, if unlabeled data or knowledge bases are available, our method is also flexible to utilize these resources with a simple but effective conditional generation technique (§3.4).

Although some recent work (Anaby-Tavor et al., 2020; Raille et al., 2020; Kumar et al., 2020) also leverages LM for data augmentation, their methods are conditioned on sentence-level tags to generate or modify training data, hence applicable to classification tasks exclusively. To the best of our knowledge, we are the first to utilize generative language models to generate fine-grained synthetic data from scratch for sequence tagging tasks, which introduces a new paradigm for data augmentation in NLP. Furthermore, our method does not rely on large pre-trained models and in fact, it employs a simple one-layer recurrent language model (Sundermeyer et al., 2012), which is more convenient to train. Our method demonstrates encouraging performance when trained on just a few thousand sentences (§4).

To verify the effectiveness of our method, we conduct extensive experiments on different sequence tagging tasks, including named entity recognition (NER), part-of-speech (POS) and end-to-end target based sentiment analysis (E2E-TBSA). Our method consistently outperforms the baseline methods in both supervised and semi-supervised settings. Different from the baseline methods, our method generates novel synthetic data from scratch, and thus introduces more diversity to reduce overfitting. For the semi-supervised settings, our method demonstrates strong ability to exploit useful information from unlabeled data and knowledge base.

2 Background

Named Entity Recognition (NER) Named entities refer to phrases that are names of persons, organizations and locations, etc. in text. For example, "*[ORG U.N.] official [PER Ekeus] heads for [LOC Baghdad]*". Named entity recognition is an important task of information extraction and it aims to locate and classify named entities in text into the predefined types (Mikheev et al., 1999; Sang and De Meulder, 2003; Li et al., 2020). It is a challenging task for two reasons (Lample et al., 2016): 1) in most languages and domains, the amount of manually labeled training data for NER is limited; 2) it is difficult to generalize from this small sample of training data due to the constraints on the kinds of words that can be names.

Part-of-Speech (POS) Tagging Part-of-speech tagging consists of assigning a tag that represents a grammatical class to each word in a given sentence. It is a critical component of most NLP systems and is fundamental to facilitate downstream tasks such as syntactic parsing (Schütze, 1993) and opinion analysis (Liu et al., 2015). The current state-of-the-art POS taggers can achieve over 97.80% accuracy on PTB-WSJ (Akbik et al., 2018; Bohnet et al., 2018) and yield over 96.50% average test accuracy across 21 high-resource languages in UD 1.2 (Heinzerling and Strube, 2019). However, one of the problems with current POS taggers is that their accuracy can decrease significantly on low-resource languages and rare words (Plank et al., 2016; Yasunaga et al., 2018).

Target Based Sentiment Analysis The target based sentiment analysis is a fundamental task of sentiment analysis and it aims to detect the opinion targets in sentences and predict the sentiment polarities over the targets (Liu et al., 2015; Chen et al., 2017; Li et al., 2018, 2019a). For example, *"**USB3 Peripherals** are noticeably less expensive than the **ThunderBolt ones**"*. In this sentence, two opinion targets were mentioned, namely "***USB3 Peripherals***" and "***ThunderBolt ones***" and the user expresses a positive sentiment over the first, and a negative sentiment over the second. Li et al. (2019a,b) propose an end-to-end solution (E2E-TBSA) of TBSA, which converts TBSA to a tagging task, and aims to solve the two subtasks (i.e. target detection and sentiment classification) in a unified manning by predicting unified tags. For example, the tag "B-POS" indicates the beginning of a target with positive sentiment. So after annotation, the above example becomes *"[B-POS USB3] [E-POS Peripherals] are noticeably less expensive than the [B-NEG ThunderBolt] [E-NEG ones]"*.

3 Proposed Method

We propose a novel data augmentation method for sequence tagging tasks. We first linearize labeled sentences, and then train a language model to learn the distribution of words and tags from the linearized sequences for generating synthetic training data. A conditional generation technique is also proposed to exploit unlabeled data and knowledge bases when they are available.

3.1 Labeled Sentence Linearization

We first perform sentence linearization to convert labeled sentences into linear sequences, so that language models can be used to learn the distribution of words and tags in gold data. As shown in Figure 1, tags are inserted before the corresponding words during linearization and thus treated as modifiers of these words. For the tasks with frequent O tags, e.g., NER and E2E-TBSA (Li et al., 2019a), we remove such tags from the linearized sequences. Similarly, we can also insert tags after the corresponding words.

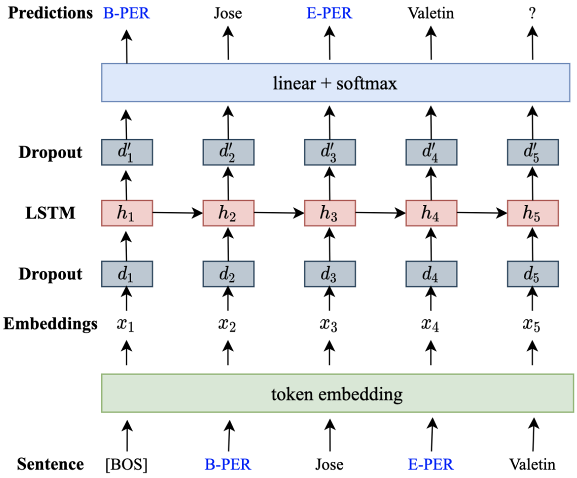

Figure 2: Language model architecture with LSTM.

After sentence linearization, we add special tokens *[BOS]* and *[EOS]* to the beginning and the end of each sentence, respectively. These special tokens are used to facilitate model training and data generation by marking the sentence boundaries.

3.2 Language Modeling and Data Generation

After linearizing labeled sentences, language models can be used to learn the distribution of words and tags. More specifically, we use a one-layer LSTM recurrent neural network language model (RNNLM) in our method, which is similar to the model proposed by Sundermeyer et al. (2012). The architecture of our RNNLM is shown in Figure 2.

Language Modeling We train RNNLM by maximizing the probability for next token prediction. Given a sentence, we first feed the sequence of tokens $(w_1, w_2, \ldots, w_N)$ into the embedding layer to lookup the corresponding embeddings $(\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N)$, where N is the sequence length. A dropout layer is applied to each token embedding $\boldsymbol{x}_t$ to generate $\boldsymbol{d}_t = \text{dropout}(\boldsymbol{x}_t)$. Then we feed $(\boldsymbol{d}_1, \boldsymbol{d}_2, \ldots, \boldsymbol{d}_N)$ into LSTM to produce hidden state $\boldsymbol{h}_t = \text{LSTM}(\boldsymbol{d}_t, \boldsymbol{h}_{t-1})$ at each position t. Another dropout layer is applied to hidden states to compute $\boldsymbol{d}'_t = \text{dropout}(\boldsymbol{h}_t)$.

Finally, a linear+softmax layer is used to predict the next token in the sequence. Assuming the index of token w_t in the vocabulary is i^*, we have the

[BOS] [labeled] B-PER Jose E-PER Valentin has a restaurant business in S-LOC London [EOS]

[BOS] [unlabeled] I have booked a flight to New York [EOS]

[BOS] [KB] We ate crepes in S-LOC Shibuya, saw cherry blossom bloom at Asakusa [EOS]

Figure 3: An example of conditional generation. The first sequence is from gold NER data. The second is from unlabeled data, so no labels. The third is labeled by knowledge base matching, where *Asakusa* cannot be labeled due to incomplete knowledge coverage.

training objective in Eq. 3:

$$\boldsymbol{s}_{t-1} = \boldsymbol{M}^{\top} \boldsymbol{d}'_{t-1} \qquad (1)$$

$$p_\theta(w_t|w_{<t}) = \frac{\exp(\boldsymbol{s}_{t-1,i^*})}{\sum_{i=1}^{V} \exp(\boldsymbol{s}_{t-1,i})} \qquad (2)$$

$$p(w_1, w_2, \ldots, w_N) = \prod_{t=1}^{N} p_\theta(w_t|w_{<t}) \qquad (3)$$

where V is the size of vocabulary, $\boldsymbol{M} \in \mathbb{R}^{r \times V}$ is a learnable weight matrix with r being the dimension of LSTM hidden states, and $\boldsymbol{s}_{t-1,i}$ is the i-th element of $\boldsymbol{s}_{t-1}$.

Generation After training the RNNLM, we can use it to generate synthetic training data for tagging tasks. During generation, only the *[BOS]* token is fed into RNNLM, and the following tokens are sampled based on the probabilities computed by Eq. 2. Given *[BOS]*, the sentence is generated autoregressively one at a time, where the token generated in the previous step is taken as input to generate the next one.

As shown in Eq. 2, RNNLM is more likely to pick the tokens with high probabilities during sampling in the generation process. Because of the randomness added by sampling, RNNLM can choose similar alternatives given the same context. Assume we insert tags before the corresponding words (during sentence linearization) to train the RNNLM, when predicting the next token given *"I have booked a flight to"*, the probability of *"S-LOC"* is much higher than the other choices, since the RNNLM has seen many similar examples in training data, such as *"a train to S-LOC"*, *"a trip to S-LOC"* and so on. Then we predict the following word given *"I have booked a flight to S-LOC"*. In the training data, all *"S-LOC"* are followed by location words, so *"London"*, *"Paris"*, *"Tokyo"*, etc., are all possible choices, and their probabilities are very close. Due to the added randomness, the model can choose any one of them. Tokens are predicted in a similar way when we insert tags after the corresponding words, except that words are predicted before the tags.

3.3 Post-Processing

The generated sequences are in the linearized format, so they need to be converted to the same format as the gold data. We also introduce several straightforward rules to clean the generated data: 1) Delete sentences with no tags; 2) Delete sentences where all words are *[unk]*[2]; 3) Delete sentences with incorrect tag prefix orders (e.g., having *E-LOC* before *B-LOC* in NER data); 4) Delete sentences that contain same sequences of words but different tags.

3.4 Conditional Generation

We propose a conditional generation method to allow the language model to utilize unlabeled data or knowledge bases when they are available in some low-resource scenarios. For example, it could be expensive to annotate a large amount of e-commerce product titles for NER, but much easier to obtain a knowledge base (i.e., dictionary) of product attributes and unlabeled data. We prepend one of these **condition tags** $\{$*[labeled]*, *[unlabeled]*, *[KB]*$\}$ at the beginning of each sequence to mark their origin, where *KB* means the sequence is labeled by matching a knowledge base against the unlabeled data. See Figure 3 for an example. This allows the language model to learn the shared information among these sequences while being aware of the different origins. When generating synthetic data, each word is conditioned on the given condition tag *[labeled]*, denoted as c (conditioning class). After we feed it into the language model, all the LSTM hidden states $\boldsymbol{h}$ in the following generation steps contain information of c. In addition, $\boldsymbol{h}$ also encodes information of all of the other previous tokens in

---

[2] To reduce the size of vocabulary when training language model, the words that only appear once in training data are replaced with the unknown token *[unk]*.

the sequence. When predicting the next token conditioned on $\boldsymbol{h}_{t-1}$, the probability $p_\theta(w_t|w_{<t})$ in Eq. 2 becomes $p_\theta(w_t|w_{<t}, c)$.[3] A similar approach is used in CTRL (Keskar et al., 2019) to control style, task-specific behavior, etc., during text generation.

4 Experiments

In this section, we present our experiments in both supervised and semi-supervised settings. In the supervised settings, only gold data are used for augmentation. In the semi-supervised settings, we also leverage unlabeled data and knowledge bases.

4.1 Basic Models

Language Model We use the language model described in Section 3.2 for synthetic data generation. We modified the decoder of the LSTM-LM model in Kruengkrai (2019) to implement this language model. We set LSTM hidden state size to 512 and embedding size to 300. We use dropout rate 0.5 for the two dropout layers. All language model are trained using Stochastic gradient descent (SGD) with initial learning rate 1 and batch size 32. Learning rate will be decayed by 0.5 in the next epoch if the perplexity on dev set does not improve. We set the maximum number of epochs to 30 and stop training early if the perplexity on dev set does not improve in 3 consecutive epochs. During synthetic data generation, we use the average length of gold sentences in the training set as our maximum sentence length.

Sequence Tagging Model We implement a BiLSTM-CRF model (Lample et al., 2016) with the Flair framework (Akbik et al., 2019) to evaluate our data augmentation method on NER and POS tasks.[4] We use a single-layer BiLSTM with hidden state size 512. Dropout layers are applied before and after the BiLSTM layer with dropout rate 0.5. All sequence tagging models are trained using Adam (Kingma and Ba, 2014) with initial learning rate 1e-3 and batch size 32. Learning rate is decayed by 0.5 if the performance on dev set does not improve in 3 consecutive epochs. We stop training when the learning rate drops below 1e-5 or number of epochs reaches 100. We use the pretrained 300-dimensional fastText word embeddings (Bojanowski et al., 2017) for all languages.

We employ relatively simple basic models because: 1) They help to avoid the possible overfitting problems due to the small data size under the low resource setting; 2) They allow more faithful understanding on the effects of the proposed data augmentation method.

4.2 Supervised Experiments

To verify the effectiveness of our data augmentation method in the supervised settings, we evaluate it on three different tagging tasks, including NER, POS and E2E-TBSA. Most of the prior works rely on additional information, so we use random deletion (**rd**) (Wei and Zou, 2019) as our baseline, where 5% of the words[5] and the corresponding tags in training data are randomly deleted. See Table 1 for the notations of the methods used in our supervised experiments.

Method	Description
gold	Only use the gold data.
gen	Our method. Generate synthetic data with the language models, and oversample gold data.
rd	Baseline method. Generate synthetic data by random deletion, and oversample gold data with the same ratio as **gen**.
rd*	Baseline method. Similar to **rd**, except that gold and synthetic data are equally sampled.

Table 1: Data sources for the supervised setting.

4.2.1 Named Entity Recognition

Dataset We evaluate our proposed methods on the CoNLL2002/2003 NER data (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), with four languages: English, German, Dutch and Spanish. Besides, we evaluate our methods on Thai and Vietnamese NER data, which are product titles obtained from major e-commerce websites in Southeast Asian countries and annotated with 11 product attribute NER tags, including *PRODUCT*, *BRAND*, *CONSUMER_GROUP*, *MATERIAL*, *PATTERN*, *COLOR*, *FABRIC*, *OCCASION*, *ORIGIN*, *SEASON* and *STYLE*. See Appendix for the statistics of the Thai and Vietnamese NER data used in our experiments.

Experimental Settings In addition to evaluating our method on the full training data, we also ran-

---

[3] Condition tag c is also in $w_{<t}$, since it is a special token added to the beginning of each sentence. We write it explicitly to emphasize the conditional effect.

[4] The baseline model provided in the original paper is used for evaluating end to end target based sentiment analysis task.

[5] For NER and E2E-TBSA, the whole entity is deleted if a selected word appears within an entity span.

domly sample 1k, 2k, 4k, 6k and 8k sentences for each language to verify its robustness in low-resource settings. We use the original development and test data. The language models are trained on the above sampled sentences, and then used to generate synthetic training data following the steps described in Section 3.

For each new batch of 1k sentences generated by the trained language model, we measure the percentage of new 1-gram tokens that appears in previous batches. Once the percentage exceeds 99%, we will stop data generation. Then we post-process (Section 3.3) the generated data, and add them to gold training data for tagging model training. For **rd** and **gen**, we oversample gold data by repeating them 4 times (shuffled) in the training set. For random deletion, we also report the result when gold and synthetic data are equally sampled, denoted by **rd***. Additional details on hyperparameter selection for the oversampling ratios can be found in Appendix A.3. Following Lample et al. (2016), the IOBES tagging scheme is used when training the language models and sequence tagging models described above.

Results and Analysis We report the average results of 3 runs in Table 2. Our method shows consistent performance improvement for all languages. Especially for the smaller sampled sets, our method demonstrates more significant performance improvement. In particular, the proposed method achieved average 1.93 and 1.38 point improvement compared with the baseline methods in the 1k and 2k settings, respectively.

Tag-Word vs. Word-Tag As discussed in Section 3.1, there are two ways to perform sentence linearization: 1) insert tags before the corresponding words (Tag-Word); 2) insert tags after the corresponding words (Word-Tag). Keeping all of the other settings same, we find Tag-Word outperforms Word-Tag in NER tasks (as shown in Appendix A.2). One possible reason is that, Tag-Word is more consistent with the Modifier-Noun pattern, which appears more often in the training data during language modeling. Therefore, we use Tag-Word for all the NER experiments.

4.2.2 Part of Speech Tagging

Dataset We use the POS data from Universal Dependencies treebanks[7] for evaluation on this task. We evaluate on five languages, including English, Spanish, Czech, Romanian and Japanese. Each language has multiple corpora in the Universal Dependencies treebanks, so we merge the corpora to build one dataset for three languages: English, Spanish and Czech. For English, we merge *GUM*, *ParTUT*, *PUD* and *Lines*. For Spanish, we merge *AnCora* and *GSD*. For Czech, we merge *PDT*, *FicTree*, *CLTT* and *CAC*. We have also evaluated our model on Japanese (*GSD*) and Romanian (*RRT*), which are either spoken by a much smaller population or from a different language family.

Settings and Results We follow similar experimental settings as NER task. The same language model and BiLSTM-CRF sequence tagging model are used for synthetic data generation and POS tagging respectively. Different from NER, Word-Tag shows slightly better performance in POS tasks (refer to Appendix A.2). We present the average Word-Tag results of 3 runs in Table 3. Our method demonstrates consistent performance improvement for all languages. Similar to NER, our method demon-

---

[6] German has large out-of-vocabulary rate when using static fastText embedding, which leads to lower F1 score compared with other languages.

strates more significant performance improvement for smaller sampled sets on POS tagging. In particular, the proposed method achieved average 0.56, 0.60 and 0.46 point improvement compared with the baseline methods in the 1k, 2k and 4k settings, respectively.

4.2.3 Target Based Sentiment Analysis

Dataset We use the laptop and restaurant review datasets processed by Li et al. (2019a) for evaluation on E2E-TBSA, which was initially obtained from SemEval ABSA challenges (Pontiki et al., 2014, 2015, 2016). We merge these two review datasets, regard 10% randomly held-out training data as the dev set, and randomly sample smaller sets from the remaining training data for low-resource settings. The original test sets are merged as our test set.

Settings and Results We follow similar experimental settings as NER and POS tasks, except that the same sequence tagging model released by Li et al. (2019a) is used for evaluation. Here Tag-Word shows better results (refer to Appendix A.2), plausibly it is because the unified tags (e.g. *B-POS*, and *B-NEG*) are similar to noun modifiers and Tag-Word is more consistent with the Modifier-Noun pattern. We present the average Tag-Word results of 3 runs in Table 4. Our method demonstrates performance improvement for 4k and above. Compared with the NER and POS datasets, the E2E-TBSA dataset has much fewer labels, so the results are less stable.

4.3 Semi-supervised Experiments

In this section we evaluate the effectiveness of our method in two semi-supervised settings: 1) only unlabeled data are available; 2) both unlabeled data and knowledge base are available. See Table 5 for the notations of the methods used in our semi-supervised experiments.

Method	Description
gold	Supervised method. Only use the gold data.
wt	Baseline method. Annotate unlabeled data with a weak tagger (i.e. a tagging model trained on the gold data).
gen$_{\text{ud}}$	Our method. Generate synthetic data with LM, where LM is trained on gold data and unlabeled data.
kb	Baseline method. Annotate unlabeled data with knowledge base.
gen$_{\text{kb}}$	Our method. Generate synthetic data with LM, where LM is trained on gold data and knowledge base annotated data.

Table 5: Data sources for the semi-supervised setting.

4.3.1 Only Using Unlabeled Data

Dataset We use CoNLL2003 English NER data (Tjong Kim Sang and De Meulder, 2003) for evaluation. In addition to the gold NER training data, we utilize unlabeled data for semi-supervised training. The Stanford CoreNLP tokenizer (Manning et al., 2014) is used to tokenize Wikipedia sentences.

Experimental Settings Similar to the above experiments, we use 1k, 2k, 4k, 6k and 8k sentences randomly sampled from NER gold data as well as the full dataset to evaluate our method. For fair comparison, we only use the same set of 10k sentences randomly sampled from Wikipedia dump in both of our and baseline methods. Let D_{gold} and $D_{unlabeled}$ be the sampled gold NER data and the Wikipedia data, respectively.

In our method, D_{gold} and $D_{unlabeled}$ are concatenated to train language models, following the steps

---

[8] UD-RRT full train set has 8k sentences for Romanian.

[9] UD-GSD full train set has 7k sentences for Japanese.

Method	1k	2k	4k	6k	8k	all
gold	58.06	67.85	74.55	77.16	80.30	83.04
+wt	65.12	72.43	77.90	79.41	81.36	84.00
+gen$_{\text{ud}}$	**66.19**	**73.00**	**78.08**	**79.75**	**81.98**	**84.33**
+kb	**67.36**	72.86	77.15	79.33	81.91	83.69

Table 6: Semi-supervised NER F1.

described in Section 3.4. Then we use the language models to generate synthetic data, from which 20k randomly sampled sentences are combined with D_{gold} to train NER models. We use **gen$_{\text{ud}}$** to denote this data generation method. The method that employs weak taggers to annotate $D_{unlabeled}$ is used as our baseline, denoted by **wt**. The weak taggers in this experiment are the NER models trained on D_{gold}. We use the same NER model (BiLSTM-CRF) and hyperparameters to evaluate our and baseline methods. When training the language model, we equally sample sentences from D_{gold} and $D_{unlabeled}$. When training the NER models, we oversample the gold data by repeating D_{gold} 4 times to create a shuffled training file.

Results and Analysis We report F1 of **wt** and **gen$_{\text{ud}}$** (average of 3 runs) in Table 6. Our method outperforms the baseline method **wt** on all settings. Moreover, it would be a promising direction to further explore our model's capability by using a larger amount of unlabeled data. It is not very convenient to utilize a large amount of unlabeled data in the baseline method **wt**, since this will directly increase the amount of augmented data. As a result, some of augmented data may not be utilized before sequence tagging models converge. However, our method **gen$_{\text{ud}}$** can conveniently utilize a large amount of unlabeled data to train the language models, thereby improving data augmentation quality directly. When the amount of unlabeled data is much larger, we can pretrain language models with the unlabeled data, and then finetune them with labeled data.

4.3.2 Using Unlabeled Data and Knowledge Base

Dataset In addition to the gold training data and unlabeled sentences used in Section 4.3.1, we also try to leverage knowledge base for further performance improvement in this experiment. We build the knowledge base by extracting entities (case sensitive and appearing at least twice) and the corresponding tags from the full gold training data. Besides, we add more *LOC* entities to this knowledge base by including the cities and countries extracted from geonames[10].

Experimental Settings We randomly sample the gold NER data and the Wikipedia data in the same way as Section 4.3.1, where the sampled sentences are denoted by D_{gold} and $D_{unlabeled}$, respectively. Our knowledge base is used to annotate $D_{unlabeled}$ by finding longest forward matches (from left to right) in each sentence. We denote this annotation method by **kb** and the annotated data by D_{kb}.

In our method, D_{gold} and D_{kb} are concatenated to train language models, following the steps described in Section 3.4. Then we use the language models to generate synthetic data, from which 20k randomly sampled sentences are combined with D_{gold} to train the NER models. We use **gen$_{\text{kb}}$** to denote this data generation method and compare it with the baseline method **kb**. Similar to the above experiments, we oversample D_{gold} when training the language and NER models.

Results and Analysis We present F1 of **kb** and **gen$_{\text{kb}}$** (average of 3 runs) in Table 6. The baseline method **kb** exhibits very strong performance when the size of D_{gold} is small, since we use a large knowledge base of countries and cities for annotation, and location names are less ambiguous compared with the other types of entities. However, our method still outperforms **kb** when the size of D_{gold} is larger than 2k, which shows that our method is more robust to the noises in D_{kb} when a slightly larger amount of gold data are available.

5 A Closer Look at Synthetic Data

In this section, we explore in more details why the synthetic data generated by our method can help improve sequence tagging performance. Through a closer look at the generated data, we have several interesting findings.

More Diversity The generated synthetic data introduces more diversity to help reduce overfitting. As the example shown in Figure 4, the name "*Sandrine*" in the gold training data always pairs up with "*Testud*" in different sentences. However, in the generated data, we can see new names have been generated like "*Sandrine Nixon*", "*Sandrine Okuda*" and "*Sandrine Neuumann*". Meanwhile,

Gold Training Data

1. ... [**B-PER Sandrine**] [**E-PER Testud**] ([**S-LOC France**]) beat ...
2. ... [**B-PER Sandrine**] [**E-PER Testud**] ([**S-LOC France**]) ...
3. ... beat [**B-PER Sandrine**] [**E-PER Testud**] ([**S-LOC France**]) ...
4. ... [**B-PER Sandrine**] [**E-PER Testud**] ([**S-LOC France**]) beat ...

Generated Data

1. ... [**B-PER Sandrine**] [**E-PER Testud**] ([**S-LOC Sweden**]) ...
2. ... [**B-PER Sandrine**] [**E-PER Nixon**] fled to ([**S-LOC Egypt**]) ...
3. ... [**B-PER Sandrine**] [**E-PER Okuda**] ([**S-LOC Australia**]) ...
4. ... [**B-PER Sandrine**] [**E-PER Neuumann**] ([**S-LOC France**]) beat ...

Figure 4: An illustration of diversity of generated data. The name "*Sandrine*" in the gold training data always pairs up with "*Testud*" in sentences.

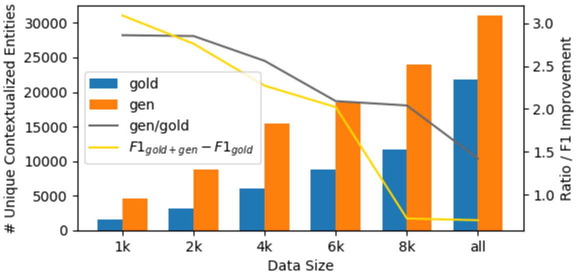

Figure 5: Statistics of unique contextualized entities.

the locations in the sentences have been replaced with new countries like "*Sweden*", "*Egypt*" and "*Australia*". With these synthetic data, the model can focus on learning the pattern of contexts that entities appear in, instead of simply memorizing "*Sandrine Testud*" as a person name and "*France*" as a location.

To quantitatively measure the diversity brought in by our method and its impact, we have done some statistical analysis of the contextualized entities (CEs) in the generated data of the supervised English NER. A CE refers to the combination of an entity and its 1-gram contexts. For example, in the sentence "*The [B-ORG European] [E-ORG Commission] said* ...", the entity is "*European Commission*" and its CE is "*The European Commission said*". As the shown in Figure 5, we calculate the number of unique CEs in the gold training data, the number of new unique CEs in the generated data, and the ratio of the two numbers. We also plot here the F1 improvement of our method (i.e. gold+gen) over only using the gold data, as given in Table 2. We can see that our method generates a large number of new CEs, and such diversity strengthens the robustness of the trained model. When the ratio is higher, the F1 improvement is more significant, which also shows that our method does help ease the low-resource problem by generating rich new entities and contexts. Refer to the Appendix A.5 for statistics of unique entities (without context), which shows the same conclusion.

Efficient Utilization of Unlabeled Data When unlabeled data are available, our method is flexible to utilize them for semi-supervised training. We find many interesting examples in the synthetic data that show our method can effectively use the unlabeled data to extract useful information. In an example generated by our method "... *the [B-ORG Bank] [I-ORG of] [E-ORG Alabama]* ...", the word "*Alabama*" has never appeared in gold NER training data. However, our language model learned that "*Alabama*" (from unlabeled data) is very similar to the other location words that appear in both gold training data and unlabelled data. So when generating the synthetic data, the language model can use this word in a similar context, or even create new entities ("*Bank of Alabama*" in this example has never appeared in gold or unlabeled data).

6 Conclusion

In this paper, we show that language models can be used to generate high quality synthetic data for sequence tagging tasks. The generated data introduce more diversity to reduce overfitting, since they are generated from scratch instead of modifying the gold training data. Our proposed method demonstrates promising performance improvements on various tagging tasks, especially in the low-resource settings. Besides, experiments demonstrate that our method can also effectively utilize unlabeled data and knowledge base for semi-supervised training.

A Appendix

A.1 Statistics of Thai and Vietnamese NER Data

We present the number of sentences in Thai and Vietnamese NER data in Table 7.

Lang.	**train**	**dev**	**test**
vi	18,922	500	500
th	11,272	499	490

Table 7: Number of sentences in TH and VI NER data.

A.2 Experiments on Tag-Word vs. Word-Tag

We conduct experiments to compare the performance of Tag-Word and Word-Tag for the tagging tasks. All of the other settings are same as the corresponding experiments presented in the main paper. Results are reported in Table 8 to 10. Tag-Word yields better average performance for NER and E2E-TBSA, while Word-Tag slightly outperforms Tag-Word for POS tagging.

Lang.	**Method**	**1k**	**2k**	**4k**	**6k**	**8k**	**full**	**average**
en	Tag-Word	**59.39**	**69.48**	**75.68**	**78.65**	**80.19**	**83.70**	**74.52**
	Word-Tag	58.97	67.32	75.45	78.06	80.43	83.58	73.97

	Word-Tag	**79.18**	**82.64**	**86.13**	90.33	92.68	**86.19**

Table 9: Universal Dependencies POS accuracy: Tag-Word vs. Word Tag.

Lang.	**Method**	**2k**	**4k**	**full(6k)**	**average**
en	Tag-Word	54.22	**61.72**	**62.88**	**59.61**
	Word-Tag	**55.58**	59.42	61.65	58.88

Table 10: E2E-TBSA micro F1: Tag-Word vs. Word-Tag.

A.3 Experiments on Oversampling Ratios

We conduct experiments to compare different oversampling ratios for NER task. Results are reported in Table 11. The notation gold$\times N$ means we oversample gold by repeating it N times in the shuffled static training data.

A.4 Semi-supervised Experiments on Part of Speech Tagging

Dataset We use the English POS data from Universal Dependencies treebanks for evaluation on this task. We merge *GUM*, *ParTUT*, *PUD* and *Lines* corpora to build the English dataset. Similar to the semi-supervised experiments on NER, we also utilize unlabeled Wikipedia sentences for training.

Experimental Settings We use 1k, 2k, 4k, 6k and 8k sentences randomly sampled from English POS gold data as well as the full dataset to evaluate our method. We follow the same experimental setting as the semi-supervised experiments on NER to

Lang.	Method	1k	2k	4k	average
en	gold×1	59.74	69.14	76.48	68.45
	gold×2	60.92	69.79	76.57	69.09
	gold×3	61.13	70.42	74.92	67.24
	gold×4	61.15	**70.61**	**76.82**	**69.53**
	gold×5	**61.43**	70.38	76.43	69.41

Table 11: CoNLL NER F1: comparison on different oversampling ratios.

generate synthetic data, train the sequence tagging models and evaluate on the POS test data.

Results and Analysis We report accuracy of **wt** and **gen$_{\mathbf{ud}}$** (average of 3 runs) in Table 12. Our method outperforms the baseline method **wt** when the number of gold sentences are less than 8k. When the number of gold sentences are more than 8k, the performance of our method is comparable with **wt**.

Method	1k	2k	4k	6k	8k	all
gold	79.18	82.17	85.83	88.62	90.21	93.00
+wt	81.11	84.00	86.91	89.64	**90.88**	**93.20**
+gen$_{ud}$	**82.11**	**84.93**	**87.52**	**89.98**	90.84	93.12

Table 12: Semi-supervised POS accuracy.

A.5 Synthetic Data Diversity: Unique Entities

To quantitatively measure the diversity introduced by our method in the supervised English NER tasks, we count the number of unique entities (without context) in the gold and generated data. Results are presented in Figure 6.

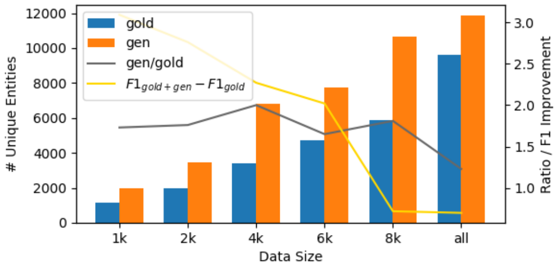

Figure 6: Statistics of unique entities (without context)

A.6 Average Runtime

Table 13 is an illustration of the average runtime of our models in English NER, POS and E2E-TBSA tasks and RNNLM.

Task	1k	2k	4k	6k	8k	all
NER	26.5	70.5	124.4	167.9	216.3	393.2
POS	83.6	112.3	231.1	257.7	277.2	298.0
E2E-TBSA	-	89.3	150.8	269.2	-	-
RNNLM	0.7	1.1	2.0	2.7	3.3	3.9

Table 13: Average runtime (min).

A.7 Computing Infrastructure

We conduct our experiments on NVIDIA V100 GPU.

Interpretable Multi-dataset Evaluation for Named Entity Recognition

Abstract

With the proliferation of models for natural language processing tasks, it is even harder to understand the differences between models and their relative merits. Simply looking at differences between *holistic* metrics such as accuracy, BLEU, or F1 does not tell us *why* or *how* particular methods perform differently and how diverse datasets influence the model design choices. In this paper, we present a general methodology for *interpretable* evaluation for the named entity recognition (NER) task. The proposed evaluation method enables us to interpret the differences in models and datasets, as well as the interplay between them, identifying the strengths and weaknesses of current systems. By making our analysis tool available, we make it easy for future researchers to run similar analyses and drive progress in this area: `https://github.com/neulab/InterpretEval`.

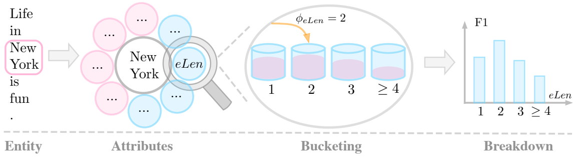

Figure 1: An example of our evaluation methodology. `eLen` (*entity length*) represents one of the attributes (detailed in Sec. 3.1) of the entity "`New York`". After bucketing, performance can be broken down over different attribute values.

1 Introduction

With improvements in model architectures (Hochreiter and Schmidhuber, 1997; Kalchbrenner et al., 2014; Lample et al., 2016; Collobert et al., 2011) and learning of pre-trained embeddings (Peters et al., 2018; Akbik et al., 2018, 2019; Devlin et al., 2018; Pennington et al., 2014), Named Entity Recognition (NER) systems are evolving rapidly but also quickly reaching a performance plateau (Akbik et al., 2018, 2019). This proliferation of methods poses a great challenge for the current evaluation methodology, which usually is based on comparing systems on a single holistic score assessing accuracy (usually entity $F1$-score). There are several issues with this practice. First, a single evaluation number does not allow us to distinguish on a fine-grained level the strengths and weaknesses among diverse systems. Second, it is hard to improve what we do not understand; if an engineer or researcher looking to make model improvements cannot tell where the model is failing, it is also hard to decide which methodological improvements to try next.

To alleviate this problem, a few works (Ichihara et al., 2015; Derczynski et al., 2015) have attempted to perform *fine-grained error analysis* of NER systems. While a step in the right direction, these analyses frequently rely upon labor-intensive manual examination and also customarily depend on pre-existing error typologies encoding assumptions about the errors a system is likely to make.

Orthogonally, some other works (Qian et al., 2018; Hu et al., 2020; Luo et al., 2020; Li et al., 2020; Lin et al., 2020) evaluate holistic metrics such as F1 *across multiple datasets* that differ in domain, language, or other characteristics (Sang and De Meulder, 2003; Collobert et al., 2011; Weischedel et al., 2013). Although this enables us to more comprehensively assess the models, the reliance on holistic metrics precludes a finer-grained view of how various aspects of the model performance vary across the different settings.

In this paper, we argue that an ideal evaluation methodology should be (1) fully or partially automatic, (2) allow evaluation and comparison across multiple datasets, and (3) allow users to dig deeper into fine-grained strengths and weaknesses of each model. To this end, we devise a generalized, fine-

---

November 16–20, 2020.

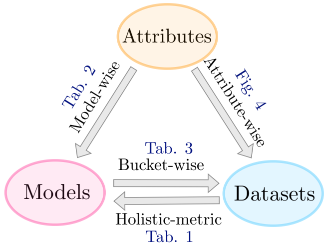

Figure 2: Relations among attributes, models, and datasets.

grained, and multi-dataset evaluation methodology for the task of NER, as demonstrated in Fig. 1. Specifically, it leverages the notion of "*attributes*", values which characterize the properties of an entity that may be correlated with the NER performance (e.g. entity length in words). Afterward, we partition test entities into a set of *buckets* based on the entity's attributes, where entities in different buckets may have different performance scores on average (e.g. entities with more words may be predicted less accurately).

Methodologically, our evaluation framework allows for three analytical views as elucidated in Fig. 2. *Model-wise* (Sec. 5.1) analysis investigates how the performances of different models vary according to attribute value (e.g. "Is a model with a CRF layer better at dealing with long entities?"). *Attribute-wise* (Sec. 5.2) analysis compares how different attributes affect performance on different datasets (e.g. "Does entity length correlate with model performance on all datasets or just some?"). *Bucket-wise* (Sec. 5.3) compares among all possible analysis dimensions, and can diagnose the strengths and weaknesses of existing models (e.g. "What entity attributes indicate that a BERT-based model will likely fail?"), or help us understand how different choices of datasets influence model performance (e.g. "On which datasets is using a CRF layer more appropriate?").

Experimentally, we conduct a comprehensive analysis over **twelve** models, **eight** attributes, and **six** datasets. Proposed quantifiable measures allow us to draw several qualitative conclusions as highlighted below: 1) *label consistency* (the degree of label agreement of an entity on the training set) and *entity length* have a consistent influence on NER task's performance (Sec. 5.2.2); 2) CRF-based systems are more likely to make a mistake compared with MLP-based systems when dealing with long entities (Sec. 5.1.2); 3) Higher-frequency tokens of a test entity cannot guarantee better performance since other crucial factors such as *label consistency* also matter (Sec. 5.2.2); 4) Even more advanced models (e.g., `BERT`, `Flair`) fail to predict entities with low *label consistency* (Sec. 5.3.2).

Finally, motivated by observation 4), we present an effective solution to improve current NER systems. Quantitative and qualitative experiments demonstrate that introducing larger context is an effective method, obtaining improvements of up to 10 points in F1 score on some datasets.

2 Background

Task Description NER is frequently formulated as a sequence labeling problem (Chiu and Nichols, 2015; Huang et al., 2015; Ma and Hovy, 2016; Lample et al., 2016), where $X = \{x_1, x_2, \ldots, x_T\}$ is an input sequence and $Y = \{y_1, y_2, \ldots, y_T\}$ are the output labels (e.g., "B-PER", "I-LOC", "O"). The goal of this task is to accurately predict entities by assigning output label y_t for each token x_t: $P(Y|X) = P(y_t|X, y_1, \cdots, y_{t-1})$

Standard Evaluation Strategy for NER The common evaluation metric for NER systems (Sang and De Meulder, 2003) is to compute a corpus-level metric using micro-averaged $F1$ score: $F1 = \frac{2 \times P \times R}{P+R}$: where P is the percentage of named entities output by learning system that are correct. R is the percentage of gold entities identified by the system. Here a named entity is correct only if it is an exact match of an annotated entity.

3 Attribute-aided Evaluation

Our proposed attribute-aided evaluation methodology involves two key elements: *attribute definition* and *bucketing*. We first define diverse attributes for each entity, by which test entities are partitioned into different buckets. We then calculate the performance for each bucket of test entities.

3.1 Attribute Definition

Attributes are defined either over a *span* or a *token* and characterize the diverse properties thereof. In practice, the span will be instantiated as a genuine or a mis-predicted entity (calculating *precision*) in the test set, while tokens can be any token in the test corpus. We classify attributes into two categories: local attributes and aggregate attributes.

Local attributes are calculated with respect to a span or token regarding attributes of the span/token itself, its label, or the sentence in which the span appeared. We define a token x or span $\mathbf{x}$, to have a

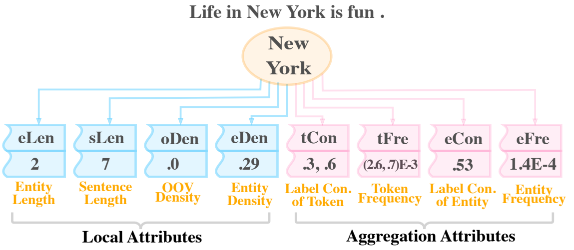

Figure 3: The eight attributes defined in this paper and corresponding values with respect to the entity "`New York`" in the sentence "`Life in New York is fun .`". The text in orange is the full name of the attribute, in which *Con.* denotes *Consistency*.

gold-standard or predicted label $y = \mathrm{lab}(\cdot)$,[1] which occurs in sentence $X = \mathrm{sent}(\mathbf{x})$. We also define two functions that count the number of words outside the training set[2] $\mathrm{oov}(\cdot)$ and the number of entities $\mathrm{ent}(\cdot)$ in a sequence of words. Based on this, we define several feature functions $\phi(\mathbf{x})$ that can compute different attributes of each span:

- $\phi_{\texttt{str}}(\mathbf{x}) = \mathbf{x}$: *span surface string*
- $\phi_{\texttt{label}}(\mathbf{x}) = \mathrm{lab}(\mathbf{x})$: *entity span label*
- $\phi_{\texttt{eLen}}(\mathbf{x}) = |\mathbf{x}|$: *entity span length*

We additionally define feature functions over tokens $\phi(x)$:

- $\phi_{\texttt{str}}(x) = x$: *token surface string*
- $\phi_{\texttt{label}}(x) = \mathrm{lab}(x)$: *token label*

We also define several features of the underlying sentence, which can be applied to either spans $\mathbf{x}$ or tokens x; we show the example of applying to token x below:

- $\phi_{\texttt{sLen}}(x) = |\mathrm{sent}(x)|$: *sentence length*
- $\phi_{\texttt{eDen}}(x) = |\mathrm{ent}(\mathrm{sent}(x))|/\phi_{sLen}(x)$: *entity density*
- $\phi_{\texttt{oDen}}(x) = |\mathrm{oov}(\mathrm{sent}(x))|/\phi_{sLen}(x)$: *OOV density*

Aggregate attributes are properties of spans or tokens based on aggregate statistics that require calculation over the whole training corpus. To calculate these attributes, we first define $\mathcal{E}^{\mathrm{tr}}$ as all spans/tokens in the training set. We then define an aggregation function that takes a particular span/token (example of tokens below), feature function $\phi(\cdot)$, and span set $\mathcal{E} \subseteq \mathcal{E}^{\mathrm{tr}}$ as arguments:

$$\mathcal{F}(x, \phi(\cdot), \mathcal{E}) = \frac{|\{\varepsilon|\phi(\varepsilon) = \phi(x), \forall \varepsilon \in \mathcal{E}\}|}{|\mathcal{E}|}, \tag{1}$$

calculating the ratio of spans/tokens in $\mathcal{E}$ that have the same feature value $\phi(\cdot)$ as x. We can define $\mathcal{E} := \mathcal{E}^{\mathrm{tr}}$, calculating statistics over the entire training set. We can also choose it to be only the spans/tokens with a particular surface form:

$$\mathcal{E}^{x} := \{\varepsilon|\phi_{\texttt{str}}(\varepsilon) = \phi_{\texttt{str}}(x), \varepsilon \in \mathcal{E}^{\mathrm{tr}}\}. \tag{2}$$

Based on the above general formulation, we defined a few specific instantiations that we use in the following experiments. First, *entity frequency* and *token frequency*:

$$\phi_{\texttt{eFre}}(\mathbf{x}) := \mathcal{F}(\mathbf{x}, \phi_{\texttt{str}}(\cdot), \mathcal{E}^{\mathrm{tr}}) \tag{3}$$

$$\phi_{\texttt{tFre}}(x) := \mathcal{F}(x, \phi_{\texttt{str}}(\cdot), \mathcal{E}^{\mathrm{tr}}) \tag{4}$$

Besides, we use two *consistency*-based attributes, which attempt to measure how consistently a particular span/token is labeled with a particular label:

$$\phi_{\texttt{eCon}}(\mathbf{x}) := \mathcal{F}(\mathbf{x}, \phi_{\texttt{label}}(\cdot), \mathcal{E}^{\mathrm{tr}}) \tag{5}$$

$$\phi_{\texttt{tCon}}(x) := \mathcal{F}(x, \phi_{\texttt{label}}(\cdot), \mathcal{E}^{\mathrm{tr}}) \tag{6}$$

We give an example to illustrate above by setting $\mathbf{x}$ = "`New York`" with gold label "`LOC`". Therefore, the numerator of ϕ_{eCon} tallies entities "`New York`" with label "`LOC`" in training set, while the denominator counts spans "`New York`". The overall ratio quantifies the degree of label consistency in train set for a given span "`New York`".

3.2 Bucketing

Bucketing is an operation that breaks down the holistic performance into different categories (Neubig et al., 2019; Fu et al., 2020). This can be achieved by dividing the set of test entities into different subsets of test entities (regarding span- and sentence-level attributes) or test tokens (regarding token-level attributes). Here we describe the entity-based bucketing strategies, which can also be similarly applied to token-based strategies. The bucketing process can be expressed in the following general form:

$$\mathcal{E}^{te}_{1}, \cdots, \mathcal{E}^{te}_{m} = \mathrm{Bucket}(\mathcal{E}^{te}, \phi(\cdot)) \tag{7}$$

where $\mathcal{E}^{te}$ represents a set of test entities or tokens, and m is the number of buckets. $\phi(\cdot)$ denotes one type of feature functions (as defined in Sec. 3.1) to calculate attribute value for a given entity (e.g., $\phi_{\texttt{eLen}}(\mathbf{x})$ to compute *span length*).

Specifically, we divide the range of attribute values into m discrete parts, whose intervals can be obtained mainly based on two ways: 1) dividing value range evenly 2) dividing test entities or tokens equally. In practice, the way to obtain intervals may

---

[1] y is a simple entity label for tokens, and does not distinguish between "B" and "I" in the BIO tagging scheme.

[2] Not considering the vocabulary of pre-trained models.

be diverse for different attributes.[3] We detail our settings in the appendix. Finally, once we have generated buckets, we calculate the F1 score with respect to entities (or tokens) of each bucket.

4 Experimental Settings

In this section we describe our experimental settings, each of which is followed by an experiment and analysis results.

4.1 NER Datasets for Evaluation

We conduct experiments on: CoNLL-2003 (`CoNLL`), [4] WNUT-2016 (`WNUT`),[5] and OntoNotes 5.0 dataset. [6] The CoNLL dataset (Sang and De Meulder, 2003) is based on Reuters data (Collobert et al., 2011). The WNUT dataset (Strauss et al., 2016) is provided by the second shared task at WNUT-2016 and consists of social media data from Twitter. The OntoNotes 5.0 dataset (Weischedel et al., 2013) is collected from broadcast news (`BN`), broadcast conversation (`BC`), weblogs (`WB`), and magazine genre (`MZ`).

4.2 Models

We varied the evaluated models mainly in terms of four aspects: 1) character/subword-sensitive encoder: `ELMo` (Peters et al., 2018), `Flair` (Akbik et al., 2018, 2019), `BERT` [7] (Devlin et al., 2018)

2) additional word embeddings: `GloVe` (Pennington et al., 2014); 3) sentence-level encoders: `LSTM` (Hochreiter and Schmidhuber, 1997), `CNN` (Kalchbrenner et al., 2014; Chen et al., 2019); 4) decoders: `MLP` or `CRF` (Lample et al., 2016; Collobert et al., 2011). In total, we study 12 NER models and we give more detailed description of models in the appendix. Detailed model settings are illustrated in Tab.1. We use the result from the model with the best development set performance, terminating training when the performance on development is not improved in 20 epochs.

4.3 Holistic Analysis

Before giving a fine-grained analysis, we present the results of different models on different datasets as traditional *multi-dataset* evaluation does. As Tab. 1 demonstrates, there is no one-size-fits-all model; different models get the best results on different datasets. Naturally, this raises the following questions: 1) what factors of the datasets significantly influence NER performance? 2) how do these factors influence the choices of models? 3) does a worse-ranked model outperform the best-ranked model in some aspects and how do datasets influence the choices of models? The following analyses will investigate these questions.

5 Fine-grained Analysis

To better characterize the relationship among models, attributes, and datasets, we propose three analysis approaches: model-, attribute-, and bucket-wise.

Formally, we refer to $M = \{m_1, \cdots, m_{|M|}\}$ as a set of **models** and $\Phi = \{\phi_1, \cdots, \phi_{|\Phi|}\}$ as a set of **attributes**. As described in Sec. 3.2, the test set $\mathcal{E}$ could be split into different **buckets** of $\mathcal{E} = \{\mathcal{E}^j_1, \cdots, \mathcal{E}^j_{|\mathcal{E}|}\}$ based on an attribute ϕ_j. We introduce the concept of a *performance table* $\mathcal{T} \in \mathbb{R}^{|M|\times|\Phi|\times|\mathcal{E}|}$, whose element $\mathcal{T}_{ijk}$ represents the performance ($F1$ score) of i-th model on the k-th sub-test set (bucket) generated by j-th attribute. Next, we will explain how above-mentioned analysis approaches are defined based on $\mathcal{T}$.

5.1 Exp-I: Model-wise Analysis

Model-wise analysis investigates how different attributes influence performance of models with different architectures and initializations, e.g. "does `eLen` influence performance of a `CNN-LSTM-CRF`-based NER system?"

5.1.1 Approach

Here we adopt two types of statistical variables $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$ to characterize how the j-th attribute influences the of performance i-th model.

$$\mathbf{S}^{\rho}_{i,j} = \mathrm{Spearman}(\mathcal{T}[i,j:], R_j) \tag{8}$$

$$\mathbf{S}^{\sigma}_{i,j} = \mathrm{Std}(\mathcal{T}[i,j:]) \tag{9}$$

where $\mathrm{Spearman}$ is a function to calculate the Spearman's rank correlation coefficient (Mukaka, 2012) and R_j is the rank values of buckets based on the j-th attribute. $\mathrm{Std}(\cdot)$ is the function to compute the standard deviation.

Intuitively, $\mathbf{S}^{\rho}_{i,j}$ characterizes how well the performance of the i-th model correlates with the values of the j-th attribute while $\mathbf{S}^{\sigma}_{i,j}$ measures the degree to which this attribute influences the model's

Table 2: Model-wise measures (Percentage) $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$ which are the average over all the datasets. The F1 score for a model is also an average case on all the datasets. The value in grey denotes the attribute does not pass a significance test ($p \geq 0.05$). The values in green and in pink support observation 1 and observation 2, respectively. The bold is the maximum value in the attribute column.

performance. For example, $\mathbf{S}^{\rho}_{CNN,\texttt{eCon}} = 0.9$ reveals that the performance of the `CNN` model positively and highly correlates with the attribute value `eCon` (label consistency). And a larger $\mathbf{S}^{\sigma}_{CNN,\texttt{eCon}}$ implies that `CNN` model's performance is heavily influenced by the factor `eCon`.

Significance Tests: We perform Friedman's test (Zimmerman and Zumbo, 1993) with $p = 0.05$. We examine whether the performance of different buckets partitioned by an attribute have the same expected performance, and the significance testing results are shown in appendix. We omit the attributes whose $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$ are not statistically significant (the values in grey in Tab. 2).

5.1.2 Observations

Tab. 2 illustrates the average case of $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$ on all datasets.[8] We highlight some major observations and more are in the appendix.

1) **The performance of character-unaware models is more sensitive to the label consistency.** We observe that the performances of *CRF++* and *CnonWrandLstmCrf* are highly correlated with `eCon`, and `tCon` with high values of $\mathbf{S}^{\rho}$ and $\mathbf{S}^{\sigma}$. Specifically, *CcnnWrandLstmCrf* achieve higher performance and lower $\mathbf{S}^{\sigma}$ than *CnonWrandLstmCrf*. This suggests that the character-level encoder plays a major role in generalization to entities with low *label consistency*.

2) **The influence of entity length varies greatly between different decoders.** Entity length is strongly negatively correlated with the performance of models, which means the performance of the model will drop with the entity length increasing. We observe that the variance scores S^{σ} of *CcnnWgloveLstmMlp* and *CbertWnoneLstmMlp* are the smallest, compared with the variances of the models using non-contextualized and contextualized pre-trained embeddings, respectively. We attribute this to the structural biases of different decoders: *MLP*-based models have better robustness when dealing with long entities, while *CRF*-based models may lead to error propagation. We will present a detailed explanation of this in Sec. 5.3.2.

5.2 Exp-II: Attribute-wise Analysis

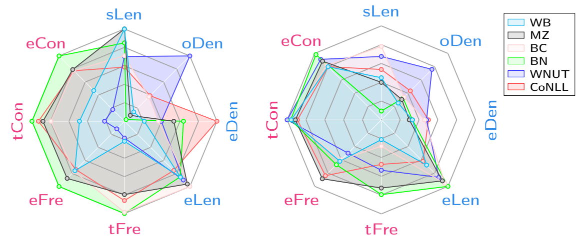
Attribute-wise analysis aims to quantify the degree to which an attribute influences NER performance overall, across all systems.

5.2.1 Approach

To achieve this, we introduce two dataset bias measures: task-independent variable ζ_j and task-dependent variable ρ_j based on Eq. 8:

---

[8] Correlations on individual datasets is in the Appendix.



(a) ζ (b) ρ

Figure 4: Dataset biases characterized by measures ζ and ρ. We normalize ζ on each attribute by dividing the maximum ζ on six datasets, and $\rho \in [0, 1]$.

$$\zeta_j(\mathcal{E}, \phi(\cdot)) = \frac{1}{N}\sum_{i}^{N} \phi_j(\mathbf{x}), \tag{10}$$

$$\rho_j = \frac{1}{|M|}\sum_{i}^{|M|} |\mathbf{S}^{\rho}_{i,j}|, \tag{11}$$

where $\mathcal{E}$ denotes a dataset, $\phi_j(\mathbf{x})$ is the feature function to calculate an attribute value

for a given entity $\mathbf{x}$, j denotes the j-th attribute function, and N and $|M|$ are the numbers of test entities and models respectively.

For example, when j denotes the attribute of sentence length, ζ_j is the average sentence length of the whole dataset. Intuitively, a higher absolute value of ρ_j suggests that attribute j is a crucial factor, whose values heavily correlate with the performances of NER systems.

5.2.2 Observations

Similar to the above section, we conduct Friedman's test at $p = 0.05$. For all attributes, we find different-valued buckets are significantly different in their expected performance ($p < 0.05$). We include a full version of p values in the appendix. Detailed observations are listed as follows:

1) **Label consistency and entity length have a more consistent influence on NER performance.** The common parts of the radar chart in Fig. 4(b) illustrate that for all datasets, the performance of the NER task is highly correlated with these attributes: `tCon` (label consisency of tokens), `eCon` (label consistency of entities), `eLen` (entity length). This reveals that the prediction difficulty of a named entity is commonly influenced by *label consistency* (`tCon`, `eCon`) and *entity length* (`eLen`).

2) **Frequency and sentence length matter but are minor factors.** The outliers in the radar chart highlight the peculiarities of different datasets. Intuitively, in Fig. 4(b), on these attributes: `sLen`, `tFre`, `oDen`, the extent to which different datasets are affected varies greatly, and thus these attributes are not, in general, decisive factors for the NER task. Typically, as observed from Fig. 4(b), Spearman correlations of ρ on the attribute `tFre` vary greatly, i.e., a smaller ρ on `BC` and `WB`. This implies that `tFre` is not a decisive factor and *higher-frequency tokens cannot guarantee better performance since other crucial factors such as label consistency also matter.* We print the performance of the buckets with respect to token frequency, and find that the bucket with higher token frequency does not achieve a better performance.

Understanding these intrinsic differences in datasets provides us with evidence to explain how different datasets may influence different choices of models, which will be elaborated later (Sec. 5.3).

5.3 Exp-III: Bucket-wise Analysis

Bucket-wise analysis aims to identify the buckets that satisfy some specific constraints. In this paper, we present two flavors of diagnostic: *self-diagnosis* and *comparative diagnosis*.

5.3.1 Approach

Self-diagnosis Given a model M_1 and a specific evaluation attribute (e.g., `eLen`), self-diagnosis selects the buckets in which test samples have achieved the highest and lowest performance (F1 score). Intuitively, this operation can help us diagnose under which conditions a particular model performs well or poorly: $\mathrm{SelfDiag}(M_1) = \mathrm{argFunc}_k \mathcal{T}[M_1, j, k]$ where argFunc can be instantiated as argMax and argMin.

Comparative diagnosis Given two models M_1, M_2 and an attribute, comparative diagnosis aims to select buckets in which the performance gap between the two systems achieve the highest and lowest values. This method can indicate under which conditions a particular system may have a relative advantage over another system: $\mathrm{CoDiag}(M_1, M_2) = \mathrm{argFunc}_k(\mathcal{T}[M_1, j, k] - \mathcal{T}[M_2, j, k])$

Significance Tests We test for statistical significance at $p = 0.05$ with Wilcoxon's signed-rank test (Wilcoxon et al., 1970). The null hypothesis is that, given a specific attribute value (e.g. long entities `eLen:XL`), two different models have the same expected performance.[9]

---

[9] We opt for Wilcoxon's signed-rank test instead of Friedman's test because the diagnosis (self- or comparative diagnosis) only has two group samples while the Friedman's

M1: *CbertWnoneLstmMlp* **Self-diagnosis**						Overall F1	M1: 90.48; M2: 88.05	M1: 40.61; M2: 32.84	M1: 85.39; M2: 81.09	M1: 76.04; M2: 70.00	M1: 86.78; M2: 84.07	M1: 60.17; M2: 56.61
M1: *CcnnWgloveLstmCrf* M2: *CcnnWgloveLstmMlp* **Comparative diagnosis**						
Table 3: *Self-diagnosis*, and *Comparative diagnosis* (Sec. 5.3.1) of different NER systems. M1 and M2 denote two models. We classify the attribute values into four categories: extra-small (XS), small (S), large (L) and extra-large (XL). In the *self-diagnosis* histogram, green (red) x ticklabels represents the bucket value of a specific attribute on which system achieved best (worst) performance. Gray bins represent worst performance while blue bins denote the gap between best and worst performance. In the *comparative diagnosis* histogram, green (red) x ticklabels represents the bucket value of a specific attribute on which system M1 surpasses (under-performs) M2 by the largest margin that is illustrated by a green (red) bin.

5.3.2 Self-Diagnosis

BERT The first row in Tab. 3 illustrates the *self-diagnosis* of the model *CbertWnonelstmMlp*. The green (red) x ticklabels represent the bucket value of a specific attribute on which system has achieved best (worst) performance. Gray bins represent worst performance while blue bins denote the gap between best and worst performance.

We observe that large performance gaps (tall blue bins) commonly occur for the attributes label consistency and entity frequency, and the worst performance on these attributes was obtained on buckets with low consistency (`eCon, tCon:XS/S`) and low entity frequency (`eFre:S`).

We conduct significance testing on the worst and best performances[10] of `eCon` (1.7×10^{-8}), `tCon` (2.3×10^{-7}) and `eFre` (1.2×10^{-5}) respectively, and they all passed with $p < 0.05$. This reveals that it is still challenging for contextualized pre-trained NER systems to handle entities with lower *label consistency* and lower *entity frequency*.

5.3.3 Comparative Diagnosis

We highlight major observations and include more analysis in the appendix.

CRF v.s. MLP The benefits of using CRF on the sentence with high entity density (`eDen:XL`) are remarkably stable, and improvement can be seen in all datasets ($p = 1.8 \times 10^{-5} < 0.05$). Similarly, based on attribute-wise metric ζ in Fig. 4(a), we find *label consistency* (`eCon`, `tCon`) is a major factor for the choices of CRF and MLP layers:

1) Introducing a CRF achieves larger improvements on long entities once the dataset has a lower *label consistency* (e.g. $\zeta_{\texttt{eCon,tCon}}(\texttt{WNUT})$, $\zeta_{\texttt{eCon,tCon}}(\texttt{WB})$, and $\zeta_{\texttt{eCon,tCon}}(\texttt{BC})$ are lowest). We conduct the significance testing on CRF and MLP systems with respect to the long entities on these three datasets[11] (`WNUT`, `WB`, and `BC`), and the result indicates that the performance of the CRF and MLP systems are significantly different on long entity bucket ($p = 6.5 \times 10^{-4} < 0.05$). 2) by contrast, if a dataset has a higher *label consistency* ($\zeta_{\texttt{eCon,tCon}}(\texttt{CoNLL})$,$\zeta_{\texttt{eCon,tCon}}(\texttt{BN})$, $\zeta_{\texttt{eCon,tCon}}(\texttt{MZ})$ are highest), using the CRF layer does not exhibit significant gains (even worse than models without CRF) on longer entities (`eLen:XL`). We do significance testing like 1), and $p = 5.1 \times 10^{-3} < 0.05$.

6 Application: Well-grounded Model Improvement

The purpose of interpretable evaluation and analysis is to provide more evidence for us to rethink current learning models and move forward. In what

---

test requires more than two groups (Zimmerman and Zumbo, 1993).

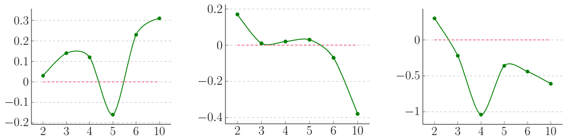
[10] We restarted the BERT-based system twice on six datasets, and we got 12 best and 12 worst F1 scores for a given attribute.

[11] We restarted the CRF and MLP systems on `WNUT`, `WB`, and `BC` for 5 times, and we got $3 \times 5 = 15$ F1 scores on CRF and MLP systems respectively.

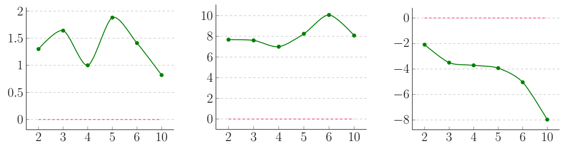
follows, we choose a piece of evidence observed from the above analysis and attempt to present one simple solution to improve the model. From Sec. 5.2 and Sec. 5.3.2, we know that *label consistency* is a decisive factor, and even more advanced models (e.g., `BERT`, `Flair`) fail to consistently predict entities with low *label consistency*. An intuitive idea to disambiguate these entities is using more contextual information. To this end, we shift the setting of traditional sentence-level training and testing to use larger context, and investigate this change's effectiveness.

6.1 Experimental Setting

We choose *CbertWnoneLstmMlp* as a base model, which will be trained under different numbers ($K = 1, 2, 3, 4, 5, 6, 10$) of contextual sentences on all six datasets respectively. For example, $K = 2$ represents that each training sample is constructed by concatenating two consecutive sentences from the original dataset ($K = 1$).



(a) CoNLL (b) BN (c) MZ



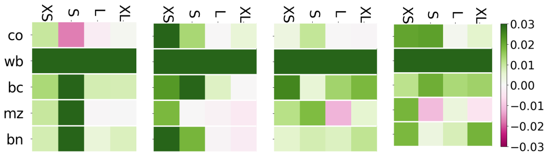
(d) BC (e) WB (f) WNUT

Figure 5: Illustration of the improvement achieved by the larger context method with different sizes (K) on different datasets. The part above the red suggests the improvement brought by the corresponding value of K.

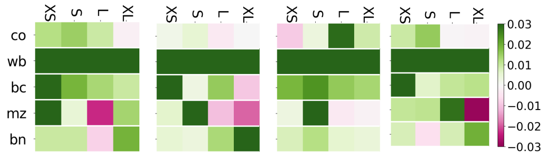
6.2 Results and Analysis

Results As presented in Fig. 5, the green line describes the relative improvement of the larger context method compared with the vanilla model ($K = 1$) with different numbers of context sentences $K = 2, \cdots, 10$. In detail, we observed:

1) For most of the datasets (except "`WNUT`"), the performance increases as more context sentences are introduced. 2) Surprisingly, we achieved a **10.07 improvement** (66.35 vs. 76.42, significance testing result[13]: $p = 5.1 \times 10^{-3} < 0.05$) F1 score on dataset "`WB`", with such a simple larger-context training method. 3) There is no gain on "`WNUT`", and the reason can be attributed to lack of dependency between samples, which are collected from *Twitter*[14] where each sentence is relatively independent with the another.



(a) eCon (b) tCon (c) eFre (d) tFre



(e) eDen (f) eLen (g) sLen (h) oDen

Figure 6: The relative increase of the larger-context method on five datasets[12] based on eight evaluation attributes. "`Co`" represents the dataset CoNLL-2003 while "`wb`", "`bc`", "`mz`", "`bn`" denote different domains from the OntoNotes.

Analysis using Multi-dimensional Evaluation To probe into where the gain afforded by larger context comes from, we use our proposed evaluation attributes to conduct a fine-grained investigation, aiming to answer the question: *how does this method influence different datasets' performance seen from different attributes?* (e.g., *label consistency* of entity, `eCon`). As expressed in Fig. 6, the value of each unit in the heat maps denotes the relative increase achieved by the larger-context method. Intuitively, a darker green area implies more significant improvement while a darker red unit suggests larger-context leads to worse performance.

Different evaluation attributes allow us to understand the source of improvement from diverse perspectives: 1) in terms of *label consistency* (`eCon`, `tCon`), test entities with lower *label consistency* will achieve larger improvements with the help of more contextual sentences. Importantly, from Fig. 6 we can see this observation holds true for all datasets. 2) in terms of entity length (`eLen`), larger-context information has no advantage in dealing with longer entities (`L`, `XL`). For example, in the three of five datasets, more contextual sentences lead to worse performance on longer test entities.

---

[12] We leave `WNUT` out due to its worse performance.

[13] We restart the system on `WB` with $K = 1$ and $K = 6$ setting for 10 times respectively.

7 Discussion

This paper has provided a framework where we can covert our understanding of the NER task (i.e., which attributes matter for the current task?) into interpretable evaluation aspects, and define axes through which we can apply them to acquire insights and make model improvements. This is just a first step towards the goal of fully-automated interpretable evaluation, and applications to new attributes and tasks beyond NER are promising future directions.

A Models Description

Tab. 1 shows the evaluated models in this paper, mainly in terms of four aspects: 1) character/subword-sensitive encoder: `ELMo`, `Flair`, `BERT` 2) additional word embeddings: `GloVe`; 3) sentence-level encoders: `LSTM`, `CNN`; 4) decoders: `MLP` or `CRF`.

For example, 1) "*CnonWrandlstmCrf*" is a model with no character features, with randomly initialized embeddings, and the sentence encoder is LSTM and the decoder is CRF. 2) "*CbertWnoneLstmMlp*" is a model that concatenates the representations from BERT and GloVe as a subword-sensitive encoder. Then the concatenation will be fed into an MLP layer, predicting a label over all classes. 3) "*CelmWgloveLstmCrf*" is a model that concatenates the representations from ELMo and GloVe as a subword-sensitive encoder. Then the concatenation will be fed into an LSTM layer, followed by the CRF layer.

B Bucketing Interval Strategy

In this section, we will illustrate the bucketing interval with respect to attribute. We divide the range of attribute values into m discrete parts. For a given attribute, the number of entities covered by an attribute value is various. For example, `oDen=0` covered nearly half of the entity in the test set for *OOV density*; for *label consistency*, `eCon=0` and `eCon=1` each occupy a large part of the test entities. We customize the interval method for each attribute in accordance with its own characteristics.

1) **Label consistency (`eCon`, `tCon`)**: first, we divide the entities in the test set with attribute values $\phi_{eCon}(\mathbf{x}) = 0$ and $\phi_{eCon}(\mathbf{x}) = 1$ into the first bucket ($\mathcal{E}_1^{te}$) and last bucket $\mathcal{E}_m^{te}$, respectively; then, divide the remaining entities equally into $m - 2$ buckets. The bucketing interval strategy of `eCon` is suitable for `tCon`.

2) **Frequency (`eFre`, `tFre`) and OOV density (`oDen`)**: first, we divide the entities in test set with attribute value $\phi_{eFre}(\mathbf{x}) = 0$ into the first bucket ($\mathcal{E}_1^{te}$); then, divide the remaining entities equally into $m - 1$ buckets. The bucketing interval strategy of `eFre` is suitable for `tFre` and `oDen`.

3) **Sentence length (`sLen`) and entity density (`eDen`)**: we divide the test entities equally into m buckets.

4) **Entity length (`eLen`)**: a small m is suitable for *entity length*, because of a few attribute values (generally, the entity length is rarely greater than 6). In this paper, we put the entities in the test set with lengths of 1, 2, 3, and ≥ 4 into four buckets, respectively.

We classify the attribute values into four categories: extra-small (XS), small (S), large (L), and extra-large (XL). In the *comparative diagnosis* histogram, green (red) x ticklabels represents the bucket value of a specific attribute on which system M1 surpasses (under-performs) M2 by the largest margin that is illustrated by a green (red) bin.

C Model-wise Analysis and Observation

Tab. 2 gives the model-wise measures $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$ which are the average case on all the datasets. We find that: **pre-trained knowledge enhanced models are tardier to the token-level attribute.** We observe that the values of $\mathbf{S}^{\rho}$ dropped sharply on `tCon` and `tFre`, when the pre-trained embedding is introduced, therefore, comparing with the models without pre-trained knowledge, the performance of the models with pre-trained knowledge is slower improved as the increasing of *token consistency* and *token frequency*. Specifically, the models with pre-trained knowledge have higher performance and lower $\mathbf{S}^{\sigma}$, compared with the models without pre-trained knowledge. This reveals that the introduction of external knowledge will handle the lower *label consistency* of token and low *token frequency*.

D Bucket-wise Analysis and Observation

Tab. 4 illustrates the comparative diagnosis of different NER systems. Here, we will give the observations.

LSTM v.s. CNN The sentence encoder of CNN is better at dealing with long entities (`eLen:XL`) on the datasets with a high value of ζ_{eCon}. As shown in Tab.4, the performance of LSTM and CNN systems are significantly different on the "`eLen:XL`" bucket ($p = 1.2 \times 10^{-2} < 0.05$) without regard to `WNUT16` and `WB` two datasets which have the lowest values of ζ_{eCon}.

The encoder of LSTM does better in dealing with highly-ambiguous entities (`eCon:S`). For example, the LSTM system has surpassed CNN on the datasets `WNUT` and `WB`, whose average label ambiguities of entities are the two largest ones.

Flair v.s. ELMo While the current state-of-the-art NER model (`Flair`) has achieved the best performance in terms of dataset-level F1 score, a worse-ranked model (`ELMo`) can outperform it in some attributes. Typically, Flair performs worse when dealing with long sentences, which holds for all the datasets ($p = 1.4 \times 10^{-3} < 0.05$). The reason can be attributed to its structural bias, which adopts an LSTM-based encoder for character language modeling, suffering from long-term dependency problems. One potential promising improvement is resorting to the Transformer-based architecture for the character language model pre-training.

E Significance Testing

We break down the holistic performance into different categories for conducting the fine-grained evaluation. Specifically, we divide the set of test entities (or tokens) into different subsets (we named buckets) of test entities. To test whether the performance of buckets with respect to an attribute is significantly different, we perform Friedman significance testing at $p = 0.05$ in dataset-dimension and model-dimension. To ensure a sufficient sample size to conduct significance testing, we restarted a model on the same dataset for twice.

Table 6: p-values from the Friedman test. The null hypothesis is that the performance of different buckets with respect to an attribute has the same means for a given **model**. The `Pink` region denote the attribute on the given model does not pass ($p \geq 0.05$) a significance test at $p = 0.05$.

Dataset-dimension significance testing It is the premise of attribute-wise analysis. The null hypothesis is that the performance of different buckets with respect to an attribute has the same means for a given **dataset**. The significance testing results are shown in Tab. 5. The p-values of these eight attributes on the six datasets are smaller than 0.05, indicating that the performance of buckets with respect to one of the eight attributes is significantly different for a given dataset.

Model-dimension significance testing It is the premise of model-wise analysis. The null hypothesis is that the performance of different buckets with respect to an attribute has the same means for a given **model**. The significance testing results are shown in Tab. 6. We observe that the p-values of `eDen`, `oDen`, and `sLen` are larger than 0.05, therefore, `eDen`, `oDen`, and `sLen` does not pass the significance testing for a given model. The performance of the buckets with respect to `eDen` (`oDen`, `sLen`) are not significantly different.

Adversarial Semantic Decoupling for Recognizing Open-Vocabulary Slots

Abstract

Open-vocabulary slots, such as file name, album name, or schedule title, significantly degrade the performance of neural-based slot filling models since these slots can take on values from a virtually unlimited set and have no semantic restriction nor a length limit. In this paper, we propose a robust adversarial model-agnostic slot filling method that explicitly decouples local semantics inherent in open-vocabulary slot words from the global context. We aim to depart entangled contextual semantics and focus more on the holistic context at the level of the whole sentence. Experiments on two public datasets show that our method consistently outperforms other methods with a statistically significant margin on all the open-vocabulary slots without deteriorating the performance of normal slots.

1 Introduction

Slot filling is a critical component of spoken language understanding (SLU) in task-oriented dialogue systems. It aims at extracting semantic constituents from the user queries. Given an immense amount of labeled training data, recent neural networks (Mesnil et al., 2015; Liu and Lane, 2015, 2016; Goo et al., 2018; Haihong et al., 2019; Chen et al., 2019; He et al., 2020a,b) have been actively applied to slot filling task and achieved good results.

Although most previous neural-based models achieve state-of-the-art performance across a wide range of slot filling datasets, they often suffer from poor slot filling accuracy while dealing with 'open-vocabulary' slots. Open-vocabulary slots signify slot types that can take on values from a virtually unlimited set, such as file name, album name, text body, or schedule title. Typically, these slot values have no constraints on the length and specific semantic patterns of content. Besides, these words are employed differently from the meaning inherent in themselves, as Fig 1 shows. Intrinsically, the complexity of recognizing open-vocabulary slots comes from the inconsistent context with different granularity. For example, consider the utterance "add the song don't drink the water to my playlist" in Fig 1. While identifying the slot type of the word "water", the slot filling model will mistakenly recognize the word "water" as "entity_name" slot type if it only focuses on the local context "don't drink the water". By contrast, it should instead focus on the global context "add the song ... to my playlist" to recognize the "don't drink the water" as the correct "playlist" slot type. Therefore, these characteristics of open-vocabulary slots confuse

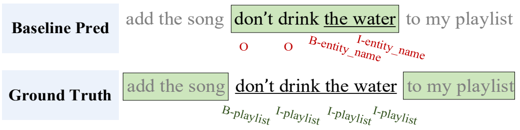

Figure 1: An error case of open-vocabulary slot "playlist" in Snips dataset (Coucke et al., 2018). Here "water" is mistakenly recognized as "entity_name" type by the baseline model (Liu and Lane, 2016) due to the local context "don't drink the water". However, it represents a playlist at the level of the whole sentence.

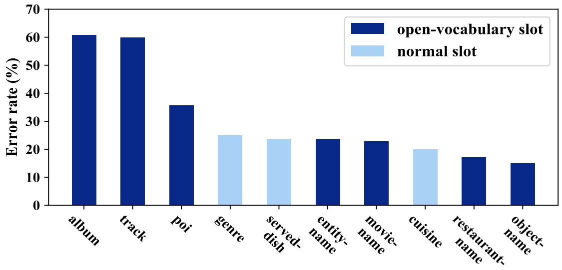

Figure 2: Error rates of open-vocabulary slots compared to normal slots in Snips from Baseline (Liu and Lane, 2016). We display the top10 slot types of the highest error rates.

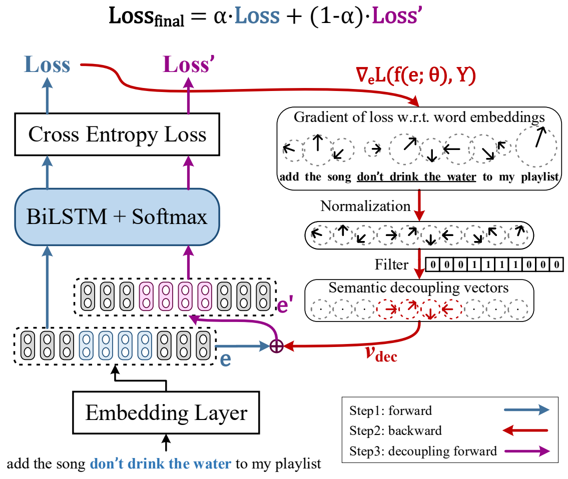

Figure 3: The overall architecture of our approach, including three core steps: forward, backward, and decoupling forward. Forward calculates the traditional classification loss and backward adds adversarial decoupling perturbations. Then decoupling forward calculates a new adversarial loss. Finally, the model is updated by the weighted sum of two losses.

the models to recognize the correct slot type. Fig 2 displays slot error rates of open-vocabulary slots are generally higher than normal slots. The results confirm that traditional neural networks can not adequately handle issues caused by open-vocabulary slots.

Kim et al. (2018) exploits a long-term aware attention structure and positional encoding with multi-task learning to capture global information. Kim et al. (2019) focuses on data augmentation by adding random noise in the embeddings of all slot words. Ray et al. (2019) proposes an iterative delexicalization algorithm that utilizes model uncertainty to improve delexicalization for open-vocabulary slots. One major limitation is that these methods can't explicitly distinguish semantic representation inherent in open-vocabulary slot words from the holistic context.

In this paper, we propose a robust adversarial slot filling approach that explicitly decouples local semantic representation inherent in open-vocabulary slot words from the global context. Our approach aims to focus more on the holistic semantics at the level of the whole sentence, not only the vicinity of the local context within open-vocabulary slots. Specifically, our approach generates model-agnostic adversarial worst-case perturbations to the inputs in the direction that significantly increases the model's loss. Our main contributions are threefold: (1) We dive into the issues of open-vocabulary slots in slot filling task and propose a novel adversarial semantic decoupling method which distinguishes local semantics from the global context. (2) Our method can be easily applied to all the previous slot filling neural-based models. (3) Experiments show that our proposed method consistently outperforms various SOTA baselines, especially in open-vocabulary slot f1.[1]

2 Approach

Problem Formulation Given a sentence $X = \{x_1, ..., x_n\}$ with n tokens, the slot filling task is to predict a corresponding tag sequence $Y = \{y_1, ..., y_n\}$ in BIO format, where each y_i can take three types of values: B-slot_type, I-slot_type and O.

Fig 3 shows the overall architecture of our method. Here we adopt BiLSTM (Liu and Lane, 2016) as our backbone.[2] Our method includes three core steps: forward, backward, and decoupling forward. We first feed each word to an embedding layer to get word embeddings $e_i = \mathrm{E}(x_i)$. Then in the forward step, we adopt a BiLSTM layer and softmax output layer to calculate the classification cross-entropy loss $\mathcal{L}(f(\boldsymbol{e};\theta), Y)$ for each word.

Then in the second backward step, we perform adversarial attacks (Goodfellow et al., 2015; Kurakin et al., 2016; Miyato et al., 2016; Jia and Liang, 2017; Zhang et al., 2019; Ren et al., 2019) to explicitly shift the local semantics of open-vocabulary slot words and decouple them from the global context. Theoretically, we need to compute a decoupling vector $\widetilde{\boldsymbol{v}}_{\text{dec}}$ that effectively degrades the current model's performance (i.e., maximum the loss function):

$$\widetilde{\boldsymbol{v}}_{\text{dec}} = \arg\max_{||\boldsymbol{v}_{\text{dec}}||\le\epsilon} \mathcal{L}(f(\boldsymbol{e}+\boldsymbol{v}_{\text{dec}};\theta), Y) \qquad (1)$$

where $\mathcal{L}$ indicates the loss function and ϵ is the norm bound of the decoupling vector. However, due to model complexity, accurate computation for $\widetilde{\boldsymbol{v}}_{\text{dec}}$ is costly and inefficient. Similar to Vedula et al. (2020) and Ru et al. (2020), we apply Fast Gradient Value (FGV) (Rozsa et al., 2016) to approximate a worst-case perturbation as our decoupling vector:

$$\widetilde{\boldsymbol{v}}_{\text{dec}} = \epsilon\frac{g}{||g||}; \text{where } g = \nabla_{\boldsymbol{e}}\mathcal{L}(f(\boldsymbol{e};\theta), Y) \qquad (2)$$

---

[1] Our code is available at `https://github.com/yym6472/OVSlotTagging`

[2] Since our method is model-agnostic, we also apply our method to BERT (Devlin et al., 2019) in the experiments.

Here, the gradient g is the first-order differential of the loss function $\mathcal{L}$ w.r.t. $\boldsymbol{e}$, representing the direction that rapidly increases the loss function. We perform normalization to g and then use a small ϵ to ensure the approximate is reasonable. Finally, we perform a mask operation to filter out normal words and add the decoupling vector to the original token embeddings $\boldsymbol{e}$. Hence, the updated word embeddings are $\boldsymbol{e}' = \boldsymbol{e} + \widetilde{\boldsymbol{v}}_{\text{dec}}$ while other model parameters are fixed. Ablation study proves that only adding the decoupling vector to open-vocabulary slot words achieves better improvement.

In the third decoupling forward step, we feed $\boldsymbol{e}'$ to the same BiLSTM model and calculate a new adversarial loss $\mathcal{L}'$. The final loss is a weighted sum of $\mathcal{L}$ and $\mathcal{L}'$ controlled by a hyperparameter α[3]:

$$\mathcal{L}_{\text{final}} = \alpha \cdot \mathcal{L} + (1 - \alpha) \cdot \mathcal{L}' \qquad (3)$$

Finally, we use $\mathcal{L}_{\text{final}}$ to update all the model parameters.

By adding those decoupling vectors to open-vocabulary slot words, we break the semantics inherent in open-vocabulary slots and thus force the model to pay more attention to global context (e.g. “add the song ... to my playlist”) when identifies types of open-vocabulary slots.

3 Experiment

3.1 Setup

Datasets To evaluate our approach, we conduct experiments on two public benchmark datasets, Snips (Coucke et al., 2018) and MIT-restaurant (MR)[4]. Snips contains user utterances from various domains resulting in relatively extensive open-vocabulary slots, such as album and movie_name. MR is a single-domain dataset associated with restaurant reservations, which contains open-vocabulary slots, such as restaurant_name and amenity.[5] Table 1 shows the full statistics and Table 2 shows all the open-vocabulary slots of Snips and MR datasets. Note that we identify the open-vocabulary slots according to the diversity of different slot values as well as the average length of slot values.

	Snips	MR
Vocabulary size	11,241	3,804
Percentage of OOV words	5.95%	2.76%
Number of all slots	39	8
Number of open-vocabulary slots	9	4
Train set size	13,084	6,894
Development set size	700	766
Test set size	700	1,521

Table 1: Statistics of Snips and MR datasets.

Dataset	Open-vocabulary Slots	Normal Slots
Snips	playlist, object_name, entity_name, album, movie_name, track, poi, geographic_poi, restaurant_name	served_dish, cuisine, sort, best_rating, genre, service, movie_type, ...
MR	restaurant_name, dish, amenity, location	rating, hours, cuisine, price

Table 2: The lists of all the open-vocabulary slots and normal slots in Snips and MR datasets. We only show a part of normal slots in Snips dataset for clarity.

Baselines For a fair comparison, we use the same slot filling architecture BiLSTM (Liu and Lane, 2016) as (Kim et al., 2019; Ray et al., 2019). Kim et al. (2019) proposes two model variants, where *random noise* means adding random noise in the embeddings of all slot words and *cw* represents concatenating the context word window as input. Note that the random noise in (Kim et al., 2019) is independently sampled regardless of the global context, which is significantly different from our method. Our adversarial semantic decoupling method can take into account the impact of different contexts (global semantics) on local semantics, thereby enabling more accurate decoupling. Ray et al. (2019) proposes *greedy delex* and *iterative delex* methods for open-vocabulary slots. We also validate our method in the BERT-based models (Devlin et al., 2019) for comprehensive analysis.

Evaluation We evaluate the performance of slot filling using the F1 metric (Sang and Buchholz, 2000). Specially, we report the F1 score over all open-vocabulary slots, noted as F1-ov. We followed the set-ups in (Liu and Lane, 2016; Kim et al., 2019), and re-implement the baseline *BiLSTM*, *+random noise* and *+random noise,cw* based on the same settings. We report the original results of *greedy delex* and *iterative delex* from (Ray et al., 2019).

3.2 Main Results

We display the experiment results in Table 3. Compared to the previous state-of-the-arts , our method

---

[3] In the experiments, we set α to 0.5.

[4] `https://groups.csail.mit.edu/sls/downloads/restaurant/`

[5] Similar to (Ray et al., 2019), we do not consider the ATIS (Hemphill et al., 1990) dataset since it lacks open-vocabulary slots, hence not suited for our evaluation. And we only focus on the main slot filling task instead of intent detection.

Model	Snips				MR			
	Valid		Test		Valid		Test

Table 3: Slot filling performance on Snips and MR datasets. F1 is the overall score on all slot types and F1-ov is the score on all the open-vocabulary slots. The numbers with * indicate the significant improvement over all baselines with $p < 0.05$ under t-test.

achieves significantly superior performance for both datasets, both in F1-ov and overall slot F1. In the Snips dataset, our BiLSTM-based method outperforms the SOTA model by 3.51% in F1-ov and 1.31% in F1. In the MR dataset, our method gets improvements of 1.88% in F1-ov and 2.04% in F1. The results demonstrate that explicitly decoupling local semantics inherent in open-vocabulary slot words from the global context can effectively benefit open-vocabulary slot filling. We observe that in the Snips dataset F1-ov is extremely lower than F1, which shows the previous slot filling methods cannot tackle the critical issues of open-vocabulary slots. There is no such clear performance drop in the MR dataset. The probable reason is that open-vocabulary slots account for a large proportion(70%) of all samples on MR.

We also show the results of BERT models. Table 3 displays that our method still achieves an improvement of 8.29% in F1-ov over the original BERT model and 0.74% over the previous SOTA, which substantiates our method is model-agnostic and can be easily integrated into different slot filling architectures. Meanwhile, the F1-ov scores in BERT-based models are consistently higher than BiLSTM-based models, which indicates that BERT can effectively capture the global context semantics and tackle long-term dependency than BiLSTM.

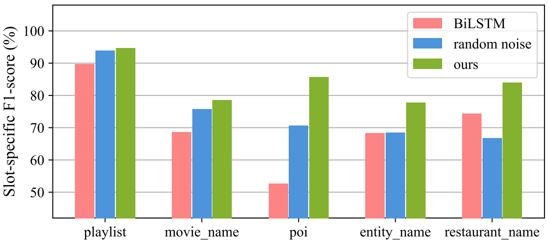

Figure 4: Test F1 scores of each open-vocabulary slot type on Snips. We show the results of five slots for clarity.

Model	F1	F1-ov	F1-normal
BiLSTM	88.99	71.78	94.50
random noise	92.46	82.35	95.51
ours	**94.55**	**86.09**	**97.10**

Table 4: Performance comparison between open-vocabulary slots and normal slots on Snips.

3.3 Qualitative Analysis

Results of all open slot categories Fig 4 shows test F1 scores of five open-vocabulary slot types to verify the improvement of each type. We choose BiLSTM and random noise as our baseline models. The results demonstrate that our method consistently outperforms other methods on each open-vocabulary slot type, which confirms our method is not specific to several slot types. For the *restaurant_name* type, the random noise model suffers from a performance drop of 7.62% compared to BiLSTM. It illustrates simply adding random noise is not constrained and has no guarantee of semantics decoupling. Conversely, our method employs adversarial deliberate disturbance and outperforms BiLSTM by 9.58%.

Open-vocabulary slots vs normal slots We also show overall test F1, F1-ov on all the open-vocabulary slots, and F1-normal on all the normal slots in Table 4 to compare the comprehensive performance. The results show that our method significantly outperforms BiLSTM by 14.31% on F1-ov and 2.6% on F1-normal, which proves our method gets notable improvement on open-vocabulary slots without harm to the performance of normal slots. We hypothesize the improvement on normal slots

Filter	Space	ϵ	α	F1-ov
OV slots	Embedding	1.5	0.5	**86.09**
All slots	Embedding	1.5	0.5	84.44
OV slots	BiLSTM	1.5	0.5	82.86
OV slots	Embedding	1.0	0.5	84.44
OV slots	Embedding	3.0	0.5	82.05
OV slots	Embedding	1.5	0.4	85.20
OV slots	Embedding	1.5	0.6	85.34

Table 5: Effects of different hyperparameters on Snips dataset for the BiLSTM-based model. Filter indicates whether the perturbation is applied to the open-vocabulary slots or all slots. Space indicates which space the perturbation is added to, where *Embedding* means the space after the word embedding layer and *BiLSTM* means the space after the BiLSTM layer. ϵ indicates the norm of perturbation and α is a hyperparameter to balance two training objectives.

is mainly because our method can effectively alleviate contextual semantic noise caused by open-vocabulary slots.

Analysis of generalization capability Table 3 shows there exists clear overfitting for BiLSTM and BERT models on open-vocabulary slots. For example, BiLSTM gets a performance drop of 7.13% comparing test F1-ov with valid F1-ov, and BERT gets a drop of 4.32%. The overfitting illustrates these baselines cannot capture contextual patterns, resulting in poor generalization capability to new slot values. By contrast, our method achieves comparable performance on valid and test sets both for BiLSTM(85.57 vs 86.09) and BERT(88.24 vs 88.06) architectures. The results demonstrate our method has a strong generalization capability for open-vocabulary slots.

Ablation studies To study the effects of different hyperparameters of our method, we conduct ablation analysis under BiLSTM architecture (Table 5). We can see that adding perturbation to the embedding layer of open-vocabulary slots gets significant improvement. Specifically, for the Filter setting, adding perturbation to open-vocabulary slots outperforms all slots by 1.65%. For the Space setting, adding perturbation to the word embedding layer is superior to the RNN layer. For the hyperparameters ϵ and α, $\epsilon = 1.5$ and $\alpha = 0.5$ achieves the best performance.

Case study Table 6 gives three examples from the Snips dataset: (1) the baseline model identifies a partial word "one" in "the sound of one hand clipping" as "rating_value" due to overfitting. (2) the baseline model fails to identify "look to you" since it is heavily coupled with "put" in local semantics. (3) the predicate "would die" in open-vocabulary slots are identified as the predicate of the whole sentence and thus are mistakenly labeled as "O" by the baseline model. In all cases, the baseline model focuses too much on local semantics and neglects the hints in global. With our proposed approach, the model is trained to pay more attention to global semantics and succeeds to identify open-vocabulary slots.

Example 1	search for *the sound of one hand clipping*
Baseline Pred.	O O B-obj_nm I-obj_nm O B-rating_value O B-obj_nm
Proposed Pred.	O O B-obj_nm I-obj_nm I-obj_nm I-obj_nm I-obj_nm I-obj_nm
Example 2	i want to put *look to you* on the playlist named *80s classic hits*
Baseline Pred.	O O O O O O O O O O O B-plist I-plist I-plist
Proposed Pred.	O O O O B-ent_nm I-ent_nm I-ent_nm O O O O B-plist I-plist I-plist
Example 3	*a day no pigs would die* deserves a best rating of 6 and a value of 4
Baseline Pred.	B-obj_nm I-obj_nm I-obj_nm I-obj_nm O O O O O O O B-best_rt O O O O B-rt_value
Proposed Pred.	B-obj_nm I-obj_nm I-obj_nm I-obj_nm I-obj_nm I-obj_nm O O O O O B-best_rt O O O O B-rt_value
Abbreviation	'object': 'obj', 'name': 'nm', 'entity': 'ent', 'playlist': 'plist', 'rating': 'rt'

Table 6: Three examples from the Snips dataset. The *italic spans* are open-vocabulary slots and should be viewed as a whole. We use RED and GREEN text to represent wrong and correct slot filling results, respectively. For brevity, we abbreviate some slot type words.

4 Conclusion

In this paper, we dive into the issues of open-vocabulary slots in slot filling task and propose a novel model-agnostic adversarial semantic decoupling method which distinguishes local semantics inherent in open-vocabulary slot words from the global context. Experiments confirm the effectiveness of semantic decoupling. We hope to provide new guidance for the future slot filling work.

Abstract

Text autoencoders are commonly used for conditional generation tasks such as style transfer. We propose methods which are plug and play, where any pretrained autoencoder can be used, and only require learning a mapping within the autoencoder's embedding space, training embedding-to-embedding (*Emb2Emb*). This reduces the need for labeled training data for the task and makes the training procedure more efficient. Crucial to the success of this method is a loss term for keeping the mapped embedding on the manifold of the autoencoder and a mapping which is trained to navigate the manifold by learning offset vectors. Evaluations on style transfer tasks both with and without sequence-to-sequence supervision show that our method performs better than or comparable to strong baselines while being up to four times faster.

1 Introduction

Conditional text generation[1] encompasses a large number of natural language processing tasks such as text simplification (Nisioi et al., 2017; Zhang and Lapata, 2017), summarization (Rush et al., 2015; Nallapati et al., 2016), machine translation (Bahdanau et al., 2015; Kumar and Tsvetkov, 2019) and style transfer (Shen et al., 2017; Fu et al., 2018). When training data is available, the state of the art includes encoder-decoder models with an attention mechanism (Bahdanau et al., 2015; Vaswani et al., 2017) which are both extensions of the original sequence-to-sequence framework with a fixed bottleneck introduced by Sutskever et al. (2014). Despite their success, these models are costly to train and require a large amount of parallel data.

Yet parallel data is scarce for conditional text generation problems, necessitating unsupervised solutions. Text autoencoders (Bowman et al., 2016) have proven useful for a particular subclass of unsupervised problems that can be broadly defined as style transfer, i.e., changing the style of a text in such a way that the content of the input is preserved. Examples include sentiment transfer (Shen et al., 2017), sentence compression (Fevry and Phang, 2018), and neural machine translation (Artetxe et al., 2018). Most existing methods specialize autoencoders to the task by conditioning the decoder on the style attribute of interest (Lample et al., 2019; Logeswaran et al., 2018), assuming the presence of labels during training of the autoencoder. The main drawback of this approach is that it cannot leverage pretraining on **unlabeled data**, which is probably the most important factor for widespread progress in supervised NLP models in recent years in text analysis (Peters et al., 2018; Radford et al., 2019; Devlin et al., 2019) and generation tasks (Song et al., 2019; Variš and Bojar, 2019). There are no style transfer methods, to the best of our knowledge, that were designed to leverage autoencoder pretraining, and only few can be used in this way (Shen et al., 2020; Wang et al.,

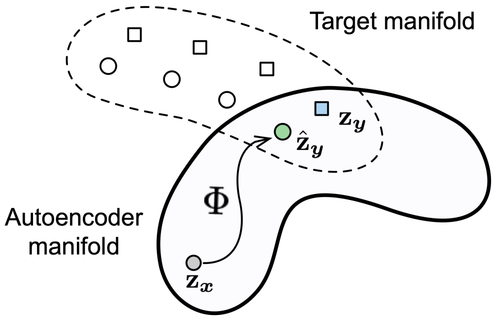

Figure 1: The *manifold* of a text autoencoder is the low-dimensional region of the high-dimensional embedding space where texts are actually embedded. The example shows the mapping of a source sequence $\boldsymbol{x}$ with embedding $\mathbf{z}_{\boldsymbol{x}}$ to $\mathbf{z}_{\boldsymbol{y}}$, which is the embedding of target sequence $\boldsymbol{y}$ such that it reflects the target manifold.

---

[1] We use this term to refer to text generation conditioned on *textual* input.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6076–6092,
November 16–20, 2020. ©2020 Association for Computational Linguistics

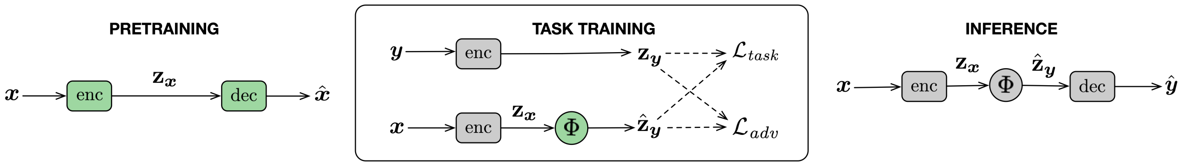

Figure 2: High-level view of the supervised variant of our framework *Emb2Emb*. *Left*: we pretrain an autoencoder on (unannotated) text, which transforms an input sentence x into an embedding $\mathbf{z}_x$ and uses it to predict a reconstruction $\hat{x}$ of the input sentence. *Center*: using the (frozen, hence depicted in gray) autoencoder, we learn a mapping Φ (trained, hence depicted in green) from the autoencoder's embedding of an input $\mathbf{z}_x$ to the embedding $\mathbf{z}_y$ of the output sentence y. The training objective consists of two losses: $\mathcal{L}_{task}$ enforces the predicted output embedding to be close to the true output embedding, and $\mathcal{L}_{adv}$ is an adversarial loss term that enforces the output embedding to be on the manifold of the autoencoder. *Right*: at inference time, Φ is composed between the autoencoder's encoder and decoder to transform input sentence x to output sentence $\hat{y}$. Not shown: the unsupervised variant where only x (not y) sequences are available in task training (Section 9).

2019).

In this paper, we propose an autoencoder-based framework that is *plug and play*,[2] meaning it can be used with any pretrained autoencoder, and thus can benefit from pretraining. Instead of learning conditional text generation in the discrete, high-dimensional space where texts are actually located, our method, called **Emb2Emb**, does all learning in the low-dimensional continuous embedding space, on the *manifold* of a pretrained text autoencoder (see Figure 1). The result of learning is simply a mapping from input embedding to output embedding. Two crucial model choices enable effective learning of this mapping. First, an adversarial loss term encourages the output of the mapping to remain on the manifold of the autoencoder, to ensure effective generation with its decoder. Second, our neural mapping architecture is designed to learn offset vectors that are added to the input embedding, enabling the model to make small adjustments to the input to solve the task. Lastly, we propose two conditional generation models based on our framework, one for supervised style transfer (Section 2.3) and the other for unsupervised style transfer (Section 2.4) that implement the criteria of content preservation and attribute transfer directly on the autoencoder manifold.

We evaluate on two style transfer tasks for English. On text simplification (Section 3.1), where supervision is available, we find that our approach outperforms conventional end-to-end training of models with a fixed-size "bottleneck" embedding (like an autoencoder) while being about four times faster. On unsupervised sentiment transfer (Section 3.2), where no parallel sentence pairs are available to supervise learning, and where models with a fixed-size bottleneck are a common choice, Emb2Emb preserves the content of the input sentence better than a state-of-the-art method while achieving comparable transfer performance. Experimentally, we find that our method, due to being plug and play, achieves performances close to the full model when only 10% of the labeled examples are used, demonstrating the importance of pretraining for this task.

Our contributions can be summarized as follows:

- Our proposed framework Emb2Emb reduces conditional text generation tasks to mapping between continuous vectors in an autoencoder's embedding space.
- We propose a neural architecture and an adversarial loss term that facilitate learning this mapping.
- We evaluate two new conditional generation models for generation tasks with and without parallel examples as supervision.
- We demonstrate that our model benefits substantially from pretraining on large amounts of unlabeled data, reducing the need for large labeled corpora.

2 Proposed Framework

The key idea of our framework is to reduce discrete sequence-to-sequence tasks to a continuous embedding-to-embedding regression problem. Our Emb2Emb framework for conditional generation based on pretrained autoencoders (Figure 2) encompasses learning sequence-to-sequence tasks both

---

[2] This term is borrowed from studies on unconditional text generation with a specific attribute (Duan et al., 2020).

where parallel input/output sentence pairs are available ("supervised") and where they are not ("unsupervised"). Given a pretrained autoencoder (left of Figure 2, Section 2.1) we use its encoder to encode both input and, during supervised training, the output sequence (Section 2.3).[3] We then learn a continuous mapping Φ from input sequence embeddings to output sequence embeddings (center of Figure 2). In the unsupervised case (Section 2.4), the task loss reflects the objectives of the task, in our experiments consisting of two terms, one to encourage content preservation and the other to encourage style transfer. In both supervised and unsupervised cases, the task-specific loss $\mathcal{L}_{task}$ is combined with an adversarial term $\mathcal{L}_{adv}$ that encourages the output vector to stay on the autoencoder's manifold (see Figure 1; Section 2.5), so that the complete loss function is:

$$\mathcal{L} = \mathcal{L}_{task} + \lambda_{adv}\mathcal{L}_{adv}. \tag{1}$$

At inference time (right of Figure 2; Section 2.4), the decoder from the pretrained autoencoder's decoding function is composed with Φ and the encoder to generate a discrete output sentence $\hat{\boldsymbol{y}}$ conditioned on an input sentence $\boldsymbol{x}$:

$$\hat{\boldsymbol{y}} = (\mathrm{dec} \circ \Phi \circ \mathrm{enc})(\boldsymbol{x}) \tag{2}$$

2.1 Text Autoencoders

The starting point for our approach is an autoencoder $\mathcal{A} = \mathrm{dec} \circ \mathrm{enc}$ trained to map an input sentence to itself, i.e., $\mathcal{A}(\boldsymbol{x}) = \boldsymbol{x}$. Letting $\mathcal{X}$ denote the (discrete) space of text sequences, the encoder $\mathrm{enc} : \mathcal{X} \to \mathbb{R}^d$ produces an intermediate continuous vector representation (embedding), which is turned back into a sequence by the decoder $\mathrm{dec} : \mathbb{R}^d \to \mathcal{X}$. Note that an autoencoder can, in principle, be pretrained on a very large dataset, because it does not require any task-related supervision.

While our framework is compatible with any type of autoencoder, in practice, learning the mapping Φ will be easier if the embedding space is smooth. How to train smooth text autoencoders is subject to ongoing research (Bowman et al., 2016; Shen et al., 2020). In this work, we will focus on denoising recurrent neural network autoencoders (Vincent et al., 2010; Shen et al., 2020; see Appendix A). However, any advancement in this research direction will directly benefit our framework.

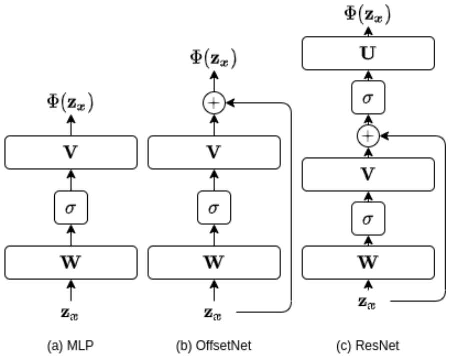

Figure 3: Illustration of the three neural architectures (1 layer) considered in this study. OffsetNet (b) differs from ResNet (c) in that there is no non-linear activation after the skip-connection (+), satisfying the notion of computing an offset vector that is added to the input.

2.2 Mapping Function Φ

A common choice for the mapping Φ to learn a regression task would be a k-layer MLP (Rumelhart et al., 1986), which transforms the input $\mathbf{z}_{\boldsymbol{x}} \in \mathbb{R}^d$ as:

$$\mathbf{y}^{(0)} = \mathbf{z}_{\boldsymbol{x}} \tag{3}$$

$$\forall j \in \{1, \ldots, k\}, \quad \mathbf{y}^{(j)} = \sigma(\mathbf{W}^{(j)}\mathbf{y}^{(j-1)}) \tag{4}$$

$$\Phi(\mathbf{z}_{\boldsymbol{x}}) = \mathbf{W}^{(k)}\mathbf{y}^{(k)}, \tag{5}$$

where $\mathbf{W}^{(j)} \in \mathbb{R}^{d\times d}$ are linear transformations and σ denotes a non-linear activation function. The linear transformation at the output layer allows Φ to match the unbounded range of the regression task. Note that we have suppressed the bias terms of the transformations for clarity. In past work (Shen et al., 2020), a mapping function was chosen with a specific form,

$$\phi(\mathbf{z}) = \mathbf{z} - \mathbf{v}_1 + \mathbf{v}_2, \tag{6}$$

where the "offset" vectors $\mathbf{v}_1$ and $\mathbf{v}_2$ correspond to encodings of the input style and the output style, computed as the average of sentences with the respective style. Because dimensions not relating to style information cancel each other out, the output remains close to the input. However, this model lacks generality because the offset vectors are independent of the input.

We propose a mapping which incorporates the notion of an offset vector, but is conditioned on the input. Each layer of the Φ network moves through the embedding space by an input-specific offset, computed using a "skip" connection at each layer:

$$\mathbf{y}^{(j)} = \mathbf{y}^{(j-1)} + \underbrace{\mathbf{V}^{(j)}\sigma(\mathbf{W}^{(j)}\mathbf{y}^{(j-1)})}_{\text{offset } j}. \tag{7}$$

---

[3] Our code is available at: `https://github.com/florianmai/emb2emb`

$\mathbf{V}^{(j)}, \mathbf{W}^{(j)} \in \mathbb{R}^{d \times d}$ again denote linear transformations. Unlike the MLP, the skip connections bias the output to be close to the input. We refer to this architecture as **OffsetNet**.

Note that a residual network (He et al., 2016) corresponds to Equation 7 but with an additional non-linear transformation (typically of bounded range) applied to the output of Equation 7, again necessitating a linear transformation at the output layer. However, transforming the output all together would defeat the purpose of navigating the manifold with learned offsets. Figure 3 illustrates the differences. Our experiments (Section 3.1.2) validate the design choice for OffsetNet.

2.3 Supervised Task Loss $\mathcal{L}_{task}$

For supervised tasks, a collection of parallel sentence pairs $\langle(\boldsymbol{x}_i, \boldsymbol{y}_i)\rangle_{i=1}^{N}$ is available as supervision for the conditional generation task. After pretraining the autoencoder, enc is available to transform the training data into pairs of vectors $(\mathbf{z}_{\boldsymbol{x}_i}{=}\text{enc}(\boldsymbol{x}_i), \mathbf{z}_{\boldsymbol{y}_i}{=}\text{enc}(\boldsymbol{y}_i))$, giving us:

$$\mathcal{L}_{task} = \frac{1}{N} \sum_{i=1}^{N} \mathcal{L}_{emb}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}; \boldsymbol{\theta}), \mathbf{z}_{\boldsymbol{y}_i}). \quad (8)$$

The multivariate regression in Equation 8 requires that we specify a loss function, $\mathcal{L}_{emb}$, which should reflect semantic relatedness in the autoencoder's embedding space. For sentence and word embeddings, past work has concluded that cosine distance is preferable to Euclidean distance (i.e., mean squared error) in such settings (Xing et al., 2015; Bhat et al., 2019), which agreed with our preliminary experiments; hence, we adopt cosine distance for the task-specific loss $\mathcal{L}_{emb}$.

Kumar and Tsvetkov (2019) showed that another alternative, the Von Mises-Fisher loss, was preferable in learning to generate continuous word vector outputs. Their loss is not applicable in our setting, because the embedding space of an autoencoder is not unit-normalized like word vectors typically are. Therefore, we employ cosine loss and leave the exploration of other regression losses to future work.

2.4 Unsupervised Task Loss $\mathcal{L}_{task}$

In the unsupervised case, we do not have access to parallel sentence pairs $(\boldsymbol{x}, \boldsymbol{y})$. Instead, we have a collection of sentences labeled with their style attribute (e.g., sentiment), here denoted $\langle(\boldsymbol{x}_i, a_i)\rangle_{i=1}^{N}$. The goal of the task is twofold (Logeswaran et al., 2018): preserve the content of the input and match the desired value for the style attribute. We view this as a tradeoff, defining $\mathcal{L}_{task}$ as an interpolation between loss terms for each. With $\hat{\mathbf{z}}_{\boldsymbol{x}_i}{=}\Phi(\mathbf{z}_{\boldsymbol{x}_i}; \boldsymbol{\theta})$, for the unsupervised case we have:

$$\mathcal{L}_{task} = \lambda_{sty} \mathcal{L}_{sty}(\hat{\mathbf{z}}_{\boldsymbol{x}_i}) + (1 - \lambda_{sty}) \mathcal{L}_{cont}(\hat{\mathbf{z}}_{\boldsymbol{x}_i}, \mathbf{z}_{\boldsymbol{x}_i}). \quad (9)$$

where $\mathcal{L}_{cont}$ and $\mathcal{L}_{sty}$ are described in the following. Lastly, we describe an inference-time method that can improve the loss after applying the mapping even further.

Content preservation. We encourage the output to stay close to the input, on the assumption that embeddings are primarily about semantic content. To this end, we choose $\mathcal{L}_{cont}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}; \boldsymbol{\theta}), \mathbf{z}_{\boldsymbol{x}_i})$ to be cosine distance.

Style. Following previous approaches (Engel et al., 2018; Liu et al., 2020; Wang et al., 2019), our style objective requires that we pretrain a (probabilistic) classifier that predicts the style attribute value from the (fixed) autoencoder's embedding. The classifier is then frozen (like the autoencoder) and our minimizing objective requires the output of our method to be classified as the target style. Formally, in a preliminary step, we train a style classifier $\mathbf{c} : \mathbb{R}^d \rightarrow \{0, 1\}$ on the embeddings of the autoencoder to predict one of the attributes (labeled as 0 and 1, respectively). We then freeze the classifier's parameters, and encourage Φ to produce outputs of the target attribute ($y{=}1$) via a negative log-likelihood loss:

$$\mathcal{L}_{sty}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}; \boldsymbol{\theta}), \mathbf{z}_{\boldsymbol{x}_i}) = -\log(\mathbf{c}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}; \boldsymbol{\theta}))).$$

Inference Time. The mapping Φ is trained to try to optimize the objective (1). In the unsupervised case, we can actually verify at test time whether it has succeeded, since nothing is known at training time that is not also known at test time (i.e., no labeled output). We propose a second stage of the mapping for the unsupervised case which corrects any suboptimality. We apply fast gradient iterative modification (FGIM; Wang et al., 2019) to improve the predicted embeddings further. Formally, we modify the predicted embedding $\hat{\mathbf{z}}_{\boldsymbol{x}_i}{=}\Phi(\mathbf{z}_{\boldsymbol{x}_i}; \boldsymbol{\theta})$ as

$$\hat{\hat{\mathbf{z}}}_{\boldsymbol{x}_i} = \hat{\mathbf{z}}_{\boldsymbol{x}_i} + \omega \nabla_{\hat{\mathbf{z}}_{\boldsymbol{x}_i}} \mathcal{L}(\hat{\mathbf{z}}_{\boldsymbol{x}_i}, \mathbf{z}_{\boldsymbol{x}_{\mathbf{i}}}),$$

where ω is the stepsize hyperparameter. This step is repeated for a fixed number of steps or until

$\mathbf{c}(\hat{\hat{\mathbf{z}}}_{\boldsymbol{x}_i}) > t$, where, $\mathbf{c}$ is the style classifier from above, and $t \in [0, 1]$ denotes some threshold.

Wang et al. (2019) use this method to modify the input embedding $\mathbf{z}_{\boldsymbol{x}_\mathbf{i}}$ by only following the gradient of the classifier $\mathbf{c}$, i.e., $\hat{\hat{\mathbf{z}}}_{\boldsymbol{x}_i} = \mathbf{z}_{\boldsymbol{x}_\mathbf{i}} + \omega\nabla_{\mathbf{z}_{\boldsymbol{x}_\mathbf{i}}} - \log \mathbf{c}(\mathbf{z}_{\boldsymbol{x}_\mathbf{i}})$. In contrast, our variant takes the entire loss term into account, including the adversarial term that encourages embeddings that lie on the manifold of the autoencoder, which we explain next.

2.5 Adversarial Loss $\mathcal{L}_{adv}$

Recall that at test time the output of Φ is the input to the pretrained decoding function dec. Even for supervised training, we do not expect to obtain zero loss during training (or to generalize perfectly out of sample), so there is a concern that the output of Φ will be quite different from the vectors dec was trained on (during pretraining). In other words, there is no guarantee that Φ will map onto the manifold of the autoencoder.

To address this issue, we propose an adversarial objective that encourages the output of Φ to remain on the manifold. Our method is similar to the "realism" constraint of Engel et al. (2018), who train a discriminator to distinguish between latent codes drawn from a prior distribution (e.g., a multivariate Gaussian) and the latent codes actually produced by the encoder. Instead of discriminating against a prior (whose existence we do not assume), we discriminate against the embeddings produced by Φ. We build on the adversarial learning framework of Goodfellow et al. (2014) to encourage the transformation Φ to generate output embeddings indistinguishable from the embeddings produced by the encoder enc.

Formally, let disc be a (probabilistic) binary classifier responsible for deciding whether a given embedding was generated by enc or Φ. The discriminator is trained to distinguish between embeddings produced by enc and embeddings produced by Φ:

$$\max_{\text{disc}} \sum_{i=1}^{N} \log(\text{disc}(\mathbf{z}_{\tilde{\boldsymbol{y}}_i})) + \log(\overline{\text{disc}}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}))) \tag{10}$$

where $\text{disc}(\mathbf{z})$ denotes the probability of vector $\mathbf{z}$ being produced by enc and $\overline{\text{disc}}(\mathbf{z}) = 1 - \text{disc}(\mathbf{z})$. The mapping Φ is trained to "fool" the discriminator:

$$\mathcal{L}_{adv}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}); \boldsymbol{\theta}) = -\log(\text{disc}(\Phi(\mathbf{z}_{\boldsymbol{x}_i}); \theta)) \tag{11}$$

Training the discriminator requires encoding negatively sampled sentences, $\mathbf{z}_{\tilde{\boldsymbol{y}}_i} = \text{enc}(\tilde{y}_i)$, where we want these sentences to contrast with the output of the mapping $\Phi(\mathbf{z}_{\boldsymbol{x}_i})$. For the supervised case, we achieve this by taking the negative samples from the target sentences of the training data, $\tilde{y}_i = y_i$. In the unsupervised case, $\tilde{y}_i$ are sampled randomly from the data.

The mapping Φ is trained according to the objective in (1), in which $\mathcal{L}_{adv}$ depends on training the discriminator disc according to (10). In practice, we alternate between batch updates to Φ and disc. Our experiments in Section 3 will explore sensitivity to λ_{adv}, finding that it has a large effect. In practical applications, it should therefore be treated as a hyperparameter.

2.6 Summary

Our framework is *plug and play*, since it is usable with any pretrained autoencoder. Unlike previous methods by Shen et al. (2020) and Wang et al. (2019), which are specific to style transfer and do not learn a function (like Φ in Emb2Emb), ours can, in principle, be used to learn a mapping from any sort of input data to text, as long as the desired attributes of the generated text can be expressed as a loss function that is tied to the autoencoder manifold. In this study, we apply it to supervised and unsupervised text style transfer. The key component is the mapping function Φ, which is trained via a regression loss (plus auxiliary losses) to map from the embedding of the input sequence to the embedding of the output sequence. Learning the function is facilitated through the proposed **OffsetNet** and an adversarial loss term that forces the outputs of the mapping to stay on the manifold of the autoencoder.

3 Experiments

We conduct controlled experiments to measure the benefits of the various aspects of our approach. First, we consider a supervised sentence simplification task and compare our approach to others that use a fixed-size representational bottleneck, considering also the model's sensitivity to the strength of the adversarial loss and the use of OffsetNet (Section 3.1). We then turn to an unsupervised sentiment transfer task, first comparing our approach to other methods that can be considered "plug and play" and then investigating the effect of plug and play when only a little labeled data is available

(Section 3.2). We note that the current state of the art is based on transformers (Vaswani et al., 2017); since our aim is to develop a general-purpose framework and our computational budget is limited, we focus on controlled testing of components rather than achieving state-of-the-art performance.

Autoencoder. In all our experiments, we use a one-layer LSTM as encoder and decoder, respectively. We pretrain it on the text data of the target task as a denoising autoencoder (DAE; Vincent et al., 2010) with the noise function from Shen et al. (2020). Additional training and model details can be found in Appendix A.

3.1 Sentence Simplification

Sentence simplification provides a useful testbed for the supervised variant of our approach. The training data contains pairs of input and output sentences $(\boldsymbol{x}_i, \boldsymbol{y}_i)$, where $\boldsymbol{x}_i$ denotes the input sentence in English and $\boldsymbol{y}_i$ denotes the output sentence in simple English. We evaluate on the English WikiLarge corpus introduced by Zhang and Lapata (2017), which consists of 296,402 training pairs, and development and test datasets adopted from Xu et al. (2016). Following convention, we report two scores: BLEU (Papineni et al., 2002), which correlates with grammaticality (Xu et al., 2016), and SARI (Xu et al., 2016), found to correlate well with human judgements of simplicity. We also compare training runtimes.

3.1.1 Comparison to Sequence-to-Sequence

Our first comparisons focus on models that, like ours, use a fixed-size encoding of the input. Keeping the autoencoder architecture fixed (i.e., the same as our model), we consider variants of the sequence-to-sequence model of Sutskever et al. (2014).[4] All of these models are trained "end-to-end," minimizing token-level cross-entropy loss. The variants are:

- **S2S-Scratch**: trains the model from scratch.
- **S2S-Pretrain**: uses a pretrained DAE and finetunes it.
- **S2S-MLP**: further adds the trainable mapping Φ used in our approach.
- **S2S-Freeze**: freezes the pretrained autoencoder parameters, which we expect may help with the vanishing gradient problem arising in the rather deep S2S-MLP variant.

Model	BLEU	SARI	Time
S2S-Scratch	3.6	15.6	3.7×
S2S-Pretrain	5.4	16.2	3.7×
S2S-MLP	10.5	17.7	3.7×
S2S-Freeze	23.3	22.4	2.2×
Emb2Emb	**34.7**	**25.4**	1.0×

Table 1: Text simplification performance of model variants of end2end training on the test set. "Time" is wall time of one training epoch, relative to our model, Emb2Emb.

For all the models, we tuned the learning rate hyperparameter in a comparable way and trained with the ADAM optimizer by Kingma and Ba (2015) (more details in the Appendix A.4).

Results. Table 1 shows test-set performance and the runtime of one training epoch relative to our model (Emb2Emb). First, note that the end-to-end models are considerably more time-consuming to train. S2S-Freeze is not only more than two times slower per epoch than Emb2Emb, but we find it to also require 14 epochs to converge (in terms of validation performance), compared to 9 for our model. Turning to accuracy, as expected, adding pretraining and the MLP to S2S-Scratch does improve its performance, but freezing the autoencoder (S2S-Freeze) has an outsized benefit. This observation may seem counter to the widely seen success of finetuning across other NLP scenarios, in particular with pretrained transformer models like BERT (Devlin et al., 2019). However, finetuning does not always lead to better performance. For instance, Peters et al. (2019) not only find the LSTM-based ELMo (Peters et al., 2018) difficult to configure for finetuning in the first place, but also observe performances that are often far lower than when just freezing the parameters. Hence, our results are not entirely unexpected. To further eliminate the possibility that the finetuned model underperformed merely because of improper training, we verified that the training loss of S2S-Pretrain is indeed lower than that of S2S-Freeze. Moreover,

---

[4] On this task, much stronger performance than any we report has been achieved using models without this constraint (Mathews et al., 2018; Zhang and Lapata, 2017). Our aim is not to demonstrate superiority to those methods; the fixed-size encoding constraint is of general interest because (i) it is assumed in other tasks such as unsupervised style transfer and (ii) it is computationally cheaper.

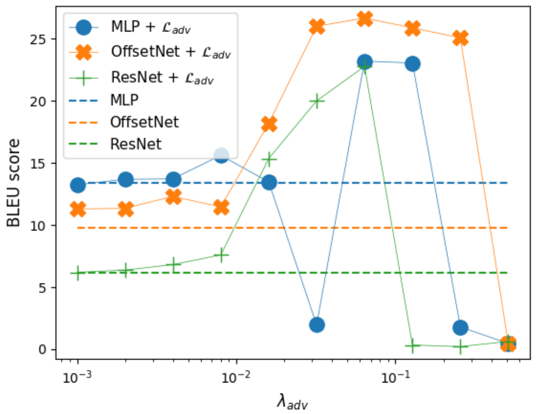

Figure 4: Performance on WikiLarge in terms of BLEU score on the development set (higher is better) by weight for the adversarial term λ_{adv}. Note that the x-axis is on a log scale.

the poor performance is also unlikely to be a problem of overfitting, because we mitigate this via early stopping. This suggests that the differences are largely due to the generalization abilities coming from the pretraining, which is partly forgotten when finetuning the entire model on the target task. Our results thus support the hypothesis of Mathews et al. (2018) that fixed-size bottlenecks and deeper networks make end-to-end learning harder. In contrast, training Emb2Emb even outperforms the best end-to-end model, S2S-Freeze.

From these results, we conclude that, when pretraining a fixed-size-representation autoencoder for plug and play text generation, learning text transformations entirely in continuous space may be easier and more efficient than using conventional sequence-to-sequence models.

3.1.2 Sensitivity Analysis

We next explore two of the novel aspects of our model, the adversarial loss and the use of OffsetNet in the mapping function Φ. We vary the tradeoff parameter λ_{adv} and consider variants of our approach using an MLP, ResNet, and OffsetNet at each value. All other hyperparameters are kept fixed to default values reported in Appendix A.

Results. Figure 4 plots the BLEU scores, with $\lambda_{adv} = 0$ as horizontal dashed lines. Each model's BLEU score benefits, in some λ_{adv} range, from the use of the adversarial loss. Gains are also seen for SARI (see Appendix A.4.3). OffsetNet is also consistently better than ResNet and, when using the adversarial loss, the MLP. From this we conclude that OffsetNet's approach of starting close to the input's embedding (and hence on/near the manifold), facilitates (adversarial) training compared to the MLP and ResNet, which, at the beginning of training, map to an arbitrary point in the embedding space due to the randomly initialized projection at the last layer.

3.2 Sentiment Transfer

We next evaluate our model on an unsupervised style transfer task. For this task, the training data is given pairs of input sentences and sentiment attributes $(\boldsymbol{x}_i, a_i)$, where $\boldsymbol{x}_i$ denotes the input sentence in English and a_i denotes its target sentiment, a binary value. For training, we use the Yelp dataset preprocessed following Shen et al. (2017). At inference time, we follow common evaluation practices in this task (Hu et al., 2017; Shen et al., 2017; Lample et al., 2019) and evaluate the model on its ability to "flip" the sentiment (measured as the accuracy of a DistilBERT classifier trained on the Yelp training set, achieving 97.8% on held-out data; Sanh et al., 2019),[5] and "self-BLEU," which computes the BLEU score between input and output to measure content preservation. There is typically a tradeoff between these two goals, so it is useful to visualize performance as a curve (accuracy at different self-BLEU values). We conduct three experiments. First, we compare to two other unsupervised sentiment transfer models that can be considered "plug and play" (Section 3.2.1). Second, we conduct controlled experiments with variants of our model to establish the effect of pretraining (Section 3.2.2). Third, we confirm the effectiveness of OffsetNet and the adversarial loss term for the sentiment transfer (Appendix A.5.4).

3.2.1 Comparison to Plug and Play Methods

To the best of our knowledge, there are only two other autoencoder-based methods that can be used in a plug and play fashion, i.e., training the autoencoder and sentiment transfer tasks in succession. These are the method of Shen et al. (2020), which is based on addition and subtraction of mean vectors of the respective attribute corpora (see Section 4), and FGIM (see Section 2.4); both of them are inference-time methods and do not learn a function (like Φ in Emb2Emb). Even though these methods are not specifically introduced with pretraining plug and play in mind, we can consider them in this way as alternatives to our model. Note that Wang

---

[5] Due to budget constraints, we evaluate only on transforming sentiment from negative to positive.

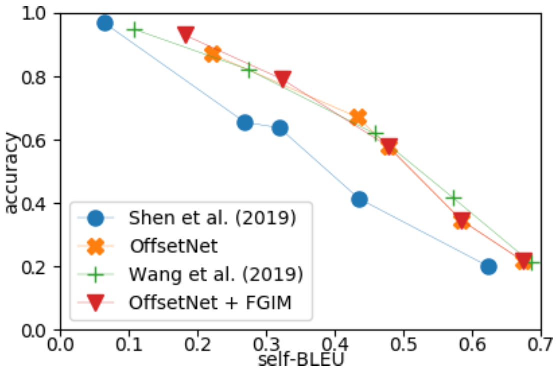

Figure 5: Comparison of plug and play methods for unsupervised style transfer on the Yelp sentiment transfer task's test set. Up and right is better

et al. (2019) achieve state-of-the-art on unsupervised sentiment transfer using FGIM, but applied to the latent space of a powerful transformer autoencoder. Since we want to conduct controlled experiments to find the best plug and play method, we integrated FGIM into our framework rather than directly comparing to their results. We treat the method by Shen et al. (2020) analogously.

For our learning-based model, we tune λ_{adv} on the development set from Yelp. After finding the best λ_{adv}, we inspect the behavior of the models at different levels of transfer by varying λ_{sty} ($\{0.1, 0.5, 0.9, 0.95, 0.99\}$), giving a tradeoff curve (more details in Appendix A.5.4). Analogously, we vary the multiplier for Shen et al. (2020) and the thresholds t for Wang et al. (2019) to obtain different tradeoffs between accuracy and self-BLEU. We also report the computational overhead each method incurs in addition to encoding and decoding.

Results. Figure 5 plots the tradeoff curves for the existing models, and ours with and without FGIM at inference time. We report accuracy and computational overhead in Table 2, for the most accurate points. Note that our model clearly outperforms that of Shen et al. (2020), confirming that learning the offset vectors in the autoencoder manifold is indeed beneficial.[6] Our model's performance is close to that of Wang et al. (2019), even without FGIM at inference time. Consequently, our model has a much lower computational overhead. With FGIM, our model shows an advantage at the high-accuracy end of the curve (top), increasing content preservation by 68% while reaching 98% of FGIM's transfer accuracy, though this is computationally expensive. This confirms that our training framework, while being very flexible (see Section 2.6), is a strong alternative not only in the supervised, but also in the unsupervised case.

Model	Acc.	s-BLEU	+Time
Shen et al.	96.8	6.5	0.5×
FGIM	94.9	10.8	70.0×
Emb2Emb + FGIM	93.1	18.1	2820.0×
Emb2Emb	87.1	22.1	1.0×

Table 2: Self-BLEU ("s-BLEU") on the Yelp sentiment transfer test set for the configurations in Figure 5 with highest transfer accuracy ("Acc."). "+Time" reports the inference-time slowdown factor due to each model's additional computation (relative to our method).

3.2.2 Pretraining

We have argued for a plug and play use of autoencoders because it allows generation tasks to benefit from independent research on autoencoders and potentially large datasets for pretraining. Here we measure the benefit of pretraining directly by simulating low-resource scenarios with limited style supervision. We consider three pretraining scenarios:

- **Upper bound**: We pretrain on all of the texts and labels; this serves as an upper bound for low-resource scenarios.

- **Plug and play**: A conventional plug and play scenario, where all of texts are available for pretraining, but only 10% of them are labeled (chosen at random) for use in training Φ.

- **Non plug and play**: A matched scenario with no pretraining ("non plug and play"), with only the reduced (10%) labeled data.

Results. Figure 6 shows the tradeoff curves in the same style as the last experiment. The benefit of pretraining in the low-resource setting is very clear, with the gap compared to the plug and play approach widening at lower transfer accuracy levels. The plug and play model's curve comes close to the "upper bound" (which uses ten times as much labeled data), highlighting the potential for pretraining an autoencoder for plug and play use in text generation tasks with relatively little labeled data.

---

[6] In Appendix B, we analyze the differences between these models' outputs qualitatively.

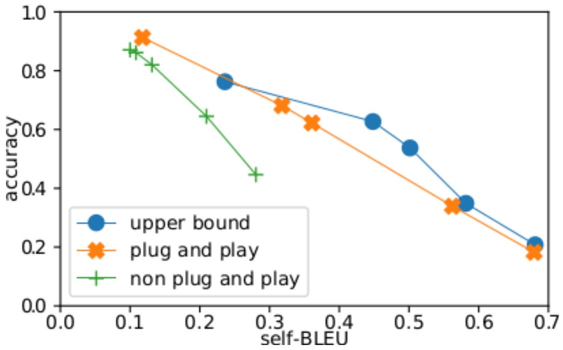

Figure 6: Sentiment transfer results for different model scenarios. Up and right is better.

4 Related Work

Text Style Transfer The most common approach to text style transfer is to learn a disentangled shared latent space that is agnostic to the style of the input. Style transfer is then achieved by training the decoder conditioned on the desired style attribute, (Hu et al., 2017; Shen et al., 2017; Fu et al., 2018; Zhao et al., 2018; Lample et al., 2019; Li et al., 2018; Logeswaran et al., 2018; Yang et al., 2018; Li et al., 2019), which hinders their employment in a plug and play fashion. Most methods either rely on adversarial objectives (Shen et al., 2017; Hu et al., 2017; Fu et al., 2018), retrieval (Li et al., 2018), or backtranslation (Lample et al., 2019; Logeswaran et al., 2018) to make the latent codes independent of the style attribute. Notable exceptions are Transformer-based (Dai et al., 2019; Sudhakar et al., 2019), use reinforcement learning for backtranslating through the discrete space (Liu and Liu, 2019), build pseudo-parallel corpora (Kruengkrai, 2019; Jin et al., 2019), or modify the latent-variable at inference time by following the gradient of a style classifier (Wang et al., 2019; Liu et al., 2020). Similar to our motivation, Li et al. (2019) aim at improving in-domain performance by incorporating out-of-domain data into training. However, because their model again conditions on the target data, they have to train the autoencoder jointly with the target corpus, defeating the purpose of large-scale pretraining.

In contrast to previous methods, Emb2Emb can be combined with any pretrained autoencoder even if it was not trained with target attributes in mind. It is therefore very close in spirit to plug and play language models by Dathathri et al. (2020) who showed how to use pretrained language models for controlled generation without any attribute conditioning (hence, the name). It is also similar to pretrain-and-plugin variational autoencoders (Duan et al., 2020), who learn small adapters with few parameters for a pretrained VAE to generate latent codes that decode into text with a specific attribute. However, these models cannot be conditioned on input text, and are thus not applicable to style transfer.

Textual Autoencoders Autoencoders are a very active field of research, leading to constant progress through denoising (Vincent et al., 2010), variational (Kingma and Welling, 2014; Higgins et al., 2017; Dai and Wipf, 2019), adversarial (Makhzani et al., 2016; Zhao et al., 2018), and, more recently, regularized (Ghosh et al., 2020) autoencoders, to name a few. Ever since Bowman et al. (2016) adopted variational autoencoders for sentences by employing a recurrent sequence-to-sequence model, improving both the architecture (Semeniuta et al., 2017; Prato et al., 2019; Liu and Liu, 2019; Gagnon-Marchand et al., 2019) and the training objective (Zhao et al., 2018; Shen et al., 2020) have received considerable attention. The goal is typically to improve both the reconstruction and generation performance (Cífka et al., 2018).

Our framework is completely agnostic to the type of autoencoder that is used, as long as it is trained to reconstruct the input. Hence, our framework directly benefits from any kind of modelling advancement in autoencoder research.

5 Conclusion

In this paper, we present *Emb2Emb*, a framework that reduces conditional text generation tasks to learning in the embedding space of a pretrained autoencoder. We propose an adversarial method and a neural architecture that are crucial for our method's success by making learning stay on the manifold of the autoencoder. Since our framework can be used with any pretrained autoencoder, it will benefit from large-scale pretraining in future research.

A Experimental Details

We first describe the experimental details that are common to the experiments on both datasets. Dataset-specific choices are listed in their respective subsections.

A.1 Preprocessing and Tokenization

We do not apply any further preprocessing to the datasets that we obtain. We use BPE for tokenization, and restrict the vocabulary to 30,000. We truncate all inputs to 100 tokens at maximum.

A.2 Experimental Setup

Computing Infrastructure. For all of our experiments, we relied on a computation cluster with a variety of different GPUs with at minimum 12GB GPU memory and 50GB RAM. For the text simplification experiments where we measure training speed, we ran all experiments on the same machine (with a GeForce GTX 1080 Ti) in succession to ensure a fair comparison.

Implementation. We used Python 3.7 with PyTorch 1.4 for all our experiments. Our open-source implementation is available at `https://github.com/florianmai/emb2emb`.

Adversarial Training. We employ a 2-layer MLP with 300 hidden units and ReLU activation as discriminator, and train it using Adam with a learning rate of 0.00001 (the remaining parameters are left at their PyTorch defaults). We train it in alternating fashion with the generator Φ, in batches of size 64.

A.3 Neural Architectures

Encoder For encoding, we employ a one-layer bidirectional LSTM as implemented in PyTorch. To obtain the fixed-size bottleneck, we average the last hidden state of both directions. The input size (and token embedding size) is 300.

Decoder For decoding, we initialize the hidden state of a one-layer LSTM decoder as implemented in PyTorch with the fixed size embedding. During training, we apply teacher forcing with a probability of 0.5. The input size is 300. We use greedy decoding at inference time.

Transformation Φ. We train all neural network architectures with one layer. The hidden size is set to the same as the input size, which in turn is determined by the size of the autoencoder bottleneck. Hence, the MLP and OffsetNet have the same number of parameters. Due to its extra weight matrix at the output-layer, the ResNet has 50% more parameters than the other models. All networks use the SELU activation function. All training runs with our model were performed with the Adam optimizer.

A.4 Text Simplification

A.4.1 Dataset Details

We evaluate on the WikiLarge dataset by Zhang and Lapata (2017), which consists of sentence pairs extracted from Wikipedia, where the input is in English and the output is in simple English. It contains of 296,402 training pairs, 2,000 development pairs, and 359 pairs for testing. The 2,359 development and test pairs each come with 8 human-written reference sentences to compute the BLEU and SARI overlap with. The dataset can be downloaded from `https://github.com/XingxingZhang/dress`.

A.4.2 Experimental Details

Training our model. We use a fixed learning rate of 0.0001 to train our model for 10 epochs. We evaluate the validation set performance in terms of BLEU after every epoch and save the iteration with the best validation loss performance.

Training S2S models. For all S2S models we compare against in Section 3.1.1, we select the best performing run on the validation set among the learning rates $\{0.001, 0.0005, 0.0001, 0.00005, 0.00001, 0.000005\}$, and also assess the validation set performance after each of the 20 epochs. Training is performed with the Adam optimizer.

Encoder hyperparameters We use a 1-layer bidirectional LSTM with a memory size of 1024 and an input size of 300.

Number of Parameters All models share the same encoder and decoder architecture, consisting of 34,281,600 parameters in total. The mappings MLP, OffsetNet, and ResNet have 2,097,132, 2,097,132, and 3,145,708 parameters, respectively. We report total numbers for the models used in the experimental details below.

Evaluation metrics. For computing BLEU, we use the Python NLTK 3.5 library.[7]

---

[7] `https://www.nltk.org/api/nltk.translate.html#module-nltk.translate.bleu_score`

For computing SARI score, we use the implementation provided by (Xu et al., 2016) at `https://github.com/cocoxu/simplification/blob/master/SARI.py`.

A.4.3 SARI Score by λ_{adv}

Experimental details. We measure the performance of our model on the development set of WikiLarge in terms of SARI score. These results are for the same training run for which we reported the BLEU score, hence, the stopping criterion for early stopping was BLEU, and we report the results for all 10 exponentially increasing values of λ_{adv}. The best value when using BLEU score as stopping criterion is $\lambda_{adv} = 0.032$.

Results. The results in Figure 7 show the same pattern as for the BLEU score, although with a smaller relative gain of 23% when using the adversarial term.

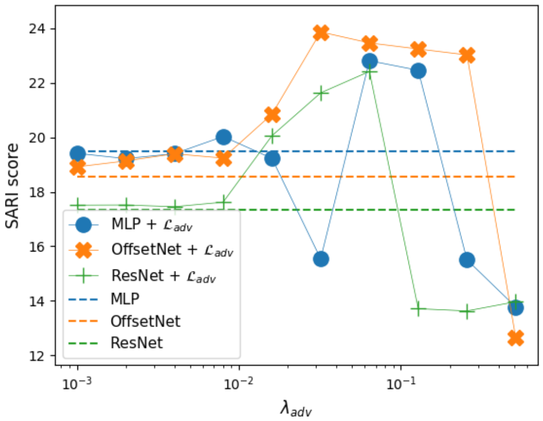

Figure 7: Performance on WikiLarge in terms of SARI score (higher is better) by weight for the adversarial term λ_{adv}.

A.4.4 Development Set Results for Comparison to S2S Models

In Table 3, we report the development set performances corresponding to the experiments reported in Section 3.1.1. For each model, we also specify the best learning rate, if applicable, and the number of parameters in the model

A.5 Sentiment Transfer

A.5.1 Dataset Details

We evaluate on the Yelp dataset as preprocessed by (Shen et al., 2017), which consists of sentences with positive or negative sentiment extracted from restaurant reviews. The training set consists of 176,787 negative and 267,314 positive examples. The development set has 25,278 negative and 38,205 positive examples, and the test set has 50,278 negative and 76,392 positive examples. The dataset can be downloaded from `https://github.com/shentianxiao/language-style-transfer/tree/master/data/yelp`.

Model	BLEU	SARI	LR	$\lvert\Theta\rvert$
S2S-Scratch	3.2	14.3	0.0001	34.3m
S2S-Pretrain	5.9	15.1	0.0005	34.3m
S2S-MLP	8.6	16.0	0.0001	36.4m
S2S-Freeze	17.4	20.1	0.00005	36.4m
Ours	**26.7**	**23.5**	-	36.4m

Table 3: Text simplification performance of model variants of seq2seq training on the development set. $|\Theta|$ denotes the number of parameters for each model.

Training our models. We use a fixed learning rate of 0.00005 to train our model for 10 epochs (for the ablations) or 20 epochs (for the final model). We evaluate the validation set performance in terms of self-BLEU plus transfer accuracy after every epoch and save the iteration with the best validation loss performance.

For all models involving training the mapping Φ (including the ablation below), we perform a search of λ_{adv} among the values $\{0.008, 0.016, 0.032, 0.0640.128\}$. We select them based on the following metric: $\sum_{i=1}^{5}(BLEU(\lambda_{adv}, \lambda_{sty}^{i}) + accuracy(\lambda_{adv}, \lambda_{sty}^{i})$, where λ_{sty}^{i} corresponds to the i-th value of λ_{sty} that we have used to obtain the BLEU-accuracy tradeoff curve. By $BLEU(\lambda_{adv}, \lambda_{sty}^{i})$ and $accuracy(\lambda_{adv}, \lambda_{sty}^{i})$, respectively, we mean the score resulting from training with the given parameters.

Encoder hyperparameters We use a 1-layer bidirectional LSTM with a memory size of 512.

Number of Parameters All models again share the same encoder and decoder architecture, consisting of 22,995,072 parameters in total. The mappings MLP, OffsetNet, and ResNet have 524,288, 524,288, and 786,432 parameters, respectively. Hence, the total number of parameters for our models is 23.5m, whereas the variants we report as Shen et al. and FGIM have 23m parameters.

Sentiment classifier on autoencoder manifold. For binary classification, we train a 1-layer MLP with a hidden size of 512 with Adam using a learning rate of 0.0001. For regularization, we use dropout with $p = 0.5$ at the hidden and input layer, and also add isotropic Gaussian noise with a standard deviation of 0.5 to the input features.

BERT classifier. The DistilBERT classifier is trained using the HuggingFace transformers library.[8] We train it for 30 epochs with a batch size of 64 and a learning rate of 0.00002 for Adam, with a linear warm-up period over the first 3000 update steps. We evaluate the validation set performance every 5000 steps and save the best model.

A.5.2 Implementation of Wang et al. Baseline

We reimplemented the Fast Gradient Iterative Modification method by (Wang et al., 2019) to either i) follow the gradient of the sentiment classifier from the input, or ii) from the output of Φ, follow the gradient of the complete loss function of training Φ.

Following the implementation by (Wang et al., 2019), in all runs, we repeat the computation for weights $\omega \in \{1, 10, 100, 1000\}$ and stop at the first weight that leads to the classification probability exceeding a threshold t. For each weight, we make 30 gradient steps at maximum.

The Wang et al. (2019) baseline is generated from choosing $t = \{0.5, 0.9, 0.99, 0.999, 0.9999\}$, i.e., we choose lower thresholds to stop the gradient descent from changing the input too much towards the target attribute, leading to lower transfer accuracy performances.

When we apply FGIM to the output of Φ in our model (with the more sophisticated loss function, where we set $\lambda_{sty} = 0.5$), we apply the same thresholds.

A.5.3 Development Set Result for Comparison of Plug and Play

In Figure 8, we report the development set result corresponding to the test set results of the experiments presented in Section 3.2.1. These results are shown for $\lambda_{adv} = 0.008$, which performed the best in terms of the development score metric introduced in the training details.

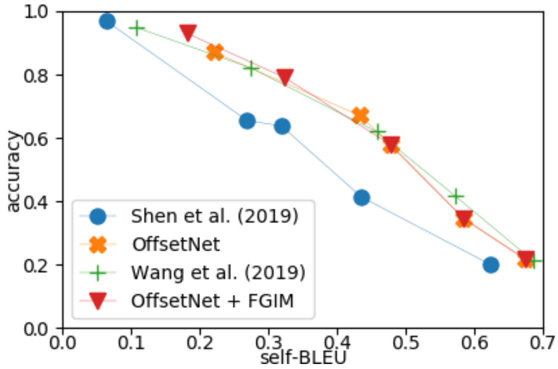

Figure 8: Comparison of plug and play methods for unsupervised style transfer on the Yelp sentiment transfer task's development set. Up and right is better

A.5.4 Model Analysis

Experimental Setup We investigate the effect of OffsetNet and the adversarial training term on our unsupervised style transfer model by measuring the self-BLEU score with the input sentence and the accuracy of a separately trained BERT classifier (achieving 97.8% classification accuracy) on the Yelp development set. We again report the best performance among 6 exponentially increasing λ_{adv} values for each model. To inspect the behavior of the models at varying levels of transfer, we trained and plotted one model each for $\lambda_{sty} \in \{0.1, 0.5, 0.9, 0.95, 0.99\}$.

Results. The results in Figure 9 show that OffsetNet reaches better transfer accuracy than the MLP at comparable self-BLEU scores. The performance drops significantly if the adversarial term is not used. This confirms the importance of our design decisions.

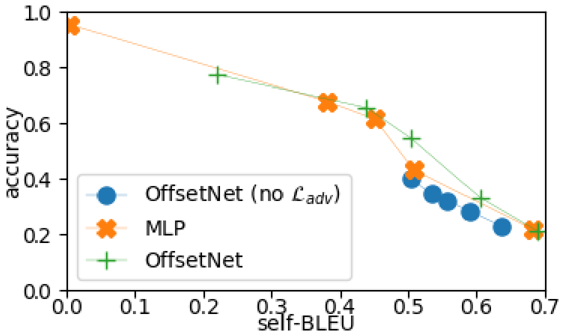

Figure 9: Ablation of our model components on the Yelp sentiment transfer tasks. Up and right is better.

---

[8] Specifically, we use the run_glue.py script in from https://github.com/huggingface/transformers and only replace the SST-2 dataset with the Yelp dataset. We used the commit “11c3257a18c4b5e1a3c1746eefd96f180358397b” for training our model.

B Qualitative Analysis

We provide several example outputs of our method in comparison to the outputs of the baseline by Shen et al. (2020) in Tables 4, 5, 6, and 7. Moreover, we show how the output evolves as the multiplier and λ_{sty} (i.e., the level of transfer accuracy) increases.

In our qualitative analysis we generally observe that both models generate similar outputs when the inputs are short and can be transferred by only changing or deleting single words (e.g., Table 4). We observe that grammaticality degrades in both methods for higher transfer levels. However, our method is more often able to preserve the content of the input as the transfer accuracy increases: At a multiplier of 3.0, the method by Shen et al. (2020) outputs rather general positive statements that are mostly disconnected from the input, whereas our method is able to stay on the topic of the input statement. This observation matches the quantitative results from Section 3.2.1, where our method attains substantially higher self-BLEU scores at comparable levels of transfer accuracy.

However, it is clear that both models mostly rely on exchanging single words in order to change the sentiment classification. In the example from Table 5, our model changes the input “the cash register area was empty and no one was watching the store front .” to the rather unnatural sentence “the cash area was great and was wonderful with watching the front desk .” instead of the more natural, but lexically distant reference sentence “the store front was well attended ”. We think that this is best explained by the fact that we use a denoising autoencoder with a simple noise function (deleting random words) for these experiments, which encourages sentences within a small edit-distance to be close to each other in the embedding space (Shen et al., 2020). Denoising autoencoders with a more sophisticated noise functions focused on semantics could possibly mitigate this, but is out of scope for this study.

multiplier / λ_{sty}	Shen et al. (2019)	Ours
1.5 / 0.5	i will be back .	i will be back .
2.0 / 0.9	i will be back back	i will definitely be back .
2.5 / 0.95	i will definitely be back .	i will definitely be back
3.0 / 0.99	i love this place !	i will be back !

Table 4: **Input**: i will never be back .

multiplier / λ_{sty}	Shen et al. (2019)	Ours

Abstract

Learning low-dimensional representations for entities and relations in knowledge graphs using contrastive estimation represents a scalable and effective method for inferring connectivity patterns. A crucial aspect of contrastive learning approaches is the choice of corruption distribution that generates hard negative samples, which force the embedding model to learn discriminative representations and find critical characteristics of observed data. While earlier methods either employ too simple corruption distributions, i.e. uniform, yielding easy uninformative negatives or sophisticated adversarial distributions with challenging optimization schemes, they do not explicitly incorporate known graph structure resulting in suboptimal negatives. In this paper, we propose Structure Aware Negative Sampling (SANS), an inexpensive negative sampling strategy that utilizes the rich graph structure by selecting negative samples from a node's k-hop neighborhood. Empirically, we demonstrate that SANS finds semantically meaningful negatives and is competitive with SOTA approaches while requires no additional parameters nor difficult adversarial optimization.

1 Introduction

Knowledge Graphs (KGs) are repositories of information organized as factual triples (h, r, t), where head and tail entities are connected via a particular relation (r). Indeed, KGs have seen wide application in a variety of domains such as question answering (Yao and Van Durme, 2014; Hao et al., 2017; Moldovan and Rus, 2001) and machine reading (Weissenborn et al., 2018; Yang and Mitchell, 2017) to name a few and have a rich history within the natural language processing (NLP) community (Berant et al., 2013; Yu and Dredze, 2014; Collobert and Weston, 2008; Peters et al., 2019). While often large, real-world KGs such as FreeBase (Bollacker et al., 2008) and WordNet (Miller, 1995) are known to be incomplete. Consequently, KG completion via link prediction constitutes a fundamental research topic ameliorating the practice of important NLP tasks (Sun et al., 2019; Angeli and Manning, 2013).

In recent years, there has been a surge of methods employing graph embedding techniques that encode KGs into a lower-dimensional vector space facilitating easier data manipulation (Zhang et al., 2019) while being an attractive framework for handling data sparsity and incompleteness (Wang et al., 2018). To learn such embeddings, contrastive learning has emerged as the de facto gold standard. Indeed, contrastive learning approaches enjoy significant computational benefits over methods that require computing an exact softmax over a large candidate set, such as over all possible tail entities given a head and relation. Another important consideration is modeling needs, as certain assumptions are best expressed as some score or energy in margin-based or un-normalized probability models (Smith and Eisner, 2005). For example, modeling entity relations as translations or rotations in a vector space naturally leads to a distance-based score to be minimized for observed entity-relation-entity triplets (Bordes et al., 2013).

Leveraging contrastive estimation to train KG embedding models involves optimizing the model by pushing up the energy with respect to observed positive triplets while simultaneously pushing down energy on negative triplets. Consequently, the choice of negative sampling distribution plays a crucial role in shaping the energy landscape as simple random sampling—e.g. Noise Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2010)—produces negatives that are easily classified and provide little information alongside in the form of a gradient signal. This is easily remedied if the

corruption process selects a hard negative example through more complex negative sampling distribution, such as adversarial samplers (Cai and Wang, 2018; Bose et al., 2018; Sun et al., 2019). However, adversarial negative sampling methods are computationally expensive, while more tractable approaches—e.g. cache-based methods (Zhang et al., 2019)—are not tailored to the KG setting as they fail to incorporate known graph structure as part of the sampling process. This raises the important question of whether we can obtain a computationally inexpensive negative sampling strategy while benefiting from the rich graph structure of KGs.

Present Work. In this work, we introduce *Structure Aware Negative Sampling* (SANS), an algorithm that utilizes the graph structure of a KG to find hard negative examples. Specifically, SANS constructs negative samples using a subset of entities restricted to either the head or tail entity's *k*-hop neighborhood. We hypothesize that entities that are within each other's neighborhood but share no direct relation have higher chances of being related to one another and thus are good candidates for negative sampling. We also experiment with a dynamic sampling scheme based on random walks to approximate a node's local neighborhood. Empirically, we find that negative sampling using SANS consistently leads to improvements upon uniform sampling and sophisticated Generative Adversarial Network (Goodfellow et al., 2014) (GAN) based approaches at a fraction of the computational cost, and is competitive with other SOTA approaches with no added parameters.

2 Related Work

Negative Sampling. Negative sampling is a method that can be employed to enable the scaling of log-linear models. In essence, negative sampling resolves computational intractability of computing the normalization constant by changing the task to distinguishing observed positive data and fictitious negative examples that are generated by corrupting the positive examples. This general approach is a simplification of NCE, which is based on a Monte-Carlo approximation of the partition function used in Importance Sampling (IS) (Bengio et al., 2003).

Non-Fixed Negative Sampling. As proposed in (Mikolov et al., 2013), negative triplets can be generated using a uniform sampling scheme. However, such uniform and fixed sampling schemes result in easily-classified negative triplets during training, which do not provide any meaningful information (Sun et al., 2019; Zhang et al., 2019). Hence, as the training progresses, most of the sampled negative triplets receive small scores and almost zero gradients, impeding the training of the graph embedding model after only a small number of iterations.

To address the issue of easy negatives, Sun et al. (2019) propose Self-Adversarial negative sampling, which weighs each sampled negative according to its probability under the embedding model. Alternatively, the authors in (Wang et al., 2018) and (Cai and Wang, 2018) try creating high-quality negative samples by exploiting GANs, which, while effective, are expensive to train and require black-box gradient estimation techniques. Another elegant approach that uses fewer parameters and is easier to train compared to GAN-based methods is NSCaching (Zhang et al., 2019), which involves using a cache of high-quality negative triplets—i.e. those with high scores.

3 Structure Aware Negative Sampling

Given an observed positive triplet (h, r, t), a negative sample can be constructed by corrupting either the head or tail entity to form a new triplet—i.e. (h', r, t')—where either $h', t' \in E$, where E is the set of all entities in the KG. Additionally, we assume that the graph embedding models are trained using a loss function of the following form:

$$\begin{aligned}\mathcal{L} = &-\log\sigma(\gamma - d_r(\boldsymbol{h}, \boldsymbol{t})) \\ &-\sum_{i=1}^{n}\frac{1}{n}\log\sigma(d_r(\boldsymbol{h}_i', \boldsymbol{t}_i') - \gamma)\end{aligned} \qquad (1)$$

where $d_r(h, t)$ denotes the score assigned to the compatibility of head and tail entities under the relation r, γ is a fixed margin, σ is the sigmoid function, and n is the number of negative samples.

In this paper, we seek to explicitly use the rich graph structure surrounding a particular node when generating negative triplets. We motivate our approach based on the observation that prior work in learning word embeddings (Mikolov et al., 2013), where negative sampling has historically developed, lacked the richness of graph structure that is immediately accessible in the KG setting. Consequently, we hypothesize that enriching the negative sampling process with structural information can yield harder negative examples, crucial to learning effective embeddings. Fig. 1 highlights our approach, which requires the construction of the k-hop neighborhood ($\mathbb{K}$) for each node at its first step,

$$\mathbb{K} = S^{+}(A^{k} + A^{k-1}) \tag{2}$$

for $k > 0$, where k is an integer, representing the neighborhood radius, A is the KG's adjacency matrix, and S^{+} is the element-wise sign function set to 1 if a path exists and 0 otherwise.

To construct negatives triplets, we may now simply sample from the nonzero cell of $\mathbb{K}$, which represents a subset of all entities for each node in the KG—i.e. $\mathbb{K} \subset \mathbf{1}^{E \times E}$. Intuitively, SANS exploits the locality of an entity's neighborhood, where negative samples are defined as entities that are not directly linked under a relation r but can be accessed through a path of at most length k. We argue that such local negatives are harder to distinguish and lead to higher scores as evaluated by the embedding model. One important technical detail in constructing $\mathbb{K}$ is the existence of multiple relation types, which requires an additional dimension to represent the graph connectivity as adjacency and k-hop tensors.

3.1 Variants of SANS

Although SANS requires a one-time preprocessing step to construct $\mathbb{K}$ as defined in Eqn. 2, this may still be costly for large and dense KGs. To combat this inefficiency, we introduce *RW-SANS* in Alg. 1, which uses ω random walks (Perozzi et al., 2014) of length k in the adjacency tensor to approximate the k-hop neighborhood.

As SANS constructs a local neighborhood from which negative samples are drawn, it can also be combined with other negative sampling approaches. In this work, we extend the Self-Adversarial approach in (Sun et al., 2019) and combine it with SANS by restricting the negative triplet candidate set to the k-hop neighborhood. In the subsequent sections, we refer to this technique as *Self-Adversarial (Self-Adv.) SANS*, whereas the former approach is referred to as *Uniform SANS*.

Algorithm 1 Approximating the k-hop Neighborhood Using Random Walks

```
Input: $A, R, k, \omega$ {A}: adjacency tensor, R: set of relation types, k: # of $k$-hops, $\omega$: # of random walks
$K \leftarrow$ sparseTensor($|A| \times |R| \times |A|$)
for all entity $e$ do
    $K[e] \leftarrow$ randomWalk(k, $\omega$)
end for
return $K$
```

4 Experiments

We investigate the application of SANS-based negatives to train KG embedding models based on the TransE, DistMult, and RotatE models for the task of KG completion*. We evaluate our proposed approach on standard benchmarks, consisting of FB15K-237 (Bollacker et al., 2008), WN18 and WN18RR (Miller, 1995). From our experiments we seek to answer the following questions:

(Q1) Hard Negatives: Can we sample hard negatives purely using graph structure?

(Q2) Can we combine graph structure with other SOTA negative samplers?

(Q3) Can we effectively approximate the adjacency tensor with random walks?

In our experiments, we rely on three representative baselines, namely uniform negative sampling (Bordes et al., 2013), KBGAN (Cai and Wang, 2018), and NSCaching (Zhang et al., 2019). We also compare with the current SOTA approach in Self-Adversarial negative sampling (Sun et al., 2019), and we test whether local graph structure can also be leveraged in this setting.

4.1 Results

We now address the core experimental questions.
Q1:. Table 1 summarizes our main quantitative results where we highlight SANS and RW-SANS. We also compute the difference between the best variant of SANS against the best performing baseline in row Δ. Overall, we find that SANS negatives almost always lead to harder negative samples over Uniform and KBGAN negatives on all three datasets. Furthermore, SANS achieves competitive performance with NSCaching when combined

Table 2: Comparison of the Self-Adversarial negative sampling technique with our Self-Adversarial SANS. **Marked bold*** numbers are the results of the best SANS implementation.

with TransE, and is the second best-performing algorithm when combined with DistMult without requiring additional parameters. We observe average Δ values of 0.0231, -0.0341, and 0.0056 in MRR for TransE, DisMult, and RotateE respectively, which confirm our approach's effectiveness compared to SOTA while remaining computationally efficient.

We also qualitatively investigate the semantic hardness of SANS negatives against negatives generated via uniform sampling. For instance, using the center node "arachnoid" in the WN18RR dataset as an example, the negatives sampled via SANS within a 2-hop neighborhood are "arachnida," "biology," "arthropod," "wolf spider," and "garden spider," while the ones picked by uniform sampling are "diner," "refusal," "landscape," "rise," and "nurser." Clearly, the negatives found via SANS are semantically harder to distinguish, and as a result, they also confirm the importance of incorporating graph structure into negative samplers to aid in 'hard' negative mining. A more detailed qualitative analysis of negative samples—including the effect of varying neighborhood sizes—generated by SANS can be found in C.1.

Q2:. We now combine our approach SANS with Self-Adversarial negative sampling (Sun et al., 2019). Our results are presented in Table 2 under Self-Adv. SANS and Self-Adv. RW-SANS, both of which reweigh the negative triplets as done in (Sun et al., 2019). We observe comparable performance between the two approaches, but crucially this is achieved by mostly considering 0.2% to 9% of the entities in the datasets like in WN18 and WN18RR, as indicated in Table 3. By considering that the partially-filled adjacency tensors improve computational feasibility for requiring less memory and allowing sparse tensor operations to take place, the appeal of incorporating graph structure while choosing negative samples is further highlighted.

k	2	3	4	5
FB15K-237	34	83	97	99
WN18	0.19	0.75	3.22	10.2
WN18RR	0.16	0.65	2.76	8.67

Table 3: Percentage (%) of filled entries in the k-hop adjacency tensor.

Q3:. We now analyze the impact of approximating the local neighborhood using random walks. Fig. 2 depicts the effect of varying the number of random walks (ω) with neighborhoods of different radii and MRR. We report two baselines, one being the performance of uniform sampling, and the other being our best performance achieved by Uniform SANS when combined with TransE, for which the k-hop tensor was explicitly computed. Interestingly, we find that the k-hop tensor can not only be well approximated with 3000 random walks, but RW-SANS beats both baselines. We reconcile this result by noting that certain nodes have a higher probability of being sampled due to sharing a larger number of paths with the center node, resulting in an implicit weighted negative sampling scheme.

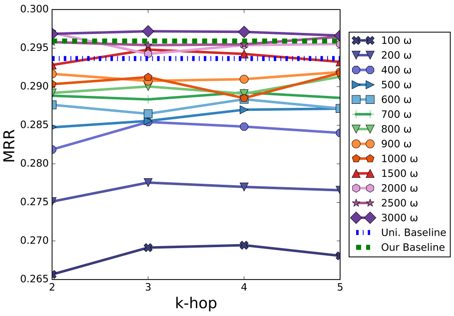

Figure 2: The performance of Uniform RW-SANS with TransE on FB15K-237 using different ω values.

5 Conclusion and Future Directions

In this work, we introduced SANS, a novel negative sampling strategy, which directly leverages information about k-hop neighborhoods to select negative examples. Our work sheds light on the need and importance of incorporating graph structure when designing negative samplers for KGs, and for which SANS can be seen as a cheap yet powerful baseline that requires no additional parameters or difficult optimization. Empirically, we find that SANS-based negatives have comparable performance with SOTA approaches and even outperform previous sophisticated GAN-based approaches.

A Experimental Settings

This section provides an overview of the datasets and evaluation protocols used for obtaining our results.

A.1 Datasets

To conduct experiments for our proposed methods, datasets FB15K-237, WN18, and WN18RR were used. FB15K-237 is a subset of FB15K, which has been derived from the FreeBase Knowledge Base (KB) (Bollacker et al., 2008), a large database that contains general facts about the world with many different relation types. On the other hand, WN18RR is a subset of WN18, which has been derived from the WordNet KB (Miller, 1995), which is a large lexical English database that captures lexical relations—e.g. the super-subordinate relations between words. The WN18 and FB15K were first introduced in (Bordes et al., 2013) and were used in the majority of KG-related researches. In comparison, WN18 and WN18RR contain less relation types than FB15K-237. A summary of the number of entities and relation types corresponding to each of these datasets is provided in Table 4.

Dataset	#entity	#relation
FB15K-237	14,541	237
WN18	40,943	18
WN18RR	40,943	11

Table 4: Dataset Information (Sun et al., 2019).

A.2 Evaluation Protocols

To evaluate our negative sampling approach, we used standard evaluation metrics, consisting of Mean Reciprocal Rank (MRR) and Hits at N (H@N). The train/validation/test split information is provided in Table 5.

Dataset	#training	#validation	#test
FB15K-237	272,115	17,535	20,466
WN18	141,442	5,000	5,000
WN18RR	86,835	3,034	3,134

Table 5: Train/Validation/Test Split Information (Sun et al., 2019).

B Implementation Details

This section of the supplemental goes over the implementation details of our RW-SANS algorithms—i.e. Uniform RW-SANS and Self-Adv. RW-SANS, which use random walks to approximate the k-hop adjacency tensor. Other experimental setups are further detailed herein.

B.1 Hyperparameters

k and ω (for when the k-hop neighborhood is being approximated by Alg. 1) are the hyperparameters in our negative sampling algorithms. To find the optimal hyperparameter values that resulted in the highest performance on the validation set of different datasets, k and ω values in range 2 to 8 and 1000 to 5000 were used respectively during the negative sampling step. In other words, the best performances on the validation sets in our empirical study were found by manual tuning of the hyperparameters. More information about the experimental trials can be found in Table 6, where the total number of trials for training each of the graph embedding models on each dataset is also indicated.

SANS Algorithm	k-range	ω-set	#trials
Uniform/ Self-Adv	2-8	N/A	7
Uniform RW/ Self-Adv RW	2-5	$\{1000, 1500, \ldots, 4500\}$	32

Table 6: Hyperparameter combination sets and number of trials per model.

Additionally, Table 7 lists the hyperparameters with which different graph embedding models were trained to reach their optimal performance on the validation sets.

Hyper-parameter	TransE	DistMult	RotatE
Embedding Dimension	1024	1024	1024
Batch Size	1000	2000	1000
γ	9	200	9
Optimizer	Adam	Adam	Adam
α	5E-05	1E-03	5E-05

Table 7: Graph Embedding Models' Hyperparameters.

B.2 Preprocessing

Building the k-hop neighborhood of the nodes within the KG can be regarded as the preprocessing step, essential to implementing SANS. In this paper, we propose two techniques for doing so, which are:

1. explicit computation of the k-hop neighborhood by manipulating Eqn. 2 while accounting for different relation types and,
2. approximation of the k-hop neighborhood using random walks, as detailed in Alg. 1.

B.3 Infrastructure Settings

The experiments in our study were carried on a server with one NVIDIA V100 GPU, 10 CPU cores, and 46GB RAM.

C Experimental Results

C.1 Qualitative Assessment of Negative Samples

In this section, we assess the semantic meaningfulness of negative samples produced by Uniform SANS and those produced by uniform sampling using the WN18RR dataset. As presented by the

Anchor Node	Candidate Nodes

Table 9: The hyperparameter values associated with the best performance on the validation sets, used for obtaining the test results. The different variations of SANS in this table explicitly compute the k-hop adjacency tensor.

examples given in Table 8, Uniform SANS results in negative examples that are harder to distinguish semantically compared to uniform sampling. We also notice the semantic meaningfulness of SANS-based negatives decline as we increase the size of the k-hop neighbourhood. This observation is indeed expected since as the neighbourhood increases in size (i.e. $k \to \infty$) Uniform SANS will become analogous to uniform sampling.

C.2 SOTA Algorithms

Results for the Uniform and Self-Adversarial algorithms in Table 1 and Table 2 respectively were achieved by re-running the code provided by (Sun et al., 2019) using the hyperparameters they reported for the best performance on the validation set of different datasets. Additionally, the results for KBGAN and NSCaching in Table 1 are the *scratch* results directly taken from (Zhang et al., 2019).

C.3 SANS Algorithms

Table 9 and Table 10 report the performance of the graph embedding models fused with our negative sampling techniques on the validation and test sets with respect to the evaluation metrics. Additionally, they list the hyperparameter values corresponding to Uniform/Self-Adv. SANS and Uniform/Self-Adv. RW-SANS that resulted in the best performance on the validation sets. Based on our out-

Uniform SANS (ours)	$O(\|V\|^3 \log k)$	$O(bn)$	$O(\|V\|^2)$
Self-Adv. SANS (ours)	$O(\|V\|^3 \log k)$	$O(bn + bd)$	$O(\|V\|^2)$
Uniform RW-SANS (ours)	$O(rk\|V\|)$	$O(bn)$	$O(r\|V\|)$
Self-Adv. RW-SANS (ours)	$O(rk\|V\|)$	$O(bn + bd)$	$O(r\|V\|)$

Table 11: Comparison of different negative sampling algorithms in terms of preprocessing, runtime, and space complexities given batch size b, negative sample size n, cache size c, cache extension size e, node set V, edge set E, relation set R, embedding dimension d, hops count k, random walks count r, and GAN parameters count t.

comes, we hypothesize that the usage of random walks in approximating the k-hop neighborhood implicitly results in the removal of nodes with the least number of walks to the center node—i.e. outlier nodes.

D Computational Complexity

Table 11 is representative of the time and space complexities of different negative sampling approaches including SANS.

Neural Mask Generator: Learning to Generate Adaptive Word Maskings for Language Model Adaptation

Minki Kang[1*] **Moonsu Han**[1*] **Sung Ju Hwang**[1,2]

KAIST[1], Daejeon, South Korea

Abstract

We propose a method to automatically generate a domain- and task-adaptive maskings of the given text for self-supervised pre-training, such that we can effectively adapt the language model to a particular target task (e.g. question answering). Specifically, we present a novel reinforcement learning-based framework which learns the masking policy, such that using the generated masks for further pre-training of the target language model helps improve task performance on unseen texts. We use off-policy actor-critic with entropy regularization and experience replay for reinforcement learning, and propose a Transformer-based policy network that can consider the relative importance of words in a given text. We validate our *Neural Mask Generator (NMG)* on several question answering and text classification datasets using BERT and DistilBERT as the language models, on which it outperforms rule-based masking strategies, by automatically learning optimal adaptive maskings. [1]

1 Introduction

The recent success of the *language model pre-training* approaches (Devlin et al., 2019; Peters et al., 2018; Radford et al., 2019; Raffel et al., 2019; Yang et al., 2019), which train language models on diverse text corpora with self-supervised or multi-task learning, have brought up huge performance improvements on several natural language understanding (NLU) tasks (Wang et al., 2019; Rajpurkar et al., 2016). The key to this success is their ability to learn generalizable text embeddings that achieve near optimal performance on diverse tasks with only a few additional steps of fine-tuning on each downstream task.

Most of the existing works on language model aim to obtain a universal language model that can address nearly the entire set of available natural language tasks on heterogeneous domains. Although this train-once and use-anywhere approach has been shown to be helpful for various natural language tasks (Devlin et al., 2019; Radford et al., 2019; Dong et al., 2019; Raffel et al., 2019), there have been considerable needs on adapting the learned language models to domain-specific corpora (e.g. healthcare or legal). Such domains may contain new entities that are not included in the common text corpora, and may contain only a small amount of labeled data as obtaining annotation on them may require expert knowledge. Some recent works (Sun et al., 2019a; Lee et al., 2019; Beltagy et al., 2019; Gururangan et al., 2020) suggest to further pre-train the language model with self-supervised tasks on the domain-specific text corpus for adaptation, and show that it yields improved performance on tasks from the target domain.

Masked Language Models (MLMs) objective in BERT (Devlin et al., 2019) has shown to be effective for the language model to learn the knowledge of the language in a bi-directional manner (Vaswani et al., 2017). In general, masks in MLMs are sampled at random (Devlin et al., 2019; Liu et al., 2019c), which seems reasonable for learning a generic language model pre-trained from scratch, since it needs to learn about as many words in the vocabulary as possible in diverse contexts.

However, in the case of further pre-training of the already pre-trained language model, such a conventional selection method may lead a domain adaptation in an inefficient way, since not all words will be equally important for the target task. Repeatedly learning for uninformative instances thus will be wasteful. Instead, as done with instance selection (Ngiam et al., 2018; Jiang et al., 2018; Yoon et al., 2019; Zhu et al., 2019), it will be more effective if the masks focus on the most important words for the target domain, and for the specific

---

[*] Equal contribution.

NLU task at hands. How can we then *obtain* such a masking strategy to train the MLMs?

Several works (Joshi et al., 2019; Sun et al., 2019b,c; Glass et al., 2019) propose rule-based masking strategies which work better than random masking (Devlin et al., 2019) when applied to language model pre-training from scratch. Based on those works, we assume that adaptation of the pre-trained language model can be improved via a *learned* masking policy which selects the words to mask. Yet, existing models are inevitably suboptimal since they do not consider the target domain and the task. To overcome this limitation, in this work, we propose to adaptively generate mask by learning the optimal masking policy for the given task, for the task-adaptive pre-training (Gururangan et al., 2020) of the language model.

As described in Figure 1, we want to further pre-train the language model on a specific task with a task-dependent masking policy, such that it directs the solution to the set of parameters that can better adapt to the target domain, while task-agnostic random policy leads the model to an arbitrary solution. To tackle this problem, we pose the given learning problem as a meta-learning problem where we learn the task-adaptive mask-generating policy, such that the model learned with the masking strategy obtains high accuracy on the target task. We refer to this meta-learner as the **N**eural **M**ask **G**enerator (NMG). Specifically, we formulate mask learning as a bi-level problem where we pre-train and fine-tune a target language model in the inner loop, and learn the NMG at the outer loop, and solve it using renforcement learning. We validate our method on diverse NLU tasks, including question answering and text classification. The results show that the models trained using our NMG outperforms the models pre-trained using rule-based masking strategies, as well as finds a proper adaptive masking strategy for each domain and task.

Our contribution is threefold:

- We propose to learn the mask generating policy for further pre-training of masked language models, to obtain optimal maskings that focus on the most important words for the given text domain and the NLU task.

- We formulate the problem of learning the task-adaptive mask generating policy as a bi-level meta-learning framework which learns the LM in the inner loop, and the mask generator at the outer loop using reinforcement learning.

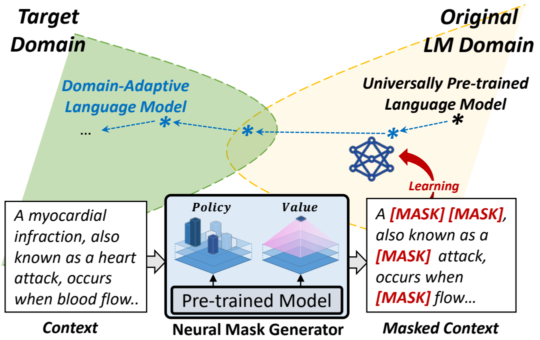

Figure 1: **Concept.** Pre-training on domain text leads the language model parameters to adapt to the given target domain. We assume that adjusting the masking policy of the MLM objective affects the training trajectory of the language model, such that it moves towards a better solution space for the target domain. This illustration of the solution spaces for the two domains is motivated by (Gururangan et al., 2020).

- We validate our mask generator on diverse tasks across various domains, and show that it outperforms heuristic masking strategies by learning an optimal task-adaptive masking for each LM and domain. We also perform empirical studies on various heuristic masking strategies on the language model adaptation.

2 Related Work

Language Model Pre-training Ever since Howard and Ruder (2018) suggested language model pre-training with multi-task learning, inspired by the success of fine-tuning on ImageNet pre-trained models on computer vision tasks (Liu et al., 2019b), research on the representation learning for natural language understanding tasks have focused on obtaining a global language model that can generalize to any NLU tasks. A popular approach is to use self-supervised pre-training tasks for learning the contextualized embedding from large unannotated text corpora using auto-regressive (Peters et al., 2018; Yang et al., 2019) or auto-encoding (Devlin et al., 2019; Liu et al., 2019c) language modeling. Following the success of the Masked Language Model (MLM) from (Devlin et al., 2019; Liu et al., 2019c), several works have proposed different model architecture (Lan et al., 2019; Raffel et al., 2019; Clark et al., 2020) and pre-training objectives (Sun et al., 2019b,c; Liu et al., 2019c; Joshi et al., 2019; Glass et al., 2019; Dong et al., 2019), to improve upon its performance. Some works have also proposed alternative masking policies for the MLM pre-training over random sampling, such as SpanBERT (Joshi et al., 2019) and ERNIE (Sun et al., 2019b). Yet, none of the existing approaches have tried to *learn* the task-adaptive mask in a context-dependent manner which is the problem we target in this work.

Language Model Adaptation Pre-training the language model on the target domain, then fine-tuning on downstream tasks, is the most simple yet successful approach for adapting the language model to a specific task. Some studies (Lee et al., 2019; Beltagy et al., 2019; Whang et al., 2019) have shown the advantage of further pre-training the language model on a large unlabeled text corpus collected from a specific domain. Moreover, Sun et al. (2019a) and Han and Eisenstein (2019) investigate the effectiveness of further pre-training of the language model on small domain-related text corpora. Recently, Gururangan et al. (2020) integrates prior works and defines domain-adaptive pre-training and task-adaptive pre-training, showing that domain adaptation of the language model can be done with additional pre-training with the MLM objective on a domain-related text corpus, as well as a smaller but directly task-relevant text corpus.

Meta-Learning Meta-learning (Thrun and Pratt, 1998) aims to train the model to generalize over a distribution of tasks, such that it can generalize to an unseen task. There exist large number of different approaches to train the meta-learner (Santoro et al., 2016; Vinyals et al., 2016; Ravi and Larochelle, 2017; Finn et al., 2017; Liu et al., 2019a). However, existing meta-learning approaches do not scale well to the training of large models such as masked language models. Thus, instead of the existing meta-learning method such a gradient based approach, we formulate the problem as a bi-level problem (Franceschi et al., 2018) of learning the language model in the inner loop and the mask at the outer loop, and solve it using reinforcement learning. Such optimization of the outer objective using RL is similar to the formulation used in previous works on neural architecture search (Zoph and Le, 2017; Zoph et al., 2018).

3 Problem Statement

We now describe how to formulate the problem of *learning to generate masks* for the Masked Language Model (MLM) as a bi-level optimization problem. Then, we describe how we can reformulate it as a reinforcement learning problem.

3.1 Masked Language Model

For pre-training of the language models, we need an unannotated text corpus $\boldsymbol{S} = \{s^{(1)}, \cdots, s^{(T)}\}$. Here the $s = [w_1, w_2, \cdots, w_N]$ is the context, whose element $\boldsymbol{w}_i \in s$ is a single word or token. To formulate the meta-learning objective, we assume each context corpus as the part of the task $\mathcal{T} = \{\boldsymbol{S}, D_{tr}, D_{te}\}$ consisting of the context and its corresponding task dataset. For the MLM, we need to generate a noisy version of s, which we denote as $\hat{s}$. Let z_i be the indicator of masking i-th word of s. If $z_i = 1$, i-th word is replaced with the [MASK] token. The objective of the MLM then is to predict the original token of each [MASK] token. Therefore, we can formulate this problem as follows:

$$\min_{\theta} \mathcal{L}_{MLM}(\theta; \boldsymbol{S}, \hat{\mathbf{S}}) = \sum_{s, \hat{s} \in \boldsymbol{S}, \hat{\mathbf{S}}} -\log p_\theta(\bar{s}|\hat{s})$$

where θ is the parameter of the language model and $\bar{s}$ is the original tokens of each [MASK] token, and $\hat{\mathbf{S}}$ is the set of masked contexts. Following the formulation from (Yang et al., 2019), we can approximate the MLM objective with z_i as follows:

$$\max_{\theta} \log p_\theta(\bar{s}|\hat{s}) \approx \sum_{i=1}^{N} z_i \log p_\theta(w_i|\hat{s}) \quad (1)$$

$$p_\theta(w_i|\hat{s}) = \frac{\exp(H_\theta(\hat{s})_i^\top e(w_i))}{\sum_{w'} \exp(H_\theta(\hat{s})_i^\top e(w'))}$$

where $H_\theta(\hat{s})$ indicates the contextualized representation of $\hat{s}$ from the language model layer (e.g. Pre-trained Transformer layers in (Devlin et al., 2019)), and $e(w_i)$ denotes the embedding of word w_i from the last prediction layer. Our objective then is to learn the optimal policy for determining each mask indicator z_i, which we will describe in detail in the next subsection.

3.2 Bi-level formulation

We now describe how to formulate this learning problem as a bi-level problem consisting of inner and outer level objectives. Consider that z_i can be represented using an arbitrary function $\mathcal{F}$ parameterized with λ:

$$\pi_\lambda(a_t = i|s) = \mathcal{F}_\lambda(w_i) \quad (2)$$

$$\mathbf{a}_\lambda = \arg\max_{a} \prod_{t} \pi_\lambda(a_t|s) \quad (3)$$

$$z_{\lambda,i} = \begin{cases} 1, & \text{if } i \in \mathbf{a}_\lambda \\ 0, & \text{if } i \notin \mathbf{a}_\lambda \end{cases} \quad (4)$$

where $\pi_\lambda(a_t = i|s)$ is the probability of masking i-th word w_i from s, and a_λ indicates the list of word indices to be masked and $z_{\lambda,i}$ is the mask indicator parameterized by the parameter λ. The details of corresponding equations will be described in section 3.3. Therefore, the MLM objective has been slightly changed from its original form, into the following objective:

$$\begin{aligned}\theta(\lambda) &= \arg\min_{\theta} \mathcal{L}_{MLM}(\theta, \lambda; \boldsymbol{S}, \hat{\mathbf{S}}) \\ &= \arg\max_{\theta} \sum_{s\in\boldsymbol{S}} \log p_{\theta}(\bar{s}|\hat{s}) \\ &\approx \arg\max_{\theta} \sum_{s\in\boldsymbol{S}} \sum_{i=1}^{N} z_{\lambda,i} \log p_{\theta}(w_i|\hat{s})\end{aligned} \tag{5}$$

where the masked context $\hat{s}$ is parameterized by the parameter λ. Now assume that we have found the optimal parameter $\theta(\lambda)$ for language model from equation 5. Then, we need to fine-tune the language model on the downstream task. Although linear heads used in both pre-training and fine-tuning are different, we describe the parameter of both models as $\theta(\lambda)$ for simplicity. Following the bi-level framework notation described in (Franceschi et al., 2018), the inner objective function for fine-tuning can be written as follows:

$$\min_{\theta(\lambda)} \mathcal{L}_{train}(\theta(\lambda), \lambda) = \sum_{(x,y)\in D_{tr}} l(g_{\theta(\lambda)}(x), y) \tag{6}$$

where D_{tr} is a training dataset, l is the loss function of the supervised learning, and $g_{\theta(\lambda)}$ is the function representation of downstream task solver model. In case of question answering task, each x consists of a context and corresponding question and y is the corresponding answer spans.

Assume that we find optimal parameter $\theta^*(\lambda)$ from supervised task fine-tuning. Then, the final outer-level objective can be described as follows:

$$\begin{aligned}&\min_{\lambda} \mathcal{L}_{test}(\lambda, \theta^*(\lambda)) = \sum_{(x,y)\in D_{te}} l(g_{\theta^*(\lambda)}(x), y) \\ &\quad s.t. \quad \theta^*(\lambda) = \arg\min_{\theta(\lambda)} \mathcal{L}_{train}(\theta(\lambda), \lambda) \\ &\quad and \quad \theta(\lambda) = \arg\min_{\theta} \mathcal{L}_{MLM}(\theta, \lambda)\end{aligned} \tag{7}$$

This will allow us to obtain the optimal parameter λ^* which minimizes the task objective function on a test dataset D_{te}.

Although the outer objective is differentiable, we formulate the optimization problem of the outer objective as a reinforcement learning problem to avoid excessive computation cost caused by the two constraint terms.

Justification of Reinforcement Learning In this paragraph, we explain why we use the Reinforcement Learning (RL) instead of the differentiable method to train the parameter λ. As indicated in the equation 7, our inner loop includes consecutive two steps of language model training. The NMG model λ is addressed to the pre-training step rather than the task fine-tuning step. Therefore, the direct differentiation of the outer objective contains two second-derivative terms for both the MLM loss $\mathcal{L}_{MLM}$ and the task train loss $\mathcal{L}_{train}$. With a single-step approximation, the derivative of the outer objective is approximated as follows:

$$\begin{aligned}&\nabla_{\lambda}\mathcal{L}_{test}(\lambda, \theta^*(\lambda)) \\ &\approx \nabla_{\lambda}\mathcal{L}_{test}(\lambda, \tilde{\theta}^*(\lambda)) \\ &- \alpha\nabla^2_{\lambda,\theta}\mathcal{L}_{MLM}(\theta,\lambda)\nabla_{\theta}\mathcal{L}_{test}(\tilde{\theta}^*(\lambda), \lambda) \\ &- \beta\nabla^2_{\lambda,\tilde{\theta}(\lambda)}\mathcal{L}_{train}(\tilde{\theta}(\lambda), \lambda)\nabla_{\tilde{\theta}(\lambda)}\mathcal{L}_{test}(\tilde{\theta}(\lambda), \lambda)\end{aligned}$$

where $\tilde{\theta}(\lambda) = \theta - \alpha\nabla_{\theta}\mathcal{L}_{MLM}(\theta,\lambda), \tilde{\theta}^*(\lambda) = \tilde{\theta}(\lambda) - \beta\nabla_{\tilde{\theta}(\lambda)}\mathcal{L}_{train}(\tilde{\theta}(\lambda), \lambda)$ are approximated parameters, and α, β are learning rates. Such gradient estimation requires high computational costs since it includes the computation of Hessian-product vectors of the massive language model's parameters approximated as 110 millions (Finn et al., 2017; Devlin et al., 2019).

Instead, we can address the first-order approximation ($\alpha = 0, \beta = 0$) to the derivative of the outer objective to avoid second-order derivative computation as follows:

$$\nabla_{\lambda}\mathcal{L}_{test}(\lambda, \theta^*(\lambda)) \approx \nabla_{\lambda}\mathcal{L}_{test}(\theta)$$

where $\theta^*(\lambda)$ is approximated to θ. Such approximation trivially results in a meaningless optimization since it ignores the pre-training step induced by the parameter λ, which decides the masking policy (Liu et al., 2019a). Therefore, we approach solving this optimization problem with RL instead of the differential method to avoid such an issue. In the next section, we introduce how we formulate this problem as the RL with the outer objective as a non-differentiable reward.

3.3 Reinforcement learning formulation

We now propose a reinforcement learning (RL) framework, which given the context s as the state, decides on the actions $\mathbf{a} = \{a_1, \cdots, a_T\}$ where T is the number of masked tokens in the given context, each $a_t \in [1, N]$ is the token index that indicates a decision on masking the token w_{a_t} following equation 4, and $a_1 \neq a_2 \neq \cdots \neq a_T$. The objective of the RL agent then is to find an optimal masking policy that minimizes $E(\lambda, \theta)$ from the section 3.2. In addition, minimizing $E(\lambda, \theta)$ on D_{te} can be seen as maximizing its performance. Therefore, the objective is the maximization of the performance of the model on D_{te}. We can induce it by setting the reward R as the accuracy improvement on D_{te}. We will describe the detail of the reward design in section 4.

In general RL formulation (Sutton and Barto, 2018) following Markov Decision Process (MDP), state transition probability can be described as $p(s_{t+1}|s_t, a_t)$. The probability of masking T tokens is formulized as $p(\hat{s}|s) = \prod_{t=1}^{T} p(s_{t+1}|s_t, a_t)$, where $\hat{s}$ consists of T number of [MASK] tokens. Although the representation of s_t and s_{t+1} are slightly different because of the addition of [MASK] token, we can approximate them as $s_t \approx s_{t+1}$ following the approximation in equation 1, which inductively approximates representations after each word masking as a representation of original context.

Therefore, we can approximate the probability of masking T tokens from the MDP problem to the problem without state-transition formulation as follows:

$$p(\hat{s}|s) = \prod_{t=1}^{T} p(s_{t+1}|s_t, a_t) \approx \prod_{t=1}^{T} \pi(a_t|s)$$

where a_t denotes the index of masked word included in the context s and $\pi(\cdot|s)$ is the masking policy of the agent. By this approximation, we do not need to consider the trajectory along the temporal horizon, which makes the problem much easier. Instead, we approximate the problem as the task of selecting multiple discrete actions simultaneously for the same state. We approximate the policy with neural network parameterized by λ as $\pi_\lambda(a|s)$. As in equations 3 and 4, the mask $z_{\lambda,i}$ is determined by actions generated from the neural policy $\pi_\lambda(a|s)$. In the next section, we will describe how to train the Neural Mask Generator to generate the neural policy $\pi_\lambda(a|s)$ maximizing the reward R using RL in Section 4.

4 Neural Mask Generator

In this section, we describe our model, *Neural Mask Generator (NMG)*, which learns the masking policy to generate an optimal mask on an unseen context using deep RL with the detailed descriptions of the framework setup. The overview of the meta mask generator framework is shown in Figure 2. For detailed descriptions of the approaches, the procedures of both training and test phase, and algorithm, please **see Appendix A**.

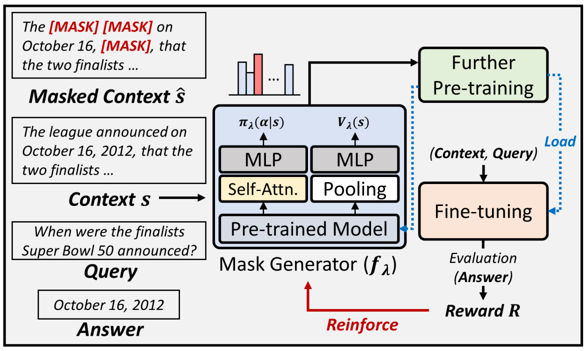

Figure 2: The overview of the meta-training framework for our Neural Mask Generator (NMG). In each episode, masked contexts by the NMG are used for further pre-training. Then, the further pre-trained language model is used in both the mask generator and fine-tuning.

4.1 Reinforcement Learning Details

Model Architecture The probability of selecting i-th word w_i of s as t-th action a_t can be described as $\pi_\lambda(a_t = i|s)$, where $\sum_i \pi_\lambda(a_t = i|s) = 1$. Instead of $\mathcal{F}_\lambda$ in equation 2, the neural policy from the NMG is given as follows:

$$\pi_\lambda(a_t = i|s) = \frac{\exp(f_\lambda(H_{\theta'}(s)_i))}{\sum_t \exp(f_\lambda(H_{\theta'}(s)_t))}$$

where f_λ is a deep neural network parameterized by λ, which has a self-attention layer (Vaswani et al., 2017) followed by linear layers with gelu activation (Hendrycks and Gimpel, 2016), and $H_{\theta'}(s)_i$ is the contextualized representation of w_i of context s from the frozen language model layer θ'. Note that θ' is shared with the target language model θ and not trained during the NMG training. Further, $f_\lambda(H_{\theta'}(s)_i)$ outputs the scalar logit of the w_i, and the final probabilistic policy is computed by the softmax function.

Training Objective We train the NMG model using the Advantage Actor-Critic method (Mnih et al., 2016) with the value estimator. Furthermore, we resort to off-policy learning (Degris et al., 2012) such that the agent can explore the optimal policy based on its past experiences. To this end, we leverage a prioritized experience replay, in which we store every state, action, reward, and old-policy pairs (Mnih et al., 2013), and sample them based on their absolute value of the advantage (Schaul et al., 2016). We use importance sampling to estimate the value of the target policy π_λ with the samples from the behavior policy $\pi_{\lambda_{old}}$, which are sampled from the replay buffer (Degris et al., 2012; Schulman et al., 2015, 2017; Wang et al., 2017). To sum up, the objectives for both policy and value network are as follows:

$$\mathcal{L}_{policy} = \sum_{(s,a,R,\pi_{\lambda_{old}})} -\frac{\pi_\lambda(a|s)}{\pi_{\lambda_{old}}(a|s)}(R - V_\lambda(s)) - \alpha\,\mathcal{H}(\pi_\lambda(a|s)) \tag{8}$$

$$\mathcal{L}_{value} = \sum_{(s,a,R,\pi_{\lambda_{old}})} \frac{1}{2}(R - V_\lambda(s))^2 \tag{9}$$

where the $(s, a, R, \pi_{\lambda_{old}})$ is set of sampled replays from the replay buffer, $\mathcal{H}$ is an entropy function $\mathcal{H}(\pi_\lambda(a|s)) = -\sum_t \pi_\lambda(a_t|s) \log \pi_\lambda(a_t|s)$, and α is a hyperparameter for entropy regularization. $V_\lambda(s)$ is an estimated value of the state s. The value network consists of linear layers with activation function after mean pooling $\frac{1}{N}\sum_t H_{\theta'}(s)_t$.

To summarize, the outer-level objective for updating the NMG parameter λ can be written as follows:

$$\min_\lambda \mathcal{L}_{policy} + \mathcal{L}_{value} \tag{10}$$

At each episode of meta-training, we update the NMG parameter λ by optimizing the above objective function.

Reward Design and Self-Play As in Section 3.3, the reward function is considered as the accuracy improvement on the test set D_{te}. Therefore, the pre-training step (equation 5) and the fine-tuning then evaluation step (equation 6, 7) should be done to get the reward in every episodes.

Since using the full size of dataset in the inner loop is generally not feasible, we randomly sample smaller sub-task $\mathcal{T}' = \{\boldsymbol{S}', D'_{tr}, D_{val}\}$ from $\mathcal{T}$ at every episode. For the evaluation, we randomly split the training set D_{tr} to generate a hold-out validation set D_{val} and replace D_{te} in equation 7 to D_{val} while meta-training where D_{te} is unobservable. We use a sufficiently large hold-out validation set D_{val} to prevent the masking policy from overfitting to D_{val}. We assume that the meta-learner NMG also performs well on $\mathcal{T}$ if it is trained on diverse sub-tasks $\mathcal{T}'$ where $|\mathcal{T}| \gg |\mathcal{T}'|$.

The problem to be considered for using diverse sub-tasks is that the NMG model encounters different sub-task $\mathcal{T}'$ at every new episode. Since $\mathcal{T}'$ determines the state distribution $\boldsymbol{S}'$ and the data D_{tr} to be trained, it results in the reward scale problem that the expectation of the validation accuracy on D_{val} varies depending on the composition of $\mathcal{T}'$ then makes it harder to evaluate the performance increment of the neural policy across episodes.

To address this problem, we introduce the random policy as an opponent policy to evaluate the neural policy relative to it. Therefore, the reward R is defined as $sgn(r - b)$, where sgn is the sign function, r and b are the accuracy score on D_{val} from neural and random policy respectively. However, the random policy may be too weak as the opponent. To overcome this limitation, we add another neural policy as an additional opponent to induce the zero-sum game of two learning agent by the concept of the self-play algorithm (Wei et al., 2017; Grau-Moya et al., 2018).

Then, three distinct policies are compared with each other during episodes and two neural policies are individually trained. Furthermore, in each neural agent training, only actions corresponding to disjoint comparing with others are stored in a global replay buffer for a more accurate reward assignment of each action.

Continual Adaptive Learning For fair comparison at every episode, the same language model should be used to evaluate the policy. Initializing the language model before the start of each inner loop can be the simplest choice to handle this. However, since we pre-train the language model for only few steps during each episode of meta-training, the model is always evaluated around the original language model domain (see Figure 1). To avoid this, at each episode, the language model which is pre-trained by the NMG model of former step is continually loaded instead of the fixed checkpoint except for the first episode. By this, we intend that our agent learns the optimal policy of various environments. Furthermore, the agent can learn dynamic policy based on the learned degree of the target language model.

5 Experiment

We now experimentally validate our Neural Mask Generator (NMG) model on multiple NLU tasks, including question answering and text classification tasks using two different language models, and analyze its behaviors. In Section 5.1, we evaluate the NMG with several baselines. Then, we evaluate the effect of the specific design choices made for our model through ablation studies in Section 5.2.

Finally, we analyze how the policy learned by the NMG model works in Section 5.3.

Tasks and Datasets For question answering, we use three datasets, namely SQuAD v1.1 (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017), and emrQA (Pampari et al., 2018) to validate our model. We use the MRQA[2] version for both SQuAD and NewsQA to sustain a coherency. We also preprocess emrQA to fit the format of other datasets. We use a standard evaluation metric named Exact-Matchs (EM) and F1 score for question answering task. For text classification, we use IMDb (Maas et al., 2011) and ChemProt (Kringelum et al., 2016), following the experimental settings of (Gururangan et al., 2020).

Baselines According to Devlin et al. (2019) and Joshi et al. (2019), training the language models with difficult objectives is much more beneficial when pre-training from scratch. To test whether it is also the case for task-adaptive pre-training, we experiment with two heuristic masking strategies, which we refer to as whole-random and span-random. In addition, we also tested the named entity masking proposed by Sun et al. (2019b) (entity-random). Below is the complete list of the heuristic baselines we compare against in the experiments.

1) No-PT A baseline without any further pre-training of the language model.

2) Random A random masking strategy introduced in BERT (Devlin et al., 2019).

3) Whole-Random A random masking strategy which masks the entire word instead of the token (sub-word). This method is introduced by the authors of BERT (Devlin et al., 2019)[3].

4) Span-Random A random masking strategy which selects multiple consecutive tokens.

5) Entity-Random A random masking strategy which selects named entities with highest priorities, then randomly selects other tokens.

6) Punctuation-Random A random masking strategy which selects punctuation tokens first, then randomly selects other tokens.

Implementation Details For the language model θ, we use the same hyperparameters and architecture with DistilBERT (Sanh et al., 2019) model (66M params) and BERT$_{BASE}$ (Devlin et al., 2019) model (110M params). Our implementation is based on the huggingface's Pytorch implementation version (Wolf et al., 2019; Paszke et al., 2019). We load the pre-trained parameters from the checkpoint of each language model in meta-testing and the first episode of meta-training. As for the text corpus S to pre-train the language model, we use the collection of contexts from the given NLU task. We only use the Masked Language Model (MLM) objective for further pre-training. In the initial stage of meta-training, the NMG randomly selects actions for exploration. In meta-testing, it takes maximum probability indices as actions. We describe the details of language model training in **Appendix B** since we use different settings for each task and experiments. As for reinforcement learning (RL), we use the off-policy actor-critic method described in Section 4. For more details of the reinforcement learning framework, please **see Appendix B**.

5.1 Results

First of all, we need to discuss how the MLM works on the language model pre-training. In practice, the Cloze task (Taylor, 1953) benefits when words that need to learn are masked. However, for the MLM, we observed that the masking prevents learning the masked words in the language model. Rather the MLM learns representations and relations between non-masked words by predicting the masked words using them. In the case of adaptive pre-training, learning the domain-specific vocabulary is crucial for the domain adaptation. Therefore, masking out trivial words (e.g. Punctuations) may be more beneficial than masking out unique words (e.g. Named Entities) for the language model to learn the knowledge of a new domain. To see how it works, we experiment for punctuation-random, which masks only the punctuations, which are clearly useless for the domain adaptation.

In Table 1 and 2, we report the performance of baselines and our model on both question answering and text classification tasks. From the baseline results of Table 1, we speculate on the important aspects of a masking strategy for better adaptation. The whole-word, span and entity maskings often lead to better results since it makes the MLM objective more difficult and meaningful (Joshi et al., 2019; Sun et al., 2019b). For instance, in emrQA, most words are tokenized to sub-words since contexts include a lot of unique words such as medical terminologies. Therefore, whole-word masking could be most suitable for domain adaptation on

emrQA. In contrast, such maskings sometimes lead to worse results than random masking on some domains such as in NewsQA. Especially, in the case of DistilBERT, punctuation masking performs better than others. These result suggests that masking complicated words is rather disturbing for the adaptation of small language model.

On the other hand, our NMG learns the optimal masking policy for a given task and domain in an adaptive manner on any language model. In Table 1 and 2, we can see that this adaptive characteristic of our model makes the neural masking results in better or at least comparable performances to the baselines for all tasks. We further analyze the learned masking strategy in Section 5.3.

5.2 Ablation study

Effectiveness of Self-Play We further investigate the effectiveness of self-play by comparing it with the NMG model without self-play, where the model only competes with the random agent. We validate this on the NewsQA dataset. The result in Table 3 shows that the NMG model with self-play obtains better performance than its counterpart without self-play. This result verifies that competing with the opponent neural agent while learning helps the NMG model to learn better policy.

Continual Adaptation We also perform an ablation study of the continual adaptation learning. The result in Table 3 shows that the continual-adaptive masking strategy is significantly effective for the language model adaptation. The result suggests that helpful words for the language model to learn depends on the adaptation degree of it.

5.3 Analysis

Masked Word Statistics To analyze how our model performs, we measure the difference between which kind of word token is masked by both the random and neural policy on the pre-trained checkpoint. For qualitative analysis, we provide examples of masked tokens on the context in Figure 3. As shown in Figure 3, NMG tends to mask highly informative words such as *seminary* or *islam*, which are parts of the answer spans. Furthermore, we analyze the masking behavior of our NMG by performing Part-of-Speech (POS) tagging on the masked words using spaCy[4]. Figure 4 shows

the six most frequent tags for the words masked out by the random and neural policy. Figure 4 shows that the neural policy masks more words in noun, verb, and proper noun tags than the random policy, suggesting that our NMG model learns that masking such informative words is beneficial to adapt on the NewsQA task with the BERT$_{BASE}$ model as a language model.

Learning Curves As already known, the RL-based methods often suffer from the instability problem. Therefore, we further analyze the learning curves of the NMG training in this section. In Figure 5, we plot three kinds of learning curves to show the detailed training process. *Cumulative Regret* indicates how many times the neural agent is defeated against the random agent until certain episodes. The grey plot indicates the worst case that the random agent always defeats against the neural agent. *Entropy* indicates the average entropy of policy for states given in a certain episode. Lower entropy means that the policy has a high probability of a few significant actions. *Loss* indicates the RL loss described in the equation 10. We ignore outliers in the loss plot for brevity.

From the entropy and loss plots, we can notice that the policy converges as learning proceeds. However, it seems that such convergence is not continually sustained. From the cumulative regret plot, we can observe that the neural policy still often loses against the random policy, although it is trained for a while. Such instability may come from the difficulty of the exact credit assignment on each action. Otherwise, continuous change of state distribution from the continual adaptive learning may hinder the neural policy's convergence.

Even if the NMG shows the notable results, there is room for improvement on RL in terms of efficiency and stability. We leave it as the future work.

6 Conclusion

We proposed a novel framework which automatically generates an adaptive masking for masked language models based on the given context, for language model adaptation to low-resource domains. To this end, we proposed the *Neural Mask Generator (NMG)*, which is trained with reinforcement learning to mask out words that are helpful for domain adaptation. We performed an empirical study of various rule-based masking strategies on multiple datasets for question answering and text classification tasks, which shows that the optimal masking strategy depends on both the language model and the domain. We then validated NMG against rule-based masking strategies, and the results show that it either outperforms, or obtains comparable performance to the best heuristic. Further qualitative analysis suggests that such good performance comes from its ability to adaptively mask meaningful words for the given task.

A Algorithms

We provide the pseudocode of algorithm for meta-training of the Neural Mask Generator (NMG).

In the case of meta-testing, *InnerLoop* with the full task $\mathcal{T}$, pre-trained language model checkpoint θ, and trained policy π_λ as inputs can be considered as the meta-testing algorithm.

Algorithm 1 NMG Training Algorithm

```
Initialize random policy $\psi \sim Uniform$
Initialize two neural agents $\lambda, \lambda^{op}$ for Self-Play
Initialize replay buffer $\mathcal{D}, \mathcal{D}^{op}$
Arbitrarily split $D_{tr} \rightarrow D_{tr}, D_{val}$
Load pre-trained language model $\theta$
while not done do
    Randomly Sample $\mathcal{T}'$ from $\mathcal{T}$
    $r_\psi, \mathcal{E}_\psi, \theta(\psi) = InnerLoop(\mathcal{T}', \theta, \psi)$
    $r_{op}, \mathcal{E}_{\lambda^{op}}, \theta(\lambda^{op}) = InnerLoop(\mathcal{T}', \theta, \pi_{\lambda^{op}})$
    $r, \mathcal{E}_\lambda, \theta(\lambda) = InnerLoop(\mathcal{T}', \theta, \pi_\lambda)$
    $\mathcal{A}^{op} \leftarrow \mathcal{E}_\psi, r_\psi, \mathcal{E}, r, \mathcal{E}_{op}, r_{op}$
    $\mathcal{D}^{op}, \lambda^{op} \leftarrow OuterLoop(\mathcal{D}^{op}, \mathcal{A}^{op}, \lambda^{op})$
    $\mathcal{A} \leftarrow \mathcal{E}_\psi, r_\psi, \mathcal{E}_{op}, r_{op}, \mathcal{E}, r$
    $\mathcal{D}, \lambda \leftarrow OuterLoop(\mathcal{D}, \mathcal{A}, \lambda)$
    $\theta \leftarrow \theta(\lambda)$
end while
```

Algorithm 2 InnerLoop

```
Input:
    Task $\mathcal{T}$, LM $\theta$, Policy $\pi$
Output:
    Episode buffer $\mathcal{E}$, Accuracy $r$, LM $\theta(\lambda)$
Initialize episode buffer $\mathcal{E}$
$\hat{\mathbf{S}} = \{\}, \boldsymbol{S}, D_{tr}, D_{val} \leftarrow \mathcal{T}$
for $s$ in $\boldsymbol{S}$ do
    Masking $s$ following equation 3, 4
    $\hat{\mathbf{S}} \leftarrow \hat{\mathbf{S}} \cup \hat{s}, \mathcal{E} \leftarrow \mathcal{E} \cup (s, a, \pi)$
end for
# Actually, below two updates are done with mini-batch optimization with multiple steps
$\theta(\lambda) \leftarrow \theta - \nabla_\theta \mathcal{L}_{MLM}(\theta, \lambda; \boldsymbol{S}, \hat{\mathbf{S}})$
$\theta^*(\lambda) \leftarrow \theta(\lambda) - \nabla_{\theta(\lambda)} \mathcal{L}_{train}(\theta(\lambda), \lambda; D_{tr})$
Evaluate $\theta$ on $D_{val}$ and acquire $r$
```

B Hyperparameters

B.1 Reinforcement Learning (Outer Loop)

We describe detailed hyperparameters in Table 4 for reinforcement learning (RL). We use the prioritized experience replay (Schaul et al., 2016) with

Algorithm 3 OuterLoop

```
Input:
    $\mathcal{D}$, $\mathcal{E}_{\psi}$, $r_{\psi}$, $\mathcal{E}_{op}$, $r_{op}$, $\mathcal{E}$, $r$, Agent $\lambda$
Output:
    Replay buffer $\mathcal{D}$, Trained Agent $\lambda$
$R \leftarrow sgn(r - r_{op})$
for $(s, a)$ in $\mathcal{E}$ do
    if $(s, a) \notin \mathcal{E} \cap \mathcal{E}_{op}$ and $(s, a) \notin \mathcal{E} \cap \mathcal{E}_{\psi}$ then
        $R \leftarrow \min(sgn(r - r_{\psi}), sgn(r - r_{op}))$
    else if $(s, a) \notin \mathcal{E} \cap \mathcal{E}_{op}$ then
        $R \leftarrow sgn(r - r_{op})$
    else if $(s, a) \notin \mathcal{E} \cap \mathcal{E}_{\psi}$ then
        $R \leftarrow sgn(r - r_{\psi})$
    else
        continue
    end if
    $\mathcal{D} \leftarrow \mathcal{D} \cup \{(s, a, R, \pi_{old})\}$
end for
Sample a mini-batch $\{(s, a, R, \pi_{old})\}$ from $\mathcal{D}$
$\lambda \leftarrow \lambda + \nabla_{\lambda}\mathcal{L}$ following equation 8, 9 using sampled replays
```

exponent value as 1. In addition, we address the concept of susampling (Mikolov et al., 2013) on replay sampling. Specifically, we divide the priority of each replay by the square root of word frequency within the corresponding context. For optimization, we use Adam (Kingma and Ba, 2015) optimizer to train the NMG model and its opponent (Self-Play).

Hyperparameters	Value
Learning Rate	0.0001
Number of Epochs	10
Minibatch Size	64
Replay Buffer Size	50000
Entropy Regularization	0.01
Maximum Episodes	200

Table 4: Hyperparameters for Reinforcement Learning Training (Outer Loop). QA is short for Question Answering and TC is short for Text Classification.

B.2 LM Training in Meta-Train (Inner Loop)

We describe detailed hyperparameters in Table 5 for language model (LM) training in the meta-training. In the case of pre-processing of pre-training dataset, we use the context of triplets in Question Answering and sentences in Text Classification. Especially for emrQA (Pampari et al., 2018), we preprocess it to be same as other QA's formats by removing yes-no and multiple answer type questions. Furthermore, we arbitrarily split a train dataset to a train and a validation set by 8 to 2 since Pampari et al. (2018) do not provide a separate validation set. For optimization, we used AdamW optimizer (Loshchilov and Hutter, 2019), with a linear learning rate scheduler. Each meta-training is done on the two Titan XP or RTX 2080 Ti GPUs and it costs maximum of 2 days in the case of BERT. The batch size is adequately selected according to the size of the data and the model.

B.3 LM Training in Meta-Test

We describe detailed hyperparameters in Table 6 for LM training meta-testing. In the meta-testing, we use same setting described in Section B.2 for pre-processing and optimization. The batch size is also adequately selected according to the size of the data and the model.

Regarding the pre-training epoch and the masking probability p in meta-testing, we use two distinct settings for the baselines and NMG model. For the baselines, we train the LM for 1 epoch with $p = 0.15$ following a conventional setting. However, we observed that the fewer masking with a more pre-training epoch is much more beneficial in the meta-training on the task with long contexts since it makes the NMG evaluate actions more precisely. Therefore, for the NMG model, we train the LM for 3 epochs with $p = 0.05$, following the setting of the meta-training.

B.4 Neural Mask Generator Architecture

The policy network of the NMG model consists of the single self-attention layer and two linear layers. The self-attention layer follows the configuration of the transformer layer of BERT$_{BASE}$. We omit the linear layers of the original transformer (Vaswani et al., 2017) implementation in our architecture. The hidden size of linear layers is 128 and gelu (Hendrycks and Gimpel, 2016) is used as an activation function. The value network also consists of the same linear layers after mean-pooling of word representations. The total number of parameters of the NMG model is approximately 2.5M, which is far smaller than the conventional language model.

B.5 Hyperparameter Searching

For searching proper hyperparameter, we use a manual tuning which tries conventional hyperparameters for the reinforcement learning (RL) and the language model (LM) training. A selection

Table 5: Hyperparameters for LM Training of Meta-Train (Inner Loop).

Hyperparameters	Value
Pre-Training Masking Probability	0.05
Pre-Training Learning Rate	0.00002
Pre-Training Epoch	3
Sampled Pre-training Dataset Size	200
Pre-Training Batch Size	Chosen from {8,16,32}
Maximum sequence length in Pre-Training	512 (QA) or 256 (TC)
Fine-Tuning Learning Rate	0.00003 (QA) or 0.00002 (TC)
Fine-Tuning Epoch	1 (QA) or 5 (TC)
Maximum Training Set Size	1000
Validation set Size	10000
Fine-Tuning Batch Size	Chosen from {8,16,32}

Table 6: Hyperparameters for LM Training of Meta-Test.

Hyperparameters	Value
Pre-Training Masking Probability	Chosen from {0.05, 0.15}
Pre-Training Learning Rate	0.00002
Pre-Training Epoch	Chosen from {1, 3}
Pre-Training Batch Size	Chosen from {12,16,24}
Maximum sequence length in Pre-Training	512 (QA) or 256 (TC)
Fine-Tuning Learning Rate	0.00003 (QA) or 0.00002 (TC)
Fine-Tuning Epoch	2 (QA) or 3 (TC)
Fine-Tuning Batch Size	Chosen from {12,16,32}

criterion depends on the result of the meta-testing. Especially, we set the criterion to F1 score and accuracy for question answering and classification task respectively.

C More Examples

To show the masking strategy from our NMG model, we additionally append additional examples from various datasets used in our experiments.

Context [CLS] architecturally, the school has a catholic character. atop the main building's gold dome is a golden statue of the virgin mary. immediately in front of the main building and facing it, is a copper statue of christ with arms upraised with the legend \“venite ad me omnes\". next to the main building is the basilica of the sacred heart. immediately behind the basilica is the grotto, a marian place of prayer and reflection. It is a replica of the grotto at lourdes, france where the virgin mary reputedly appeared to saint bernadette soubirous in 1858. at the end of the main drive (and in a direct line that connects through 3 statues and the gold dome), is a simple, modern stone statue of mary. [SEP]

Question 1 To whom did the Virgin Mary allegedly appear in 1858 in Lourdes France?
Answer 1 Saint Bernadette Soubirous

Question 2 What sits on top of the Main Building at Notre Dame?
Answer 2 A golden statue of the Virgin Mary

Question 3 What is the Grotto at Notre Dame?
Answer 3 A Marian place of prayer and reflection

Context [CLS] all of notre dame's undergraduate students are a part of one of the five undergraduate colleges at the school or are in the first year of studies program. the first year of studies program was established in 1962 to guide incoming freshmen in their first year at the school before they have declared a major. each student is given an academic advisor from the program who helps them to choose classes that give them exposure to any major in which they are interested. the program also includes a learning resource center which provides time management, collaborative learning, and subject tutoring. this program has been recognized previously, by u.s. news & world report, as outstanding. [SEP]

Question 1 What was created at Notre Dame in 1962 to assist first year students?
Answer 1 The First Year of Studies program

Question 2 Which organization declared the First Year of Studies program at Notre Dame’s outstanding?
Answer 2 U.S. News & World Report

Question 3 How many colleges for undergraduates are at Notre Dame?
Answer 3 Five

Context [CLS] the university owns several centers around the world used for international studies and research, conferences abroad, and alumni support. the university has had a presence in london, england, since 1968. since 1998, its london center has been based in the former united university club at 1 suffolk street in trafalgar square. the center enables the colleges of arts & letters, business administration, science, engineering and the law school to develop their own programs in london, as well as hosting conferences and symposia. other global gateways are located in beijing, chicago, dublin, jerusalem and rome. [SEP]

Question 1 In what year did Notre Dame first have a facility in England?
Answer 1 1968

Question 2 Notre Dame has a center in Beijing, what is it referred to as?
Answer 2 Global Gateways

Question 3 In what year did the Suffolk Street location start to house a Notre Dame facility?
Answer 3 1998

Figure 6: **SQuAD** Examples of masked tokens using the Neural Mask Generator (NMG). The red mark and yellow box indicates masked tokens by the model and the answer given a question, respectively.

Context [CLS] is awake, alert, in mild to moderate respiratory distress, breathing with a respiratory rate at 34, oximetry noted at 88% on room air, temperature is 102 fahrenheit, pulse is 104, blood pressure is 213/89, and oximetry came up nicely to 93% on 4 liters and 100% on nonrebreather facemask. neck is supple. mucous membranes are dry. lungs reveal slightly decreased breath sounds at the bases; however, there are few crackles noted in the left lower base. heart is tachycardic but regular. the remainder of the exam is unremarkable. laboratory data: white count is noted at 11.6 and hematocrit 28.2. this is close to the patient's baseline. bun and creatinine 69 and 5.8, 5.8 quite elevated for this patient. however, he has been evaluated for recent diagnosis of renal failure by the nephrology service.

(Ellipsis)

he also received nitro paste for preload reduction as well as a foley catheter and lasix, all for his chf. disposition: the patient was admitted to the hospital. ******** not reviewed by attending physician ******** diagnoses: pneumonia, chf, and renal failure. ________________________________ sorensen, saul d: 08/13/79 t: 08/13/79 dictated by: sorensen, saul escription document:4-5119504 bffocus record date: 2080-11-09 manamana impatient rental transplant admit note referring physician: dr. amar jacoby outpatient nephrologist: dr. pao arias reason for admission: living unrelated renal transplant cmv status: donor negative, recipient negative h [SEP]

Question What were the results of the abnormal blood pressure in 2079-08-13?
Answer Blood pressure is 213/89

Context [CLS] and mid thoracic back pain. she has had no motor weakness, abnormal sensation, numbness, tingling or incontinence of bowel or bladder. she denied fevers, chills or sweats. there has been no gi or gu symptoms except for constipation. past medical history: unremarkable. medications: on admission included percocet for pain and multivitamins. allergies: no known drug allergies. family history: the patient 's father died at age 69 with metastatic prostate cancer. the patient 's sister has a history of cervical cancer. social history: the patient is married and lives with her husband. she has no children. she is a nonsmoker. she drinks socially.

(Ellipsis)

Abstract

The performance of autoregressive models on natural language generation tasks has dramatically improved due to the adoption of deep, self-attentive architectures. However, these gains have come at the cost of hindering inference speed, making state-of-the-art models cumbersome to deploy in real-world, time-sensitive settings. We develop a compression technique for autoregressive models that is driven by an imitation learning perspective on knowledge distillation. The algorithm is designed to address the exposure bias problem. On prototypical language generation tasks such as translation and summarization, our method consistently outperforms other distillation algorithms, such as sequence-level knowledge distillation. Student models trained with our method attain 1.4 to 4.8 BLEU/ROUGE points higher than those trained from scratch, while increasing inference speed by up to 14 times in comparison to the teacher model.[1]

1 Introduction

Autoregressive models are ubiquitous in natural language processing. Due to the sequential nature of text generation, they are often the tool of choice for tackling sequence-to-sequence problems such as translation (Sutskever et al., 2014), summarization (Rush et al., 2015), and dialogue (Eric and Manning, 2017). Furthermore, they form the backbone of several successful generative pre-training architectures (Howard and Ruder, 2018; Peters et al., 2018; Radford et al., 2019; Dai et al., 2019).

Two recent trends have made autoregressive models cumbersome to deploy in real-world, natural language generation (NLG) applications. First, state-of-the-art models have grown larger and larger, amounting to hundreds of millions and even billions of parameters (Dong et al., 2019; Liu and Lapata, 2019; Raffel et al., 2019). The increase in size and depth dramatically slows down inference speed. Second, the architecture of choice for autoregressive models seems to have shifted from the recurrent neural network (RNN) (Bahdanau et al., 2014; Luong et al., 2015) to the Transformer (Vaswani et al., 2017). Though the Transformer's self-attention mechanism improves performance, it also increases the computational complexity of the step-by-step generation algorithms that are used at test time. Thus, both of these trends have contributed to significantly increasing inference time costs, especially on CPUs and low-resource devices, hindering their use in production systems.

Knowledge distillation (KD) (Buciluǎ et al., 2006; Hinton et al., 2015) is one popular method for model compression. It transfers the information learned by a large, pretrained *teacher* to a smaller, untrained *student*. In comparison to other methods such as weight pruning and quantization, KD allows the compressed model's architecture to significantly differ from that of the original teacher. This feature enables models trained with KD to achieve high performance while meeting particular inference requirements (e.g. memory, speed, etc.).

Sequence-level knowledge distillation (SeqKD), proposed by Kim and Rush (2016), is the dominant technique for autoregressive KD in the current NLG literature, especially for machine translation (Gu et al., 2017; Ren et al., 2019; Zhou et al., 2019). This method trains a student model using a modified dataset generated by the teacher model and the standard negative log-likelihood objective. While SeqKD is simple and efficient, we argue that it does not take advantage of the teacher's full potential.

Training the student model with a *static* dataset leads to the exposure bias problem. During training, the student model learns to predict the next token given previous tokens provided by the data.

November 16–20, 2020.

However, at inference time, the student generates the entire sequence from scratch by repeatedly using its own outputs as context for subsequent steps. This training-inference inconsistency causes a decrease in generation quality. Alternatively, we propose that the student can leverage the teacher in a *dynamic* fashion during the learning process.

We devise a new compression algorithm for autoregressive models called *imitation-based knowledge distillation* (ImitKD). It is inspired by an imitation learning (IL) perspective on the autoregressive distillation problem. Our algorithm trains a student model within an IL framework by treating the teacher as an oracle, and allows the student to explore its own generation during training. The teacher corrects the student's generation at every time step, thereby guiding the student in learning how to generate.

Experimental results in translation and summarization show that ImitKD is especially suitable for compressing deep Transformer models that achieve high performance into shallow RNNs that generate up to 14 times faster at inference time. Our method consistently outperforms other distillation algorithms (such as word-level KD and sequence-level KD), and yields student models that beat models trained without a teacher by 1.4 to 4.8 points on generation metrics such as BLEU and ROUGE.

2 Background

2.1 Autoregressive Distillation

First, we formalize the task of autoregressive distillation. An *autoregressive model* π specifies a joint distribution over a T-dimensional *target sequence* $\boldsymbol{y} = \{y_1, \ldots, y_T\} \in \mathcal{Y}$ by decomposing it into a product of univariate conditionals:

$$\pi(\boldsymbol{y}) = \prod_{t=1}^{T} \pi(y_t \mid \boldsymbol{y}_{<t}), \tag{1}$$

where $\boldsymbol{y}_{<t}$ denotes $\{y_1, \ldots, y_{t-1}\}$ for $t > 1$ and $\emptyset$ for $t = 1$. The joint distribution over $\boldsymbol{y}$ may itself be conditional on some related *source feature* $\boldsymbol{x} \in \mathcal{X}$ (e.g. translation, summarization) or not (e.g. language modeling). Since the former case can generalize the latter by letting $\mathcal{X} = \emptyset$, we will specify the presence of $\boldsymbol{x}$ in the rest of the paper.

In autoregressive distillation, the goal is to learn a *student model* π that performs well at sequence generation by minimizing its loss with respect to a pre-trained *teacher model* π^*. In many cases, the training objective can be expressed as

$$\mathcal{L}(\pi) = \mathbb{E}_{\boldsymbol{y}|\boldsymbol{x}\sim\mathcal{D}} \left[\sum_{t=1}^{T} \ell^{\pi^*}(\boldsymbol{y}_{<t}, \boldsymbol{x}; \pi) \right], \tag{2}$$

where $\ell^{\pi^*}(\cdot; \pi)$ is the next-token loss function measuring the discrepancy between the teacher and student models given some prior context $\{\boldsymbol{y}_{<t}, \boldsymbol{x}\}$.

Here, $\mathcal{D}$ denotes a distribution (or dataset) of source-target pairs $\boldsymbol{x} \to \boldsymbol{y}$. Due to the combinatorial nature of sequence generation, an autoregressive distillation method must maximize its learning efficiency by carefully $\mathcal{D}$, i.e. how it explores the exponentially-sized space. We motivate this choice with the field of *imitation learning*, an active research area of reinforcement learning.

2.2 Distillation as Imitation Learning

Autoregressive text generation can be interpreted as a T-step Markov decision process (MDP). In particular, the autoregressive model π we wish to learn can be treated as a policy learner that maps a state to a distribution over actions. In our case, a state is a partial sequence $\boldsymbol{y}_{<t}$ for $t < T$, an action is the next token y_t, and the action space is the vocabulary. Given a state (partial sequence) and a chosen action (next token), the transition function is deterministic and simply concatenates them to form a new state (partial sequence).

The policy learner must be trained using some form of supervision. One option is to use reward-based reinforcement learning, which requires defining the numerical quality of a state. However, for the autoregressive distillation problem, an arguably better choice is *imitation learning* (IL), which optimizes the policy by learning from demonstrations. In IL settings, an *oracle* policy π^* that is known to achieve high performance is provided during training. As a result, we can recast the overall goal as minimizing the divergence of the policy π from the oracle π^*. For example, it may be difficult to objectively define what it means for an aspiring translator to perform well at the local token-by-token level. Yet, if we were given access to an expert translator, we could simply say the learner is performing well if they translate in the same way as the expert.

The IL framework is well-suited for autoregressive distillation, since the student and teacher models naturally fill the respective roles of the learner π and the oracle π^*. Thus, we can easily apply theoretical results and practical methods from the IL literature to the autoregressive distillation problem.

2.3 SeqKD as Behavioral Cloning

One distinguishing feature between different imitation learning methods pertains to how to define the state distribution $\mathcal{D}$ in the training objective (Equation 2). Indeed, this is also one of the key design questions of autoregressive distillation. For instance, one simple and effective IL method is *behavioral cloning* (Ross and Bagnell, 2010), which obtains $\mathcal{D}$ by running the oracle π^* on the MDP.

The popular sequence-level knowledge distillation (SeqKD) algorithm of Kim and Rush (2016) can be interpreted as behavioral cloning. For each source feature $\boldsymbol{x}$ in the original training data, the teacher/oracle generates its (approximate) mode $\boldsymbol{y}^* = \arg\max_{\boldsymbol{y}'} \pi^*(\boldsymbol{y}' \mid \boldsymbol{x})$, typically using beam search. This new set of $\boldsymbol{x} \rightarrow \boldsymbol{y}^*$ pairs forms a teacher-generated dataset $\mathcal{D}^*$ that serves as the state distribution for training the student. In addition, the negative log-likelihood of the teacher's tokens $\boldsymbol{y}^* = \{y_1^*, \cdots, y_T^*\}$ is used as the loss $\ell^{\pi^*}(\cdot; \pi)$. The overall training objective $\mathcal{L}_{\text{SeqKD}}(\pi)$ is

$$\mathbb{E}_{\boldsymbol{y}^* \mid \boldsymbol{x} \sim \mathcal{D}^*} \left[\sum_{t=1}^{T} - \log \pi(y_t^* \mid \boldsymbol{y}_{<t}^*, \boldsymbol{x}) \right]. \qquad (3)$$

The key advantage of SeqKD (as well as behavioral cloning) lies in its simplicity – we only need some samples from the teacher/oracle to work with. In comparison to vanilla supervised learning (which minimizes the negative log-likelihood of human-generated text), SeqKD has no additional training overhead other than the creation of $\mathcal{D}^*$.

However, the simplicity of the algorithm also limits its potential. Ross and Bagnell (2010) argued that training a policy π via behavioral cloning incurs regret with respect to the oracle π^* that is a quadratic function of the time horizon T. Intuitively, behavioral cloning suffers from the *exposure bias problem*. During training, the student model learns to perform good actions for the teacher/oracle's state distribution $\mathcal{D}^*$, but is never exposed to its own states. Thus, during testing (when the student must walk an MDP of self-generated states), the step-by-step errors compound over time, resulting in suboptimal generations.

We argue that in autoregressive distillation, the teacher/oracle can do more than produce a static dataset. It is a dynamic entity capable of interacting with the student throughout training. By querying the teacher with its own states, the student has the opportunity to ameliorate exposure bias and learn how to generate.

3 Imitation-Based Distillation Algorithm

In this section, we present our IL-based algorithm for autoregressive distillation. We begin by describing the key design principles and why we expect them to work well. Then, we elaborate on the algorithm's implementation in detail.

3.1 Design Principles and Rationale

One key principle of our algorithm is that the student model must be trained on its own state distribution so that it will perform better at generation. In practice, we achieve this by sampling training examples from $\tilde{\mathcal{D}}$, a mixture of an initial distribution $\mathcal{D}$ (e.g. a static training set) and the distribution $\mathcal{D}_\pi$ of generations from the student π. We use $\mathcal{D}$ to alleviate the cold-start problem, in which an untrained π generates poorly at the start of training.

This idea builds upon the empirical and theoretical foundation of dataset aggregation (DAgger), one of the most popular imitation learning methods that improve upon behavioral cloning. DAgger (Ross et al., 2011) successively populates its training set by adding new data generated from the oracle-learner mixture. It then re-trains the policy learner on the aggregated dataset at each iteration. Under some assumptions (such as the loss function being strongly convex in π), Ross et al. (2011) proved that DAgger yields a policy π that has linear regret in T with respect to π^*. This is a significant improvement over the behavior cloning result and can be attributed to fixing exposure bias. We expect a similar strategy of mixing oracle and learner distributions to work well for non-convex neural networks, as shown in other applications (Zhang and Cho, 2016; Sun et al., 2017).

Another key principle of our algorithm is that the teacher model should play the role of the oracle and correct the student's generations at each time step. In order for such a training strategy to be successful, the teacher must be able to provide better actions than the student for the student's own states. To test this hypothesis, we experiment with a deep Transformer-based translation model completing the partial translations of a shallow RNN. As shown in Table 1, the Transformer completions achieve much higher BLEU score than the RNN's full generations. This validates our assumption that a strong teacher model can indeed play the role of the oracle and guide the student to better states.

Decoding Method	Bleu ↑
Transformer only	33.8
RNN only	28.6
RNN first, Transformer completes	31.4

Table 1: Greedy decoding BLEU scores on the IWSLT validation set for the preliminary test.

3.2 The ImitKD Algorithm

Our imitation-based knowledge distillation algorithm (ImitKD) is given in Algorithm 1. The central training objective is

$$\mathcal{L}_{\text{ImitKD}}(\pi) = \mathbb{E}_{\boldsymbol{y}|\boldsymbol{x}\sim\tilde{\mathcal{D}}}\left[\sum_{t=1}^{T}\ell^{\pi^*}(\boldsymbol{y}_{<t},\boldsymbol{x};\pi)\right], \quad (4)$$

where $\tilde{\mathcal{D}}$ is the data mixture defined by sampling from the initial dataset $\mathcal{D}$ and generating with the student (lines 8-11). The probability $\beta_i \in [0,1]$ (line 8) controls how often an example comes from $\mathcal{D}$. The loss function ℓ^{π^*} can be realized as the negative log-likelihood of the oracle's optimal next token/action,

$$\ell^{\pi^*}_{\text{opt}}(\boldsymbol{y}_{<t},\boldsymbol{x};\pi) = -\log\pi(v^* \mid \boldsymbol{y}_{<t},\boldsymbol{x}), \quad (5)$$

where $v^* = \arg\max_{v\in\mathcal{V}}\pi^*(v \mid \boldsymbol{y}_{<t},\boldsymbol{x})$. Alternatively, ℓ^{π^*} can be the cross-entropy loss between the full distributions,

$$\begin{aligned}&\ell^{\pi^*}_{\text{full}}(\boldsymbol{y}_{<t},\boldsymbol{x};\pi) \quad (6)\\ &= -\sum_{v\in\mathcal{V}}\pi^*(v \mid \boldsymbol{y}_{<t},\boldsymbol{x})\cdot\log\pi(v \mid \boldsymbol{y}_{<t},\boldsymbol{x}).\end{aligned}$$

Next, we describe some practical implementations in order to make Algorithm 1 suitable for compressing deep learning systems. One limitation of DAgger is that the training data keeps growing, making each iteration successively more expensive. As an alternative to aggregation, we perform *data replacement* within each training batch.

As shown in Algorithm 1, we treat each mini-batch $\tilde{\mathcal{D}}_i$ as a new iteration of the dataset and perform a single step of stochastic gradient descent on $\mathcal{L}_{\text{ImitKD}}$ (Equation 4) with respect to the parameters of the previous model π_i to yield π_{i+1}. Thus, the number of iterations I becomes the number of mini-batches used to train the student model.

Our practical algorithmic changes are inspired by theory. The dataset aggregation algorithm (Ross et al., 2011) achieves its regret bounds because it reduces to the Follow-the-Leader algorithm for online learning (Kakade et al., 2009). Our training paradigm can be similarly interpreted as an online gradient descent algorithm, which has comparable guarantees for strongly convex losses (Hazan et al., 2007) and even certain non-strongly convex losses (Garber, 2019). Variants of this paradigm have also been employed in other deep learning work (Bengio et al., 2015; Sun et al., 2017).

Algorithm 1 Imitation-Based Distillation

```
 1: Let $\mathcal{D}$ be initial dataset.
 2: Initialize $\pi_1$ at random.
 3: for $i = 1, \ldots, I$ do
 4:     Initialize new dataset $\tilde{\mathcal{D}}_i = \emptyset$.
 5:     repeat $B$ times
 6:         Sample an example $e = \boldsymbol{y} \mid \boldsymbol{x} \sim \mathcal{D}$.
 7:         Sample uniformly $u \sim [0, 1]$.
 8:         if $u > \beta_i$ then
 9:             Generate $\hat{\boldsymbol{y}}$ from $\pi_i$ given $\boldsymbol{x}$.
10:             Replace example with $e = \hat{\boldsymbol{y}} \mid \boldsymbol{x}$.
11:         end if
12:         Append example $e$ to $\tilde{\mathcal{D}}_i$.
13:     Compute $\mathcal{L}_{\text{ImitKD}}(\pi_i)$ on $\tilde{\mathcal{D}}_i$ with $\pi^*$.
14:     Let $\pi_{i+1} = \pi_i - \alpha_i \cdot \partial\mathcal{L}_{\text{ImitKD}}/\partial\pi_i$.
15: end for
16: return Best policy $\pi$ on validation set.
```

3.3 Data Mixture Selection and Annealing

Dataset replacement requires an initial dataset that can be potentially replaced at each step. A natural candidate for this initial dataset is the original supervised training data (denoted as $\mathcal{D}'$), which can be interpreted as a collection of samples from a human oracle. Alternatively, we can use the SeqKD dataset $\mathcal{D}^*$, which has generations from the teacher.

If we take samples from $\mathcal{D}'$ or $\mathcal{D}^*$ and replace some of them with student-generated samples, we effectively create a teacher-student dataset mixture. Unlike DAgger, this mixture occurs at the sequence level instead of the token/state level. An advantage of sequence-level mixtures is that they do not require generating with the teacher during each training iteration, which can be quite expensive if the teacher is a large neural network. Instead, the teacher only needs to compute the batched loss, which is comparatively much cheaper. The exact mixing schedule $\beta_1, \ldots, \beta_I$ is a customizable feature of Algorithm 1. Empirically, we have found an exponential decay to work well, i.e. $\beta_i = r^{i/I}$, where $r \in [0, 1]$ is the final mixing rate.

3.4 Speeding Up Training

Generating sequences $\hat{\boldsymbol{y}}$ on the fly at every iteration (line 9) can be a major computation bottleneck during training. We speed up this step by generating a pool of $B \cdot M$ examples in parallel only once every M iterations, where B is the batch size and M is a hyperparameter. One caveat of this modification is that at iteration i, the loss function may no longer be computed on examples generated by the most recent set of model parameters, but rather parameters from up to M iterations prior. Nonetheless, we have found that setting M to a small integer (e.g. 2-8) can speed up training time without impacting final model performance.

We use greedy decoding or top-K sampling with small K to produce samples $\hat{\boldsymbol{y}}$ (line 9) in our algorithm. These two strategies are efficient to run, operate similarly to the generation employed at inference time, and have empirically worked well in our experiments. Of course, the generation strategy can be customized for different tasks.

4 Related Work

The distillation problem for autoregressive models was first tackled by Kim and Rush (2016), who introduced sequence-level knowledge distillation for neural machine translation. Subsequent works have used seqKD for non-autoregressive translation models (Gu et al., 2017; Zhou et al., 2019), low-resource settings (Chen et al., 2017), and ensemble distillation with multiple teachers (Kuncoro et al., 2016; Tan et al., 2019). Wei et al. (2019) proposed a behavioral cloning method for distilling autoregressive translation models into non-autoregresssive translation models. In contrast, our method aims to address the learning challenges in autoregressive distillation, such as exposure bias.

Various methods other than standard supervised learning have been explored for training generative models of language. MIXER (Ranzato et al., 2015) and Beam Search Optimization (Wiseman and Rush, 2016) also perform generation during training, but use sequence-level metrics (e.g. BLEU score) as training supervision. Simlarly, SEARNN (Leblond et al., 2017) trains RNNs to iteratively generate sequences with beam search to compute the local loss of a single action during the decoding process. Scheduled sampling (Bengio et al., 2015) and its extensions (Goyal et al., 2017; Zhang et al., 2019) alleviate exposure bias by replacing some words in the true context with the model's prediction. However, without a dynamic queryable oracle, these methods face the challenge of properly defining the training signal when the generated sequence no longer exists in the static training data. For example, directly reusing the tokens in the static dataset as the target next token leads to an inconsistent training procedure (Huszár, 2015). In contrast to these methods, distillation can fully leverage the teacher oracle, allowing us to design a simple and efficient imitation learning algorithm.

5 Experimental Setup

We test our autoregressive distillation method and all baselines on three language generation tasks – IWSLT 2014 German → English translation, WMT 2016 English → German translation, and CNN/DailyMail abstractive news summarization.

Datasets The IWSLT 2014 De→En dataset consists of approximately 170K sequence pairs. Following standard practice (Bahdanau et al., 2016; Deng et al., 2018; Wang et al., 2019), we randomly sample 4% of this dataset as the validation set and let the remaining be the training set. The test set is the concatenation of the dev2010, tst2010, tst2011, and tst2012 files. We use a shared vocabulary of 14K lowercased BPE tokens (Sennrich et al., 2015).

The WMT 2016 En→De dataset has 4.5 million training pairs. We use the same preprocessing of the prior work (Ott et al., 2018), newstest2013 as the validation set and newstest2014 as the test set. The vocabulary consists of 32K cased BPE tokens.

The CNN/DailyMail summarization dataset has 287K, 13K and 12K pairs in the training, validation and test sets, respectively. Following prior work (See et al., 2017), we truncate documents to 400 tokens and summaries to 100 tokens in the training set. During evaluation, we generate up to 128 tokens. We use a pre-trained BERT (Devlin et al., 2018) tokenizer with a vocabulary of 30K lowercased tokens (Liu and Lapata, 2019).

Models Transformers often attain state-of-the-art performance on common language generation tasks. On the other hand, RNNs (without self-attention) generate much faster at inference time. Thus, from a practitioner's standpoint, it may be most desirable to compress a high-performing Transformer into a lightweight RNN. For all tasks, we use the state-of-the-art Transformer architecture (Vaswani et al., 2017) as the teacher model. The teacher models are trained using vanilla super-

Variant	Context (States)	Loss
Vanilla	Data	NLL
SeqKD	Teacher	NLL
ImitKD	Student/Data Mix	NLL
ImitKD*	Student/Teacher Mix	NLL
Vanilla + Full	Data	$\ell^{\pi^*}_{\text{full}}$
SeqKD + Full	Teacher	$\ell^{\pi^*}_{\text{full}}$
ImitKD + Full	Student/Data Mix	$\ell^{\pi^*}_{\text{full}}$
ImitKD* + Full	Student/Teacher Mix	$\ell^{\pi^*}_{\text{full}}$

Table 2: Summary of training variants. Base variants use the negative log-likelihood (NLL) of the optimal next token – which is taken from the data for Vanilla, found using beam search for SeqKD, and queried from the teacher for ImitKD (i.e. $\ell^{\pi^*}_{\text{opt}}$). All "+ Full" variants are trained with the full teacher-student cross entropy.

vised learning. For WMT, we directly use the pre-trained Transformer model provided by the Fairseq library (Ott et al., 2018, 2019).

In all tasks, we use a recurrent neural network, specifically SRU (Lei et al., 2017), as the student model. For completeness, we also train Transformer, GRU (Cho et al., 2014), and LSTM (Hochreiter and Schmidhuber, 1997) based student models on the IWSLT translation task, illustrating the effectiveness of our distillation method for various neural architectures. All RNN-based models follow the seq2seq, encoder-decoder architecture (Sutskever et al., 2014) and employ a single scaled dot-product attention between the encoder and decoder (Bahdanau et al., 2014; Luong et al., 2015).

All models are trained using the Adam optimizer (Kingma and Ba, 2014) with an inverse-square-root learning rate scheduler and learning rate warmup (Vaswani et al., 2017). Our experiments were conducted using Flambé, a PyTorch-based model training and evaluation library (Wohlwend et al., 2019). More implementation details such as hyperparameter settings are provided in Appendix A.

Variants For the student models, we compare a wide range of training variants, including baselines such as vanilla supervised learning (which directly uses the original training set) and sequence-level knowledge distillation (SeqKD). All SeqKD variants form the teacher-generated dataset using beam search with beam size $K = 5$. For our imitation-based method, we experiment with annealing from the original training set (ImitKD) or the teacher-generated SeqKD dataset (ImitKD*). We also experiment with different token-level losses; base variants are trained with the optimal next token while "+ Full" variants are trained with the full cross entropy. Table 2 summarizes all variants and highlights their differences. Note that the Vanilla + Full baseline – referred to as "WordKD" by Kim and Rush (2016) – has appeared in other distillation works (e.g. Tan et al., 2019; Sanh et al., 2019).

Evaluation We use BLEU score (Papineni et al., 2002) for translation and report ROUGE-1, ROUGE-2 and ROUGE-L scores (Lin, 2004) for summarization. For all models, the training checkpoint with the highest BLEU/ROUGE-1 score on the validation set is used for test set evaluation. We also report the perplexity metric for all tasks.

6 Results

IWSLT De→En Translation Table 3 compares all distillation methods on the IWSLT dataset. The teacher model is an 8-layer Transformer. We use a 3-layer SRU, a 2-layer SRU and a 2-layer Transformer as student models. For all three student models, our ImitKD method outperforms all baselines in terms of BLEU score with beam size 1 (Bleu$_1$), BLEU score with beam size 5 (Bleu$_5$) and perplexity (PPL). The improvement on Bleu score ranges from 1.4 to 4.8 points compared to the Vanilla training method. The 3-layer SRU model trained with ImitKD + Full even slightly exceeds the performance of the teacher model. Furthermore, our method consistently outperforms SeqKD by up to 1.4 BLEU, highlighting the benefit of training the student model with its own state distribution.

To further demonstrate the effectiveness of ImitKD across different model types, we report validation set Bleu$_1$ for various 2-layer neural architectures in Table 4. Our ImitKD method outperforms the baselines in all cases, with the gains being especially large for recurrent architectures.

WMT En→De Translation Table 5 presents our results for the WMT dataset. The teacher is a 6-layer Transformer and the student is a 4-layer SRU. Here, we see that ImitKD performs closer to SeqKD. These results reveal that direct behavioral cloning (SeqKD) can be quite effective when the amount of oracle demonstrations is sufficiently high, e.g. several millions of examples. Nonetheless, ImitKD and ImitKD* can improve on SeqKD by training the student with its own states. Among all variants, ImitKD + Full performs

Variant	PPL ↓	Bleu$_1$ ↑	Bleu$_5$ ↑

SeqKD + Full	7.1	34.0	34.4
ImitKD + Full	**5.9**	**34.4**	**34.8**

Table 3: Results on IWSLT test dataset.

Variant	SRU	GRU	LSTM	Transf.
Vanilla	28.6	28.6	27.7	32.4
SeqKD	31.4	31.2	30.5	33.3
ImitKD	**32.7**	**32.7**	**32.4**	**33.7**

Table 4: BLEU scores of different student architectures on the IWSLT validation set. We use a beam size of 1. The teacher attains a validation BLEU of 33.8.

the best while avoiding the overhead of creating a teacher-modified dataset. Furthermore, we see that ImitKD is especially effective in low-data regimes. As shown in the bottom block of Table 5, ImitKD methods achieve much stronger results over baselines when we reduce the WMT training data to the same size as IWSLT.

CNN/DailyMail Summarization In Table 6, we present the CNN/DailyMail results for a 6-layer Transformer teacher and a 2-layer SRU student. Once again, the best student is ImitKD + Full, which achieves ROUGE scores that are within 1 point of the teacher's. ImitKD variants outperform the baselines on all ROUGE metrics, showcasing the utility of our method on a different NLG task.

Variant	PPL ↓	Bleu$_1$ ↑	Bleu$_5$ ↑
Teacher	3.2	28.7	29.2

ImitKD* + Full	17.9	38.1	**17.1**	34.6

Table 6: Results on CNN/DailyMail dataset. All models generate using beam search $K = 5$ decoding.

Size and Speed Analysis In Table 7, we analyze how our distillation technique can reduce computational costs, using the IWSLT (Table 3), WMT (Table 5), and CNN/DailyMail (Table 6) teacher/student pairs as case studies. By training small student models with ImitKD, we can substantially decrease model size and increase inference speed, while minimizing performance loss. Shallow, recurrent architectures are especially attractive, because they can generate 4-14 times faster than deep Transformer teachers, and 2-3 times faster than Transformer students of similar size.

Performance Analysis at Different Lengths Figure 1 breaks down BLEU score vs. decoding length for IWSLT models trained with different algorithms (Vanilla, SeqKD, ImitKD). We show results for the three types of RNNs and the Transformer of Table 4. All models have two layers.

Task	Model	Size	% Compress	CPU Time	× Faster	% Perform
IWSLT	Transf. (8-layer)†	20.1 M	—	269 / 518 ms	—	—
	SRU (3-layer)	14.0 M	68.7%	55 / 97 ms	4.9 / 5.3	101.2%
	SRU (2-layer)	8.6 M	42.7%	37 / 56 ms	7.2 / 9.3	98.0%
	Transf. (2-layer)	8.5 M	42.3%	78 / 144 ms	3.4 / 3.6	100.0%
WMT	Transf. (6-layer)†	209.9 M	—	816 / 1466 ms	—	—
	SRU (4-layer)	34.2 M	16.3%	174 / 306 ms	4.7 / 4.8	88.2%
CNN/DM	Transf. (6-layer)†	59.8 M	—	1900 / 12138 ms	—	—
	SRU (2-layer)	14.4 M	24.1%	258 / 826 ms	7.4 / 14.7	98.5%

Table 7: Model types, along with statistics on size (in number of parameters) and CPU inference time per decoding (in milliseconds) for beam search with beam size $K \in \{1, 5\}$. Teacher models are marked with †. The "% Perform" column records the ratio of the best student's performance to the teacher's performance on BLEU score for translation tasks and ROUGE-1 for the summarization task.

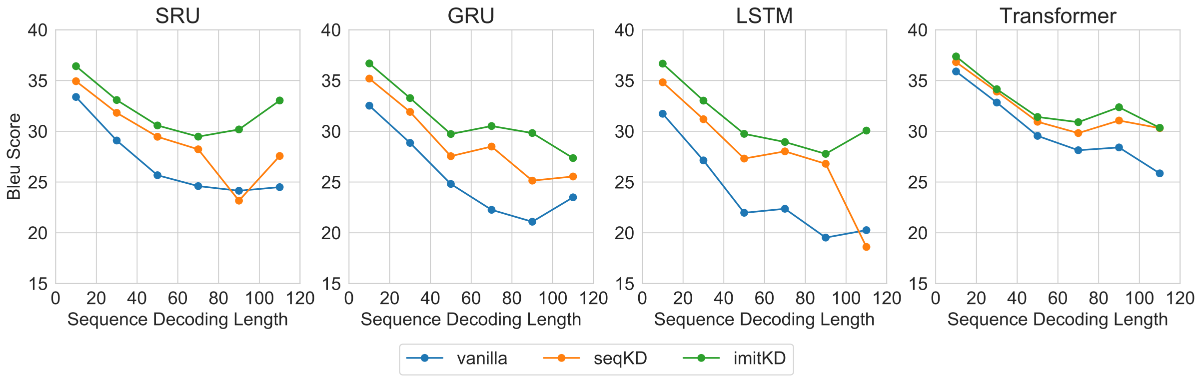

Figure 1: Bleu score versus sequence decoding length across different models and training variants. Each point on the graph represents the Bleu score of all sequences whose length is within a bin of width 20.

As expected, we observe that the generation quality (in terms of BLEU score) degrades as the decoding length increases. This phenomenon can be explained by the global error compounding with each additional decision step (Ross et al., 2011) and has been reported in previous works (Bahdanau et al., 2014; Zhang et al., 2019). As shown in Figure 1, models trained with the vanilla objective, especially RNN-based models, suffer the most from this problem. SeqKD improves the performance across all sequence lengths, but still experiences some BLEU score degradation for longer sequences. ImitKD further improves the BLEU score across all bins, and more importantly, the improvement is most significant for longer sequences. This analysis suggests that ImitKD explicitly addresses the exposure bias problem for training student models.

Additive Effect of Fine-Tuning Kim and Rush (2016) propose a fine-tuning method for autoregressive distillation called SeqInter. This method can further improve pretrained student models by exposing them to the sequence in the teacher beam's that is closest to the target in terms of sentence-level BLEU. In Table 8, we show the results of applying SeqInter to each of the IWSLT models that were trained from scratch in Table 4. While SeqInter enables Vanilla models to "close the gap" on SeqKD models, ImitKD models clearly maintain their superior performance even after fine-tuning.

Variant	SRU	GRU	LSTM	Transf.
Vanilla	32.1	31.9	31.2	34.0
SeqKD	32.2	32.0	31.4	34.2
ImitKD	**33.5**	**33.4**	**33.1**	**34.4**

Table 8: IWSLT validation set BLEU scores of SeqInter fine-tuning applied to the different student architectures of Table 4. We use a beam size of 1. The teacher (without fine-tuning) attains a validation BLEU of 33.8.

7 Conclusion

In this work, we developed a new knowledge distillation technique inspired by imitation learning for compressing large and cumbersome autoregressive models into smaller and faster counterparts. We demonstrated the empirical success of our method over popular baselines on several natural language generation tasks.

We are excited about several possible avenues for future work. One branch of ideas involves incorporating more advanced IL algorithms beyond DAgger, such as LOLS (Chang et al., 2015), to further improve the distillation process. Another possibility is to design imitation-based fine-tuning analogs to the SeqInter method. Finally, although our experiments in this paper focused on sequence-to-sequence settings, we are interested in exploring the use of ImitKD for compressing large language models aimed at transfer learning.

A Appendices

A.1 DAgger Algorithm

The dataset aggregation (DAgger) algorithm (Ross et al., 2011) minimizes the following objective:

$$\mathcal{L}_{\text{Imit}}(\pi) = \mathbb{E}_{s_1,\ldots,s_T\sim\mathcal{D}}\left[\sum_{t=1}^{T}\ell^{\pi^*}(s_t;\pi)\right], \qquad (7)$$

where $\mathcal{D}$ is a distribution (or dataset) of T-step state trajectories and $\ell^{\pi^*}(s,\pi)$ is the action-discrepancy loss between the oracle π^* and the policy learner π in state s. The full DAgger algorithm is given in Algorithm 2.

Algorithm 2 Dataset Aggregation

```
Let $\mathcal{D} = \emptyset$ be initial dataset.
Initialize $\pi_1$ at random.
for $i = 1, \ldots, I$ do
    Let mixture policy $\tilde{\pi}_i = \beta_i\pi^* + (1-\beta_i)\pi_i$.
    Initialize new dataset $\mathcal{D}^i = \emptyset$.
    repeat $B$ times
        Run MDP on $\tilde{\pi}_i$, sample $\{s_1, \ldots, s_T\}$.
        Append new states $\{s_1, \ldots, s_T\}$ to $\mathcal{D}^i$.
    Aggregate $\mathcal{D} = \mathcal{D} \cup \mathcal{D}^i$.
    Train $\pi_{i+1}$ on $\mathcal{D}$ to min $\mathcal{L}_{\text{Imit}}$ with $\pi^*$.
end for
return Best policy $\pi$ on validation set.
```

A.2 Implementation Details

In all experiments, all RNN-based models with hidden dimension N consist of a bidirectional encoder with hidden dimension $N/2$ and a left-to-right decoder with hidden dimension N.

For BLEU score evaluation, we use the NLTK library.[2] For ROUGE score evaluation, we use the py-rouge library.[3]

Preliminary Study For Table 1, we train both an 8-layer Transformer and a 2-layer RNN (specifically SRU) on the IWSLT dataset using standard supervised learning. The architectural and training details are the same as those outlined in the IWSLT experiments. At test time, both the Transformer and the RNN perform greedy decoding. On average, ground-truth translations in the IWSLT test set have 24.5 tokens. The "RNN first, Transformer completes" mixed decoding strategy generates 12 tokens (i.e. half on average) with the RNN and the rest with the Transformer. We measure generation quality using Bleu score.

IWSLT The IWSLT 2014 German → English dataset is taken directly from the source website.[4]

We train an 8-layer Transformer teacher model with model dimension 256, feedforward dimension 1024, and four attention heads as the teacher model. The 2-layer student SRU model has a hidden dimension 512, and the 3-layer model has hidden dimension 1024 and projection dimension 256. The student Transformer model has model dimension 256, feedforward dimention 768 and 4 attention heads.

All models have word embedding dimension 256 and exhibit weight tying between the decoder embeddings and the output layer (Press and Wolf, 2016). We train models for 80K steps with batch size 128 using the Adam optimizer with base learning rate 0.1. We use an inverse-square-root learning rate scheduler (Vaswani et al., 2017) with 10K warmup steps for the teacher and 5K warmup steps for all students. Validation set metrics are recorded every 1K steps. For all ImitKD variants, we set the final mixing rate $r = 0.005$ (i.e. very close to 0), and use top-K sampling with $K = 5$ as the generation algorithm during training. We use $M = 4$ as the batch parallelization parameter.

In Table 4, the 2-layer SRU and the 2-layer Transformer follow the same architecture as those in Table 3. To standardize architecture across RNNs, the GRU and the LSTM have the same embedding dimension (i.e. 256) and hidden dimension (i.e. 512) as the SRU.

WMT The WMT 2016 dataset is taken from the Fairseq library.[5]

We use a pre-trained Transformer-large model from the Fairseq library (Ott et al., 2018, 2019) as our teacher model. It has embedding dimension 1024, model dimension 1024, and feedforward dimension 4096. The student is a 4-layer SRU with hidden size 1024, projection size 256, and embedding size 256. The student is trained for 15 epochs with batch size 512, base learning rate 0.1, and 4K warmup steps. We record validation metrics every 1/4 of the epoch. The encoder embeddings, decoder embeddings, and decoder output layer share

[3] `https://github.com/Diego999/py-rouge`

[4] `https://sites.google.com/site/iwsltevaluation2014/data-provided`

[5] `https://github.com/pytorch/fairseq/tree/master/examples/translation`

the same weight parameters. We tune the final mixing rate $r \in \{0.5, 0.1, 0.005\}$ for our ImitKD variants.

CNN/Dailymail The CNN/DailyMail dataset is taken from Professor Kyunghyun Cho's website, a commonly used source for this dataset.[6] The teacher model is a 6-layer Transformer-base model with embedding dimension 512, model dimension 512, and feedforward dimension 2048. The student is a 2-layer SRU with embedding dimension 256, hidden size 1024, and projection size 256. We use a batch size of 128. For both models, the learning rate follows an inverse-square root schedule with warmup of 2K steps. Validation set metrics are recorded every 2K steps. The teacher has a base learning rate of 0.03, while the student has a base learning rate of 0.1. The teacher benefits from larger effective batch sizes by accumulating gradients every eight steps. On the other hand, the student does not seem to benefit from gradient accumulation and therefore takes a gradient step after processing each batch. All ImitKD variants use final mixing rate $r = 0.1$ and greedy decoding during training. We use $M = 4$ as the batch parallelization parameter.

Size and Speed Analysis CPU generation times for all models were measured on a 2019 MacBook Pro with a 2.6GHz 6-core Intel Core i7 processor. Time estimates reported in Table 7 were averaged over examples in the test set of the corresponding dataset.

Performance Analysis at Different Lengths For each IWSLT variant, we ran greedy decoding (i.e. beam search decoding with beam size $K = 1$) on the test set. Then, we sorted the decoded sequences by length into the following bins: [0, 20], [21, 40], [41, 60], [61, 80], [81, 100], [101, 120]. Each point in Figure 1 is the Bleu score of all sequences within one of these bins for the corresponding IWSLT variant.

Additive Effect of Fine-Tuning For the fine-tuning experiments, we generated SeqInter data with a beam size of $K = 5$ and NLTK's sentence-level BLEU implementation. We used the Adam optimizer with a base learning rate of 0.01 and an inverse-square root scheduler with 2K warmup steps. All models were fine-tuned for 20K iterations. Models were validated every 1K iterations.

Abstract

Adversarial attacks against natural language processing systems, which perform seemingly innocuous modifications to inputs, can induce arbitrary mistakes to the target models. Though raised great concerns, such adversarial attacks can be leveraged to estimate the robustness of NLP models. Compared with the adversarial example generation in continuous data domain (*e.g.*, image), generating *adversarial text* that preserves the original meaning is challenging since the text space is discrete and non-differentiable. To handle these challenges, we propose a *target-controllable* adversarial attack framework T3, which is applicable to a range of NLP tasks. In particular, we propose a tree-based autoencoder to embed the discrete text data into a continuous representation space, upon which we optimize the adversarial perturbation. A novel tree-based decoder is then applied to regularize the syntactic correctness of the generated text and manipulate it on either sentence (T3(SENT)) or word (T3(WORD)) level. We consider two most representative NLP tasks: sentiment analysis and question answering (QA). Extensive experimental results and human studies show that T3 generated adversarial texts can successfully manipulate the NLP models to output the *targeted* incorrect answer without misleading the human. Moreover, we show that the generated adversarial texts have high transferability which enables the black-box attacks in practice. Our work sheds light on an effective and general way to examine the robustness of NLP models. Our code is publicly available at https://github.com/AI-secure/T3/.

1 Introduction

Recent studies have demonstrated that deep neural networks (DNNs) are vulnerable to carefully crafted adversarial examples (Goodfellow et al., 2015; Papernot et al., 2016; Eykholt et al., 2017; Moosavi-Dezfooli et al., 2016). These examples are helpful in exploring the vulnerabilities and interpretability of the neural networks. *Target-controllable* attacks (or targeted attacks) are more dangerous and challenging than untargeted attacks, in that they can mislead systems (e.g., self-driving cars) to take targeted actions, which raises safety concerns for the robustness of DNN-based applications. While there are a lot of successful attacks proposed in the continuous data domain, including images, audios, and videos, how to effectively generate adversarial examples in the discrete text domain remains a challenging problem.

Question: Who ended the series in 1989?
Paragraph: The BBC drama department's serials division produced the programme for 26 seasons, broadcast on BBC 1. Falling viewing numbers, a decline in the public perception of the show and a less-prominent transmission slot saw production suspended in 1989 by Jonathan Powell, controller of BBC 1. ... the BBC repeatedly affirmed that the series would return. *Donald Trump ends a program on 1988 .*
QA Prediction: Jonathan Powell → Donald Trump

Yelp Review: *I kept expecting to see chickens and chickens walking around.* If you think Las Vegas is getting too white trash, don' t go near here. This place is like a steinbeck novel come to life. I kept expecting to see donkeys and chickens walking around. Wooo - pig - soooeeee this place is awful!!!
Sentiment Prediction: Most Negative → Most Positive

Table 1: Two adversarial examples generated by T3 for QA models and sentiment classifiers. Adding *the adversarial sentence* to the original paragraph can lead the correct prediction to a targeted wrong answer configured by the adversary.

Unlike adversarial attacks in computer vision that add imperceptible noise to the input image, editing even one word of the original paragraph may change the meaning dramatically and fool the human as well. So in this paper, we focus on generating an adversarial sentence and adding it to the input paragraph. There are several challenges for generating adversarial texts: 1) it is hard to measure

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6134–6150,
November 16–20, 2020.

the validity and naturalness of the adversarial text compared to the original ones; 2) gradient-based adversarial attack approaches are not directly applicable to the discrete structured data; 3) compared with in-place adversarial modification of original sentences, adversarial sentence generation is more challenging since the generator needs to consider both sentence semantic and syntactic coherence. So far, existing textual adversarial attacks either inefficiently leverage heuristic solutions such as genetic algorithms (Jin et al., 2019) to search for word-level substitution, or are limited to attacking specific NLP tasks (Jia and Liang, 2017; Lei et al., 2018).

Moreover, effective *target-controllable* attacks, which can control the models to output expected incorrect answers, have proven difficult for NLP models. Wallace et al. (2019) creates universal triggers to induce the QA models to output targeted answers, but the targeted attack success rates are low. Other work (Cheng et al., 2018; Jin et al., 2019; Zhang et al., 2019; Zang et al., 2019) performs word-level in-place modification on the original paragraph to achieve targeted attack, which may change the meaning of original input. Therefore, how to generate adversarial sentences that do not alter the meaning of original input while achieving high targeted attack success rates seems to be an interesting and challenging problem.

In this paper, we solved these challenges by proposing an adversarial evaluation framework T3 to generate adversarial texts against general NLP tasks and evaluate the robustness of current NLP models. Specifically, the core component of T3 is a novel tree-based autoencoder pretrained on a large corpus to capture and maintain the semantic meaning and syntactic structures. The tree encoder converts discrete text into continuous semantic embedding, which solves the discrete input challenge. This empowers us to leverage the optimization based method to search for adversarial perturbation on the continuous embedding space more efficiently and effectively than heuristic methods such as genetic algorithms, whose search space grows exponentially w.r.t. the input space. Based on different levels of a tree hierarchy, adversarial perturbation can be added on leaf level and root level to impose word-level (T3(WORD)) or sentence-level (T3(SENT)) perturbation. Finally, a tree-based decoder will map the adversarial embedding back to adversarial text by a set of tree grammar rules, which preserve both the semantic content and syntactic structures of the original input. An iterative process can be applied to ensure the attack success rate.

In summary, our main contributions lie on: (1) unlike previous textual adversarial attack studies, we achieve targeted attack through concatenative adversarial text generation that is able to manipulate the model to output targeted wrong answers. (2) we propose a novel tree-based text autoencoder that regularizes the syntactic structure of the adversarial text while preserves the semantic meaning. It also addresses the challenge of attacking discrete text by embedding the sentence into continuous latent space, on which the optimization-based adversarial perturbation can be applied to guide the adversarial sentence generation; (3) we conduct extensive experiments and successfully achieve targeted attack for different sentiment classifiers and QA models with higher attack success rates and transferability than the state-of-the-art baseline methods. Human studies show that the adversarial text generated by T3 is valid and effective to attack neural models, while barely affects human's judgment.

2 Related work

A large body of works on *adversarial examples* focus on perturbing the continuous input space. Though some progress has been made on generating adversarial perturbations in the discrete space, several challenges remain unsolved. For example, (Zhao et al., 2017) exploit the generative adversarial network (GAN) to generate natural adversarial text. However, this approach cannot explicitly control the quality of the generated instances. Most existing methods (Ren et al., 2019; Zhang et al., 2019; Jia and Liang, 2017; Li et al., 2018; Jin et al., 2019) apply heuristic strategies to synthesize adversarial text: 1) first identify the features (e.g. characters, words, and sentences) that influence the prediction, 2) follow different search strategies to perturb these features with the constructed perturbation candidates (e.g. typos, synonyms, antonyms, frequent words). For instance, (Liang et al., 2017) employ the loss gradient ∇L to select important characters and phrases to perturb, while (Samanta and Mehta, 2017) use typos, synonyms, and important adverbs/adjectives as candidates for insertion and replacement. Once the influential features are obtained, the strategies to apply the perturbation generally include *insertion*, *deletion*, and *replacement*. Such textual adversarial attack approaches cannot guarantee the grammar correctness of generated text. For instance, text generated by (Liang et al., 2017) are almost random stream of characters. To generate grammarly correct perturbation, Jia and Liang adopt another heuristic strategy which adds *manually* constructed legit distracting sentences to the paragraph to introduce fake information. These heuristic approaches are in general not scalable, and cannot achieve targeted attack where the adversarial text can lead to a chosen adversarial target (e.g. adversarial label in classification). Recent work starts to use gradient (Michel et al., 2019; Ebrahimi et al., 2017) to guide the search for universal trigger (Wallace et al., 2019) that are applicable to arbitrary sentences to fool the learner, though the reported attack success rate is rather low or they suffer from inefficiency when applied to other NLP tasks. In contrast, our proposed T3 framework is able to effectively generate syntactically correct adversarial text, achieving high targeted attack success rates across different models on multiple tasks.

3 Framework

3.1 Preliminaries

Before delving into details, we recapitulate the attack scenario and attack capability supported by T3 framework.

Attack Scenario. Unlike previous adversarial text generation works (Lei et al., 2018; Cheng et al., 2018; Papernot et al., 2016; Miyato et al., 2016; Alzantot et al., 2018) that directly modify critical words in place and might risk changing the semantic meaning or editing the ground truth answers, we are generating the *concatenative adversaries* (Jia and Liang, 2017) (*abbr.*, concat attack). Concat attack does not change any words in original paragraphs or questions, but instead appends a new adversarial sentence to the original paragraph to fool the model. A valid adversarial sentence needs to ensure that the appended text is *compatible* with the original paragraph, which in other words means it should not contradict any stated facts in the paragraph, especially the correct answer.

Attack Capability. T3 is essentially an optimization based framework to find the adversarial text with the optimization goal set to achieve the **targeted attack**. For the sentiment classification task, T3 can perform the targeted attack to make an originally positive review be classified as the most negative one, and vice versa. Particularly in the QA task, we design and implement two kinds of targeted attacks: *position targeted attack* and *answer targeted attack*. A successful position targeted attack means the model can be fooled to output the answers at specific targeted positions in the paragraph, but the content on the targeted span is optimized during the attack. So the answer cannot be determined before the attack. In contrast, a successful answer targeted attack is a stronger targeted attack, which refers to the situation when the model always outputs the pre-defined targeted answer no matter what the question looks like. In Table 1, we set the targeted answer as "Donald Trump" and successfully changes the model predictions. More examples of answer targeted attacks and position targeted attacks can be found in Appendix §C.

Although our framework is designed as a white-box attack, our experimental results demonstrate that the adversarial text can transfer to other black-box models with high attack success rates. Finally, because T3 is a unified adversarial text generation framework whose outputs are discrete tokens, it applies to different downstream NLP tasks. In this paper, we perform an adversarial evaluation on sentiment classification and QA as examples to illustrate this point.

3.2 Tree Auto-Encoder

In this subsection, we describe the key component of T3: a tree-based autoencoder. Compared with standard sequential generation methods, generating sentence in a non-monotonic order (e.g., along parse trees) has recently been an interesting topic (Welleck et al., 2019). Our motivation comes from the fact that sentence generation along parse trees can intrinsically capture and maintain the syntactic information (Eriguchi et al., 2017; Aharoni and Goldberg, 2017; Iyyer et al., 2018), and show better performances than sequential recurrent models (Li et al., 2015; Iyyer et al., 2014). Therefore we design a novel tree-based autoencoder to generate adversarial text that can simultaneously preserve both semantic meaning and syntactic structures of original sentences. Moreover, the discrete nature of language motivates us to make use of autoencoder to map discrete text into a high dimensional continuous space, upon which the adversarial perturbation can be calculated by gradient-based approaches to achieve targeted attack.

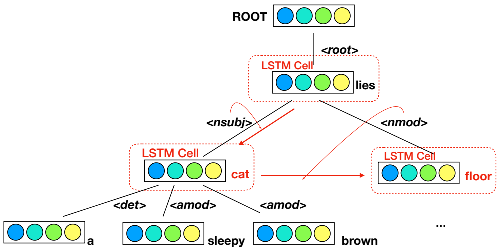

Figure 1: The tree decoder. Each node in the dependency tree is a LSTM cell. Black lines refer to the dependencies between parent and child nodes. Red arrows refer to the directions of decoding. During each step the decoder outputs a token that is shown on the right of the node.

Formally, let X be the domain of text and S be the domain of dependency parse trees over element in X, a tree-based autoencoder consists of an encoder $\mathcal{E} : X \times S \to Z$ that encodes text $\boldsymbol{x} \in X$ along with its dependency parsing tree $\boldsymbol{s} \in S$ into a high dimensional latent representation $\boldsymbol{z} \in Z$ and a decoder $\mathcal{G} : Z \times S \to X$ that generates the corresponding text $\boldsymbol{x}$ from the given context vector $\boldsymbol{z}$ and the expected dependency parsing tree $\boldsymbol{s}$. Given a dependency tree $\boldsymbol{s}$, $\mathcal{E}$ and $\mathcal{G}$ form an antoencoder. We thus have the following reconstruction loss to train our tree-based autoencoder:

$$\mathcal{L}_{\text{recon}} = -\mathbb{E}_{\boldsymbol{x}\sim X}[\log p_{\mathcal{G}}(\boldsymbol{x}|\boldsymbol{s}, \mathcal{E}(\boldsymbol{x}, \boldsymbol{s})] \tag{1}$$

Encoder. We adopt the Child-Sum Tree-LSTM (Tai et al., 2015) as our tree encoder. Specifically, in the encoding phase, each child state embedding is its hidden state of Tree LSTM concatenated with the dependency relationship embedding. The parent state embedding is extracted by summing the state embedding from its children nodes and feeding forward through Tree-LSTM cell. The process is conducted from bottom (leaf node, i.e. word) to top (root node) along the dependency tree extracted by CoreNLP Parser (Manning et al., 2014).

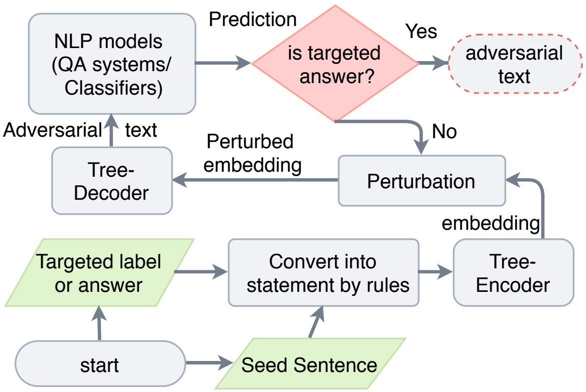

Figure 2: The pipeline of adversarial text generation.

Decoder. As there is no existing tree-based autoencoder, we design a novel Tree Decoder (Shown in Figure 1). In the decoding phase, we start from the root node and traverse along the same dependency tree in level-order. The hidden state $\boldsymbol{h}_j$ of the next node j comes from (i) the hidden state $\boldsymbol{h}_i$ of the current tree node, (ii) current node predicted word embedding $\boldsymbol{w}_i$, and (iii) the dependency embedding $\boldsymbol{d}_{ij}$ between the current node i and the next node j based on the dependency tree. The next node's corresponding word y_j is generated based on the hidden state of the LSTM Cell $\boldsymbol{h}_j$ via a linear layer that maps from the hidden presentation $\boldsymbol{h}_j$ to the logits that represent the probability distribution of the tree's vocabulary.

$$\boldsymbol{h}_j = \text{LSTM}([\boldsymbol{h}_i; \boldsymbol{w}_i; \boldsymbol{d}_{ij}]) \tag{2}$$

$$y_j = \text{one-hot}(\text{argmax}\,(\boldsymbol{W} \cdot \boldsymbol{h}_j + \boldsymbol{b})) \tag{3}$$

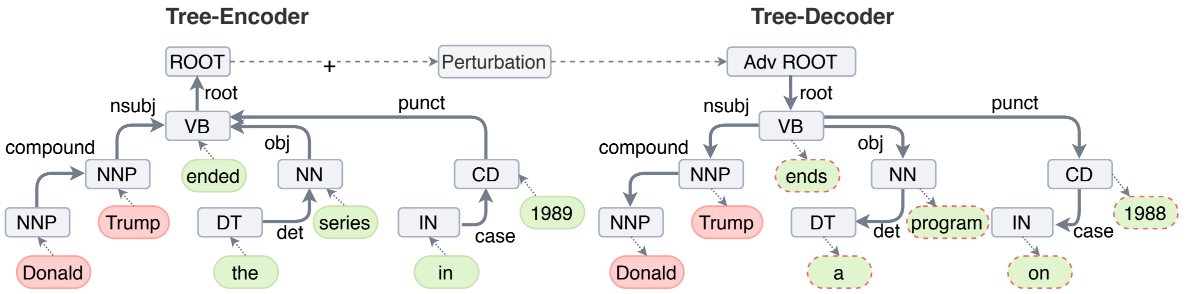
Moreover, the tree structure allows us to modify the tree node embedding at different tree hierarchies in order to generate controllable perturbation on word level or sentence level. Therefore, we explore the following two types of attacks at root level and leaf level T3(SENT) and T3(WORD), which are shown in Figure 3 and Figure 4.

3.3 Pipeline of Adversarial Text Generation

Here we illustrate how to use our tree-based autoencoder to perform adversarial text generation and attack NLP models, as illustrated in Figure 2.

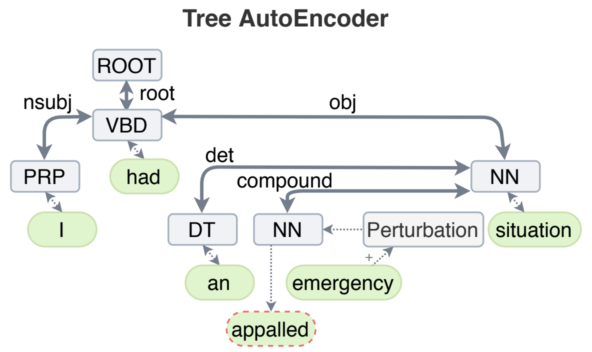
Step 1: Choose the adversarial seed. The adversarial seed is the input sentence to our tree autoencoder. After adding perturbation on the tree node embedding, the decoded adversarial sentence will be added to the original paragraph to perform concat attack. For sentiment classifiers, the adversarial seed can be an arbitrary sentence from the paragraph. For example, the adversarial seed of Yelp Review example in Table 1 is a random sentence from the paragraph *"I kept expecting to see donkeys and chickens walking around.'*

In contrast, when performing answer targeted attack for QA models, we need add our targeted answer into our adversarial seed in a reasonable context. Based on a set of heuristic experiments on how the adversarial seed correlates the attack efficacy (Appendix A.4), we choose to use question words to craft an adversarial seed, because it receives higher attention score when the model is matching semantic similarity between the context



Adversarial Seed: [Donald Trump] ended the series in 1989. **Adversarial Sentence**: [Donald Trump] ends a program on 1988.

Figure 3: An example of how T3(SENT) generates the adversarial sentence. Perturbation is added on the ROOT embedding and optimized to ensure the success of targeted attack while the magnitude of perturbation is minimized.



Adversarial Seed: I had an emergency situation.
Adversarial Sentence: I had an appalled situation.

Figure 4: T3(WORD) adds perturbation on the leaf node embedding. Arrow denotes the direction of encoding/decoding.

and the question. Specifically, we convert a question sentence to a meaningful declarative statement and assign a targeted fake answer. The fake answer can be crafted according to the perturbed model's predicted answer (position targeted attack §3.1), or can be manually chosen by adversaries (answer targeted attack). For instance, the answer targeted attack example shown in Table 1 converts the question *"Who ended the series in 1989?"* into a declarative statement *"someone ended the series in 1989."* by a set of coarse grained rules (Appendix A.4). Then our targeted wrong answer is assigned to generate the adversarial seed *"Donald Trump ended the series in 1989."* Following steps will make sure that the decoded adversarial sentence does not contradict with the original paragraph.

Step 2: Embed the discrete text into continuous embedding. One difference between T3(SENT) and T3(WORD) is on which tree level we embed our discrete sentence. For T3(SENT), we use tree root node embedding of Tree-LSTM $\boldsymbol{z} = \boldsymbol{h}_{\text{root}}$ to represent the discrete sentence ("ROOT" node in the Figure 3). As for T3(WORD), we concatenate all the leaf node embedding of Tree-LSTM $\boldsymbol{h}_i$ (corresponding to each word) $\boldsymbol{z} = [\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_n]$ to embed the discrete sentence.

Step 3: Perturb the embedding via optimization. Finding the optimal perturbation z^* on the embedding vector z is equivalent to solving the optimization problem that can achieve the target attack goal while minimize the magnitude of perturbation

$$\min \quad ||\boldsymbol{z}^*||_p + cf(\boldsymbol{z} + \boldsymbol{z}^*), \tag{4}$$

where f is the objective function for the targeted attack and c is the constant balancing between the perturbation magnitude and attack target. Specifically, we design the objective function f similar to Carlini and Wagner (2016) for classification tasks

$$\ell = \max\left\{Z\left(\left[\mathcal{G}(\boldsymbol{z}', \boldsymbol{s}); \boldsymbol{x}\right]\right)_i : i \neq t\right\}, \tag{5}$$

$$f(\boldsymbol{z}') = \max\left(\ell - Z\left(\left[\mathcal{G}(\boldsymbol{z}', \boldsymbol{s}); \boldsymbol{x}\right]\right)_t, -\kappa\right), \tag{6}$$

where $\boldsymbol{z}' = \boldsymbol{z} + \boldsymbol{z}^*$ is the perturbed embedding, model input $[\mathcal{G}(\boldsymbol{z}', \boldsymbol{s}); \boldsymbol{x}]$ is the concatenation of adversarial sentence $\mathcal{G}(\boldsymbol{z}', \boldsymbol{s})$ and original paragraph $\boldsymbol{x}$, t is the target class, $Z(\cdot)$ is the logit output of the classification model before softmax, ℓ is the maximum logits of the classes other than the targeted class and κ is the confidence score to adjust the misclassification rate. The confidence score κ is chosen via binary search to search for the tradeoff-constant between attack success rate and meaning perseverance. The optimal solution z^* is iteratively optimized via gradient descent.

Similarly to attack QA models, we subtly change the objective function f due to the difference between QA model and classification model:

$$\ell_j = \max\left\{Z_j\left(\left[\boldsymbol{x}; \mathcal{G}(\boldsymbol{z}', \boldsymbol{s})\right]\right)_i : i \neq t_j\right\},$$

$$f(\boldsymbol{z}') = \sum_{j=1}^{2} \max\left(\ell_j - Z_j\left(\left[\boldsymbol{x}; \mathcal{G}(\boldsymbol{z}', \boldsymbol{s})\right]\right)_{t_j}, -\kappa\right),$$

where $Z_1(\cdot)$ and $Z_2(\cdot)$ are respectively the logits of answer starting position and ending position of the QA system. t_1 and t_2 are respectively the targeted start position and the targeted end position. ℓ_j is the maximum logits of the positions other than the targeted positions. Different from attacking sentiment classifier where we prepend the adversarial sentence, we choose to follow the setting of Jia and Liang to add the adversary to the end of the paragraph so that we can make a fair comparison with their results.

Step 4: Decode back to adversarial sentence. There are three problems we need to deal with when mapping embeddings to adversarial sentences: (1) the adversarial sentence may contradict to the stated fact of the original paragraph; (2) the decoding step (Eq. 3) uses argmax operator that gives no gradients, but the step 3 needs to perform gradient descent to find the optimal z^*; (3) for answer targeted attack, the targeted answer might be perturbed and changed during decoding phase.

To solve problem (1), we guarantee our appended adversarial sentences are not contradictory to the ground truth by ensuring that the adversarial sentence and answer sentence have no common words, otherwise keep the iteration steps. If the maximum steps are reached, the optimization is regarded as a failure.

For problem (2), during optimization we use a continuous approximation based on softmax with a decreasing temperature τ (Hu et al., 2017)

$$y_j^* \sim \mathrm{softmax}((\boldsymbol{W} \cdot \boldsymbol{h_j} + \boldsymbol{b})/\tau). \qquad (7)$$

to make the optimization differentiable. After finding the optimal perturbation z^*, we still use the hard argmax to generate the adversarial texts.

As for problem (3), we keep targeted answers unmodified during the optimization steps by setting gates to the targeted answer span: $y_j \leftarrow g_1 \odot y_j + g_2 \odot x_j, (j = t_1, t_1 + 1, ..., t_2)$, where y_j are the adversarial tokens decoded by tree. We set $g_1 = 1$ and $g_2 = 0$ in the position targeted attack, and $g_1 = 0$ and $g_2 = 1$ in the answer targeted attack.

4 Experiments

We now present the experimental evaluation results for T3. In particular, we target on two popular NLP tasks, sentiment classification and QA. For both models, we perform whitebox and transferability based blackbox attacks. In addition to the model accuracy (untargeted attack evaluation), we also report the targeted attack success rate for T3. We show that the proposed T3 can outperform other state of the art baseline methods on different models. The details of pretraining tree decoder and experimental setup can be found in Appendix §A and §B.

4.1 Adversarial Evaluation Setup for Sentiment Classifier

In this task, sentiment analysis model takes the user reviews from restaurants and stores as input and is expected to predict the number of stars (from 1 to 5 star) that the user was assigned.

Dataset. We choose the Yelp dataset (Challenge) for sentiment analysis task. It consists of 2.7M yelp reviews, in which we follow the process of Lin et al. (2017) to randomly select 500K review-star pairs as the training set, and 2000 as the development set, 2000 as the test set.

Models. *BERT* (Devlin et al., 2019) is a transformer (Vaswani et al., 2017) based model, which is unsupervisedly pretrained on a large corpus and is proven to be effective for downstream NLP tasks. *Self-Attentive Model (SAM)* (Lin et al., 2017) is a state-of-the-art text classification model uses self-attentive mechanism. More detailed model settings are listed in the appendix.

Evaluation metrics. *Targeted attack success rate* (abbr. target) is measured by how many examples are successfully attacked to output the targeted label in average, while *untargeted attack success rate* (abbr. untarget) calculates the percentage of examples attacked to output a label different from the ground truth.

Attack Baselines. *Seq2sick* (Cheng et al., 2018) is a whitebox projected gradient method to attack seq2seq models. Here, we perform seq2sick attack on sentiment classification models by changing its loss function, which was not evaluated in the original paper. *TextFooler* (Jin et al., 2019) is a simple yet strong blackbox attack method to perform word-level in-place adversarial modification. Following the same setting, Seq2Sick and TextFooler are only allowed to edit the prepended sentence.

4.2 Adversarial Evaluation Setup for Question Answering Systems

Task and Dataset. In this task, we choose the SQuAD dataset (Rajpurkar et al., 2016) for question answering task. The SQuAD dataset is a reading comprehension dataset consisting of 107,785 questions posed by crowd workers on a set of

Model	Original Acc		Whitebox Attack		Blackbox Attack		
			T3(WORD)	Seq2Sick	T3(WORD)	Seq2sick	TextFooler
BERT	0.703	target	**0.990**	0.974	**0.499**	0.218	0.042
		untarget	**0.993**	0.988	**0.686**	0.510	0.318
SAM	0.704	target	**0.956**	0.933	**0.516**	0.333	0.113
		untarget	**0.967**	0.952	**0.669**	0.583	0.395

Table 2: Adversarial evaluation on sentiment classifiers in terms of targeted and untargeted attack success rate.

Model	Origin		Whitebox Attack		Blackbox Attack		
			Pos-T3(WORD)	Ans-T3(WORD)	Pos-T3(WORD)	Ans-T3(WORD)	AddSent
BERT	EM	81.2	**29.3**	43.2	**32.3** / 52.8	45.2 / 51.7	46.8
	F1	88.6	**33.2**	47.3	**36.4** / 57.6	49.0 / 55.9	52.6
BiDAF	EM	60.0	**15.0**	21.0	**18.9** / 29.2	20.5 / 28.9	25.3
	F1	70.6	**17.6**	23.6	**22.5** / 34.5	24.1 / 34.2	32.0

Table 3: Adversarial evaluation on QA models. Pos-T3 and Ans-T3 respectively refer to the position targeted attack and answer targeted attack. The transferability-based blackbox attack uses adversarial text generated from whitebox models of the same architecture (the former score) and different architecture (the latter score).

Wikipedia articles, where the answer to each question must be a segment of text from the corresponding reading passage. To compare our method with other adversarial evaluation works (Jia and Liang, 2017) on the QA task, we evaluate our adversarial attacks on the same test set as Jia and Liang (2017), which consists of 1000 randomly sampled examples from the SQuAD development set.

Model. We adapt the *BERT* model to run on SQuAD v1.1 with the same strategy as that in Devlin et al. (2019), and we reproduce the result on the development set. *BiDAF*(Seo et al., 2016) is a multi-stage hierarchical process that represents the context at different levels of granularity and uses bidirectional attention flow mechanism to obtain a query-aware context representation.

Evaluation metrics. For untargeted attack evaluation, We use the official script of the SQuAD dataset (Rajpurkar et al., 2016) to measure both adversarial exact match rates and F1 scores. The lower EM and F1 scores mean the better attack success rate. For targeted attack evaluation, we use the targeted exact match rates and targeted F1 Score that calculate how many model outputs match the targeted fake answers (*e.g.*, the fake answer "Donald Trump" in Table 1). Higher targeted EM and F1 mean higher targeted attack success rate.

Attack Baseline. *AddSent* (Jia and Liang, 2017) appends a manually constructed legit distracting sentence to the given text so as to introduce fake information, which can only perform untargeted attack. *Universal Adversarial Triggers* (Wallace et al., 2019) are input-agnostic sequences of tokens that trigger a model to produce a specific prediction when concatenated to any input from a dataset.

4.3 Adversarial Evaluation

4.3.1 T3(WORD)

Attack Sentiment Classifiers. We perform the baseline attacks and our T3 attack in concat attack scenario under both whitebox and blackbox settings. Our targeted goal for sentiment classification is the opposite sentiment. Specifically, we set the targeted attack goal as 5-star for reviews originally below 3-star and 1-star for reviews above. We compare our results with a strong word-level attacker Seq2sick, as shown in the Table 2. We can see our T3(WORD) outperforms the baselines and achieves nearly 100% attack success rate on the BERT model under whitebox settings.

We also perform transferability based blackbox attacks. Specifically, the transferability-based blackbox attack uses adversarial text generated from whitebox BERT model to attack blackbox SAM, and vice versa. We compare our blackbox attack success rate with the blackbox baseline TextFooler and blackbox Seq2Sick based on transferability. Table 2 demonstrates our T3(WORD) model still has the best blackbox targeted and untargeted success rate among all the baseline models.

Attack QA models. We perform the whitebox attack and transferability-based attack on our testing models. As is shown in Table 3, T3(WORD) achieves the best whitebox attack results on both

Model		T3(SENT)	T3(WORD)	UT
BERT	target EM	32.1	**43.4**	1.4
	target F1	32.4	**46.5**	2.1
BiDAF	target EM	53.3	**71.2**	21.2
	target F1	56.8	**75.6**	22.6

Table 4: Targeted Attack Results of whitebox attack on QA. UT is short for Universal Trigger baseline.

BERT and BiDAF. It is worth noting that although BERT has better performances than BiDAF, the performance drop for BERT $\Delta \text{F1}_{\text{BERT}}$ is 55.4 larger than the performance drop for BiDAF $\Delta \text{F1}_{\text{BiDAF}} = 53.0$, which again proves the BERT is insecure under the adversarial evaluation. We also find the position targeted attack is slightly stronger than the answer targeted attack. We assume it is because the answer targeted attack has fixed targeted answer and limited freedom to alter the appended sentence, but the position targeted attack has more freedom to alter the fake answer from the targeted position spans.

Then we evaluate the targeted attack performance on QA models. The results are shown in Table 4. It shows that T3(WORD) has the best targeted attack ability on QA. And all our attack methods outperform the baseline.

We also transfer adversarial texts generated from whitebox attacks to perform blackbox attacks. Table 3 shows the result of the blackbox attack on testing models. All our proposed methods outperform the baseline method (AddSent) when transferring the adversaries among models with same architectures.

4.4 Human Evaluation & T3(SENT)

We conduct a thorough human subject evaluation to assess the human response to different types of generated adversarial text. The main conclusion is that even though these adversarial examples are effective at attacking machine learning models, they are much less noticeable by humans.

4.4.1 Evaluation Metrics and Setup

We focus on two metrics to evaluate the validity of the generated adversarial sentence: **adversarial text quality** and **human performance** on the original and adversarial dataset. To evaluate the adversarial text quality, human participants are asked to choose the data they think has better quality. To ensure that human is not misled by our adversarial examples, we ask human participants to perform the sentiment classification and question answering tasks both on the original dataset and adversarial dataset. We hand out the adversarial dataset and origin dataset to 533 Amazon Turkers to perform the human evaluation. More experimental setup details can be found in Appendix §B.4.

4.4.2 Analysis

Human evaluation results are shown in Table 5. We see that the overall vote ratio for T3(SENT) is higher, which means it has better language quality than T3(WORD) from a human perspective. We assume the reason is that T3(SENT) decodes under the dependency constraints during decoding phase so that it can more fully harness the tree-based autoencoder structure. And it is reasonable to see that better language quality comes at the expense of a lower adversarial success rate. As Table 5 shows, the adversarial targeted success rate of T3(SENT) on SAM is 20% lower than that of T3(WORD), which confirms the trade-off between language quality and adversarial attack success rate.

The human scores on original and adversarial datasets are also shown in Table 5. We can see that human performances are barely affected by concatenated adversarial sentence. Specifically, the scores drop around 10% for both QA and classification tasks based on T3. This is superior to the state-of-the-art algorithm (Jia and Liang, 2017) which has 14% performance drop for human performance.

We also analyze the human error cases. A further quantitative analysis (Appendix §B.5) shows that most wrong human answers do not point to our generated fake answers but may come from the sampling noise when aggregating human results.

Also, we find the average length of the adversarial paragraph is around 12 tokens more than the average length of the original one after we append the adversarial sentence. We guess the increasing length of the paragraph also has an impact on the human performance.

In Appendix §A, we conduct some ablation studies to explore the attack effectiveness of different autoencoders. We also investigate BERT attention by changing different attack parameters such as the position of the appended adversarial sentence, and draw several interesting conclusions. Appendix §C shows more adversarial examples.

Method	Sentiment Classifier				QA			
	Origin Human	Human	Models	Quality	Origin Human	Human	Models	Quality
T3(SENT)	0.95	0.82	0.363 / 0.190	65.67%	90.99	81.78	49.1 / 29.3	69.50%
T3(WORD)		0.82	0.007 / 0.033	34.33%		82.90	29.3 / 15.0	30.50%

Table 5: Human evaluation on T3(SENT) and T3(WORD). "Origin Human" is the human scores on the original dataset. "Human" are the human scores on adversarial datasets.

5 Discussion and Future Works

In addition to the general adversarial evaluation framework T3, this paper also aims to explore several scientific questions: 1) Since T3 allows the flexibility of manipulating at different levels of a tree hierarchy, which level is more attack effective and which one preserves better grammatical correctness? 2) Is it possible to achieve the targeted attack for general NLP tasks such as sentiment classification and QA, given the limited degree of freedom for manipulation? 3) Is it possible to perform a blackbox attack for many NLP tasks? 4) Is BERT robust in practice? 5) Do these adversarial examples affect human reader performances?

We find that: 1) both word and sentence level attacks can achieve high attack success rate, while the sentence level manipulation integrates the global grammatical constraints and can generate high-quality adversarial sentences. 2) various targeted attacks on general NLP tasks are possible (*e.g.*, when attacking QA, we can ensure the target to be a specific answer or a specific location within a sentence); 3) the transferability based blackbox attacks are successful in NLP tasks. 4) Although BERT has achieved state-of-the-art performances, we observe the performance drops are also more substantial than other models when confronted with adversarial examples, which indicates BERT is not robust enough under the adversarial settings.

Besides the conclusions pointed above, we also summarize some interesting findings: (1) While T3(WORD) achieves the best attack success rate among multiple tasks, we observe a trade-off between the freedom of manipulation and the attack capability. For instance, T3(SENT) has dependency tree constraints and becomes more natural for human readers than but less effective to attack models than T3(WORD). Similarly, since the targeted answers are fixed, the answer targeted attack in QA can manipulate fewer words than the position targeted attack, and therefore has slightly weaker attack performances. (2) Transferring adversarial text from models with better performances to weaker ones is more successful. For example, transfering the adversarial examples from BERT-QA to BiDAF achieves much better attack success rate than in the reverse way. (3) We also notice adversarial examples have better transferability among the models with similar architectures than different architectures. (4) BERT models give higher attention scores to the both ends of the paragraphs and tend to overlook the content in the middle, as shown in §A.2 ablation study that adding adversarial sentences in the middle of the paragraph is less effective than in the front or the end.

To defend against these adversaries, here we discuss about the following possible methods and will in depth explore them in our future works: (1) **Adversarial Training** is a practical methods to defend against adversarial examples. However, the drawback is we usually cannot know in advance what the threat model is, which makes adversarial training less effective when facing unseen attacks. (2) **Interval Bound Propagation** (IBP) (Dvijotham et al., 2018) is proposed as a new technique to theoretically consider the worst-case perturbation. Recent works (Jia et al., 2019; Huang et al., 2019) have applied IBP in the NLP domain to certify the robustness of models. (3) **Language models** including GPT2 (Radford et al., 2019) may also function as an anomaly detector to probe the inconsistent and unnatural adversarial sentences.

6 Conclusions

In summary, we propose a general targeted attack framework for adversarial text generation. To the best of our knowledge, this is the first method that successfully conducts arbitrary targeted attack on general NLP tasks. Our results confirmed that our attacks can achieve high attack success rate without fooling the human. These results shed light on an effective way to examine the robustness of a wide range of NLP models, thus paving the way for the development of a new generation of more reliable and effective NLP methods.

A Ablation Study

A.1 Autoencoder Selection

As an ablation study, we compare the standard LSTM-based autoencoder with our tree-based autoencoder.

Table 6: Ablation study on posistion targeted attack capability against QA. The lower EM and F1 scores mean the better attack success rate. T3(SENT) and T3(WORD) respectively refer to T3(SENT) and T3(WORD). Adv(seq2seq) refers to T3 that uses LSTM-based seq2seq model as text autoencoder.

	Origin	T3(SENT)	T3(WORD)	Adv(seq2seq)
EM	60.0	29.3	**15.0**	51.3
F1	70.6	34.0	**17.6**	57.5

Tree Autoencoder. In the whole experiments, we used Stanford TreeLSTM as tree encoder and our proposed tree decoder together as tree autoencoder. We trained the tree autoencoder on yelp dataset which contains 500K reviews. The model is expected to read a sentence, map the sentence in a latent space and reconstruct the sentence from the embedding along with the dependency tree structure in an unsupervised manner. The model uses 300-d vectors as hidden tree node embedding and is trained for 30 epochs with adaptive learning rate and weight decay. After training, the average reconstruction loss on test set is 0.63.

Seq2seq Autoencoder. We also evaluate the standard LSTM-based architecture (seq2seq) as a different autoencoder in the T3 pipeline. For the seq2seq encoder-decoder, we use a bi-directional LSTM as the encoder (Hochreiter and Schmidhuber, 1997) and a two-layer LSTM plus soft attention mechanism over the encoded states as the decoder (Bahdanau et al., 2015). With 400-d hidden units and the dropout rate of 0.3, the final testing reconstruction loss is 1.43.

The comparison of the whitebox attack capability against a well-known QA model BiDAF is shown in Table 6. We can see seq2seq based T3 fails to achieve good attack success rate. Moreover, because the vanilla seq2seq model does not take grammatical constraints into consideration and has higher reconstruction loss, the quality of generated adversarial text cannot be ensured.

A.2 Ablation Study on BERT Attention

To further explore how the location of adversarial sentences affects the attack success rate, we conduct the ablation experiments by varying the position of appended adversarial sentence. We generate the adversarial sentences from the whitebox BERT classification and QA models. Then we inject those adversaries into different positions of the original paragraph and test in another blackbox BERT with the same architecture but different parameters. The results are shown in Table 7 and 8. We see in most time appending the adversarial sentence at the beginning of the paragraph achieves the best attack performance. Also the performance of appending the adversarial sentence at the end of the paragraph is usually slightly weaker than front. This observation suggests that the BERT model might pay more attention to the both ends of the paragraphs and tend to overlook the content in the middle.

A.3 Attack Settings

We use Adam (Kingma and Ba, 2014) as the optimizer, set the learning rate to 0.6 and the optimization steps to 100. We follow the Carlini and Wagner (2016) method to find the suitable parameters in the object function (weight const c and confidence score κ) by binary search.

A.4 Heuristic Experiments on choosing the adversarial seed for QA

We conduct the following heuristic experiments about how to choose a good initialization sentence to more effectively attack QA models. Based on the experiments we confirm it is important to choose a sentence that is semantically close to the context or the question as the initial seed when attacking QA model, so that we can reduce the number of iteration steps and more effectively find the adversary to fool the model. Here we describe three ways to choose the initial sentence, and we will show the efficacy of these methods given the same maximum number of optimization steps.

Random adversarial seed sentence. Our first trial is to use a random sentence (other than the answer sentence), generate a fake answer similar to the real answer and append it to the back as the initial seed.

Question-based adversarial seed sentence. We also try to use question words to craft an initial sentence, which in theory should gain more attention when the model is matching characteristic similarity between the context and the question. To convert a question sentence to a meaningful declarative statement, we use the following steps:

Table 7: Blackbox Attack Success Rate after inserting the whitebox generated adv sentence to different positions for BERT-classification.

Method		Back	Mid	Front
T3(WORD)	target	0.739	0.678	**0.820**
	untarget	0.817	0.770	**0.878**
T3(SENT)	target	**0.220**	0.174	0.217
	untarget	0.531	0.504	**0.532**

Table 8: Blackbox Attack Success Rate after inserting the whitebox generated adversarial sentence to different positions for BERT-QA.

Method		Back	Mid	Front
T3(WORD)	EM	32.3	39.1	**31.9**
	F1	36.4	43.4	**36.3**
T3(SENT)	EM	47.0	51.3	**42.4**
	F1	52.0	56.7	**47.0**

In step 1, we use the state-of-the-art semantic role labeling (SRL) tools (He et al., 2017) to parse the question into verbs and arguments. A set of rules is defined to remove the arguments that contain interrogative words and unimportant adjectives, and so on. In the next step, we access the model's original predicted answer and locate the answer sentence. We again run the SRL parsing and find to which argument the answer belongs. The whole answer argument is extracted, but the answer tokens are substituted with our targeted answer or the nearest words in the GloVe word vectors (Pennington et al., 2014) (position targeted attack) that is also used in the QA model. In this way, we craft a fake answer that shares the answer's context to solve the compatibility issue from the starting point. Finally, we replace the declarative sentence's removed arguments with the fake argument and choose this question-based sentence as our initial sentence.

Answer-based adversarial seed sentence. We also consider directly using the model predicted original answer sentence with some substitutions as the initial sentence. To craft a fake answer sentence is much easier than to craft from the question words. Similar to step 2 for creating question-based initial sentence, we request the model's original predicted answer and find the answer sentence. The answer span in the answer sentence is directly substituted with the nearest words in the GloVe word vector space to avoid the compatibility problem preliminarily.

Experimental Results. We tried the above initial sentence selection methods on T3(WORD) and perform position targeted attack on BERT-QA given the same maximum optimization steps. The experiments results are shown in table 9. From the table, we find using different initialization methods will greatly affect the attack success rates. Therefore, the initial sentence selection methods are indeed important to help reduce the number of iteration steps and fastly converge to the optimal z^* that can attack the model.

B Experimental Settings

B.1 Sentiment Classification Model

BERT. We use the 12-layer BERT-base model [1] with 768 hidden units, 12 self-attention heads and 110M parameters. We fine-tune the BERT model on our 500K review training set for text classification with a batch size of 32, max sequence length of 512, learning rate of 2e-5 for 3 epochs. For the text with a length larger than 512, we only keep the first 512 tokens.

Self-Attentive Model (SAM). We choose the structured self-attentive sentence embedding model (Lin et al., 2017) as the testing model, as it not only achieves the state-of-the-art results on the sentiment analysis task among other baseline models but also provides an approach to quantitatively measure model attention and helps us conduct and analyze our adversarial attacks. The SAM with 10 attention hops internally uses a 300-dim BiLSTM and a 512-units fully connected layer before the output layer. We trained SAM on our 500K review training set for 29 epochs with stochastic gradient descent optimizer under the initial learning rate of 0.1.

B.2 Sentiment Classification Attack Baseline

Seq2sick (Cheng et al., 2018) is a whitebox projected gradient method combined with group lasso and gradient regularization to craft adversarial examples to fool seq2seq models. Here, we define the loss function as $L_{target} = \max_{k \in Y} \left\{ z^{(k)} \right\} - z^{(t)}$ to perform attack on sentiment classification models which was not evaluated in the original paper. In our setting, Seq2Sick is only allowed to edit the appended sentence or tokens.

TextFooler (Jin et al., 2019) is a simple but strong black-box attack method to generate adversarial text. Here, TextFooler is also only allowed to edit the appended sentence.

---

[1] https://github.com/huggingface/pytorch-pretrained-BERT

Table 9: Whitebox attack results on BERT-QA in terms of exact match rates and F1 scores by the official evaluation script. The lower EM and F1 scores mean the better attack success rate.

Model		Origin	Position Targeted Attack			Baseline
			Random	Question-based	Answer-based	AddSent
BERT	EM	81.2	67.9	**29.3**	50.6	46.8
	F1	88.6	74.4	**33.2**	55.2	52.6

B.3 QA Model

BiDAF. Bi-Directional Attention Flow (BIDAF) network(Seo et al., 2016) is a multi-stage hierarchical process that represents the context at different levels of granularity and uses bidirectional attention flow mechanism to obtain a query-aware context representation. We train BiDAF without character embedding layer under the same setting in (Seo et al., 2016) as our testing model.

B.4 Human Evaluation Setup

We focus on two metrics to evaluate the validity of the generated adversarial sentence: **adversarial text quality** and **human performance** on the original and adversarial dataset. To evaluate the adversarial text quality, human participants are asked to choose the data they think has better quality.

To evaluate the adversarial text quality, human participants are asked to choose the data they think has better quality. In this experiement, we prepare 600 adversarial text pairs from the same paragraphs and adversarial seeds. We hand out these pairs to 28 Amazon Turks. Each turk is required to annotate at least 20 pairs and at most 140 pairs to ensure the task has been well understood. We assign each pair to at least 5 unique turks and take the majority votes over the responses.

To ensure that human is not misled by our adversarial examples, we ask human participants to perform the sentiment classification and question answering tasks both on the original dataset and adversarial dataset. Specifically, we respectively prepare 100 benign and adversarial data pairs for both QA and sentiment classification, and hand out them to 505 Amazon Turkers. Each turker is requested to answer at least 5 questions and at most 15 questions for the QA task and judge the sentiment for at least 10 paragraphs and at most 20 paragraphs. We also perform a majority vote over these turkers' answers for the same question.

B.5 Human Error Analysis in Adversarial Dataset

We compare the human accuracy on both benign and adversarial texts for both tasks (QA and classification) in revision section 5.2. We spot the human performance drops a bit on adversarial texts. In particular, it drops around 10% for both QA and classification tasks based on AdvCodec as shown in Table 5. We believe this performance drop is tolerable and the stoa generic based QA attack algorithm experienced around 14% performance drop for human performance (Jia and Liang, 2017).

We also try to analyze the human error cases. In QA, we find most wrong human answers do not point to our generated fake answer, which confirms that their errors are not necessarily caused by our concatenated adversarial sentence. Then we do a further quantitative analysis and find aggregating human results can induce sampling noise. Since we use majority vote to aggregate the human answers, when different answers happen to have the same votes, we will randomly choose one as the final result. If we always choose the answer that is close to the ground truth in draw cases, we later find that the majority vote F1 score increases from 82.897 to 89.167, which indicates that such randomness contributes to the noisy results significantly, instead of the adversarial manipulation. Also, we find the average length of the adversarial paragraph is around 12 tokens more than the average length of the original one after we append the adversarial sentence. We assume the increasing length of the paragraph will also have an impact on the human performances.

C Adversarial examples

C.1 Adversarial examples for QA

C.1.1 Adversarial examples generated by T3(SENT)

Table 10: Answer Targeted Concat Attack using T3(SENT) on QA task. The targeted answer is “Donald Trump”.

Input (*Italic* = Inserted or appended tokens, underline = Model prediction, red = Ground truth)
Question: Who ended the series in 1989? **Paragraph:** The BBC drama department’s serials division produced the programme for 26 seasons, broadcast on BBC 1. Falling viewing numbers, a decline in the public perception of the show and a less-prominent transmission slot saw production suspended in 1989 by Jonathan Powell, controller of BBC 1. Although (as series co-star Sophie Aldred reported in the documentary Doctor Who: More Than 30 Years in the TARDIS) it was effectively, if not formally, cancelled with the decision not to commission a planned 27th series of the show for transmission in 1990, the BBC repeatedly affirmed that the series would return. *Donald Trump ends a program on 1988* .
Question: Who served his dinner? **Paragraph:** Tesla worked every day from 9:00 a.m. until 6:00 p.m. or later, with dinner from exactly 8:10 p.m., at Delmonico’s restaurant and later the Waldorf-Astoria Hotel. Tesla would telephone his dinner order to the headwaiter, who also could be the only one to serve him. Ťhe meal was required to be ready at eight o’clock ... He dined alone, except on the rare occasions when he would give a dinner to a group to meet his social obligations. Tesla would then resume his work, often until 3:00 a.m. *Donald Trump serves her supper* .
Question: Which network regained the ratings lead in America in 1984? **Paragraph:** As far as programming is concerned, four of ABC’s marquee shows of the 1970s ended their runs during the mid-1980s: Laverne & Shirley ended its run in 1983, Happy Days and Three’s Company ended in 1984 (with the latter producing a short-lived spinoff that year), while The Love Boat ended its run in 1986. After nearly a decade of ratings trouble, NBC had regained the ratings lead among the Big Three networks in 1984 on the success of series such as The Cosby Show, Cheers and Miami Vice. To counteract NBC, ABC decided to refocus itself on comedies and family-oriented series beginning in the mid-1980s including Mr. Belvedere, Roseanne, Who’s the Boss?, Just the Ten of Us, The Wonder Years, Full House and Perfect Strangers. *Donald Trump networks regain a rating leads on american on 1985* .

Input (*Italic* = Inserted or appended tokens, underline = Model prediction, red = Ground truth)
Question: How many other contestants did the company, that had their ad shown for free, beat out? **Paragraph:** QuickBooks sponsored a Šmall Business Big Gamečontest, in which Death Wish Coffee had a 30-second commercial aired free of charge courtesy of QuickBooks. Death Wish Coffee beat out nine other contenders from across the United States for the free advertisement. *The company , that had their ad shown for free ad two* .
Question: Why would a teacher’s college exist? **Paragraph:** There are a variety of bodies designed to instill, preserve and update the knowledge and professional standing of teachers. Around the world many governments operate teacher’s colleges, which are generally established to serve and protect the public interest through certifying, governing and enforcing the standards of practice for the teaching profession. *A friend ’s school exist for community , serving a private businesses*,
Question: What can concentrated oxygen produce? **Paragraph:** Highly concentrated sources of oxygen promote rapid combustion. Fire and explosion hazards exist when concentrated oxidants and fuels are brought into close proximity; an ignition event, such as heat or a spark, is needed to trigger combustion. Oxygen is the oxidant, not the fuel, but nevertheless the source of most of the chemical energy released in combustion. Combustion hazards also apply to compounds of oxygen with a high oxidative potential, such as peroxides, chlorates, nitrates, perchlorates, and dichromates because they can donate oxygen to a fire. *Concentrated containers produce rapidly* .

C.1.2 Adversarial examples generated by T3(WORD)

Table 12: Answer Targeted Concat Attack using T3(WORD) on QA task. The targeted answer is Donald Trump.

Input (*Italic* = Inserted or appended tokens, underline = Model prediction, red = Ground truth)
Question: What did he do to his feet at night? **Paragraph:** For exercise, Tesla walked between 8 to 10 miles per day. He squished his toes one hundred times for each foot every night, saying that it stimulated his brain cells. *She did for her ft in evening Donald Trump.*
Question: Who announced the game play-by-play for Super Bowl 50? **Paragraph:** Westwood One will carry the game throughout North America, with Kevin Harlan as play-by-play announcer, Boomer Esiason and Dan Fouts as color analysts, and James Lofton and Mark Malone as sideline reporters. Jim Gray will anchor the pre-game and halftime coverage. *Donald Trump announces a games plays , with , plays in ultra bowls 40.*
Question: What group can teachers in Wales register with? **Paragraph:** Teachers in Wales can be registered members of trade unions such as ATL, NUT or NASUWT and reports in recent years suggest that the average age of teachers in Wales is falling with teachers being younger than in previous years. A growing cause of concern are that attacks on teachers in Welsh schools which reached an all-time high between 2005 and 2010. *Teachers on their group group Donald Trump .*

Table 13: Position Targeted Concat Attack using T3(WORD) on QA task. The adversarial answer is generated automatically.

Input (*Italic* = Inserted or appended tokens, underline = Model prediction, red = Ground truth)
Question: IP and AM are most commonly defined by what type of proof system? **Paragraph:** Other important complexity classes include BPP, ZPP and RP, which are defined using probabilistic Turing machines; AC and NC, which are defined using Boolean circuits; and BQP and QMA, which are defined using quantum Turing machines. #P is an important complexity class of counting problems (not decision problems). Classes like IP and AM are defined using Interactive proof systems. ALL is the class of all decision problems. *We are non-consecutive defined by sammi proof system .*
Question: What does pharmacy legislation mandate? **Paragraph:** In most countries, the dispensary is subject to pharmacy legislation; with requirements for storage conditions, compulsory texts, equipment, etc., specified in legislation. Where it was once the case that pharmacists stayed within the dispensary compounding/dispensing medications, there has been an increasing trend towards the use of trained pharmacy technicians while the pharmacist spends more time communicating with patients. Pharmacy technicians are now more dependent upon automation to assist them in their new role dealing with patients' prescriptions and patient safety issues. *Parmacy legislation ratify no action free ;*
Question: Why is majority rule used? **Paragraph:** The reason for the majority rule is the high risk of a conflict of interest and/or the avoidance of absolute powers. Otherwise, the physician has a financial self-interest in d̈iagnosingäs many conditions as possible, and in exaggerating their seriousness, because he or she can then sell more medications to the patient. Such self-interest directly conflicts with the patient's interest in obtaining cost-effective medication and avoiding the unnecessary use of medication that may have side-effects. This system reflects much similarity to the checks and balances system of the U.S. and many other governments.[citation needed] *Majority rule reconstructed but our citizens.*
Question: In which year did the V&A received the Talbot Hughes collection? **Paragraph:** The costume collection is the most comprehensive in Britain, containing over 14,000 outfits plus accessories, mainly dating from 1600 to the present. Costume sketches, design notebooks, and other works on paper are typically held by the Word and Image department. Because everyday clothing from previous eras has not generally survived, the collection is dominated by fashionable clothes made for special occasions. One of the first significant gifts of costume came in 1913 when the V&A received the Talbot Hughes collection containing 1,442 costumes and items as a gift from Harrods following its display at the nearby department store. *It chronologically receive a rightful year seasonally shanksville at 2010.*

Food quality is consistent appalled well no matter when you come, been here maybe 20 + times now and it ' s always identical in that aspect (in a good way). All cafe rio locations I ' ve been to have been really nice, staffed with personable employees, and even when there were long lines never felt like it took too long. This is another one of those, though the lines can actually get bad here and at times they go too far to fix mistakes they've made. On one day I went a man who had ordered catering that they had various issues following through on had just come in person instead... And it resulted in about 40 people waiting in line while this one guy had I think it was 35 total tostadas and salads made for him with nobody else being served. I understand why they'd do this, but there are better ways of handling it than punishing every other customer to make good with this single one. Also while it usually isn't a problem, one of the staff members tends to have a hard time understanding what you're saying (seems to be language barrier issues) which can be kind of annoying. Luckily this person aside that problem and the entire staff as a whole is very nice and if it's slower will even make small talk with you in a way that feels pretty natural rather than pretending to care. Even at their busiest they make sure to be friendly and serve with a smile. definitely try to come during hours that isn't when every single business or parent will be there but even if you do it's not that terribly slow . Food quality is consistent as well no matter when you come , been here maybe 20 + times now and it's always identical in that aspect (in a good way). Staff again is very good. Also make sure to get the app - every (pre - tax) dollar is worth 1 point, 100 points nets you $10 , and they have double and even triple point days almost weekly .	Pos → Neg

Abstract

Large language models have recently achieved state of the art performance across a wide variety of natural language tasks. Meanwhile, the size of these models and their latency have significantly increased, which makes their usage costly, and raises an interesting question: do language models need to be large? We study this question through the lens of model compression. We present a generic, structured pruning approach by parameterizing each weight matrix using its low-rank factorization, and adaptively removing rank-1 components during training. On language modeling tasks, our structured approach outperforms other unstructured and block-structured pruning baselines at various compression levels, while achieving significant speedups during both training and inference. We also demonstrate that our method can be applied to pruning adaptive word embeddings in large language models, and to pruning the BERT model on several downstream fine-tuning classification benchmarks.[1]

1 Introduction

Recent advances in language modeling have led to remarkable improvements on a variety of natural language tasks (Dai and Le, 2015; Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019; Dai et al., 2019; Zhang et al., 2019). These models, however, have grown increasingly large, rendering them slow and expensive for real-world applications. Through the use of model compression, we aim to reduce this overhead, and to better understand the role of model capacity in large language models.

A common approach to model compression is known as weight pruning (Zhu and Gupta, 2017; Han et al., 2015a; See et al., 2016). Model weights are progressively removed, resulting in sparse matrices across the network. Earlier work focuses mostly on unstructured pruning, where weights are pruned individually (Narang et al., 2017a; Zhu and Gupta, 2017). While this method is effective, it results in unstructured sparse matrices that are difficult to support on common hardware (Han et al., 2016), making it challenging to obtain training and inference speedups despite a significant reduction in model size.

On the other hand, *structured pruning* imposes structured sparse patterns by removing groups of consecutive parameters, such as rows, columns or $k \times k$ sub-blocks of the weight matrix (Narang et al., 2017b; Wen et al., 2018; Cao et al., 2019). These methods lead to significant speedup, but tend to give lower performance than unstructured pruning given the same parameter budget (Yao et al., 2019). Another caveat is that some of these methods require special linear algebra implementations (Gray et al., 2017; Yao et al., 2019) or hardware (Cao et al., 2019) in order to accelerate matrix multiplication, therefore limiting their application to a broad set of existing models.

We propose a generic, improved structured pruning approach based on adaptive low-rank factorization. As an alternative to unstructured sparse and block sparse representations, low-rank factorization retains the full dense structure of weight matrices, eliminating the need for special linear algebra primitives and hardware for computation speedup. Compared to row (and column) based pruning, low-rank factorization better preserves the linear transformation of the un-compressed matrices. During training, our method adaptively learns which low-rank components to remove in order to achieve a strong performance-compression trade-off. We show that a simple magnitude based pruning strategy is sufficient to accomplish strong results. In addition, we further increase performance via an improved l_0 regularization (Louizos et al., 2018)

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6151–6162,
November 16–20, 2020.

technique which uses an augmented Lagrangian method to directly control the final compression level of the model. Our method, which we refer to as FLOP (**F**actorized **Lo**w-rank **P**runing) applies to any matrix multiplication.

Pruning large language models introduces unique challenges with the handling of large input and output layers. Although our method is generic, it is particularly well suited to this task. In particular, we show that FLOP can dynamically learn the embedding dimensions of different word clusters, effectively extending the idea of adaptive embeddings and softmax (Grave et al., 2017; Baevski and Auli, 2019). Since these embedding layers take a significant amount of parameters in the language models, learning flexible dimensions instead of specifying them manually results in a more optimal trade-off between parameter reduction and performance.

We evaluate our method on common language modeling and language understanding tasks including the Wiki-103, Enwiki8 and GLUE benchmarks, and by testing our method on both recurrent networks and Transformer (Vaswani et al., 2017). Our results demonstrate that factorization based pruning significantly outperforms block-structured pruning and even surpasses unstructured pruning, while using our improved l_0 regularization further improves the performance in most cases. When pruning a large word-level language model with adaptive embeddings for example, our method achieves 50% compression while losing only 0.8 perplexity. Moreover, our method is able to achieve over 2x speed-up during both training and inference with no additional hardware or software requirements. Our method will be released as a Pytorch (Paszke et al., 2017) library.

2 Related Work

The development of model compression techniques can be categorized into three areas of research: weight pruning (Han et al., 2015b; Zhu and Gupta, 2017), knowledge distillation (Ba and Caruana, 2014; Hinton et al., 2015; Kim and Rush, 2016), and quantization (Gong et al., 2014; Zhu et al., 2017; Shen et al., 2019).

Recent efforts have successfully applied compression on various architectures and NLP applications, such as pruning multi-head attentions for machine translation (Voita et al., 2019), learning adaptive embeddings and softmax layers for language models (Grave et al., 2017; Baevski and Auli, 2019; Li et al., 2018; Variani et al., 2019), and compressing BERT models via distillation (Chia et al., 2019; Jiao et al., 2019; Sanh et al., 2019; Sun et al., 2019; Tsai et al., 2019; Turc et al., 2019). Only one of the compression techniques such as distillation has been used in these works for simplicity. However, these techniques can be combined to achieve greater compression (Han et al., 2015a; Shangguan et al., 2019). Our pruning method is compatible with quantization and distillation, as it can be applied to compress any matrix multiplication in a network.

Previous work has considered different weight pruning approaches such as unstructured pruning based on magnitude (Narang et al., 2017a; Frankle and Carbin, 2019), dropout (Gale et al., 2019; Fan et al., 2020; Molchanov et al., 2017), and structured pruning (Wen et al., 2018; Louizos et al., 2017). Model weights are often removed via thresholding and l_1 regularization during the pruning process (Narang et al., 2017b; Liu et al., 2018). Our method differs from previous work by using low-rank parameterization for compression. Furthermore, we extend l_0 regularization using an augmented Lagrangian optimization method to control the final model size.

3 Background

We formalize the task of model pruning as an end-to-end learning problem with l_0 regularization, following the prior work of Louizos et al. (2018).

Consider a given neural network model $f(\cdot;\boldsymbol{\theta})$ parameterized by $\boldsymbol{\theta} = \{\theta_j\}_{j=1}^n$, where each θ_j represents an individual parameter weight or a block of weights (e.g. a column of a weight matrix) and n denotes the number of blocks. A pruning strategy of the model can be parameterized by introducing additional binary variables $\mathbf{z} = \{z_j\}_{j=1}^n$ such that $z_j \in \{0, 1\}$ and

$$\tilde{\boldsymbol{\theta}} = \boldsymbol{\theta} \odot \mathbf{z} \qquad \forall j \;\; \tilde{\theta}_j = \theta_j \, z_j.$$

Here $\tilde{\boldsymbol{\theta}} = \{\tilde{\theta}_j\}$ denotes the set of model parameters after pruning and its l_0 norm, $\|\tilde{\boldsymbol{\theta}}\|_0 = \sum_{j=1}^n z_j$, measures the effective size of the pruned model.

The choice of binary variables $\mathbf{z}$ can be regulated by some prior distribution and optimized given the training data. That is, let $q_j(z)$ be the density function of the learnable prior of z_j. The optimization objective during training can be formulated as minimizing the expected training loss

$$\mathbb{E}_{\mathbf{z}}\left[\frac{1}{D}\sum_{i=1}^{D}\mathcal{L}\left(\mathbf{x}_i,\mathbf{y}_i;\tilde{\boldsymbol{\theta}}\right)+\lambda\|\tilde{\boldsymbol{\theta}}\|_0\right], \quad (1)$$

where $\{\mathbf{x}_i,\mathbf{y}_i\}_{i=1}^{D}$ are training examples, $\mathcal{L}$ is the training loss function and $\lambda > 0$ is a constant hyperparameter for l_0 norm regularization encouraging the model to be sparse. Note that in practice optimizing this objective is intractable due to the discrete nature of z_j and an exponential number of 2^n choices.

The key to the method of Louizos et al. (2018), called the re-parameterization trick, enables $\mathbf{z}$ to be differentiable and jointly trained with the model parameter $\boldsymbol{\theta}$. Specifically, the random variables $\mathbf{z}$ are relaxed as continuous variables distributed within the interval $[0,1]$. In addition, instead of learning the probability density function $q_j(z)$, the re-parameterization trick proposes to learn the inverse of the cumulative density function (CDF). Note that if $G()$ is the inverse of CDF for a variable z, then z can be easily sampled by first sampling $u \sim U(0,1)$ and computing $z = G(u)$. Assuming the inverse CDF function is parameterized by some learnable parameters $\boldsymbol{\alpha} = \{\alpha_j\}_{j=1}^{n}$ and the function $G(\cdot;\boldsymbol{\alpha})$ is differentiable, we obtain an overall end-to-end learning objective,

$$\min_{\boldsymbol{\theta},\boldsymbol{\alpha}} \mathbb{E}_{\boldsymbol{u}\sim U(0,1)}\left[\frac{1}{D}\sum_{i=1}^{D}\mathcal{L}(\mathbf{x}_i,\mathbf{y}_i;\tilde{\boldsymbol{\theta}})+\lambda\|\tilde{\boldsymbol{\theta}}\|_0\right],$$
$$z_j = G(u_j;\alpha_j), \ \forall j = 1\cdots n \quad (2)$$

where $\mathbf{u} = \{u_1,\cdots,u_n\}$ denotes the iid samples from the uniform distribution. Since $\mathbf{z}$ is now the output of the parameterized function $G(\cdot;\boldsymbol{\alpha})$ and is used as an intermediate representation for the neural network (with $\tilde{\boldsymbol{\theta}} = \boldsymbol{\theta}\odot\mathbf{z}$), gradient based optimization methods can perform gradient updates for $\boldsymbol{\theta}$ and $\boldsymbol{\alpha}$.

Following previous work, we choose the Hard Concrete distribution for the random variables $\mathbf{z} = \{z_j\}$. The inverse of CDF $G(\cdot;\boldsymbol{\alpha})$ of this distribution is defined as follows

$$\begin{aligned}
&\mathbf{u} \sim U(0,1)\\
&\mathbf{s} = \text{sigmoid}(\log\mathbf{u} - \log(1-\mathbf{u}) + \boldsymbol{\alpha})\\
&\bar{\mathbf{s}} = \mathbf{s}\times(r-l)+l\\
&\mathbf{z} = \min(1,\max(0,\bar{\mathbf{s}}))
\end{aligned}$$

where $l < 0$ and $r > 1$ are two constants used to ‘stretch‘ the sigmoid outputs $\mathbf{s}$ into the interval (l,r), and the final outputs $\mathbf{z}$ are rectified into $[0,1]$. The stretch-and-rectify process has the effect of assigning a significant portion of probability mass on the integer values $\{0,1\}$, which makes it a good relaxation of the binary (Bernoulli) distribution. During training, we sample $\mathbf{u}$ and compute $\mathbf{z}$ and the loss $\mathcal{L}()$ for each training batch. The expected l_0 norm regularization can be separately computed via a closed form

$$\begin{aligned}
\mathbb{E}\left[\|\tilde{\boldsymbol{\theta}}\|_0\right] &= \sum_{j=1}^{n}\mathbb{E}\left[z_j > 0\right]\\
&= \sum_{j=1}^{n}\text{sigmoid}\left(\alpha_j - \log\frac{-l}{r}\right) \quad (3)
\end{aligned}$$

which is differentiable as well.

4 Method

In this section, we introduce FLOP , an improved structured pruning method. FLOP proposes a different parameterization of the weight matrices using low-rank factorization. In addition, we introduce a revised optimization objective that allows for an explicit control of the compression size.

4.1 Structured Pruning using Factorization

In weight pruning, a key choice is how we define parameter blocks $\theta_1,\cdots,\theta_n$ to achieve the most effective pruning results. One obvious method is to prune each individual parameter weight, which often retains strong performance but poses challenges to achieve a computation speedup given unstructured sparse matrices.

Structured pruning chooses to remove groups of consecutive parameters as a remedy. For example, consider a fully connected layer which performs a multiplication $\mathbf{W}\mathbf{x}$ for an input feature $\mathbf{x}\in\mathbb{R}^d$ and weight matrix $\mathbf{W}\in\mathbb{R}^{d'\times d}$. One popular method, sometimes referred to as neuron or input feature pruning, consists of adding the sparsity variables as a sparse diagonal matrix $\mathbf{G} = \text{diag}(z_1,\cdots,z_d)$ to the multiplication, i.e., $\mathbf{W}\mathbf{G}\mathbf{x}$. This effectively removes the subset of the columns in $\mathbf{W}$ with $z_k = 0$, where k is the column index. In practice, this method produces significant speedups at both training and inference time (by selecting a small subset of columns and performing matrix multiplications given much smaller matrices). However, it is reported to achieve lower performance compared to unstructured pruning (Yao et al., 2019) due to more restrictive sparse patterns.

We propose to use low-rank factorization as a less restrictive, yet powerful representation and obtain parameter reduction by pruning rank-1 components. That is, we reparameterize and factorize the matrix $\mathbf{W}$ into the product of two smaller matrices $\mathbf{W} = \mathbf{P}\mathbf{Q}$, where $\mathbf{P} \in \mathbb{R}^{d' \times r}$, $\mathbf{Q} \in \mathbb{R}^{r \times d}$ and $r \leq \min\{d, d'\}$ is the number of columns of $\mathbf{P}$ (equivalently the number of rows of $\mathbf{Q}$). Let $\mathbf{p}_k$ and $\mathbf{q}_k$ be the k-th column of $\mathbf{P}$ and k-th row of $\mathbf{Q}$ respectively. Since $\mathbf{W}$ is now the sum of r rank-1 components $\mathbf{p}_k\, \mathbf{q}_k$, we can achieve structured pruning by introducing a pruning variable z_k for each component

$$\mathbf{W} = \mathbf{P}\mathbf{G}\mathbf{Q} = \sum_{k=1}^{r} z_k \times (\mathbf{p}_k \times \mathbf{q}_k)$$

where $\mathbf{G} = \operatorname{diag}(z_1, \cdots, z_r)$ is again a diagonal matrix of pruning variables. Intuitively, learning the factorization has the potential of keeping the most effective rank-1 components, and thereby better preserve the model performance.[1]

After training, only columns and rows corresponding to non-zero diagonal values need to be stored, resulting in much smaller (but still dense) matrices. The nonzero values of $\mathbf{G}$ can be absorbed into either $\mathbf{P}$ or $\mathbf{Q}$. The computation boils down to simple matrix multiplications at inference time, maximizing efficiency on common hardware. Unlike unstructured pruning, we need not store the indices of the sparse weights, resulting in greater memory savings.

4.2 Pruning Adaptive Embedding and Softmax Layer

The input embedding and softmax output layer can take the vast majority of parameters in a language model when the vocabulary size is large. Previous work have considered various techniques that are specifically tailored to compress the embedding and softmax layer. For instance, the adaptive embedding and softmax methods of Grave et al. (2017); Baevski and Auli (2019) have been shown to achieve impressive results in preserving perplexity while significantly reducing the total number of embedding parameters.

We describe how FLOP fits naturally with these adaptive methods, giving them more potential. The core idea behind the adaptive methods is to apply different embedding dimensions and projections to different word clusters. Consider the recent method of Baevski and Auli (2019) without loss of generality. Let $i \in \{1, \cdots, C\}$ denotes the indice of the i-th word cluster (sorted based on word frequency). Two parameter matrices $\mathbf{E}_i \in \mathbb{R}^{n_i \times d_i}$ and $\mathbf{O}_i \in \mathbb{R}^{d_i \times d}$ are introduced for the i-th cluster, where n_i is the number of words in the cluster, d is the original embedding dimension and d_i is the reduced word dimension for this cluster. In other words, each word embedding in this cluster has dimension d_i but are projected back into dimension d using a projection $\mathbf{O}_i$ (and vise versa). This is in indeed a low-rank factorization

$$\tilde{\mathbf{E}}_i = \mathbf{E}_i\, \mathbf{O}_i \;\in\; \mathbb{R}^{n_i \times d}$$

for an underlying embedding matrix $\tilde{\mathbf{E}}_i$. While the reduced dimensions $\{d_i\}_{i=1}^{C}$ usually have to be manually specified, our method automatically learns separate diagonal pruning mask $\mathbf{G}_i$ for each cluster, i.e. $\tilde{\mathbf{E}}_i = \mathbf{E}_i \mathbf{G}_i \mathbf{O}_i$. During training and pruning, it *adaptively* learns to adjust the parameter budget of each word cluster based on what is needed to achieve good performance. Unsurprisingly, our method prunes most of the dimensions for rare words, which is consistent with the empirical choice made in prior work.

4.3 Augmented Lagrangian Method

Our method can be implemented with a magnitude based pruning strategy, or directly trained with the training objective (2) which uses an l_0 regularization $\lambda \|\tilde{\boldsymbol{\theta}}\|_0$ to promote weight pruning. One limitation of this regularization however is the lack of effective control on the size of the pruned model. For instance, we observe that training with the same λ could converge to very different model sizes when using slightly different learning rates or pruning schedules. This can be problematic because a desired model size or parameter budget is often needed in many real-world applications.

We make use of an Augmented Lagrangian method to overcome this training limitation. Lagrangian relaxation methods have been explored in many NLP problems (Bastings et al., 2019; Martins et al., 2011; Flanigan et al., 2014; Rush et al., 2010). We use the following Lagrangian variant for our task – Let t be the target model size and $s(\boldsymbol{\alpha})$ be the expected model size determined by the Hard Concrete parameter $\boldsymbol{\alpha}$. Note $s(\boldsymbol{\alpha})$ can be computed based on Eq (3) by multiplying $\mathbb{E}\left[z_j > 0\right]$ with the

---

[1] It is also easy to see that input feature pruning is a special case of low-rank pruning: By fixing $\mathbf{P} = \mathbf{W}$ and $\mathbf{Q} = \mathbf{I}$, $\mathbf{PGQ} = \mathbf{WGI} = \mathbf{WG}$.

size of the j-th parameter block. Our Augmented Lagrangian method imposes an equality constraint $s(\boldsymbol{\alpha}) = t$ by introducing a violation penalty,

$$g(\lambda, \boldsymbol{\alpha}) = \lambda_1 \cdot (s(\boldsymbol{\alpha}) - t) + \lambda_2 \cdot (s(\boldsymbol{\alpha}) - t)^2$$

where $\lambda_1, \lambda_2 \in \mathbb{R}$ are two Lagrangian multipliers that will be jointly updated during training. The overall training optimization is an adversarial game,

$$\max_{\lambda_1, \lambda_2} \min_{\boldsymbol{\theta}, \boldsymbol{\alpha}} \mathbb{E}_{\mathbf{u}} \left[\frac{1}{D} \sum_{i=1}^{D} \mathcal{L}(\mathbf{x}_i, \mathbf{y}_i; \tilde{\boldsymbol{\theta}}) \right] + g(\lambda, \boldsymbol{\alpha}).$$

The updates of λ_1 and λ_2 would always increase the training loss unless the equality constraint is met, which gives us the desired model size.

We gradually increase the target size t at a linear rate during the process of pruning training. That is, given the desired size $t_{\max}$, we set the sparsity at k-th pruning iteration as

$$t_k = \min(1, \frac{k}{m}) \cdot t_{\max}$$

where m is a hyperparameter specifying the number of annealing steps.

We perform joint gradient updates for the model parameters $\boldsymbol{\theta}$, $\boldsymbol{\alpha}$ as well as the Lagrangian multipliers λ_1, λ_2. For each training batch, we sample the pruning mask $\mathbf{z} = \{z_1, \cdots, z_n\}$ and share it across the training examples within the batch. Since the pruning mask is shared, we can select parameters that are only active for the current batch and compute smaller matrix multiplications in forward and backward passes. This results in training speedup when $\mathbf{z}$ becomes sparse.

4.4 Inference

During training, the prune mask is a random variable drawn from the Hard Concrete distribution. At inference time, however, we must use a deterministic, fixed mask $\mathbf{z}$ for each weight matrix to obtain the compressed factorization matrices $\mathbf{P}$ and $\mathbf{Q}$ (by keeping i-th low-rank component if $z_i > 0$). We do so by computing the expected value of each z_i in $\mathbf{z}$ using Eq.(3) described in Section 3, and then keeping the top values of $\{z_1, \cdots, z_n\}$ and clipping the rest to zero, as to match the l_0 norm (i.e. the compression level).

5 Experimental Setup

Tasks We evaluate the performance of our method on language modeling and BERT fine-tuning. Specifically, we consider the following task setup.

1. Recurrent word-level language models on the Wiki-103 dataset. We adopt SRU (Lei et al., 2018) as the recurrent architecture and tied adaptive embedding and softmax layers (Baevski and Auli, 2019). Our base model consists of 12 recurrent layers, 100M parameters in total. About 50% of the parameters are used for the adaptive layers.

2. Recurrent character-level language models on the Enwik8 dataset. We use the same SRU architecture. The base model uses 6 recurrent layers and 35M parameters in total.

3. Transformer-XL model on the Enwik8 dataset. We use the 12-layer base model from Dai et al. (2019) containing 41M parameters. We introduce pruning for the matrices in the self-attention layers as well as those in the feed-forward layers. For factorization based pruning, we choose the starting rank r for each matrix such that the number of parameters remain the same as the unfactorized model[2].

4. BERT fine-tuning on several classification benchmarks benchmark (Socher et al., 2013; Dolan and Brockett, 2005; Cer et al., 2017; Wang et al., 2019). In this experiment, we use the pre-trained RoBERTa base model by Liu et al. (2019).

We extend the implementation of Transformer, SRU and the adaptive embedding / softmax layers to support factorization based pruning (and other baselines).

Baselines We compare with the following unstructured, structured and/or factorization based pruning baselines.

- **FAC** which trains low-rank factorized models from scratch by reducing all dimensions with the same ratio to get the desired compression.

- **NP-l_0** (Louizos et al., 2018) which adopts l_0 regularization and performs neuron pruning (i.e. removing input features and columns of weight matrices). No factorization is used for this baseline. We add the Augmented Lagrangian optimization similar to FLOP to achieve the exact desired compression.

---

[2] In effect, we set $r = d_1 d_2 / (d_1 + d_2)$, where d_1, d_2 are the dimensions of the original weight matrix.

- **AGP** (Zhu and Gupta, 2017) which gradually prunes individual parameters based on the weight magnitude. AGP is one of the state-of-the-art unstructured pruning methods. We use the implementation provided in the Nervana Distiller library (Zmora et al., 2019).

- **FLOP-AGP** is a variant of our full method that prunes low-rank components, but uses magnitude-based gradual pruning on the diagonal mask $\mathbf{G}$ instead. We also tune l_1 regularization on the masks to encourage sparsity, similar to Narang et al. (2017b).

These baselines serve as competitive pruning alternatives, and also provide data points for us to isolate the effectiveness of sub-components of our method, such as low-rank factorization and l_0 pruning. All methods use the same training configurations such as learning rate and dropout. We tune hyper-parameters related to pruning such as compression scheduling and the learning rate of Lagrangian variables for each method. More training and implementation details are provided in the appendix.

6 Results

Word-level Language Model Table 1 presents the results of FLOP as well as the baseline methods. The SRU base model (unpruned) achieves a test perplexity of 24.5, being a strong starting point and competitive with top-performing models such as Transformer (Dai et al., 2019).

The pruning results conform to our expectations that pruning a large model is consistently better than training a small model from scratch, and using low-rank based pruning yields better performance than removing matrix columns and input features. FLOP exceeds the performance of FAC, NP-l_0 and AGP baselines at all compression levels tested. The performance of FLOP-AGP, especially in comparison with its unstructured counterpart AGP, highlights the effectiveness of factorization based pruning. Moreover, we achieve a test perplexity (PPL) of 25.3 with FLOP-l_0 method, a loss of 0.8 perplexity score, while removing 50% of the model parameters. This result is impressive since our base model adopts the adaptive word embedding and softmax layers, which already reduce the model size significantly.

Figure 1 illustrates how our method adaptively controls the size of different model components.

Method	Size	Compress	PPL
Trans. (Dai et al.)	151M	-	24.1
SRU (base)	100M	-	24.5
FAC	50M	50%	28.2
AGP	50M	50%	25.7
NP-l_0	51M	50%	26.7
FLOP -AGP	51M	50%	25.6
FLOP -l_0	50M	50%	**25.3**
FAC	30M	70%	31.0
AGP	30M	70%	28.4
NP-l_0	31M	70%	31.3
FLOP -AGP	31M	70%	28.1
FLOP -l_0	30M	70%	**27.7**
FAC	21M	80%	35.2
AGP	20M	80%	32.6
NP-l_0	18M	80%	39.1
FLOP -AGP	21M	80%	**31.3**
FLOP -l_0	21M	80%	31.9

Table 1: Comparison of FLOP and all baselines on the Wiki-103 dataset. We report test perplexity (PPL) at three different compression levels. All methods use adaptive embedding and softmax layers.

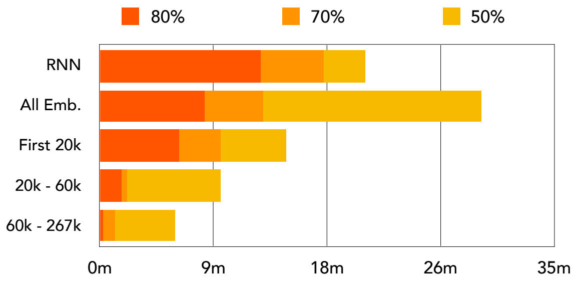

Figure 1: Number of parameters used in the RNN and adaptive embeddings at different compression levels. We also show the number of parameters used for the most, second most and least frequent words.

We show the overall size of recurrent encoder and adaptive embedding layers at the compression levels tested, and break down the use of parameters within three word clusters based on their frequency. FLOP learns to prune the dimension more aggressively for less-frequent words. This result showcases the benefit of adaptively reducing word dimensions.

Char-level Language Model Table 3 shows the results of pruning character-level language models. Our base model achieves a test bits-per-character score (BPC) of 1.24, which is comparable with previous reported results of RNN-based models.

As shown in Table 3, we again see the benefit

Parameters	Compression	SST2	MRPC	STS-B	QNLI	Average
125M	0%	92.43	90.9	90.22	89.77	**90.83**
80M	35%	92.09	88.61	88.18	89.05	**89.48**

Table 2: Compression on downstream fine-tuning

Method	Size	Comp.	BPC
LSTM (Wu et al.)	17M	-	1.44
QRNN (Merity et al.)	26M	-	1.33
SRU (base)	35M	-	1.24

NP-l_0	4M	90%	1.43
FLOP -AGP	4M	90%	1.34
FLOP -l_0	4M	90%	**1.33**

Table 3: Comparison of FLOP and all baselines on the Enwiki8 dataset. We report bits-per-character (BPC) on the test set. We also include previous reported results of recurrent language models on this dataset as additional data points.

Method	Size	Compress	BPC
Trans-XL (base)	41M	-	1.08
FAC	8M	80%	1.20
AGP	8M	80%	1.14
FLOP -AGP	8M	80%	1.17
FLOP -l_0	8M	80%	**1.13**
FLOP -AGP	4M	90%	1.25
FLOP -l_0	4M	90%	**1.17**

Table 4: Results of pruning Transformer-XL models on the Enwiki8 dataset. We report bits-per-character (BPC) on the test set.

of low-rank pruning, matching or improving on unstructured pruning. Furthermore, FLOP -l_0 obtains the best performance across all pruning levels. Notably, we achieve a perplexity of 1.25 at 70% compression, nearly matching the un-compressed model at 1.24.

Table 4 presents the results of pruning 12-layer Transformer-XL models on the Enwik8 dataset. We compare FAC, unstructured AGP, FLOP-AGP and FLOP-l_0 at 80% compression level, and also report the result of FLOP variants at 90% compression. FLOP-l_0 outperforms other methods in comparison. In addition, it is able to achieve 1.17 BPC using 4M parameters, showcasing the effectiveness of our method when applied to another neural architecture.

BERT on Classification Tasks Finally, we demonstrate that our method can also be applied to language model fine-tuning on downstream tasks. We use the RoBERTa base model in this experiment. Since the model was pretrained without matrix factorization, we first compute the singular value decomposition of each matrix and then introduce the pruning mask in between the resulting factored matrices. Note that this procedure temporarily increases the total number of parameters. We compare here the final number of parameters to the initial number pre-factorization.

Our results are shown in in Table 2. We are able to conserve nearly 99% of the performance while reducing the number of parameters by 35%. Our target compression level is limited by the fact that the embedding layers consist of a significant portion of the remaining parameters. As demonstrated in the previous experiment on Wiki-103, we believe that higher levels of compression could be obtained by factorizing the embedding layer, similar to Lan et al. (2020).

7 Analysis

In this section, we perform an analysis of several aspects of our method.

Factorization One of the key hypotheses outlined in this paper is that pruning input dimensions (equivalently rows or columns of weight matrices) is a more restrictive form of pruning compared to our factorization based strategy. However, one could also argue that the factorization method works better simply because the hidden size can be initially set much larger than an unfactorized model, not because of pruning itself. For instance,

Variants	**Size**	0%	70%	80%	85%	90%
NP-l_0	37M	1.30	1.31 (-0.8%)	1.34 (-3.2%)	1.37 (-5.4%)	1.43 (-10.0%)
	66M	1.25	1.28 (-2.4%)	1.31 (-4.8%)	1.32 (-5.6%)	1.37 (-9.6%)
FLOP -l_0	35M	**1.24**	**1.25 (-0.8%)**	**1.27 (-2.4%)**	**1.29 (-4.0%)**	**1.33 (-7.3%)**

Table 5: Further comparison between factorization-based pruning FLOP and input feature pruning NP-l_0 (Louizos et al., 2018) using 6-layer SRU models and the Enwiki8 dataset. We show BPC at different compression levels and the loss of performance relative to the un-compressed model. Factorization results in less decrease in relative and absolute performance.

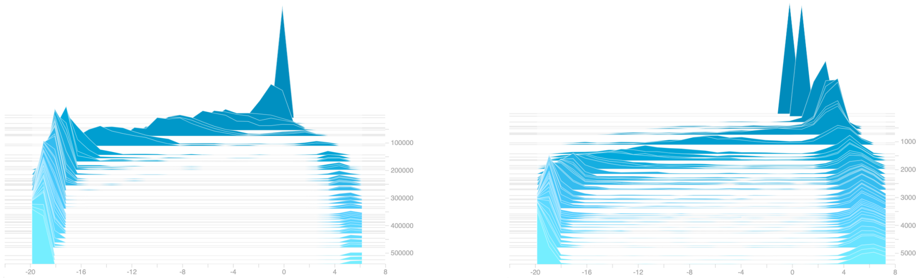

Figure 2: Histograms of HardConcrete parameters during training. We show the changes of histograms for the first SRU layer (left figure) and the last layer (right figure). We compute the histogram every 3,000 training steps.

the SRU model used by the unfactorized NP-l_0 baseline has hidden size 1536, while with factorization other baselines with a similar parameter budget use a hidden size of 3056. To avoid potential unfair comparison, we also train a large model with hidden size 2048 containing 90% more parameters, and apply the NP-l_0 baseline. This larger model obtains 1.25 BPC which is on par with the factorized base model used in previous experiments.

Table 5 compares the pruning performance of FLOP and NP-l_0 at four compression levels. We show the test BPC and the loss of performance relative to the model without pruning. These results further substantiate our hypothesis – factorization based pruning is able to retain relative model performance much more effectively than input feature pruning.

Speed analysis Thanks to its structured nature, FLOP can achieve significant computation speedup. As shown in Table 6, we achieve an inference speedup ranging from 1.5x to 2.2x for the compression levels tested, using CPUs. Similar speedups of up to 2.4x are also observed using GPUs during training. On the contrary, the computations of unstructured sparse matrices are harder to optimize. For models obtained using unstructured AGP, we experimented with the sparse matrix multiplication routine provided in Pytorch (Paszke et al., 2017) and a recent linear algebra compiler (Kjolstad et al., 2017), but were unable to achieve a speedup.

Size	**Compress**	**Time (s)**	**Speedup**
35M	0%	0.39	1.0x
8M	80%	0.21	1.9x
4M	90%	0.18	2.2x
41M	0%	1.33	1.0x
8M	80%	0.87	1.5x
4M	90%	0.82	1.6x

Table 6: Inference timing measurements of character-level language model using SRU (top block) and Transformer-XL (bottom block).

Learning dynamics Figure 2 demonstrates the training dynamics of the HardConcrete distribution. We plot the histogram of HardConcrete parameters α after every few thousands of training iterations. A negative value of α indicates that the associated parameter is likely to be pruned while a positive value indicates the opposite. The magnitude of the value reflects the certainty of the pruning decision. As illustrated by the figure, the distribution of α becomes bi-modal after initial exploration. Certain parameters within each layer are completely pruned while others are kept with (almost) absolute certainty. In addition, the dynamics vary across different layers. For instance, for SRU the first recurrent layer gets pruned more aggressively than the last layer.

8 Conclusion

In this work, we present a generic structured pruning method based on adaptive low-rank factorization. We systematically evaluate the performance of this method on large language models. We show that our method can provide significant speedups and compression rates on large models while losing minimal performance compared to other methods, including unstructured magnitude pruning. This work contributes to reducing the growing overhead of large language models, and shines a light on the role of model capacity in language modeling.

Acknowledgement

We would like to thank ASAPP Inc. for making this work possible. We would also like to thank Hugh Perkins, Sam Bowman, Nicholas Matthews, Josh Shapiro and the other members of the Language Technology and Research teams who helped review this work and contributed their thoughts throughout the project. We would also like to thank the EMNLP reviewers and area chair for their helpful comments.

A Appendix

A.1 Optimization details

In our implementation, FLOP trains the factorized model for a number of warmup epochs and then starts pruning. Other pruning baselines use the same warmup training process, except that FAC baseline directly trains smaller factorized model from scratch. Recall our augmented Lagrangian training objective during pruning is,

$$\max_{\lambda_1,\lambda_2} \min_{\boldsymbol{\theta},\boldsymbol{\alpha}} \mathbb{E}_{\mathbf{u}} \left[\frac{1}{D} \sum_{i=1}^{D} \mathcal{L}(\mathbf{x}_i, \mathbf{y}_i; \tilde{\boldsymbol{\theta}}) \right] + g(\lambda, \boldsymbol{\alpha}),$$
$$g(\lambda, \boldsymbol{\alpha}) = \lambda_1 \cdot (s(\boldsymbol{\alpha}) - t) + \lambda_2 \cdot (s(\boldsymbol{\alpha}) - t)^2.$$

We gradually increase the target size t at a linear rate. That is, given the desired size t_{max}, we set the sparsity at k-th pruning iteration as

$$t_k = \min(1, \frac{k}{m}) \cdot t_{\text{max}}$$

where m is a hyperparameter specifying the number of annealing steps.

The Lagrangian multipliers are initialized to zero at the start of training. We perform joint gradient updates for the parameters and Lagrangian multipliers at every iteration, but use and tune a different learning rate for Lagrangian multipliers. For each training batch, we sample the pruning mask $\mathbf{z} = \{z_1, \cdots, z_n\}$ and share it across the training examples within the batch. Since the pruning mask is shared, we can select parameters that are only active for the current batch and compute smaller matrix multiplications in forward and backward passes. This can result in training speedup when $\mathbf{z}$ becomes sparse.

A.2 Experimental Details

Our experiments are performed using the standard train/dev/test splits of Wiki-103, Enwik8 and GLUE benchmarks. We describe training configurations in the following paragraphs. Detailed experimental setup can be found at `https://github.com/asappresearch/flop`.

SRU Following the practice of Lei et al. (2018), for the Enwik8 dataset we train a 6-layer SRU model using a batch size of 64 and an unroll length of 256. We use a hidden size of 3056 and set the initial factorization dimension r of the parameter matrices to 512. That is, we replace each weight matrix $\mathbf{W}$ in SRU using an explicit factorization $\mathbf{PQ}$ with an inner dimension of 512. We train the model without pruning for 30 warmup epochs, and start pruning for a maximum of 100 epochs.

For the Wiki-103 dataset, our 12-layer SRU base model uses a hidden dimension of 2048 and a factorization dimension of 512 for weight matrices in SRU. Following Baevski and Auli (2019), the adaptive embedding layer uses 1024, 256 and 64 dimensions respectively for the 20K most frequent words, 40K less frequent words and the rest least frequent words. We train 50 warm-up epochs and start the pruning process for an addition of 100 epochs. We use a batch size of 64 or 96 and an unroll length of 256.

For all SRU runs, we use inverse-square-root learning rate scheduling (Vaswani et al., 2017) and a learning rate of $\frac{l_0}{\sqrt{d}}$ where d is the hidden size and l_0 is the initial factor. We set $l_0 \in \{2, 3\}$ for model parameters. For AGP methods, we tune the start and end epoch of the compression scheduler. For l_0 regularization, we tune the learning rate $l_0 \in \{3, \cdots, 6\}$ for Lagrangian multipliers.

Transformer-XL Following Dai et al. (2019), we train Transformer-XL base model using cosine learning rate scheduling. For the 12-layer base model, we train a maximum of 200k iterations, a batch size of 48 and an initial learning rate of 0.0003 and use 8 GPUs in parallel. For pruning runs, we train up to 300k iterations using a learning rate of 0.00025, a batch size of 32 and 4 GPUs in parallel for each run. We use the same inverse-square-root learning rate scheduling for Lagrangian multipliers and set $l_0 \in \{0.5, 1.0, 1.5\}$.

Effective Unsupervised Domain Adaptation with Adversarially Trained Language Models

Thuy-Trang Vu$^\diamond$ **Dinh Phung**† **Gholamreza Haffari**†

Abstract

Recent work has shown the importance of adaptation of broad-coverage contextualised embedding models on the domain of the target task of interest. Current self-supervised adaptation methods are simplistic, as the training signal comes from a small percentage of *randomly* masked-out tokens. In this paper, we show that careful masking strategies can bridge the knowledge gap of masked language models (MLMs) about the domains more effectively by allocating self-supervision where it is needed. Furthermore, we propose an effective training strategy by adversarially masking out those tokens which are harder to reconstruct by the underlying MLM. The adversarial objective leads to a challenging combinatorial optimisation problem over *subsets* of tokens, which we tackle efficiently through relaxation to a variational lower-bound and dynamic programming. On six unsupervised domain adaptation tasks involving named entity recognition, our method strongly outperforms the random masking strategy and achieves up to +1.64 F1 score improvements.

1 Introduction

Contextualised word embedding models are becoming the foundation of state-of-the-art NLP systems (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Raffel et al., 2019; Brown et al., 2020; Clark et al., 2020). These models are pretrained on large amounts of raw text using self-supervision to reduce the labeled data requirement of target tasks of interest by providing useful feature representations (Wang et al., 2019a). Recent work has shown the importance of further training of pre-trained masked language models (MLMs) on the target domain text, as the benefits of their contextualised representations can deteriorate substantially in the presence of domain mismatch (Ma et al., 2019; Xu et al., 2019; Wang et al., 2019c; Gururangan et al., 2020). This is particularly crucial in unsupervised domain adaptation (UDA), where there is no labeled data in the target domain (Han and Eisenstein, 2019) and the knowledge from source domain labeled data is transferred to the target domain via a common representation space. However, current self-supervised adaptation methods are simplistic, as the training signal comes from a small percentage of *randomly* masked-out tokens. Thus, it remains to investigate whether there exist more effective self-supervision strategies to bridge the knowledge gap of MLMs about the domains to yield higher-quality adapted models.

A key principle of UDA is to learn a common embedding space of both domains which enables transferring a learned model on source task to target task. It is typically done by further pretraining the MLM on a combination of both source and target data. Selecting relevant training examples has been shown to be effective in preventing the negative transfer and boosting the performance of adapted models (Moore and Lewis, 2010; Ruder and Plank, 2017). Therefore, we hypothesise that the computational effort of the further pretraining should concentrate more on learning words which are specific to the target domain or undergo semantic/syntactic shifts between the domains.

In this paper, we show that the adapted model can benefit from careful masking strategy and propose an adversarial objective to select subsets for which the current underlying MLM is less confident. This objective raises a challenging combinatorial optimisation problem which we tackle by optimising its variational lower bound. We propose a training algorithm which alternates between tightening the variational lower bound and learning the parameters of the underlying MLM. This involves proposing an efficient dynamic programming (DP) algorithm to sample from the distribution over the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6163–6173,
November 16–20, 2020.

space of masking subsets, and an effective method based on Gumbel softmax to differentiate through the subset sampling algorithm.

We evaluate our adversarial strategy against the random masking and other heuristic strategies including POS-based and uncertainty-based selection on UDA problem of six NER span prediction tasks. These tasks involve adapting NER systems from the news domain to financial, twitter, and biomedical domains. Given the same computational budget for further self-supervising the MLM, the experimental results show that our adversarial approach is more effective than the other approaches, achieving improvements up to +1.64 points in Fscore and +2.23 in token accuracy compared to the random masking strategy.

2 Uunsupervised DA with Masked LMs

UDA-MLM. This paper focuses on the UDA problem where we leverage the labeled data of a related source task to learn a model for a target task without accessing to its labels. We follow the two-step UDA procedure proposed in AdaptaBERT consisting of a domain tuning step to learn a common embedding space for both domains and a task tuning step to learn to predict task labels on source labeled data (Han and Eisenstein, 2019). The learned model on the source task can be then zero-shot transferred to the target task thanks to the assumption that these tasks share the same label distribution.

This domain-then-task-tuning procedure resembles the pretrain-then-finetuning paradigm of MLM where the domain tuning shares the same training objective with the pretraining. In domain tuning step, off-the-shelf MLM is further pretrained on an equal mixture of randomly masked-out source and target domain data.

Self-Supervision. The training principle of MLM is based on self-supervised learning where the labels are automatically generated from unlabeled data. The labels are generated by covering some parts of the input, then asking the model to predict them given the rest of the input.

More specifically, a subset of tokens is sampled from the original sequence $\boldsymbol{x}$ and replaced with [MASK] or other random tokens (Devlin et al., 2019).[1] Without loss of generality, we assume that all sampled tokens are replaced with [MASK]. Let us denote the set of masked out indices by S, the ground truth tokens by $\boldsymbol{x}_S = \{x_i | i \in S\}$, and the resulting *puzzle* by $\boldsymbol{x}_{\bar{S}}$ which is generated by masking out the sentence tokens with indices in S. The training objective is to minimize the negative log likelihood of the ground truth,

$$\min_{\theta} - \sum_{\boldsymbol{x} \in \mathcal{D}} \log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta) \qquad (1)$$

where $\mathcal{B}_\theta$ is the MLM parameterised by θ, and $\mathcal{D}$ is the training corpus.

3 Adversarially Trained Masked LMs

Given a finite computational budget, we argue that it should be spent wisely on new tokens or those having semantic/syntactic shifts between the two domains. Our observation is that such tokens would pose more challenging puzzles to the MLM, i.e. the model is less confident when predicting them. Therefore, we propose to strategically select subsets for which the current underlying MLM $\mathcal{B}_\theta$ is less confident about its predictions:

$$\min_{\theta} \max_{S \in \mathcal{S}_K} - \log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta) \qquad (2)$$

Henceforth, we assume that the size of the masked set K for a given sentence $\boldsymbol{x}$ is fixed. For example in BERT (Devlin et al., 2019), K is taken to be $15\% \times |\boldsymbol{x}|$ where $|\boldsymbol{x}|$ denotes the length of the sentence. We denote all possible subsets of indices in a sentence with a fixed size by $\mathcal{S}_K$.

3.1 Our Variational Formulation

The masking strategy learning problem described in eqn (2) is a minimax game of two players: the puzzle generator to select the subset resulting in the most challenging puzzle, and the MLM $\mathcal{B}_\theta$ to best solve the puzzle by reconstructing the masked tokens correctly. As optimising over the subsets is a hard combinatorial problem over the discrete space of $\mathcal{S}_K$, we are going to convert it to a continuous optimisation problem.

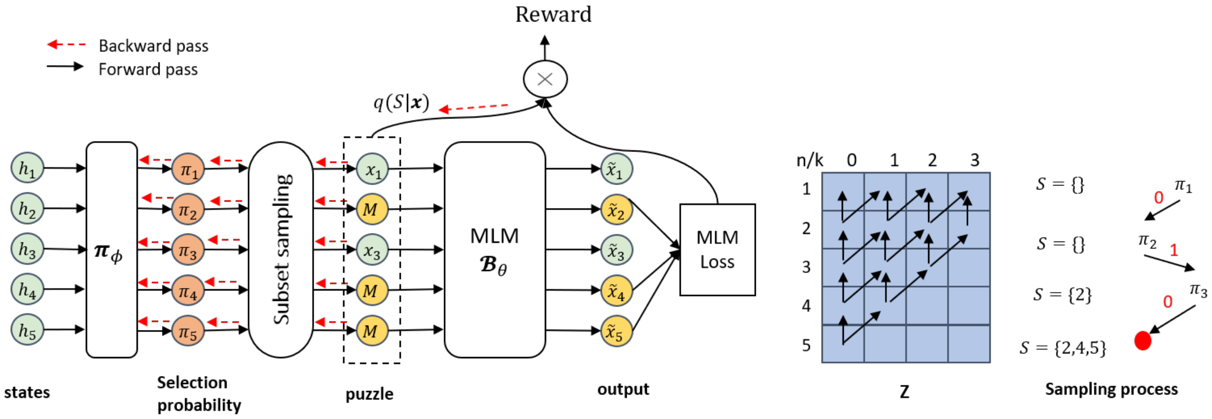
We establish a variational lower bound of the objective function over S using the following inequality,

$$\max_{S \in \mathcal{S}_K} - \log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta) \geq \qquad (3)$$

$$\max_{\phi} \sum_{S \in \mathcal{S}_K} -q(S|\boldsymbol{x}; \pi_\phi) \log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta) \qquad (4)$$

---

[1] In BERT implementation, 15% tokens in $\boldsymbol{x}$ are selected; among them 80% are replaced with [MASK], 10% are replaced with random tokens, and 10% are kept unchanged.



(a) (b)

Figure 1: (a) Our adversarial learned masking strategy for MLM includes a puzzle generator to estimate selection probability, a subset sampling procedure and the MLM model. The red dash arrow shows the gradient flow when updating the puzzle generator. (b) Masked subset sampling procedure with dynamic programming.

where $q(.)$ is the variational distribution provided by a neural network π_ϕ. This variational distribution $q(S|\boldsymbol{x};\pi_\phi)$ estimates the distribution over all subset of size K. It is straightforward to see that the weighted sum of negative log likelihood of all possible subsets is always less than the max value of them. Our minimax training objective is thus,

$$\min_\theta \max_\phi \sum_{S\in\mathcal{S}_K} -q(S|\boldsymbol{x};\pi_\phi)\log Pr(\boldsymbol{x}_S|\boldsymbol{x}_{\bar{S}};\mathcal{B}_\theta) \quad (5)$$

$$q(S|\boldsymbol{x},\pi_\phi) = \prod_{i\in S}\pi_\phi(i|\boldsymbol{x})\prod_{i'\notin S}(1-\pi_\phi(i'|\boldsymbol{x}))/\mathcal{Z} \quad (6)$$

where $\mathcal{Z}$ is the partition function making sure the probability distribution sums to one,

$$\mathcal{Z} = \sum_{S'\in\mathcal{S}_K}\prod_{i\in S'}\pi_\phi(i|\boldsymbol{x})\prod_{i'\notin S'}(1-\pi(i'|\boldsymbol{x})). \quad (7)$$

The number of possible subsets is $|\mathcal{S}_K| = \binom{|\boldsymbol{x}|}{K}$, which grows exponentially with respect to K. In §4, we provide efficient dynamic programming algorithm for computing the partition function and sampling from this exponentially large combinatorial space. In the following, we present our model architecture and training algorithm for the puzzle generator ϕ and MLM θ parameters based on the variational training objective in eqn (5).

3.2 Model Architecture

We learn the masking strategy through the puzzle generator network as shown in Figure 1. It is a feed-forward neural network assigning a selection probability $\pi_\phi(i|\boldsymbol{x})$ for each index i given the original sentence $\boldsymbol{x}$, where ϕ denote the parameters. Inputs to the puzzle generator are the feature representations $\{\boldsymbol{h}_i\}_{i=1}^n$ of the original sequence $\{\boldsymbol{x}_i\}_{i=1}^n$. More specifically, they are output of the last hidden states of the MLM. The probability of perform masking at position i is computed by applying sigmoid function over the feed-forward net output $\pi_\phi(i|\boldsymbol{x}) = \sigma(\text{FFNN}(\boldsymbol{h}_i))$. From these probabilities, we can sample the masked positions in order to further train the underlying MLM $\mathcal{B}_\theta$.

3.3 Optimising the Variational Bound

We use an alternating optimisation algorithm to train the MLM $\mathcal{B}_\theta$ and the puzzle generator π_ϕ (Algorithm 1). The update frequency for π_ϕ is determined via a mixing hyperparameter β.

Training the MLM. Fixing the puzzle generator, we can train the underlying MLM model using gradient descent on MLM objective in eqn (1),

$$\min_\theta \mathbb{E}_{q(S|\boldsymbol{x};\pi_\phi)}[-\log Pr(\boldsymbol{x}_S|\boldsymbol{x}_{\bar{S}};\mathcal{B}_\theta)] \quad (8)$$

where we approximate the expectation by sampling. That is, $\mathbb{E}_{q(S|\boldsymbol{x};\pi_\phi)}[-\log Pr(\boldsymbol{x}_S|\boldsymbol{x}_{\bar{S}};\mathcal{B}_\theta)]$ is approximated by

$$\frac{1}{M}\sum_{m=1}^{M} -\log Pr(\boldsymbol{x}_{S_m}|\boldsymbol{x}_{\bar{S}_m};\mathcal{B}_\theta) \quad (9)$$

where $S_m \sim q(S|\boldsymbol{x};\pi_\phi)$. In §4.2, we present an efficient sampling algorithm based on a sequential decision making process involving discrete choices, i.e. whether to include an index i or not.

Algorithm 1 Adversarial Training Procedure

```
Input: data $\mathcal{D}$, update freq. $\beta$, masking size $K$
Output: generator $\pi_\phi$, MLM $\mathcal{B}_\theta$

Let $\phi \leftarrow \phi_0; \theta \leftarrow \theta_0$
while stopping condition is not met do
    for $\boldsymbol{x} \in \mathcal{D}$ do
        $S, q(S) \leftarrow$ subsetSampling$(\boldsymbol{x}, \pi_\phi, K)$
        Update the MLM using Eq. (8)
        if coinToss($\beta$)==Head then
            Compute reward
            $r \leftarrow -\log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta)$
            Update the generator using Eq. (10)
        end if
    end for
end while
return $\theta, \phi$
```

Training the Puzzle Generator. Fixing the MLM, we can train the puzzle generator by considering $-\log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta)$ as the reward, and aim to optimise the expected reward,

$$\max_{\phi} \mathbb{E}_{q(S|\boldsymbol{x};\pi_\phi)}[-\log Pr(\boldsymbol{x}_S | \boldsymbol{x}_{\bar{S}}; \mathcal{B}_\theta)]. \tag{10}$$

We may aim to sample multiple index sets $\{S_1, .., S_M\}$ from $q(S|\boldsymbol{x}; \pi_\phi)$, and then optimise the parameters of the puzzle generator by maximizing the Monte Carlo estimate of the expected reward. However, as sampling each index set S_m corresponds to a sequential decision making process involving *discrete* choices, we cannot backpropagate through the sampling process to learn the parameters of the puzzle generator network. Therefore, we rely on the Gumbel-Softmax trick (Jang et al., 2017) to deal with this issue and backpropagate through the parameters of π_ϕ, which we will cover in §4.3.

4 Sampling and Differentiating Subsets

4.1 A DP for the Partition Function

In order to sample from the variational distribution in eqn (6), we need to compute its partition function in eqn (7). Interestingly, the partition function can be computed using dynamic programming (DP).

Let us denote by $Z(j, k)$ the partition function of all subsets of size k from the index set $\{j, .., |\boldsymbol{x}|\}$. Hence, the partition function of the q distribution is $Z(1, K)$. The DP relationship can be written as,

Algorithm 2 Sampling Procedure

```
Function: subsetSampling
Input: datapoint $\boldsymbol{x}$, prob. $\pi_\phi$, masking size $K$
Output: subset $S$, sample log probability $l$

Let $S \leftarrow \emptyset; l \leftarrow 0; j \leftarrow 0$
Calculate DP table $Z$ using Eq. (11)
while $|S| < K$ do
    $j \leftarrow j + 1$
    $q_{j,Y} \leftarrow q_j(\mathrm{Y}|S_{j-1}, \pi_\phi)$ // using eqn (13)
    $q_{j,N} \leftarrow 1 - q_{j,Y}$
    $\epsilon_{j,Y}, \epsilon_{j,N} \sim$ Gumbel$(0, 1)$
    $o_j \leftarrow \mathrm{argmax}_{o \in \{Y,N\}} \log q_{j,o} + \epsilon_{j,o}$
    $l \mathrel{+}= \log \mathrm{softmax}(\log q_{j,o} + \epsilon_{j,o})\big|_{o=o_j}$
    if $o_j == Y$ then
        $S \leftarrow S \cup \{j\}$
    end if
end while
return $S, l$
```

$$\begin{aligned} Z(j-1, k) = &(1 - \pi(j-1|\boldsymbol{x}))Z(j, k) \\ &+ \pi_\phi(j-1|\boldsymbol{x})Z(j, k-1). \end{aligned} \tag{11}$$

The initial conditions are $Z(j, 0) = 1$ and

$$Z(|\boldsymbol{x}| - k + 1, k) = \prod_{i=|\boldsymbol{x}|-k+1}^{|\boldsymbol{x}|} \pi_\phi(j|\boldsymbol{x}) \tag{12}$$

corresponding to two special terminal cases in selection process in which we have picked all K indices, and we need to select all indices left to fulfil K.

This amounts to a DP algorithm with the time complexity $\mathcal{O}(K|\boldsymbol{x}|)$.

4.2 Subset Sampling for MLMs

The DP in the previous section also gives rise to the sampling procedure. Given a partial random subset S_{j-1} with elements chosen from the indices $\{1, .., j-1\}$, the probability of including the next index j, denoted by $q_j(\text{yes}|S_{j-1}, \pi_\phi)$, is

$$\frac{\pi_\phi(j|\boldsymbol{x})Z(j+1, K-1-|S_{j-1}|)}{Z(j, K-|S_{j-1}|)} \tag{13}$$

where $Z(j, k)$ values come from the DP table. Hence, the probability of *not* including the index j is

$$q_j(\text{no}|S_{j-1}, \pi_\phi) = 1 - q_j(\text{yes}|S_{j-1}, \pi_\phi). \tag{14}$$

Table 1: Data statistics of named entity span prediction tasks and unlabled additional pretraining corpus.

In case the next index is chosen to be in the sample, then $S_{j+1} = S_j \cup \{j+1\}$; otherwise $S_{j+1} = S_j$.

The sampling process entails a sequence of binary decisions (Figure 1.b) in an underlying Markov Decision Process (MDP). It is an iterative process, which starts by considering the index one. At each decision point j, the sampler's action space is to whether include (or not include) the index j into the partial sample S_j based on eqn (13). We terminate this process when the partially selected subset has K elements.

The sampling procedure is described in Algorithm 2. In our MDP, we actually sample an index by generating Gumbel noise in each stage, and then select the choice (yes/no) with the maximum probability. This enables differentiation through the sampled subset, covered in the next section.

4.3 Differentiating via Gumbel-Softmax

Once the sampling process is terminated, we then need to backpropagate through the parameters of π_ϕ, when updating the parameters of the puzzle generator according to eqn (10).

More concretely, let us assume that we would like to sample a subset S. As mentioned in previous section, we need to decide about the inclusion of the next index j given the partial sample so far S_{j-1} based on the eqn (13). Instead of uniform sampling, we can equivalently choose one of these two outcomes as follows

$$o_j^* = \underset{o_j \in \{\text{yes,no}\}}{\text{argmax}} \log q_j(o_j|S_{j-1}, \pi_\phi) + \epsilon_{o_j} \quad (15)$$

where the random noise ϵ_{o_j} is distributed according to standard Gumbel distribution. Sampling a subset then amounts to a sequence of argmax operations. To backpropagate through the sampling process, we replace the argmax operators with softmax, as argmax is not differentiable. That is,

$$Pr(o_j) = \frac{\exp(\log q_j(o_j|S_{j-1},\pi_\phi)+\epsilon_{o_j})}{\sum_{o'_j} \exp(\log q_j(o'_j|S_{j-1},\pi_\phi)+\epsilon_{o'_j})}. \quad (16)$$

The $\log$ product of the above probabilities for the decisions in a sampling *path* is returned as l in Algorithm 2, which is then used for backpropagation.

5 Experiments

We evaluate our proposed masking strategy in UDA for named entity span prediction tasks coming from three different domains.

5.1 Unsupervised Domain Adaptation Tasks

Source and Target Domain Tasks. Our evaluation is focused on the problem of identifying named entity spans in domain-specific text without access to labeled data. The evaluation tasks comes from several named entity recognition (NER) dataset including WNUT2016 (Strauss et al., 2016), FIN (Salinas Alvarado et al., 2015), JNLPBA (Collier and Kim, 2004), BC2GM (Smith et al., 2008), BioNLP09 (Kim et al., 2009), and BioNLP11EPI (Kim et al., 2011). Table 1 reports data statistics.

These datasets cover three domains social media (TWEETS), financial (FIN) and biomedical (BIOMED). We utilize the CoNLL-2003 English NER dataset in newstext domain (NEWS) as the source task and others as the target. We perform domain-tuning and source task-tuning, followed by zero-shot transfer to the target tasks, as described in §2. Crucially, we do not use the labels of the training sets of the target tasks, and only use their sentences for domain adaptation. Since the number of entity types are different in each task, we convert all the labels to entity span in IBO scheme. This ensures that all tasks share the same set of labels consisting of three tags: I, B, and O.

Extra Target Domain Unlabeled Corpora. As the domain tuning step can further benefit from additional unlabeled data, we create target domain unlabeled datasets from the available corpora of relevant domains. More specifically, we use publicly available corpora, Sentiment140 (Go et al., 2009), SEC Filing 2019[2] (DeSola et al., 2019) PubMed (Lee et al., 2020) for the TWEET, FIN and BIOMED domains respectively (Table 1). From the unlabeled corpora, the top 500K and 1M similar sentences to the training set of each target task are extracted based on the average n-gram similarity where $1 \leq n \leq 4$, resulting in extra target domain unlabeled corpora.

5.2 Masking Strategies for MLM Training

We compare our adversarial learned masking strategy approach against random and various heuristic masking strategies which we propose:

- **Random.** Masked tokens are sampled uniformly at random, which is the common strategy in the literature (Devlin et al., 2019; Liu et al., 2019).
- **POS-based strategy.** Masked tokens are sampled according to a non-uniform distribution, where a token's probability depends on its POS tag. The POS tags are obtained using spaCy.[3] Content tokens such as verb (VERB), noun (N), adjective (ADJ), pronoun (PRON) and adverb (ADV) tags are assigned higher probability (80%) than other content-free tokens such as PREP, DET, PUNC (20%).
- **Uncertainty-based strategy.** We select those tokens for which the current MLM is most uncertain for the reconstruction, where the uncertainty is measured by the entropy. That is, we aim to select those tokens with high Entropy$[Pr_i(.|\boldsymbol{x}_{\bar{S}_i}; \mathcal{B}_\theta)]$, where $\boldsymbol{x}_{\bar{S}_i}$ is the sentence $\boldsymbol{x}$ with the ith token masked out, and $Pr_i(.|\boldsymbol{x}_{\bar{S}_i}; \mathcal{B}_\theta)$ is the predictive distribution for the ith position in the sentence.

  Calculating the predictive distribution for each position requires one pass through the network. Hence, it is expensive to use the exact entropy, as it requires $|\boldsymbol{x}|$ passes. We mitigate this cost by using $Pr_i(.|\boldsymbol{x}; \mathcal{B}_\theta)$ instead, which conditions on the original unmasked sentence. This estimation only costs one pass through the MLM.
- **Adversarial learned strategy.** The masking strategy is learned adversarially as in §3. The puzzle-generator update frequency β (Algorithm 1) is set to 0.3 for all experiments.

These strategies only differ in how we choose the candidate tokens. The number of to-be-masked tokens is the same in all strategies (15%). Among them, 80% are replaced with [MASK], 10% are replaced with random words, the rest are kept unchanged as in (Devlin et al., 2019). In our experiments, the masked sentences are generated dynamically on-the-fly.

To evaluate the models, we compute precision, recall and F1 scores on a per token basis. We report average performance of five runs.

5.3 Implementation Details

Our implementation is based on Tensorflow library (Abadi et al., 2016)[4]. We use BERT-Base model architecture which consists of 12 Transformer layers with 12 attention heads and hidden size 768 (Devlin et al., 2019) in all our experiments. We use the cased wordpiece vocabulary provided in the pretrained English model. We set learning rate to 5e-5 for both further pretraining and task tuning. Puzzle generator is a two layer feed-forward network with hidden size 256 and dropout rate 0.1.

5.4 Empirical Results

Under the same computation budget to update the MLM, we evaluate the effect of masking strategy in the domain tuning step under various size of additional target-domain data: none, 500K and 1M. We continue pretraining BERT on a combination of unlabeled source (CoNLL2003), unlabeled target task training data and additional unlabeled target domain data (if any). If target task data is smaller, we oversample it to have equal size to the source data. The model is trained with batch size 32 and max sequence length 128 for 50K steps in 1M target-domain data and 25K steps in other cases. It equals to 3-5 epochs over the training set. After domain tuning, we finetune the adapted MLM on the source task labeled training data (CoNLL2003) for three epochs with batch size 32. Finally, we evaluate the resulting model on target task. On the largest dataset, random and POS strategy took around 4 hours on one NVIDIA V100 GPU while entropy

Table 3: F1 score in UDA with additional data under several mixed masking strategies. **Bold** shows the highest score of task on each UDA setting.

and adversarial approach took 5 and 7 hours respectively. The task tuning took about 30 minutes.

Results are shown in Table 2. Overall, strategically masking consistently outperforms random masking in most of the adaptation scenarios and target tasks. As expected, expanding training data with additional target domain data further improves performance of all models. Comparing to random masking, prioritising content tokens over content-free ones can improve up to 0.7 F1 score in average. By taking the current MLM into account, uncertainty-based selection and adversarial learned strategy boost the score up to 1.64. Our proposed adversarial approach yields highest score in 11 out of 18 cases, and results in the largest improvement over random masking across all tasks in both UDA with and without additional target domain data.

Figure 2: Vocabulary overlap (%) between NER tasks.

We further explore the mix of random masking and other masking strategies. We hypothesise that the combination strategies can balance the learning of challenging tokens and effortless tokens when forming the common semantic space, hence improve the task performance. In a minibatch, 50% of sentences are masked according to the corresponding strategy while the rest are masked randomly. Results are shown in Table 3. We observe an additional performance to the corresponding single-strategy model across all tasks.

5.5 Analysis

Domain Similarity. We quantify the similarity between source (CoNLL2003) and target domains by vocabulary overlap between the domains (excluding stopwords). Figure 2 shows the vocabulary overlap across tasks. As seen, all the target domains are dissimilar to the source domain, with FIN having the lowest overlap. FIN has gained the

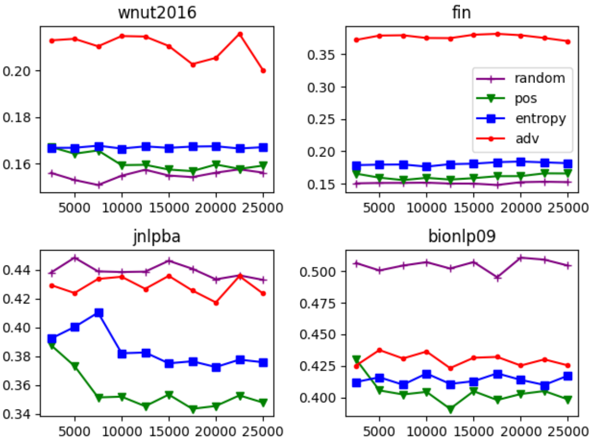

Figure 3: Average density ratio of masked-out tokens of every 2500 training steps in UDA setting.

largest improvement from the adversarial strategy in the UDA results in Tables 2 and 3. As expected, the biomedical datasets have relatively higher vocabulary overlap with each other.

Density Ratio of Masked Subsets. We analyze the density ratio of masked-out tokens in the target and source domains

$$r(w) = \max(1 - \frac{Pr_s(w)}{Pr_t(w)}, 0)$$

where $Pr_s(w)$ and $Pr_t(w)$ is the probability of token w in source and target domains, respectively. These probabilities are according to unigram language models trained on the training sets of the source and target tasks. The higher value of $r(w)$ means the token w is new or appears more often in the target text than in the source. Figure 3 plots the density ratio of masked-out tokens during domain tuning time for four UDA tasks. Comparing to other strategies, we observed that adversarial approach tends to select tokens which have higher density ratio, i.e. more significant in the target.

Syntactic Diversity in Masked Subset. Table 4 describes the percentage of POS tags in masked subset selected by different masking strategies. We observed that our method selects more tokens from the major POS tags (71%) compared to random (45%) and entropy-based (55%) strategies. It has chosen less nouns compared to the POS strategy, and more pronouns compared to all other strategies.

POS Tag	rand	pos	ent	adv
ADJ	9%	17%	11%	13%
VERB	8%	16%	10%	17%
NOUN	25%	51%	31%	34%
PRON	1%	2%	1%	3%
ADV	2%	4%	2%	4%
Others	55%	10%	45%	29%

Table 4: The tag ratio of the POS tags of tokens in masked subset on BIONLP11 under different masking strategies.

Tagging Accuracy of OOV and non-OOV. We compare the tagging accuracy of out-of-vocabulary (OOV) words which are in target domain but not presenting in source, and non-OOV tokens in Table 5. As seen, our adversarial masking strategy achieves higher accuracy on both OOV and non-OOV tokens in most cases.

6 Related Work

Unsupervised Domain Adaptation. The main approaches in neural UDA include discrepancy-based and adversarial-based methods. The discrepancy-based methods are based on the usage of the maximum mean discrepancy or Wasserstein distance as a regularizer to enforce the learning of domain non-discriminative representations (Shen et al., 2018). Inspired by the Generative Adversarial Network (GAN) (Goodfellow et al., 2014), the adversarial-based methods learn a representation that is discriminative for the target task and indiscriminative to the shift between the domains (Ganin and Lempitsky, 2015).

Domain Adaptation with MLM. Performance of fine-tuned MLM can deteriorate substantially on the presence of domain mismatch. The most straightforward domain adaptation approach in MLM is to adapt general contextual embedding to a specific domain (Lee et al., 2020; Alsentzer et al., 2019; Chakrabarty et al., 2019), that is to further improve pretrained MLM by continuing to pretrain language models on related domain or similar tasks (Gururangan et al., 2020), or via intermediate task which is also referred to as STILTs (Phang et al., 2018). Recent works have proposed two-step adaptive domain adaptation framework which consists of domain tuning and task finetuning (Ma et al., 2019; Xu et al., 2019; Wang et al., 2019c; Logeswaran et al., 2019). They have demonstrated that domain tuning is necessary to adapt MLM with both domain knowledge and task knowledge before finetuning, especially when the labelled data

in target task is extremely small. Our experiment setting is similar to Han and Eisenstein (2019)'s work. However, we focus on learning masking strategy to boost the domain-tuning step.

Adversarial Learning. Recent research in adversarial machine learning has either focused on attacking models with adversarial examples (Alzantot et al., 2018; Iyyer et al., 2018; Ebrahimi et al., 2018), or training models to be robust against these attacks (Zhou et al., 2019). Wang et al. (2019b); Liu et al. (2020) propose the use of adversarial learning for language models. They consider autoregressive LMs and train them to be robust against adversarial perturbations of the word embeddings of the target vocabulary.

7 Conclusion

We present an adversarial objective for further pretraining MLM in UDA problem. The intuition behind the objective is that the adaptation effort should focus on a subset of tokens which are challenging to the MLM. We establish a variational lower bound of the objective function and propose an effective sampling algorithm using dynamic programming and Gumbel softmax trick. Comparing to other masking strategies, our proposed adversarial masking approach has achieve substantially better performance on UDA problem of named entity span prediction for several domains.

Abstract

Modern text classification models are susceptible to adversarial examples, perturbed versions of the original text indiscernible by humans which get misclassified by the model. Recent works in NLP use rule-based synonym replacement strategies to generate adversarial examples. These strategies can lead to out-of-context and unnaturally complex token replacements, which are easily identifiable by humans. We present `BAE`, a black box attack for generating adversarial examples using contextual perturbations from a BERT masked language model. `BAE` replaces and inserts tokens in the original text by masking a portion of the text and leveraging the BERT-MLM to generate alternatives for the masked tokens. Through automatic and human evaluations, we show that `BAE` performs a stronger attack, in addition to generating adversarial examples with improved grammaticality and semantic coherence as compared to prior work.

1 Introduction

Recent studies have exposed the vulnerability of ML models to adversarial attacks, small input perturbations which lead to misclassification by the model. Adversarial example generation in NLP (Zhang et al., 2019) is more challenging than in commonly studied computer vision tasks (Szegedy et al., 2014; Kurakin et al., 2017; Papernot et al., 2017) because of (i) the discrete nature of the input space and (ii) the need to ensure semantic coherence with the original text. A major bottleneck in applying gradient based (Goodfellow et al., 2015) or generator model (Zhao et al., 2018) based approaches to generate adversarial examples in NLP is the backward propagation of the perturbations from the continuous embedding space to the discrete token space.

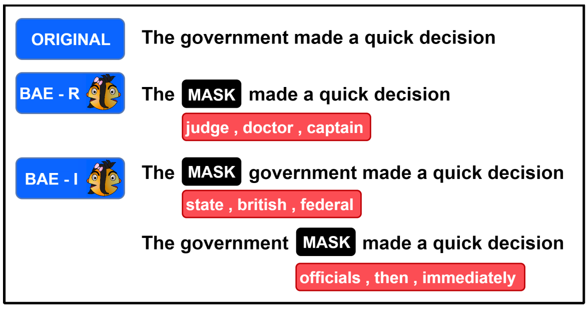

Figure 1: We use BERT-MLM to predict masked tokens in the text for generating adversarial examples. The MASK token replaces a word (`BAE-R` attack) or is inserted to the left/right of the word (`BAE-I`).

Initial works for attacking text models relied on introducing errors at the character level (Ebrahimi et al., 2018; Gao et al., 2018) or adding and deleting words (Li et al., 2016; Liang et al., 2017; Feng et al., 2018) for creating adversarial examples. These techniques often result in unnatural looking adversarial examples which lack grammatical correctness, thereby being easily identifiable by humans.

Rule-based synonym replacement strategies (Alzantot et al., 2018; Ren et al., 2019) have recently lead to *more* natural looking adversarial examples. Jin et al. (2019) combine both these works by proposing TextFooler, a strong black-box attack baseline for text classification models. However, the adversarial examples generated by TextFooler solely account for the token level similarity via word embeddings, and not the overall sentence semantics. This can lead to *out-of-context* and *unnaturally complex* replacements (see Table 3), which are easily human-identifiable. Consider a simple example: "The restaurant service was *poor*". Token level synonym replacement of 'poor' may lead to an inappropriate choice such as 'broke', while a context-aware choice such as 'terrible' leads to better retention of semantics and grammaticality.

Therefore, a token replacement strategy contingent on retaining sentence semantics using a pow-

erful language model (Devlin et al., 2018; Radford et al., 2019) can alleviate the errors made by existing techniques for homonyms (tokens having multiple meanings). In this paper, we present `BAE` (BERT-based Adversarial Examples), a novel technique using the BERT masked language model (MLM) for word replacements to better fit the overall context of the English language. In addition to replacing words, we also propose inserting new tokens in the sentence to improve the attack strength of `BAE`. These perturbations in the input sentence are achieved by masking a part of the input and using a LM to fill in the mask (See Figure 1).

Our `BAE` attack beats the previous baselines by a large margin on empirical evaluation over multiple datasets and models. We show that, surprisingly, just a few replace/insert operations can reduce the accuracy of even a powerful BERT classifier by over 80% on some datasets. Moreover, our human evaluation reveals the improved grammaticality of the adversarial examples generated by `BAE` over the baseline TextFooler, which can be attributed to the BERT-MLM. To the best of our knowledge, we are the first to use a LM for generating adversarial examples. We summarize our contributions as:

- We propose `BAE`, an adversarial example generation technique using the BERT-MLM.
- We introduce 4 `BAE` attack modes by replacing and inserting tokens, all of which are almost always stronger than previous baselines on 7 text classification datasets.
- Through human evaluation, we show that `BAE` yields adversarial examples with improved grammaticality and semantic coherence.

2 Methodology

Problem Definition. We are given a dataset $(S, Y) = \{(\mathbb{S}_1, y_1), \dots (\mathbb{S}_m, y_m)\}$ and a trained classification model $C : \mathbb{S} \rightarrow Y$. We assume the soft-label black-box setting where the attacker can only query the classifier for output probabilities on a given input, and does not have access to the model parameters, gradients or training data. For an input pair ($\mathbb{S}{=}[t_1, \dots, t_n], y$), we want to generate an adversarial example $\mathbb{S}_{adv}$ such that $C(\mathbb{S}_{adv}){\neq}y$. Additionally we would like $\mathbb{S}_{adv}$ to be grammatically correct and semantically similar to $\mathbb{S}$.

`BAE`. For generating an adversarial example $\mathbb{S}_{adv}$, we introduce 2 types of token-level perturbations: (i) Replace a token $t \in \mathbb{S}$ with another and (ii) Insert a new token t' in $\mathbb{S}$. Some tokens in the input contribute more towards the final prediction by C than others. Replacing these tokens or inserting a new token adjacent to them can thus have a stronger effect on altering the classifier prediction. This intuition stems from the fact that the replaced/inserted tokens changes the local context around the original token. We estimate token importance I_i of each $t_i \in \mathbb{S}$, by deleting t_i from $\mathbb{S}$ and computing the decrease in probability of predicting the correct label y, similar to Jin et al. (2019); Ren et al. (2019).

Algorithm 1: `BAE-R` Pseudocode

```
Input: Sentence $\mathbb{S} = [t_1, \dots, t_n]$, ground truth label
    $y$, classifier model C
Output: Adversarial Example $\mathbb{S}_{adv}$
Initialization: $\mathbb{S}_{adv} \leftarrow \mathbb{S}$
Compute token importance $I_i \ \forall \ t_i \in \mathbb{S}$
for $i$ in descending order of $I_i$ do
    $\mathbb{S}_M \leftarrow \mathbb{S}_{adv[1:i-1]}[M]\mathbb{S}_{adv[i+1:n]}$
    Predict top-K tokens $\mathbb{T}$ for mask M $\in \mathbb{S}_M$
    $\mathbb{T} \leftarrow$ FILTER($\mathbb{T}$)
    $\mathbb{L} = \{\}$ // python-style dict
    for $t \in \mathbb{T}$ do
        $\mathbb{L}[t] = \mathbb{S}_{adv[1:i-1]}[t]\mathbb{S}_{adv[i+1:n]}$
    end
    if $\exists \, t \in \mathbb{T}$ s.t $C(\mathbb{L}[t]) \neq y$ then
        Return: $\mathbb{S}_{adv} \leftarrow \mathbb{L}[t']$ where $C(\mathbb{L}[t']) \neq y$,
                $\mathbb{L}[t']$ has maximum similarity with $\mathbb{S}$
    else
        $\mathbb{S}_{adv} \leftarrow \mathbb{L}[t']$ where $\mathbb{L}[t']$ causes maximum
        reduction in probability of $y$ in $C(\mathbb{L}[t'])$
    end if
end
Return: $\mathbb{S}_{adv} \leftarrow None$
```

The Replace (R) and Insert (I) operations are performed on a token t by masking it and inserting a mask token adjacent to it respectively. The pretrained BERT-MLM is used to predict the mask tokens (See Figure 1). BERT-MLM is a powerful LM trained on a large training corpus ($\sim$ 2 billion words), and hence the predicted mask tokens fit well into the grammar and context of the text.

The BERT-MLM, however, does not guarantee semantic coherence to the original text as demonstrated by the following simple example. Consider the sentence: 'the food was good'. For replacing the token 'good', BERT-MLM may predict the token 'bad', which fits well into the grammar and context of the sentence, but changes the original sentiment of the sentence. To achieve a high semantic similarity with the original text on introducing perturbations, we filter the set of top K tokens (K is a pre-defined constant) predicted by BERT-MLM for the masked token, using a Universal Sentence Encoder (USE) based sentence similarity scorer (Cer et al., 2018). For the R operation, we additionally filter out predicted tokens that do not form the same part of speech (POS) as the original token.

Model	Adversarial Attack	Datasets			
		Amazon	Yelp	IMDB	MR
wordLSTM	Original	88.0	85.0	82.0	81.16

Table 1: Automatic evaluation of adversarial attacks on 4 Sentiment Classification tasks. We report the test set accuracy. The average semantic similarity, between the original and adversarial examples, obtained from USE are reported in parentheses. Best performance, in terms of maximum drop in test accuracy, is highlighted in **boldface**.

If multiple tokens can cause C to misclassify $\mathbb{S}$ when they replace the mask, we choose the token which makes $\mathbb{S}_{adv}$ most similar to the original $\mathbb{S}$ based on the USE score. If no token causes misclassification, then we choose the one that decreases the prediction probability $P(C(\mathbb{S}_{adv}){=}y)$ the most. We apply these token perturbations iteratively in decreasing order of token importance, until either $C(\mathbb{S}_{adv}){\neq}y$ (successful attack) or all the tokens of $\mathbb{S}$ have been perturbed (failed attack).

We present 4 attack modes for BAE based on the R and I operations, where for each token t in $\mathbb{S}$:

- **BAE-R:** Replace token t (See Algorithm 1)
- **BAE-I:** Insert a token to the left or right of t
- **BAE-R/I:** Either replace token t or insert a token to the left or right of t
- **BAE-R+I:** First replace token t, then insert a token to the left or right of t

3 Experiments

Datasets and Models. We evaluate BAE on different text classification tasks. Amazon, Yelp, IMDB are sentiment classification datasets used in recent works (Sarma et al., 2018) and MR (Pang and Lee, 2005) contains movie reviews based on sentiment polarity. MPQA (Wiebe and Wilson, 2005) is a dataset for opinion polarity detection, Subj (Pang and Lee, 2004) for classifying a sentence as subjective or objective and TREC (Li and Roth, 2002) for question type classification.

We use 3 popular text classification models: word-LSTM (Hochreiter and Schmidhuber, 1997), word-CNN (Kim, 2014) and a fine-tuned BERT (Devlin et al., 2018) base-uncased classifier. We train models on the training data and perform the adversarial attack on the test data. For complete model details, refer to Appendix A.

As a baseline, we consider TextFooler (Jin et al., 2019) which performs synonym replacement using a fixed word embedding space (Mrkšić et al., 2016). We only consider the top K=50 synonyms from the BERT-MLM predictions and set a threshold of 0.8 for the cosine similarity between USE based embeddings of the adversarial and input text.

Automatic Evaluation Results. We perform the 4 BAE attacks and summarize the results in Tables 1 and 2. Across datasets and models, our BAE attacks are almost always more effective than the baseline attack, achieving significant drops of 40-80% in test accuracies, with higher average semantic similarities as shown in parentheses.

With just one exception, BAE-R+I is the strongest attack since it allows both replacement and insertion at the same token position. We observe a general trend that the BAE-R and BAE-I attacks often perform comparably, while the BAE-R/I and BAE-R+I attacks are much stronger. We observe that the BERT classifier is more robust to BAE and TextFooler attacks than

Model	Adversarial Attack	Datasets		
		MPQA	Subj	TREC

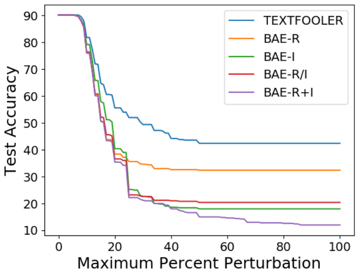
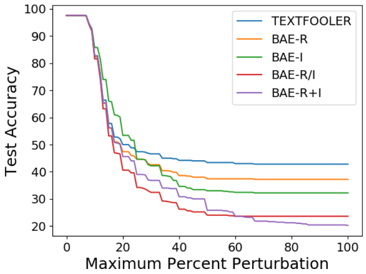
Table 2: Automatic evaluation of adversarial attacks on MPQA, Subj and TREC datasets. Other details follow those from Table 1. All 4 modes of BAE attacks almost always outperform TextFooler.



(a) Word-LSTM



(b) BERT

Figure 2: Graphs comparing attack effectiveness on the TREC dataset, as a function of maximum % perturbation to the input.

the word-LSTM and word-CNN possibly due to its large size and pre-training on a large corpus.

The TextFooler attack is sometimes stronger than the BAE-R attack for the BERT classifier. We attribute this to the shared parameter space between the BERT-MLM and the BERT classifier before fine-tuning. The predicted tokens from BERT-MLM may not be able to drastically change the internal representations learned by the BERT classifier, hindering their ability to adversarially affect the classifier prediction.

Additionally, we make some interesting observations pertaining to the average semantic similarity of the adversarial examples with the original sentences (computed using USE). From Tables 1, 2 we observe that across different models and datasets, all BAE attacks have higher average semantic similarity than TextFooler. Notably, the BAE-I attack achieves the highest semantic similarity among all the 4 modes. This can be explained by the fact that all tokens of the original sentence are retained, in the original order, in the adversarial example generated by BAE-I. Interestingly, we observe that the average semantic similarity of the BAE-R+I attack is always higher than the BAE-R attack. This lends support to the importance of the 'Insert' operation in ameliorating the effect of the 'Replace' operation. We further investigate this through an ablation study discussed later.

Effectiveness. We study the effectiveness of BAE on limiting the number of R/I operations permitted on the original text. We plot the attack performance as a function of maximum % perturbation (ratio of number of word replacements and insertions to the length of the original text) for the TREC dataset. From Figure 2, we clearly observe that the BAE attacks are consistently stronger than TextFooler. The classifier models are relatively robust to perturbations up to 20%, while the effectiveness saturates at 40-50%. Surprisingly, a 50% perturbation for the TREC dataset translates to replacing or inserting just 3-4 words, due to the short text lengths.

Qualitative Examples. We present adversarial examples generated by the attacks on sentences from the IMDB and Yelp datasets in Table 3. All attack strategies successfully changed the classification to negative, however the BAE attacks produce more natural looking examples than TextFooler. The tokens predicted by the BERT-MLM fit well in the sentence context, while TextFooler tends to replace words with complex synonyms, which can be easily detected. Moreover, BAE's additional degree of freedom to insert tokens allows for a successful attack with fewer perturbations.

Human Evaluation. We perform human evaluation of our BAE attacks on the BERT classifier. For 3 datasets, we consider 100 samples from each test set shuffled randomly with their successful ad-

Original [Positive Sentiment]: This film offers many delights and surprises.
TextFooler: This flick citations disparate revel and surprises.
`BAE-R`: This movie offers enough delights and surprises
`BAE-I`: This lovely film platform offers many pleasant delights and surprises
`BAE-R/I`: This lovely film serves several pleasure and surprises .
`BAE-R+I`: This beautiful movie offers many pleasant delights and surprises .
Original [Positive Sentiment]: Our server was great and we had perfect service.
TextFooler: Our server was tremendous and we assumed faultless services.
`BAE-R`: Our server was decent and we had outstanding service.
`BAE-I`: Our server was great enough and we had perfect service but.
`BAE-R/I`: Our server was great enough and we needed perfect service but.
`BAE-R+I`: Our server was decent company and we had adequate service.

Table 3: Qualitative examples of each attack on the BERT classifier (Replacements: Red, Inserts: Blue)

Dataset	**Sentiment Accuracy (%)**			
	Original	TF	R	R+I
Amazon	95.7	79.1	**85.2**	83.8

MR	93.3	82.0	**84.6**	82.4
Dataset	**Naturalness (1-5)**			
	Original	TF	R	R+I
Amazon	4.26	3.17	**3.91**	3.71
IMDB	4.35	3.41	**3.89**	3.76
MR	4.19	3.35	**3.84**	3.74

Table 4: Human evaluation results (TF: TextFooler and R(R+I): `BAE-R(R+I)`).

versarial examples from `BAE-R`, `BAE-R+I` and TextFooler. We calculate the sentiment accuracy by asking 3 annotators to predict the sentiment for each sentence in this shuffled set. To evaluate the *naturalness* of the adversarial examples, we first present the annotators with 50 other original data samples to get a sense of the data distribution. We then ask them to score each sentence (on a Likert scale of 1-5) in the shuffled set on its grammar and likelihood of being from the original data. We average the 3 scores and present them in Table 4.

Both `BAE-R` and `BAE-R+I` attacks almost always outperform TextFooler in both metrics. `BAE-R` outperforms `BAE-R+I` since the latter inserts tokens to strengthen the attack, at the expense of naturalness and sentiment accuracy. Interestingly, the `BAE-R+I` attacks achieve higher average semantic similarity scores than `BAE-R`, as discussed in Section 3. This exposes the shortcomings of using USE for evaluating the retention of semantics of adversarial examples, and reiterates the importance of human-centered evaluation. The gap between the scores on the original data and the adversarial examples speaks for the limitations of the attacks, however `BAE` represents an important step forward towards improved adversarial examples.

Replace vs. Insert. Our `BAE` attacks allow insertion operations in addition to replace. We analyze the benefits of this flexibility of R/I operations in Table 5. From Table 5, the splits $\mathbb{A}$ and $\mathbb{B}$ are the % of test points which *compulsorily* need I and R operations respectively for a successful attack. We can observe that the split $\mathbb{A}$ is larger than $\mathbb{B}$ thereby indicating the importance of the I operation over R. Test points in split $\mathbb{C}$ require both R *and* I operations for a successful attack. Interestingly, split $\mathbb{C}$ is largest for Subj, which is the most robust to attack (Table 2) and hence needs both R/I operations. Thus, this study gives positive insights towards the importance of having the flexibility to both replace and insert words.

Dataset	**Word-LSTM**			**Word-CNN**			**BERT**		
	$\mathbb{A}$	$\mathbb{B}$	$\mathbb{C}$	$\mathbb{A}$	$\mathbb{B}$	$\mathbb{C}$	$\mathbb{A}$	$\mathbb{B}$	$\mathbb{C}$
MR	15.1	10.1	3.1	12.4	9.6	2.8	24.3	12.9	5.7
Subj	14.4	12.3	5.1	16.2	13.8	7.4	13.9	11.4	7.5
TREC	16.6	1.6	0.2	20.0	5.0	1.4	14.0	8.6	2.4

Table 5: Analyzing relative importance of 'Replace' and 'Insert' perturbations for `BAE`. $\mathbb{A}$ denotes % of test instances which are successfully attacked by `BAE-R/I`, but not `BAE-R`, i.e. $\mathbb{A} : (\texttt{R/I}) \cap \overline{\texttt{R}}$. Similarly, $\mathbb{B} : (\texttt{R/I}) \cap \overline{\texttt{I}}$ and $\mathbb{C} : (\texttt{R/I}) \cap \overline{\texttt{R}} \cap \overline{\texttt{I}}$.

We present complete effectiveness graphs and details of human evaluation in Appendix B and C. `BAE` is implemented[1] in TextAttack (Morris et al., 2020), a popular suite of NLP adversarial attacks.

4 Conclusion

In this paper, we have presented a new technique for generating adversarial examples (`BAE`) through contextual perturbations based on the BERT Masked Language Model. We propose inserting and/or replacing tokens from a sentence, in their order of importance for the text classification task, using a BERT-MLM. Automatic and human evaluation on several datasets demonstrates the strength and effectiveness of our attack.

Broader Ethical Impact

Our work addresses the important problem of adversarial vulnerabilities of modern text classification models. While we acknowledge the possibility of its misuse to maliciously attack publicly available text classifiers, we believe our work represents an important step forward in analyzing the robustness of NLP models. We hope our work inspires improved defenses against adversarial attacks on text classification models.

A Experimental Reproducibility

Dataset and Models The dataset statistics are reported in Table 5 and we give a brief overview of the dataset and the task for which it is used along with public links to download the datasets.

- *Amazon*: Amazon product reviews dataset [2].
- *Yelp*: A restaurant reviews dataset from Yelp[2].
- *IMDB*: IMDB movie reviews dataset[2].
- *MR*: A movie reviews dataset based on subjective rating and sentiment polarity [3].
- *MPQA*: An unbalanced dataset for polarity detection of opinions [4].
- *TREC*: A dataset for classifying types of questions with 6 classes [5].
- *SUBJ*: A dataset for classifying a sentence as objective or subjective. [2]

Dataset	# Classes	Train	Test	Avg Length
Amazon	2	900	100	10.29
Yelp	2	900	100	11.66
IMDB	2	900	100	17.56
MR	2	9595	1067	20.04
MPQA	2	9543	1060	3.24
Subj	2	9000	1000	23.46
TREC	6	5951	500	7.57

Table 5: Summary statistics for the datasets

Training Details On the sentence classification task, we target three models: word-based convolutional neural network (WordCNN), word-based LSTM, and the state-of-the-art BERT. We use 100 filters of sizes 3,4,5 for the WordCNN model with a dropout of 0.3. Similar to (Jin et al., 2019) we use a 1-layer bi-directional LSTM with 150 hidden units and a dropout of 0.3. For both models, we use the 300 dimensional pre-trained counter fitted word embeddings (Mrkšić et al., 2017). For the BERT classifier, we used the BERT base uncased model which has 12-layers, 12 attention heads and 768 hidden dimension size. Across all models and datasets, we use the standard BERT uncased vocabulary of size 30522. We first train all three models on the training data split and use early stopping on the test dataset. For BERT fine-tuning, we use the standard setting of an Adam classifier having a learning rate of 2×10^{-5} and 2 fine-tuning epochs.

For our `BAE` attacks, we use a pre-trained BERT Base-uncased MLM to predict the masked tokens. We only consider the top K=50 synonyms from the BERT-MLM predictions and set a threshold of 0.8 for the cosine similarity between USE based embeddings of the adversarial and input text.

For R operations, we filter out predicted tokens which form a different POS than the original token in the sentence. For both R and I operations, we filter out stop words using NLTK from the set of predicted tokens. Additionally we filter out antonyms using synonym embeddings (Mrkšić et al., 2016) for sentiment analysis tasks.

B Results

Figures 3 - 8 are the complete set of graphs showing the attack effectiveness for all seven datasets.

C Human Evaluation

We ask the human evaluators to judge the *naturalness* of texts presented to them, i.e. whether they think they are adversarial examples or not. They were instructed to do so on the basis of grammar and how likely they think it is from the original dataset, and rate each example on the following Likert scale of 1-5: 1) Sure adversarial sample, 2) Likely an adversarial example, 3) Neutral, 4) Likely an original sample, 5) Sure original sample. From the results of Table 3, it is clear that `BAE-R` always beats the sentiment accuracy and *naturalness* score of TextFooler. The latter is due to unnaturally long and complex synonym replacements on using TextFooler.

Adversarial Self-Supervised Data-Free Distillation for Text Classification

Xinyin Ma, Yongliang Shen, Gongfan Fang, Chen Chen, Chenghao Jia, Weiming Lu[*]
College of Computer Science, Zhejiang University
{maxinyin, syl, fgf, chen_double, chjia, luwm}@zju.edu.cn

Abstract

Large pre-trained transformer-based language models have achieved impressive results on a wide range of NLP tasks. In the past few years, Knowledge Distillation(KD) has become a popular paradigm to compress a computationally expensive model to a resource-efficient lightweight model. However, most KD algorithms, especially in NLP, rely on the accessibility of the original training dataset, which may be unavailable due to privacy issues. To tackle this problem, we propose a novel two-stage data-free distillation method, named ***Adversarial self-Supervised Data-Free Distillation*** (AS-DFD), which is designed for compressing large-scale transformer-based models (e.g., BERT). To avoid text generation in discrete space, we introduce a ***Plug & Play Embedding Guessing*** method to craft pseudo embeddings from the teacher's hidden knowledge. Meanwhile, with a ***self-supervised module*** to quantify the student's ability, we adapt the difficulty of pseudo embeddings in an adversarial training manner. To the best of our knowledge, our framework is the first data-free distillation framework designed for NLP tasks. We verify the effectiveness of our method on several text classification datasets.

1 Introduction

Recently, pre-trained language models (Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019; Raffel et al., 2019) have achieved tremendous progress and reached the state-of-the-art performance in various downstream tasks such as text classification (Maas et al., 2011), language inference (Bowman et al., 2015) and question answering (Rajpurkar et al., 2016). These models become an indispensable part of current models for their transferability and generalizability.

However, such language models are huge in volume and demand highly in computational resources, making it impractical in deploying them on portable systems with limited resources (e.g., mobile phones, edge devices) without appropriate compression. Recent researches (McCarley, 2019; Gordon et al., 2020; Michel et al., 2019) focus on compressing the large-scale models to a shallow and resource-efficient network via weight pruning (Guo et al., 2019), knowledge distillation (Mukherjee and Awadallah, 2019), weight quantization (Zafrir et al., 2019) and parameter sharing (Lan et al., 2020). Among them, some methods (Sanh et al., 2019; Sun et al., 2019) draw on the idea of transfer learning, utilizing knowledge distillation (Hinton et al., 2015) to transfer latent representation information embedded in teachers to students. These knowledge distillation methods share some commonalities: they rely on the training data to achieve high accuracy. It will be intractable if we need to compress a model without publicly accessible data. Reasons for that include privacy protection, company assets, safety/security concerns and transmission. Representative samples include GPT2 (Radford et al., 2019), which has not released its training data with fears of abuse of language models. Google trains a neural machine translation system (Wu et al., 2016) using internal datasets owned and protected by the company. DeepFace (Taigman et al., 2014) is trained on user images under confidential policies for protecting users. Further, some datasets, like Common Crawl dataset used in GPT3 (Brown et al., 2020), contain nearly a trillion words and are difficult to transmit and store.

Conventional knowledge distillation methods are highly dependent on data. Some models or algorithms in Computer Vision like DAFL (Chen et al., 2019), ZSKD (Nayak et al., 2019) solve the data-free distillation by generating pseudo images or uti-

November 16–20, 2020.

lizing metadata from teacher models. Exploratory researches (Micaelli and Storkey, 2019; Fang et al., 2019) also show that GANs can synthesize harder and more diversified images by exploiting disagreements between teachers and students. However, these models only make attempts in image tasks, designing for continuous and real-valued images. Applying these models to generate sentences is challenging due to the discrete representation of words (Huszár, 2015). Backpropagation on discrete words is not reasonable, and it seems unlikely to pass the gradient through the text to the generator. Apart from the discontinuity problem of text, some promotion strategies like layer-wise statistic matching in batch normalization (Yin et al., 2019) are not suitable for transformer-based models, which transposes batch normalization into layer normalization to fit with varied sentence length (Ba et al., 2016).

To address the above issues and distill without data, we propose a novel data-free distillation framework called ”Adversarial self-Supervised Data-Free Distillation”(AS-DFD). We invert BERT to perform gradient updates on embeddings and consider parameters of the embedding layer as accessible knowledge for student models. Under constraints of constructing ”BERT-like” vectors, pseudo embeddings extract underlying representations of each category. Besides, we employ a self-supervised module to quantify the student's ability and adversarially adjust the difficulty of pseudo samples, alleviating the insufficient supervisory problem controlled by the one-hot target. Our main contributions are summarized as follows:

- We introduce AS-DFD, a data-free distillation framework, to compress BERT. To the best of our knowledge, AS-DFD is the first model in NLP to distill knowledge without data.

- We propose a Plug & Play Embedding Guessing method and align the pseudo embeddings with the distribution of BERT's embedding. We also propose a novel adversarial self-supervised module to search for samples students perform poorly on, which also encourages diversity.

- We verify the effectiveness of AS-DFD on three popular text classification datasets with two different student architectures. Extensive experiments support the conjecture that synthetic embeddings are effective for data-free distillation.

2 Related Work

2.1 Data-Driven Distillation for BERT

Knowledge Distillation (KD) compresses a large model (the teacher model) to a shallow model (the student model) by imitating the teacher's class distribution output (Hinton et al., 2015). Bert (Devlin et al., 2018) contains multiple layers of transformer blocks (Vaswani et al., 2017) which encodes contextual relationship between words. Recently, many works successfully compress BERT to a BERT-like model with knowledge distillation (Sanh et al., 2019) and achieve comparable performances on downstream-tasks. Patient-KD (Sun et al., 2019) bridges the student and teacher model between its intermediate outputs. TinyBERT (Jiao et al., 2019) captures both domain-general and domain-specific knowledge in a two-stage framework. Zhao et al. (2019) employs a dual-training mechanism and shared projection matrices to compress the model by more than 60x. BERT-of-Theseus (Xu et al., 2020) progressively module replacing and involves a replacement scheduler in the distillation process. Besides, some recent surveys focus on compress BERT to a CNN-based (Chia et al., 2019) or LSTM-based model to create a more lightweight model with additional training data (Tang et al., 2019a,b).

2.2 Data-Free Distillation Methods

Current methods for data-free knowledge distillation are applied in the field of computer vision. Lopes et al. (2017) leverages metadata of networks to reconstruct the original dataset. Chen et al. (2019) trains a generator to synthesize images that are compatible with the teacher. Nayak et al. (2019) models the output distribution space as a Dirichlet distribution and updated the random noisy images to compose a transfer set. Micaelli and Storkey (2019) and Fang et al. (2019) incorporate the idea of adversarial training into knowledge distillation, measuring the discrepancy between the student and teacher. Yin et al. (2019) introduces DeepInversion to synthesize class-conditional images. Due to the discrete nature of language, none of the above methods can be applied to natural language tasks. Melas-Kyriazi et al. (2020) proposes a generation-distillation framework in low-data settings, which employs a finetuned GPT2 as the generator and a CNN as the student model. Different from methods above, we investigate the problem of compressing BERT with no data.

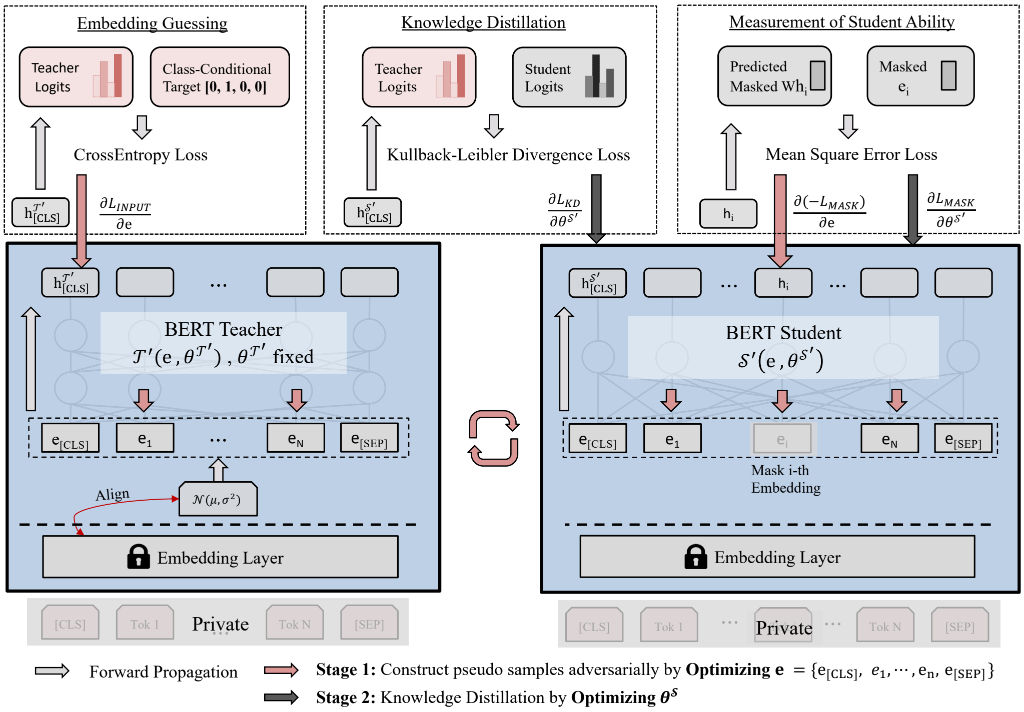

Figure 1: An overview of our two-stage Adversarial self-Supervised Data-Free Distillation framework. $\mathcal{T}'$ and $\mathcal{S}'$ contain transformer layers and classifier head. Firstly, when constructing synthetic samples, we iteratively guess and update the pseudo embeddings $\mathbf{e}$ under the feedback of the teacher's class-conditional supervision (top left) and the student's self-assessment (top right) in an adversarial training manner. Secondly, we use the generated sample $\mathbf{e}$ to distill knowledge (top middle). The parameters of embedding layer are fixed, and no inputs will go through the embedding layer when training.

3 Methods

In this section, we present our two-stage distillation framework named *Adversarial self-Supervised Data-Free Distillation* (AS-DFD). We craft well-trained embedding-level pseudo samples by controllable Plug & Play Embedding Guessing with alignment constraints (Section 3.1) and adversarially adapt synthetic embeddings under self-supervision of the student (Section 3.2). Using these pseudo samples, we transfer knowledge from the teacher to the student (Section 3.3). The workflow of AS-DFD is illustrated in Figure 1.

Problem Definition Knowledge Distillation is a compression technique to train a high-performance model with fewer parameters instructed by the teacher model (Hinton et al., 2015). Let $\mathcal{T}$ be a large transformer-based teacher model (12-layer BERT-base here) and $\mathcal{S}$ be a comparatively lightweight student model. For each sentence $\mathbf{x}$, the classification prediction can be formulated as:

$$\begin{aligned}\mathbf{e} &= \text{EmbeddingLayer}(\mathbf{x};\, \theta_{emb})\\ \mathbf{h} &= \text{TransformerLayers}(\mathbf{e};\, \theta_{layer})\\ \mathbf{y} &= \text{ClassifierLayer}(\mathbf{h}_{[\mathbf{CLS}]};\, \theta_{classifier})\end{aligned} \tag{1}$$

where θ_{emb}, θ_{layer}, $\theta_{classifier}$ represent parameters in the embedding layer, transformer layers and classification head respectively. $\mathbf{y}$ is the softmax probability output of $\mathbf{x}$ and $\mathbf{h}_{[\mathbf{CLS}]}$ denotes the hidden states in the last layer corresponding to the special token [CLS]. Parameters with superscript $\mathcal{T}$ belong to the teacher and $\mathcal{S}$ for the student.

Our goal of data-free knowledge distillation is to train the student parameters $\theta^{\mathcal{S}}$ with no data $\mathcal{X}$ available. In other words, we only have a teacher model $\mathcal{T}$ and we need to compress it.

3.1 Construct Pseudo Samples

Plug & Play Embedding Guessing In the data-free settings, we need to solve the dilemma of having no access to the original dataset. The major challenge is how to construct a set of highly reliable samples, from which the student can extract differential knowledge.

Our approach exploits representative knowledge hidden in the teacher's parameters in a Plug & Play manner (Nguyen et al., 2017; Dathathri et al., 2020). Given a sentence $\mathbf{x}$ and a label $\mathbf{y}$, the conditional probability can be written as $P(\mathbf{y}|\mathbf{x}; \theta^{\mathcal{T}})$. When finetuning the teacher, we optimize parameters $\theta^{\mathcal{T}}$ towards higher probability. To capture impression of prior training data in the teacher's parameters, we invert the model and utilize the teacher's parameters to guide the generation of $\mathbf{x}$ by ascending $P(\mathbf{y}|\mathbf{x};\theta^{\mathcal{T}})$ with $\theta^{\mathcal{T}}$ fixed.

Due to the intractable discrete problem of text, gradients updated on $\mathbf{x}$ are pointless. Most language models transform discrete words into continuous embeddings. Inspired by this, we ignore the embedding layer and apply the updating on continuous representation space of embeddings. We name this generation process ”Embedding Guessing”. We randomly guess vectors $\mathbf{e} \in \mathbb{R}^{l\times d}$, feed them into the transformer blocks and get feedback from gradients to confirm or update our guess. l is the predefined length of sentence and d is the embedding dimensionality, which is 768 in BERT-base. Those target-aware embeddings can be obtained by minimizing the objective:

$$\mathcal{L}_{INPUT} = \sum_{\mathbf{e}\in\mathcal{E}} \mathrm{CE}\left(\mathcal{T}'(\mathbf{e};\theta^{\mathcal{T}'}), \hat{\mathbf{y}}\right) \quad (2)$$

where $\mathcal{T}'$ takes pseudo embeddings $\mathbf{e}$ as input and contains $\mathrm{TransformerLayers}$ and $\mathrm{ClassifierLayer}$ in the teacher. $\theta^{\mathcal{T}'}$ includes $\theta^{\mathcal{T}}_{layer}$ and $\theta^{\mathcal{T}}_{classifier}$. $\hat{\mathbf{y}}$ is a random target class. CE refers to the cross-entropy loss. $\mathcal{E}$ is a batch of $\mathbf{e}$ initialized with Gaussian distribution. We update $\mathbf{e}$ for several iterations until convergence, representing that $\mathbf{e}$ is correct judged by the teacher. As for $\theta^{\mathcal{S}}_{emb}$, we share $\theta^{\mathcal{T}}_{emb}$ with $\theta^{\mathcal{S}}_{emb}$.

We argue that under the process of Embedding Guessing, pseudo embeddings $\mathbf{e}$ contain the target-specific information. Classification models need to find out differentiated characteristics which propitious to prediction over multiple categories. As the human learning process, examples given by teachers are encouraged to be representative and better reflecting the discrepancy among classes. Borrowed from this teaching strategy, we guess embeddings towards the direction of higher likelihood on target category and seek the local minimum regarding the target class, which reflects the characteristics of the target class within regions. In other words, these synthetic samples are more likely to comprise separation statistics between classes.

Making Pseudo-Embeddings More Realistic However, training on embeddings leads to a gap between the pseudo embeddings and the true underlying embeddings. Specifically, Embedding Guessing is independent of the parameter of the teacher's embedding and will shift the representational space. We add some additional constraints to ensure generated embeddings imitate the distribution of real data to a certain extent. Alignment strategies to restrain and reduce search space are listed as follows:

- Add $\mathbf{e}_{[\mathbf{CLS}]}$ and $\mathbf{e}_{[\mathbf{SEP}]}$ at both ends of the synthetic embeddings. $\mathbf{e}_{[\mathbf{CLS}]}$ and $\mathbf{e}_{[\mathbf{SEP}]}$ represent embeddings corresponding to [CLS] and [SEP].
- Continuously mask random length of embeddings from the tail of it. Lengths of sentences in batches are indeterminate and synthetic embeddings should cover this scenario.
- Adjust the Gaussian distribution to find the best initialization. Excessive initialization scope expands search space while small one converges to limited samples.

3.2 Adversarial self-Supervised Student

Modeling Learning Ability of the Student Effective teaching needs to grasp the student's current state of knowledge and dynamically adapt teaching strategies and contents. How to model the ability of the student without data? While processing natural language, the ability to analyze the context is an indicator of the student's capabilities and it can be quantified by a self-supervised module. Borrowing the idea of masking and predicting the entries randomly, we randomly mask one embedding in $\mathbf{e}$. Then, a new self-restricted objective is to predict the masked embedding with the following forums:

$$\begin{aligned} &\mathbf{h} = \mathcal{S}'\left(\mathbf{e}^{mask};\theta^{\mathcal{S}'}\right) \\ &L_{MASK} = \sum_{\mathbf{e}\in\mathcal{E}} \left\| \frac{\mathbf{e}_i}{\|\mathbf{e}_i\|_2} - \frac{W\mathbf{h}_i}{\|W\mathbf{h}_i\|_2} \right\|_2^2 \end{aligned} \quad (3)$$

where $\mathbf{e}$ is randomly masked on position i and converted to $\mathbf{e}^{mask}$. $\mathbf{e}_i$ is the masked embedding and W is the parameters in the fully-connected supervised module for predicting masked embedding. $\mathcal{S}'$ acts the same way as $\mathcal{T}'$. Unlike the class-conditional guidance, the self-supervised module shifts the gradients with more concrete and diverse supervision from context.

Adversarial Training of the Student To enforce $\mathbf{e}$ with more valuable and diverse information, we encourage the student to adversarially search for samples that the student is not confident. Prior works (Micaelli and Storkey, 2019; Fang et al., 2019) maximize the discrepancy between the teacher and student to encourage difficulty in samples and avoid synthesizing redundant images. We design a self-assessed confrontational mechanism, which guides the pseudo embeddings towards greater difficulty by enlarging L_{MASK} in the constructing stage and enhances the student by decreasing L_{MASK} in the distillation stage. Here, L_{MASK} acts as the timely student's feedback to improve teaching.

3.3 Two-stage Training

Distillation Objective Students learn high-entropy knowledge from teachers by matching soft targets. Taking $\mathcal{E}$ as synthetic samples, we measure the distance between the teacher and student as:

$$L_{KL} = \sum_{\mathrm{e} \in \mathcal{E}} \mathrm{KL}\left(\mathcal{T}'(\mathrm{e}; \theta^{\mathcal{T}'}), \mathcal{S}'(\mathrm{e}; \theta^{\mathcal{S}'}), \tau\right) \quad (4)$$

where KL denotes the Kullback-Leibler divergence loss and τ is the distillation temperature.

We follow PKD (Sun et al., 2019) to learn more meticulous details for students. To capture rich features, we define the additional loss as:

$$L_{PT} = \sum_{\mathrm{e} \in \mathcal{E}} \left\| \frac{\mathbf{h}_{[\mathbf{CLS}]}{}^{\mathcal{T}}}{\left\|\mathbf{h}_{[\mathbf{CLS}]}{}^{\mathcal{T}}\right\|_2} - \frac{\mathbf{h}_{[\mathbf{CLS}]}{}^{\mathcal{S}}}{\left\|\mathbf{h}_{[\mathbf{CLS}]}{}^{\mathcal{S}}\right\|_2} \right\|_2^2 \quad (5)$$

The objective of distillation can be formulated as:

$$L_{KD} = L_{KL} + \alpha L_{PT} \quad (6)$$

where α balances these two losses.

Training Procedure We summarize the training procedure in algorithm 1. The multi-round training of AS-DFD splits into two steps: the construction stage and the distillation stage. In the construction stage, after randomly sampling vectors with alignment constraints, we repeat the adversarial training of pseudo embeddings for n_{iter} times. In each iteration, we guess embeddings under class-conditional supervision information for $n_{\mathcal{T}}$ steps, and the student is asked to predict and give negative feedback to guide pseudo-embeddings' generation for $n_{\mathcal{S}}$ steps. When distilling, we train $\theta^{\mathcal{S}'}$ as well as W with those pseudo samples.

Algorithm 1: Two-stage Adversarial self-Supervised Data-Free Distillation

```
Input: Teacher model $\mathcal{T}$ with $\theta^{\mathcal{T}}$, $\mu$, $\sigma$
Output: Student model $\mathcal{S}$ with $\theta^{\mathcal{S}}$, $W$
Initial $\theta^{\mathcal{S}'}$ with $\theta^{\mathcal{T}'}$ and set $\theta^{\mathcal{S}}_{emb} \leftarrow \theta^{\mathcal{T}}_{emb}$
for $i \leftarrow 1$ to $N$ do
    // Stage 1: Construct Pseudo Samples
    Fix $\theta^{\mathcal{T}'}$, $\theta^{\mathcal{S}'}$ and $W$
    Sample $\mathcal{E} \sim \mathcal{N}(\mu, \sigma^2)$
    Add alignment constraints on $\mathcal{E}$
    for $iters \leftarrow 1$ to $n_{iter}$ do
        for $m \leftarrow 1$ to $n_{\mathcal{T}}$ do
            $\mathcal{E} \leftarrow \mathcal{E} - \eta \frac{\partial L_{INPUT}}{\partial \mathcal{E}}$
        end
        for $n \leftarrow 1$ to $n_{\mathcal{S}}$ do
            $\mathcal{E} \leftarrow \mathcal{E} - \eta \frac{\partial(-L_{MASK})}{\partial \mathcal{E}}$
        end
    end
    // Stage 2: Knowledge Distillation
    Fix $\theta^{\mathcal{T}'}$ and update $\theta^{\mathcal{S}'}$, $W$
    $\theta^{\mathcal{S}'} \leftarrow \theta^{\mathcal{S}'} - \xi \frac{\partial L_{KD}}{\partial \theta^{\mathcal{S}'}}$
    $W \leftarrow W - \xi \frac{\partial L_{MASK}}{\partial W}$
end
```

4 Experiments

4.1 Datasets

We demonstrate the effectiveness of our methods on three widely-used text classification datasets: AG News, DBPedia, IMDb (Auer et al., 2007; Maas et al., 2011). The statistics of these datasets are shown in Table 1. For datasets without validation sets (DBPedia and IMDb), we randomly sample 10% of the train set as the validation set.

Dataset	Classes	Train	Valid	Test
AG News	4	114k	6k	7.6k
DBPedia	14	504k	56k	70k
IMDb	2	22.5k	2.5k	25k

Table 1: Statistics of AG News/DBPedia/IMDb. Training samples are only available when finetuning teacher models. AG News and DBPedia are topic classification datasets and IMDb is a dataset for binary sentiment classification.

4.2 Teacher/Student Models

We experiment with official uncased BERT-base (Devlin et al., 2018) as the teacher model (BERT_{12}) for its widespread use in downstream tasks. BERT-base has 12 layers of Transformer (Vaswani et al.,

	AG News	DBPedia	IMDb
Distill on Original Dataset			
Teacher - BERT$_{12}$	94.2	99.4	88.5
Student - BERT$_6$	94.1	99.3	87.0
Student - BERT$_4$	93.8	99.3	85.9
Train on Part of the Dataset			
fastText (Chia et al., 2019)	75.2	91.0	/
8-layer BlendCNN(Chia et al., 2019)	87.6	94.6	/
Data-Free Distillation - BERT$_6$ as student			
Random Text	85.4	93.9	77.1
Modified-ZSKT	88.4	-	78.1

4.3 Baselines

To the best of our knowledge, there is no data-free distillation method for language tasks. However, when slightly modifying the data-free distillation models that are effective in Computer Vision, these models can also work on language tasks. Imitating Plug & Play Embedding Guessing method, we plug those image generators/generation methods above the embedding layer to synthesize continuous embeddings (instead of images).

Except for a baseline of random selection of words, we choose two models that represent the mainstream approaches in data-free distillation of image classification. Baselines are described as follows:

Random Text We randomly select words from vocabulary and construct literally-uninterpretable sentences.

Modified-ZSKT Modified-ZSKT is extended from ZSKT (Micaelli and Storkey, 2019). ZSKT trains an adversarial generator to search for images in which the student's prediction poorly matches that of the teacher's and reaches state-of-the-art performance.

Modified-ZSKD Modified-ZSKD is derived from ZSKD (Nayak et al., 2019). ZSKD performs Dirichlet sampling on class probability and craft Data Impression. DeepInversion (Yin et al., 2019) extends ZSKD with feature distribution regularization in batch normalization and outperforms ZSKD. However, BERT is not suitable for this performance-enhancing approach (BERT has no BN or structure like BN to store statistics of training data) and DeepInversion cannot be the baseline of our method.

Figure 2: Comparison of AS-DFD versus Modified-ZSKD using different initializations. Experiments are conducted on the 4-layer BERT student. Dash lines show the result initialized with BERT's $\{1, 4, 7, 10\}$ layers and solid lines with $\{1, 5, 8, 12\}$ layers.

4.4 Experimental Results

We first show the performance of data-driven knowledge distillation. Then we show the effectiveness of AS-DFD methods. As shown in Table 2, AS-DFD with BERT_4 and BERT_6 performs the best on three datasets. For 6-layer BERT, our algorithm improves 1.8%, 1.1% and 1.6% compared to Modified-ZSKD, closing the distance between the teacher and student. Furthermore, when coaching the 4-layer student, our methods gain 4.4%, 11.1% and 6.5% increases, which significantly improves the distillation accuracy. It seems that AS-DFD performs better with higher compression rates compared with other data-free methods. However, there is still a large gap between the performance of data-drive distillation and data-free distillation.

As for other baselines, Random Text can be regarded as a special case of unlabeled text where models can extract information to infer on, especially on text classification tasks. We use it as a criterion to judge whether a model works. Modified-ZSKT performs worse than Random Text on DBPedia. The reason lies in the structure of the generator, which is designed for image generation and is not suitable for language generation. The strength of CNN-based generators lies in its ability to capture local and hierarchical features. However, it is difficult for CNN to capture global and sequential structures, which is essential for languages.

Implementation Details We train the AS-DFD with $n_{\mathcal{T}} = 5, n_{\mathcal{S}} = 1$ and $n_{iter} = 5$. Maximum sequence lengths for three datasets are set to 128. Ideally, the more samples generated, the higher the accuracy. We impose restrictions on the number of generated samples for each dataset. Training epochs are 2.5k(AG News), 10k(DBPedia), 10k(IMDb) with 48 samples per batch for all methods except ZSKT, which needs to train its generator from scratch (25k epochs in Modified-ZSKT). In our experiments, these samples are enough for models to reach a stable status. More implementation details about finetuning teachers and distilling students are listed in Appendix A.1.

Initialization We observe that students' performance is highly sensitive to initializations (especially the Random Text baseline). Fan et al. (2019) argues that different layers play different roles in BERT. We report results using different initialization schemes and show the stability of AS-DFD. Considering that the embedding layer is separated from transformer blocks when training, we strongly recommend sharing the first layer's parameters of the teacher with the student, which is also suggested in Xu et al. (2020). Specifically, we choose two sets of layer weights. One is $\{1, 4, 7, 10\}$, which is common in data-driven distillation, and the other is $\{1, 5, 8, 12\}$, which intentionally put the last layer's parameters in. We evaluate these initialization schemes on AS-DFD and Modified-ZSKD. To eliminate the effects of distillation, we ensure that hyperparameters in the distillation step are consistent in two models, which intuitively shows the disparity in samples' quality. We do not include Modified-ZSKT because samples of Modified-ZSKT vastly outnumber the other two approaches.

Experimental results are shown in Figure 2. Modified-ZSKD highly dependent on initialization, especially on AG news and DBPedia with 23.1% and 47.1% performance drop relatively. On the

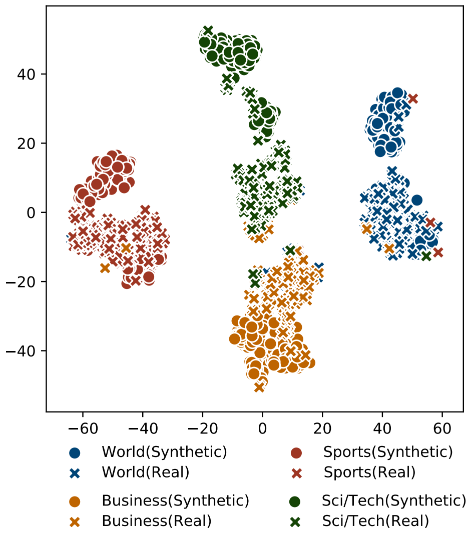

Figure 3: t-SNE dimensionality reduction results between real and synthetic samples on output of last layer.

contrary, initialization has limited impacts on AS-DFD. If pseudo-embeddings are initialized with worse parameters, our method still achieves better accuracy than other baselines (87.7% on AG News, 90.5% on DBPedia and 75.4% on IMDb). It shows that our method synthesizes higher-quality samples compared with Modified-ZSKD. Additionally, AS-DFD maintains an upward trend when the size of synthetic samples grows, suggesting that synthetic samples are useful for knowledge transfer.

Validity of Synthetic Embeddings Embeddings we generated are incomprehensible. We use t-SNE (Maaten and Hinton, 2008) to visualize the synthetic embeddings in comparison with the original dataset. As shown in Figure 3, samples generated by Embedding Guessing are close to the real samples and overlap with them to a certain extent.

4.5 Module Analysis

To verify the contribution of each module, we perform an ablation study and summarize it in Table 4.

Embedding Guessing is the foundation of the entire model. After drawing into the idea of Plug & Play Embedding Guessing, distillation performance is improved with stability, demonstrating that knowledge extracted from the teacher makes the synthetic samples reasonable. The embedding layer of the student model is completely separated in the generation-distillation process. Imitating BERT's input precisely narrows this gap, leading to a large improvement in accuracy. Additionally, choosing an appropriate normal distribution can effectively reduce search space and avoid generating completely irrelevant samples. We conduct experiments on different normal distributions in Appendix A.2.

Method	Accuracy
Random Noise	25.1
+ Embedding Guessing	44.2
+ Alignment Constraints	
+ Add [CLS] and [SEP]	80.3
+ Variable Length	82.2
+ Appropriate Gaussian Distribution	87.4
+ Adversarial self-Supervised Module	88.2

Table 4: Ablation study on AG News dataset. The Student model BERT_4 is initialized with BERT's 1st, 4th, 7th and 10th layers.

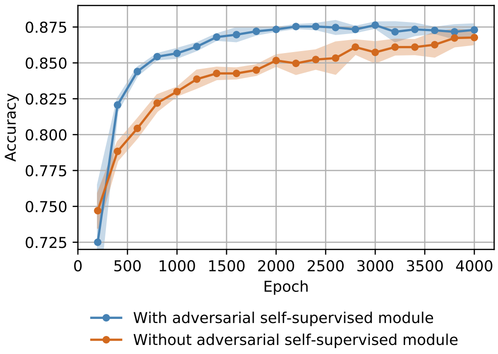

Figure 4: Accuracy curve with / without adversarial self-supervised module. The shaded area around the curve is the standard deviation over three seeds.

Effect of Adversarial self-Supervised Module To investigate whether the adversarial self-supervised module help data-free distillation, we conduct experiments on AG News to demonstrate the advantage of it in Figure 4.

We repeat each experiment 3 times and plot mean and standard deviation to reduce the contingency of experiments. With the adversarial self-supervised module, distillation converges faster and achieves higher accuracy. The number of epochs can be reduced to 2500, saving half of the time. As shown in the curve, AS-DFD does not perform well in the early stage since the self-supervised module is underfitting. After training for a while, the self-supervised module can grasp the student's ability and provide corrective feedback to synthesize more challenging samples.

5 Conclusion

In this paper, we propose AS-DFD, a novel data-free distillation method applied in text classification tasks. We use Plug & Play Embedding Guessing with alignment constraints to solve the problem that gradients cannot update on the discrete text. To dynamically adjust synthetic samples according to students' situations, we involve an adversarial self-supervised module to quantify students' abilities. Experimental results on three text datasets demonstrate the effectiveness of AS-DFD.

However, it's still challenging to ensure the diversity of generated embeddings under the weak supervision signal and we argue that the gap between synthetic and real sentences still exists. In the future, we would like to explore data-free distillation on more complex tasks.

A Appendices

A.1 Implementation Details

Hyperparameters in Finetuning Teachers We finetune BERT-base on three datasets mentioned above. We train our teacher models with Adam (Kingma and Ba, 2014) in 4 epochs. Learning rate is set to 2e-5 with a scheduler that linearly decreases it after 10% warmup steps. We set the maximum sequence length to 128 and batch size to 32 for all datasets.

Hyperparameters in Data-Free Distillation AS-DFD is trained on 1 TITAN Xp GPU. We set batch size to 48 with the student's learning rate ξ from $\{5 \times 10^{-5}, 2 \times 10^{-5}, 1 \times 10^{-5}\}$ and embedding learning rate η from $\{1 \times 10^{-2}, 5 \times 10^{-3}, 1 \times 10^{-3}\}$. We conduct an additional search over α from $\{100, 200, 250, 350, 500\}$ and select the hyperparameters with the highest accuracy. In our experiment, η equals to 1×10^{-2} and ξ equals to 1×10^{-5}. α is set to 250. Temperature $\tau = 1$ works well in our model. In the distillation step, we use Adam with a warmup proportion of 0.1 and we linearly decay the learning rate. In the construction step, the learning rate is fixed with Adam optimizer. There may be no validation set under data-free settings, which makes tuning parameters impossible. We experiment with the hyperparameters performed best on AG News and find that this set of parameters also performs well on the other two datasets.

A.2 Adjust Gaussian Distributions

The other two parameters are the mean and standard deviation for Gaussian sampling. We found in our experiments that standard deviation has a great influence on the student's performance. If vectors are initialized with small standard deviation(e.g. std=0.05, see Figure 5.b), generated samples in each category gather together, meaning that they aggregate to limited regions and leading to insufficient diversity of pseudo samples. Real data samples show no aggregation under t-SNE(see Figure 5.a). A higher standard deviation(e.g. std=1) indicates that samples are spread out from the mean, which will increase the search space and far from the embedding's distribution of BERT. It is also reflected in our testing accuracy with 83.2, 85.3, 88.2, 83.2 corresponding to $\mathcal{N}(0, 0.05^2)$, $\mathcal{N}(0, 0.2^2)$, $\mathcal{N}(0, 0.35^2)$, $\mathcal{N}(0, 1^2)$. We search standard deviations over $\{0.05, 0.1, 0.2, 0.25, 0.3, 0.35, 0.4, 0.5, 1\}$ and choose 0.35 to be the best standard deviation, which works well on all three datasets.

Abstract

Adversarial attacks for discrete data (such as texts) have been proved significantly more challenging than continuous data (such as images) since it is difficult to generate adversarial samples with gradient-based methods. Current successful attack methods for texts usually adopt heuristic replacement strategies on the character or word level, which remains challenging to find the optimal solution in the massive space of possible combinations of replacements while preserving semantic consistency and language fluency. In this paper, we propose **BERT-Attack**, a high-quality and effective method to generate adversarial samples using pre-trained masked language models exemplified by BERT. We turn BERT against its fine-tuned models and other deep neural models in downstream tasks so that we can successfully mislead the target models to predict incorrectly. Our method outperforms state-of-the-art attack strategies in both success rate and perturb percentage, while the generated adversarial samples are fluent and semantically preserved. Also, the cost of calculation is low, thus possible for large-scale generations. The code is available at `https://github.com/LinyangLee/BERT-Attack`.

1 Introduction

Despite the success of deep learning, recent works have found that these neural networks are vulnerable to adversarial samples, which are crafted with small perturbations to the original inputs (Goodfellow et al., 2014; Kurakin et al., 2016; Chakraborty et al., 2018). That is, these adversarial samples are imperceptible to human judges while they can mislead the neural networks to incorrect predictions. Therefore, it is essential to explore these adversarial attack methods since the ultimate goal is to make sure the neural networks are highly reliable and robust. While in computer vision fields, both attack strategies and their defense countermeasures are well-explored (Chakraborty et al., 2018), the adversarial attack for text is still challenging due to the discrete nature of languages. Generating of adversarial samples for texts needs to possess such qualities: (1) imperceptible to human judges yet misleading to neural models; (2) fluent in grammar and semantically consistent with original inputs.

Previous methods craft adversarial samples mainly based on specific rules (Li et al., 2018; Gao et al., 2018; Yang et al., 2018; Alzantot et al., 2018; Ren et al., 2019; Jin et al., 2019; Zang et al., 2020). Therefore, these methods are difficult to guarantee the fluency and semantically preservation in the generated adversarial samples at the same time. Plus, these manual craft methods are rather complicated. They use multiple linguistic constraints like NER tagging or POS tagging. Introducing contextualized language models to serve as an automatic perturbation generator could make these rules designing much easier.

The recent rise of pre-trained language models, such as BERT (Devlin et al., 2018), push the performances of NLP tasks to a new level. On the one hand, the powerful ability of a fine-tuned BERT on downstream tasks makes it more challenging to be adversarial attacked (Jin et al., 2019). On the other hand, BERT is a pre-trained masked language model on extremely large-scale unsupervised data and has learned general-purpose language knowledge. Therefore, BERT has the potential to generate more fluent and semantic-consistent substitutions for an input text. Naturally, both the properties of BERT motivate us to explore the possibility of attacking a fine-tuned BERT with another BERT as the attacker.

In this paper, we propose an effective and high-quality adversarial sample generation method: **BERT-Attack**, using BERT as a language model

---

November 16–20, 2020.

to generate adversarial samples. The core algorithm of BERT-Attack is straightforward and consists of two stages: finding the vulnerable words in one given input sequence for the target model; then applying BERT in a semantic-preserving way to generate substitutes for the vulnerable words. With the ability of BERT, the perturbations are generated considering the context around. Therefore, the perturbations are fluent and reasonable. We use the masked language model as a perturbation generator and find perturbations that maximize the risk of making wrong predictions (Goodfellow et al., 2014). Differently from previous attacking strategies that require traditional single-direction language models as a constraint, we only need to inference the language model once as a perturbation generator rather than repeatedly using language models to score the generated adversarial samples in a trial and error process.

Experimental results show that the proposed BERT-Attack method successfully fooled its fine-tuned downstream model with the highest attack success rate compared with previous methods. Meanwhile, the perturb percentage and the query number are considerably lower, while the semantic preservation is high.

To summarize our main contributions:

- We propose a simple and effective method, named **BERT-Attack**, to effectively generate fluent and semantically-preserved adversarial samples that can successfully mislead state-of-the-art models in NLP, such as fine-tuned BERT for various downstream tasks.

- BERT-Attack has a higher attacking success rate and a lower perturb percentage with fewer access numbers to the target model compared with previous attacking algorithms, while does not require extra scoring models therefore extremely effective.

2 Related Work

To explore the robustness of neural networks, adversarial attacks have been extensively studied for continuous data (such as images) (Goodfellow et al., 2014; Nguyen et al., 2015; Chakraborty et al., 2018). The key idea is to find a minimal perturbation that maximizes the risk of making wrong predictions. This minimax problem can be easily achieved by applying gradient descent over the continuous space of images (Miyato et al., 2017). However, adversarial attack for discrete data such as text remains challenging.

Adversarial Attack for Text

Current successful attacks for text usually adopt heuristic rules to modify the characters of a word (Jin et al., 2019), and substituting words with synonyms (Ren et al., 2019). Li et al. (2018); Gao et al. (2018) apply perturbations based on word embeddings such as Glove (Pennington et al., 2014), which is not strictly semantically and grammatically coordinated. Alzantot et al. (2018) adopts language models to score the perturbations generated by searching for close meaning words in the word embedding space (Mrkšić et al., 2016), using a trial and error process to find possible perturbations, yet the perturbations generated are still not context-aware and heavily rely on cosine similarity measurement of word embeddings. Glove embeddings do not guarantee similar vector space with cosine similarity distance, therefore the perturbations are less semantically consistent. Jin et al. (2019) apply a semantically enhanced embedding (Mrkšić et al., 2016), which is context unaware, thus less consistent with the unperturbed inputs. Liang et al. (2017) use phrase-level insertion and deletion, which produces unnatural sentences inconsistent with the original inputs, lacking fluency control. To preserve semantic information, Glockner et al. (2018) replace words manually to break the language inference system (Bowman et al., 2015). Jia and Liang (2017) propose manual craft methods to attack machine reading comprehension systems. Lei et al. (2019) introduce replacement strategies using embedding transition.

Although the above approaches have achieved good results, there is still much room for improvement regarding the perturbed percentage, attacking success rate, grammatical correctness and semantic consistency, etc. Moreover, the substitution strategies of these approaches are usually non-trivial, resulting in that they are limited to specific tasks.

Adversarial Attack against BERT

Pre-trained language models have become mainstream for many NLP tasks. Works such as (Wallace et al., 2019; Jin et al., 2019; Pruthi et al., 2019) have explored these pre-trained language models from many different angles. Wallace et al. (2019) explored the possible ethical problems of learned knowledge in pre-trained models.

3 BERT-Attack

Motivated by the interesting idea of turning BERT against BERT, we propose **BERT-Attack**, using the original BERT model to craft adversarial samples to fool the fine-tuned BERT model.

Our method consists of two steps: (1) finding the vulnerable words for the target model and then (2) replacing them with the semantically similar and grammatically correct words until a successful attack.

The most-vulnerable words are the keywords that help the target model make judgments. Perturbations over these words can be most beneficial in crafting adversarial samples. After finding which words that we are aimed to replace, we use masked language models to generate perturbations based on the top-K predictions from the masked language model.

3.1 Finding Vulnerable Words

Under the black-box scenario, the logit output by the target model (fine-tuned BERT or other neural models) is the only supervision we can get. We first select the words in the sequence which have a high significance influence on the final output logit.

Let $S = [w_0, \cdots, w_i \cdots]$ denote the input sentence, and $o_y(S)$ denote the logit output by the target model for correct label y, the importance score I_{w_i} is defined as

$$I_{w_i} = o_y(S) - o_y(S_{\backslash w_i}), \tag{1}$$

where $S_{\backslash w_i} = [w_0, \cdots, w_{i-1}, [\texttt{MASK}], w_{i+1}, \cdots]$ is the sentence after replacing w_i with $[\texttt{MASK}]$.

Then we rank all the words according to the ranking score I_{w_i} in descending order to create word list L. We only take ϵ percent of the most important words since we tend to keep perturbations minimum.

This process maximizes the risk of making wrong predictions, which is previously done by calculating gradients in image domains. The problem is then formulated as replacing these most vulnerable words with semantically consistent perturbations.

3.2 Word Replacement via BERT

After finding the vulnerable words, we iteratively replace the words in list L one by one to find perturbations that can mislead the target model. Previous approaches usually use multiple human-crafted rules to ensure the generated example is semantically consistent with the original one and grammatically correct, such as a synonym dictionary (Ren et al., 2019), POS checker (Jin et al., 2019), semantic similarity checker (Jin et al., 2019), etc. Alzantot et al. (2018) applies a traditional language model to score the perturbed sentence at every attempt of replacing a word.

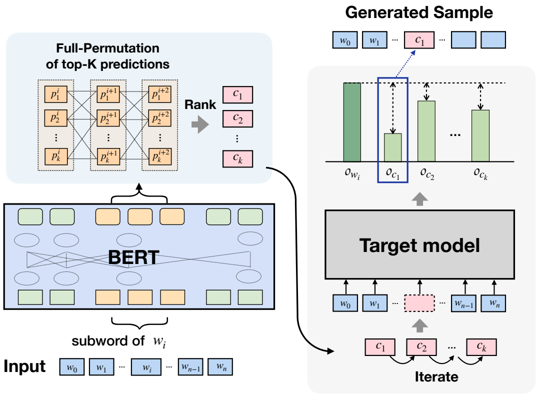

Figure 1: One step of our replacement strategy.

These strategies of generating substitutes are unaware of the context between the substitution positions (usually using language models to test the substitutions), thus are insufficient in fluency control and semantic consistency. More importantly, using language models or POS checkers in scoring the perturbed samples is costly since this trial and error process requires massive inference time.

To overcome the lack of fluency control and semantic preservation by using synonyms or similar words in the embedding space, we leverage BERT for word replacement. The genuine nature of the masked language model makes sure that the generated sentences are relatively fluent and grammar-correct, also preserve most semantic information, which is later confirmed by human evaluators. Further, compared with previous approaches using rule-based perturbation strategies, the masked language model prediction is context-aware, thus dynamically searches for perturbations rather than simple synonyms replacing.

Different from previous methods using complicated strategies to score and constrain the perturbations, the contextualized perturbation generator generates minimal perturbations with only one forward pass. Without running additional neural models to score the sentence, the time-consuming part is accessing the target model only. Therefore the process is extremely efficient.

Algorithm 1 BERT-Attack

```
procedure WORD IMPORTANCE RANKING
    $S = [w_0, w_1, \cdots]$ // input: tokenized sentence
    $Y \leftarrow$ gold-label
    for $w_i$ in $S$ do
        calculate importance score $I_{w_i}$ using Eq. 1
    select word list $L = [w_{top-1}, w_{top-2}, \cdots]$
    // sort $S$ using $I_{w_i}$ in descending order and collect $top - K$ words
procedure REPLACEMENT USING BERT
    $H = [h_0, \cdots, h_n]$ // sub-word tokenized sequence of $S$
    generate top-K candidates for all sub-words using BERT and get $P^{\in n \times K}$
    for $w_j$ in $L$ do
        if $w_j$ is a whole word then
            get candidate $C = Filter(P^j)$
            replace word $w_j$
        else
            get candidate $C$ using PPL ranking and Filter
            replace sub-words $[h_j, \cdots, h_{j+t}]$
        Find Possible Adversarial Sample
        for $c_k$ in C do
            $S^{'} = [w_0, \cdots, w_{j-1}, c_k, \cdots]$ // attempt
            if $\text{argmax}(o_y(S^{'}))! = Y$ then
                return $S^{adv} = S^{'}$ // success attack
            else
                if $o_y(S^{'}) < o_y(S^{adv})$ then
                    $S^{adv} = [w_0, \cdots, w_{j-1}, c, \cdots]$ // do one perturbation
    return None
```

Thus, using the masked language model as a contextualized perturbation generator can be one possible solution to craft high-quality adversarial samples efficiently.

3.2.1 Word Replacement Strategy

As seen in Figure 1, given a chosen word w to be replaced, we apply BERT to predict the possible words that are similar to w yet can mislead the target model. Instead of following the masked language model settings, we do not mask the chosen word w and use the original sequence as input, which can generate more semantic-consistent substitutes (Zhou et al., 2019). For instance, given a sequence *"I like the cat."*, if we mask the word *cat*, it would be very hard for a masked language model to predict the original word *cat* since it could be just as fluent if the sequence is *"I like the dog."*. Further, if we mask out the given word w, for each iteration we would have to rerun the masked language model prediction process which is costly.

Since BERT uses Bytes-Pair-Encoding (BPE) to tokenize the sequence $S = [w_0, \cdots, w_i, \cdots]$ into sub-word tokens: $H = [h_0, h_1, h_2, \cdots]$, we need to align the chosen word to its corresponding sub-words in BERT.

Let $\mathcal{M}$ denote the BERT model, we feed the tokenized sequence H into the BERT $\mathcal{M}$ to get output prediction $P = \mathcal{M}(H)$. Instead of using the argmax prediction, we take the most possible K predictions at each position, where K is a hyper-parameter.

We iterate words that are sorted by word importance ranking process to find perturbations. The BERT model uses BPE encoding to construct vocabularies. While most words are still single words, rare words are tokenized into sub-words. Therefore, we treat single words and sub-words separately to generate the substitutes.

Single words For a single word w_j, we make attempts using the corresponding top-K prediction candidates P^j. We first filter out stop words collected from NLTK; for sentiment classification tasks we filter out antonyms using synonym dictionaries (Mrkšić et al., 2016) since BERT masked language model does not distinguish synonyms and antonyms. Then for given candidate c_k we construct a perturbed sequence $H^{'} = [h_0, \cdots, h_{j-1}, c_k, h_{j+1} \cdots]$. If the target model is already fooled to predict incorrectly, we break the loop to obtain the final adversarial sample H^{adv}; otherwise, we select from the filtered candidates to pick one best perturbation and turn to the next word in word list L.

Sub-words For a word that is tokenized into sub-words in BERT, we cannot obtain its substitutes directly. Thus we use the perplexity of sub-word combinations to find suitable word substitutes from predictions in the sub-word level. Given sub-words $[h_0, h_1, \cdots, h_t]$ of word w, we list all possible combinations from the prediction $P^{\in t \times K}$ from $\mathcal{M}$, which is K^t sub-word combinations, we can convert them back to normal words by reversing the BERT tokenization process. We feed these combinations into the BERT-MLM to get the perplexity of these combinations. Then we rank the perplexity of all combinations to get the top-K combinations to find the suitable sub-word combinations.

Given the suitable perturbations, we replace the original word with the most likely perturbation and repeat this process by iterating the importance word ranking list to find the final adversarial sample. In this way, we acquire the adversarial samples S^{adv} effectively since we only iterate the masked language model once and do perturbations using the masked language model without other checking strategies.

We summarize the two-step BERT-Attack process in Algorithm 1.

4 Experiments

4.1 Datasets

We apply our method to attack different types of NLP tasks in the form of text classification and natural language inference. Following Jin et al. (2019), we evaluate our method on 1k test samples randomly selected from the test set of the given task which are the same splits used by Alzantot et al. (2018); Jin et al. (2019). The GA method only uses a subset of 50 samples in the FAKE, IMDB dataset.

Text Classification We use different types of text classification tasks to study the effectiveness of our method.

- **Yelp** Review classification dataset, containing. Following Zhang et al. (2015), we process the dataset to construct a polarity classification task.
- **IMDB** Document-level movie review dataset, where the average sequence length is longer than the Yelp dataset. We process the dataset into a polarity classification task [1].
- **AG's News** Sentence level news-type classification dataset, containing 4 types of news: World, Sports, Business, and Science.
- **FAKE** Fake News Classification dataset, detecting whether a news document is fake from Kaggle Fake News Challenge [2].

Natural Language Inference

- **SNLI** Stanford language inference task (Bowman et al., 2015). Given one premise and one hypothesis, and the goal is to predict if the hypothesis is entailment, neural, or contradiction of the premise.
- **MNLI** Language inference dataset on multi-genre texts, covering transcribed speech, popular fiction, and government reports (Williams et al., 2018), which is more complicated with diversified written and spoken style texts, compared with the SNLI dataset, including eval data matched with training domains and eval data mismatched with training domains.

4.2 Automatic Evaluation Metrics

To measure the quality of the generated samples, we set up various automatic evaluation metrics. The success rate, which is the counter-part of after-attack accuracy, is the core metric measuring the success of the attacking method. Meanwhile, the perturbed percentage is also crucial since, generally, less perturbation results in more semantic consistency. Further, under the black-box setting, queries of the target model are the only accessible information. Constant queries for one sample is less applicable. Thus query number per sample is also a key metric. As used in TextFooler (Jin et al., 2019), we also use Universal Sentence Encoder (Cer et al., 2018) to measure the semantic consistency between the adversarial sample and the original sequence. To balance between semantic preservation and attack success rate, we set up a threshold of semantic similarity score to filter the less similar examples.

Table 1: Results of attacking against various fine-tuned BERT models. TextFooler is the state-of-the-art baseline. For MNLI task, we attack the hypothesis(H) or premises(P) separately.

4.3 Attacking Results

As shown in Table 1, the BERT-Attack method successfully fool its downstream fine-tuned model. In both text classification and natural language inference tasks, the fine-tuned BERTs fail to classify the generated adversarial samples correctly.

The average after-attack accuracy is lower than 10%, indicating that most samples are successfully perturbed to fool the state-of-the-art classification models. Meanwhile, the perturb percentage is less than 10 %, which is significantly less than previous works.

Further, **BERT-Attack** successfully attacked all tasks listed, which are in diversified domains such as News classification, review classification, language inference in different domains. The results indicate that the attacking method is robust in different tasks. Compared with the strong baseline introduced by Jin et al. (2019)[3] and Alzantot et al. (2018)[4], the BERT-Attack method is more efficient and more imperceptible. The query number and the perturbation percentage of our method are much less.

We can observe that it is generally easier to attack the review classification task since the perturb percentage is incredibly low. BERT-Attack can mislead the target model by replacing a handful of words only. Since the average sequence length is relatively long, the target model tends to make judgments by only a few words in a sequence, which is not the natural way of human prediction. Thus, the perturbation of these keywords would result in incorrect prediction from the target model, revealing the vulnerability of it.

4.4 Human Evaluations

For further evaluation of the generated adversarial samples, we set up human evaluations to measure the quality of the generated samples in fluency and grammar as well as semantic preservation.

We ask human judges to score the grammar correctness of the mixed sentences of generated ad-

---

[3] https://github.com/jind11/TextFooler

[4] https://github.com/QData/TextAttack

versarial samples and original sequences, scoring from 1-5 following Jin et al. (2019). Then we ask human judges to make predictions in a shuffled mix of original and adversarial texts. We use the IMDB dataset and the MNLI dataset, and for each task, we select 100 samples of both original and adversarial samples for human judges. We ask three human annotators to evaluate the examples. For label prediction, we take the majority class as the predicted label, and for semantic and grammar check we use an average score among the annotators.

Seen in Table 2, the semantic score and the grammar score of the adversarial samples are close to the original ones. MNLI task is a sentence pair prediction task constructed by human crafted hypotheses based on the premises, therefore original pairs share a considerable amount of same words. Perturbations on these words would make it difficult for human judges to predict correctly therefore the accuracy is lower than simple sentence classification tasks.

Dataset		Accuracy	Semantic	Grammar
MNLI	Original	0.90	3.9	4.0
	Adversarial	0.70	3.7	3.6
IMDB	Original	0.91	4.1	3.9
	Adversarial	0.85	3.9	3.7

Table 2: Human-Evaluation Results.

4.5 BERT-Attack against Other Models

The BERT-Attack method is also applicable in attacking other target models, not limited to its fine-tuned model only. As seen in Table 3, the attack is successful against LSTM-based models, indicating that BERT-Attack is feasible for a wide range of models. Under BERT-Attack, the ESIM model is more robust in the MNLI dataset. We assume that encoding two sentences separately gets higher robustness. In attacking BERT-large models, the performance is also excellent, indicating that BERT-Attack is successful in attacking different pre-trained models not only against its own fine-tuned downstream models.

5 Ablations and Discussions

5.1 Importance of Candidate Numbers

The candidate pool range is the major hyperparameter used in the BERT-Attack algorithm. As seen in Figure 2, the attack rate is rising along with the candidate size increasing. Intuitively, a larger K would result in less semantic similarity. However, the semantic measure via Universal Sentence Encoder is maintained in a stable range, (experiments show that semantic similarities drop less than 2%), indicating that the candidates are all reasonable and semantically consistent with the original sentence.

Dataset	Model	Ori Acc	Atk Acc	Perturb %
IMDB	Word-LSTM	89.8	10.2	2.7
	BERT-Large	98.2	12.4	2.9
Yelp	Word-LSTM	96.0	1.1	4.7
	BERT-Large	97.9	8.2	4.1
MNLI matched	ESIM	76.2	9.6	21.7
	BERT-Large	86.4	13.2	7.4

Table 3: BERT-Attack against other models.

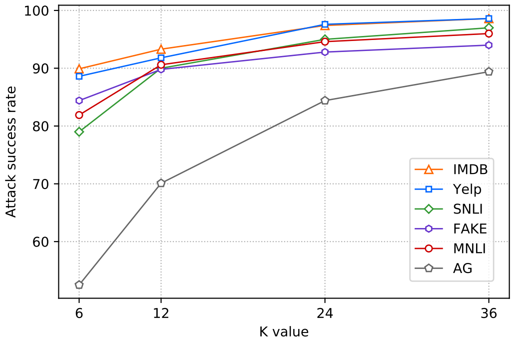

Figure 2: Using different candidate number K in the attacking process.

Further, a fixed candidate number could be rigid in practical usage, so we run a test using a threshold to cut off candidates that are less possible as a plausible perturbation.

As seen in Table 4, when using a flexible threshold to cut off unsuitable candidates, the attacking process has a lower query number. This indicates that some candidates predicted by the masked language model with a lower prediction score may not be meaningful so skipping these candidates can save the unnecessary queries.

Dataset	Method	Ori Acc	Atk Acc	Queries %
IMDB	Fixed-K	90.9	11.4	454
	With Threshold	90.9	12.4	440

Table 4: Flexible Candidates Using a threshold to cut off unsuitable candidates.

5.2 Importance of Sequence Length

The BERT-Attack method is based on the contextualized masked language model. Thus the sequence length plays an important role in the high-quality perturbation process. As seen, instead of the previous methods focusing on attacking the hypothesis of the NLI task, we aim at premises whose average length is longer. This is because we believe that contextual replacement would be less reasonable when dealing with extremely short sequences. To avoid such a problem, we believe that many word-level synonym replacement strategies can be combined with BERT-Attack, allowing the BERT-Attack method to be more applicable.

Dataset	Method	Ori Acc	Atk Acc	Perturb %
MNLI matched	BERT-Atk	85.1	7.9	8.8
	+Adv Train	84.6	23.1	10.5

Table 5: Adversarial training results.

Dataset	Model	LSTM	BERT-base	BERT-large
IMDB	Word-LSTM	-	0.78	0.75
	BERT-base	0.83	-	0.71
	BERT-large	0.87	0.86	-
Dataset	**Model**	ESIM	BERT-base	BERT-large
MNLI	ESIM	-	0.59	0.60
	BERT-base	0.60	-	0.45
	BERT-large	0.59	0.43	-

Table 6: Transferability analysis using attacked accuracy as the evaluation metric. The column is the target model used in attack, and the row is the tested model.

5.3 Transferability and Adversarial Training

To test the transferability of the generated adversarial samples, we take samples aimed at different target models to attack other target models. Here, we use BERT-base as the masked language model for all different target models. As seen in Table 6, samples are transferable in NLI task while less transferable in text classification.

Meanwhile, we further fine-tune the target model using the generated adversarial samples from the train set and then test it on the test set used before. As seen in Table 5, generated samples used in fine-tuning help the target model become more robust while accuracy is close to the model trained with clean datasets. The attack becomes more difficult, indicating that the model is harder to be attacked. Therefore, the generated dataset can be used as additional data for further exploration of making neural models more robust.

Dataset	Model	Atk Acc	Perturb %	Semantic
Yelp	BERT-Atk	5.1	4.1	0.77
	w/o sub-word	7.1	4.3	0.74
MNLI	BERT-Atk	11.9	7.9	0.68
	w/o sub-word	14.7	9.3	0.63

Table 7: Effects on sub-word level attack.

5.4 Effects on Sub-Word Level Attack

BPE method is currently the most efficient way to deal with a large number of words, as used in BERT. We establish a comparative experiment where we do not use the sub-word level attack. That is we skip those words that are tokenized with multiple sub-words.

As seen in Table 7, using the sub-word level attack can achieve higher performances, not only in higher attacking success rate but also in less perturbation percentage.

Dataset	Method	Atk Acc	Perturb %	Semantic
MNLI matched	MIR	7.9	8.8	0.68
	Random	20.2	12.2	0.60
	LIR	27.2	15.0	0.60

Table 8: Most Importance Ranking (MIR) vs Least Importance Ranking (LIR)

5.5 Effects on Word Importance Ranking

Word importance ranking strategy is supposed to find keys that are essential to NN models, which is very much like calculating the maximum risk of wrong predictions in the FGSM algorithm (Goodfellow et al., 2014). When not using word importance ranking, the attacking algorithm is less successful.

Dataset	Method	Runtime(s/sample)
IMDB	BERT-Attack(w/o BPE)	14.2
	BERT-Attack(w/ BPE)	16.0
	Textfooler(Jin et al., 2019)	42.4
	GA(Alzantot et al., 2018)	2582.0

Table 9: Runtime comparison.

Dataset					Label
MNLI	Ori	Some rooms have balconies .	Hypothesis	All of the rooms have balconies off of them .	Contradiction
	Adv	Many rooms have balconies .	Hypothesis	All of the rooms have balconies off of them .	Neutral
IMDB	Ori	it is hard for a lover of the novel northanger abbey to sit through this bbc adaptation and to keep from throwing objects at the tv screen... why are so many facts concerning the tilney family and mrs . tilney ' s death altered unnecessarily ? to make the story more ' horrible ? '			Negative
	Adv	it is hard for a lover of the novel northanger abbey to sit through this bbc adaptation and to keep from throwing objects at the tv screen... why are so many facts concerning the tilney family and mrs . tilney ' s death altered unnecessarily ? to make the plot more ' horrible ? '			Positive
IMDB	Ori	i first seen this movie in the early 80s .. it really had nice picture quality too . anyways , i 'm glad i found this movie again ... the part i loved best was when he hijacked the car from this poor guy... this is a movie i could watch over and over again . i highly recommend it .			Positive
	Adv	i first seen this movie in the early 80s .. it really had nice picture quality too . anyways , i 'm glad i found this movie again ... the part i loved best was when he hijacked the car from this poor guy... this is a movie i could watch over and over again . i inordinately recommend it .			Negative

Table 10: Some generated adversarial samples. Origin label is the correct prediction while label is adverse prediction. Only red color parts are perturbed. We only attack premises in MNLI task. Text in FAKE dataset and IMDB dataset is cut to fit in the table. Original text contains more than 200 words.

5.6 Runtime Comparison

Since BERT-Attack does not use language models or sentence encoders to measure the output sequence during the generation process, also, the query number is lower, therefore the runtime is faster than previous methods. As seen in Table 9, BERT-Attack is much faster than generic algorithm (Alzantot et al., 2018) and 3 times faster then Textfooler.

5.7 Examples of Generated Adversarial Sentences

As seen in Table 10, the generated adversarial samples are semantically consistent with its original input, while the target model makes incorrect predictions. In both review classification samples and language inference samples, the perturbations do not mislead human judges.

6 Conclusion

In this work, we propose a high-quality and effective method **BERT-Attack** to generate adversarial samples using BERT masked language model. Experiment results show that the proposed method achieves a high success rate while maintaining a minimum perturbation. Nevertheless, candidates generated from the masked language model can sometimes be antonyms or irrelevant to the original words, causing a semantic loss. Thus, enhancing language models to generate more semantically related perturbations can be one possible solution to perfect BERT-Attack in the future.

The Thieves on Sesame Street are Polyglots — Extracting Multilingual Models from Monolingual APIs

Abstract

Pre-training in natural language processing makes it easier for an adversary with only query access to a victim model to reconstruct a local copy of the victim by training with gibberish input data paired with the victim's labels for that data. We discover that this extraction process extends to local copies initialized from a pre-trained, multilingual model while the victim remains monolingual. The extracted model learns the task from the monolingual victim, but it generalizes far better than the victim to several other languages. This is done without ever showing the multilingual, extracted model a well-formed input in any of the languages for the target task. We also demonstrate that a few real examples can greatly improve performance, and we analyze how these results shed light on how such extraction methods succeed.

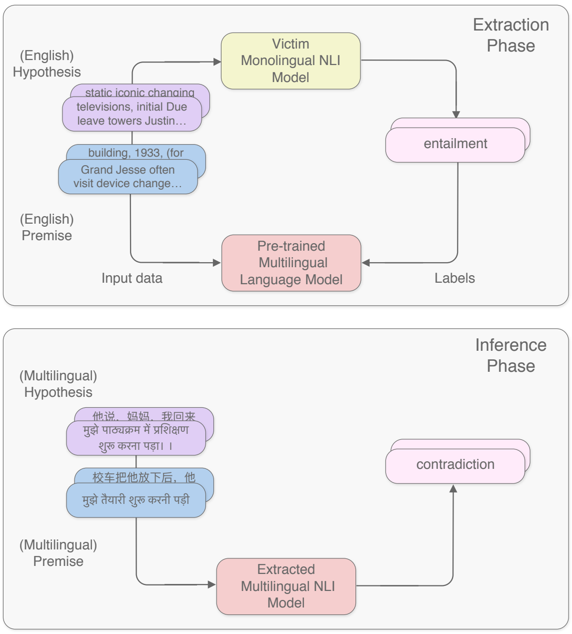

Figure 1: Extraction of multilingual models from monolingual APIs. *(Extraction phase:)* A pre-trained multilingual model is fine-tuned on gibberish data whose labels are queried from a monolingual API. *(Inference phase):* This model is then used for zero-shot cross-lingual transfer on different languages.

1 Introduction

Deploying machine learning models typically involves significant cost, including the expense of data acquisition, data cleaning, and model training and tuning. Recent work by Krishna et al. (2020) has demonstrated that deployed NLP models can be stolen by adversaries by querying victim models with gibberish input data that consists of random sequences of words. In particular, they showed that the following approach is sufficient for stealing text classification and question answering models. First, unlabeled data is created by randomly sampling words from a vocabulary. Second, a deployed API is queried with each random input sequence to obtain a label for each. Third, a pre-trained language model such as BERT (Devlin et al., 2019) is fine-tuned on the victim-labeled gibberish data. The resulting model retains a significant fraction of the victim model's performance without ever seeing a single well-formed input sentence. This process of "stealing" from an API, or "extracting" a local copy of a victim model, is not specific to NLP tasks but rather is a more general phenomenon (Tramèr et al., 2016; Orekondy et al., 2019; Juuti et al., 2019; Milli et al., 2019). Notably, it does not succeed when the extractor model is trained from scratch; a pre-trained model, such as BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2020), appears to be critical (Krishna et al., 2020).

The costs for creating and hosting multilingual NLP models can be even greater than for monolingual models. Therefore, extracting a multilingual model is potentially more valuable for an adversary. We demonstrate that it is possible to create

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6203–6207,
November 16–20, 2020.

multilingual models by stealing the task-specific knowledge from a monolingual victim model and extracting it into a new model pre-trained for multilingual language modeling, such as mBERT (Devlin et al., 2019) and XLMR (Conneau et al., 2019). These models are similar to BERT and RoBERTa discussed above but extend pre-training and fine-tuning to multiple languages. Even when fine-tuned in one language, say English, these models achieve good zero-shot performance in other pre-training languages. This phenomenon, known as zero-shot cross-lingual transfer, forms the basis of our approach. Combining it with model stealing, or extracting, we demonstrate cross-lingual transfer of task-specific knowledge stolen from a monolingual victim model without collecting a single grammatically correct sentence in any language.

Our investigation has ramifications for the discussion of model APIs as intellectual property and motivates the need to build defenses against such attacks. Since models could be deployed by adversaries in multiple languages without collecting real examples in any, defenses such as watermarking (Szyller et al., 2019) would be rendered useless.

While the reason for the surprising phenomenon is unknown, it is hypothesized (Krishna et al., 2020) that the dynamics of extraction is similar to that of model distillation (Hinton et al., 2015). During model distillation, a (student) model is trained with labels as the outputs of another (teacher) model rather than the ground truth to achieve similar or better performance than the teacher (Furlanello et al., 2018). The success of distillation could thus help explain that of model extraction.

For this short paper, we consider the problem of natural language inference on the multilingual XNLI dataset (Conneau et al., 2018) and show that:

1. Using labels obtained from an English model queried with gibberish English data, a multilingual model can be trained to a high performance on the English task and obtain good zero-shot performance on several other languages.

2. By additionally fine-tuning on 5% of the original English data, we can significantly boost performance on all languages. This post-hoc fine-tuning performs better than mixing the real and gibberish data during extraction.

3. The vocabulary used for generating gibberish data greatly impacts performance. The inability of pre-trained language models to distinguish real and gibberish examples is potential, partial explanation for the success of model extraction.

2 Methodology

We study the problem of natural language inference (NLI): classifying the relationship between a pair of sentences (premise and hypothesis) as either entailment, contradiction or neutral. We focus on this problem given the availability of data in several languages and a history of results on the benchmark (Conneau et al., 2018). We consider the setting where an NLI classification model is available as a black-box. It can be queried with any input data and returns hard labels. Consistent with earlier work, we call this model the *victim* model. We consider a separate model, the *extractor* model, that is trained by extracting task-specific knowledge from the victim model. We aim to study how multilingual pre-training affects the extractor and show that it allows transfer of task-specific knowledge from the victim model to other pre-trained languages. We consider two instances in our experiments: (i) one where the extractor has access to no real data and only queries gibberish, and (ii) extractor has access to some real data in English. Here, we refer to *real data* as data which was also used to train the victim model.

In our experiments, the victim model is trained on the MNLI dataset (Williams et al., 2018). We perform all cross-lingual experiments on the XNLI benchmark (Conneau et al., 2018). This benchmark contains NLI instances in several languages whose test sets were translated by humans using the MNLI dataset. In order to generate gibberish input data, we follow the approach of Krishna et al. (2020). For the hypothesis, we generate sentences of random length by sampling words uniformly from the word-level vocabulary of WikiText-103. The length of the sentence is sampled based on the distribution of lengths in WikiText-103. For the premise, we randomly swap three words of the hypothesis for random words leaving the rest identical. This is to mimic common NLI inputs which have several overlapping words in the hypothesis and premise. For all input sentences, we then perform inference using the victim model and use the hard labels as ground truth labels for the gibberish input data. The gibberish dataset is generated to be the same size as the MNLI dataset ($\sim$392k examples). When training the extractor, we tune the learning rate and maximum iterations, and we use the HuggingFace

Victim	Extractor	Accuracy
RoBERTa-Large	—	90.6
BERT-Large[1]	BERT-Large	76.3
RoBERTa-Large	RoBERTa-Base	74.8
RoBERTa-Large	XLMR-Base	69.0
RoBERTa-Large	RoBERTa-Large	84.3
RoBERTa-Large	XLMR-Large	78.6

Table 1: Development set accuracy on MNLI of various extractor models. [1] Result from Krishna et al. (2020).

library (Wolf et al., 2019).

For both the victim and extractor, we consider variants of the RoBERTa model (Liu et al., 2020). For the victim model, we use the RoBERTa-Large variant and, for the extractor we use the XLMR architecture (Conneau et al., 2019). The former is a language model pre-trained on a large amount of English data whereas the latter is similar but trained on data from over 100 languages. XLMR demonstrates zero-shot cross-lingual transfer: when fine-tuned on one language, say English, it is able perform well on other languages without seeing a single training example in those languages.

3 Experimental Results

Pre-trained multilingual models also succeed at model extraction with gibberish inputs. In Table 1, we present results for development set results for MNLI for the extracted models. Using the multilingual variant of RoBERTa (XLMR) does not appreciably reduce the extraction performance relative to the English-only variant. For the rest of the experiments, we use the XLMR-Large variant and note that the RoBERTa-Large — XLMR-Large pair exceeds the extraction performance reported in (Krishna et al., 2020) using BERT-Large models under identical conditions.

Models extracted with multilingual pre-trained language models perform well on zero-shot cross-lingual transfer. In Table 2, we present results for the zero-shot cross-lingual transfer. The first three rows correspond to the baseline cases in which the models are trained on 100% real English data (MNLI) and tested against the XNLI dataset (Conneau et al., 2018). Next, we include the novel extraction results where no real data is available and training is performed solely on the gibberish data in English. This model has not seen any grammatically correct sentences labeled for the task in English, and no sentences in other languages labeled for the task, yet it is better than a strong BiLSTM baseline from (Conneau et al., 2018). As is observed in other zero-shot cross-lingual work (Conneau et al., 2019; Singh et al., 2019), zero-shot performance on languages similar to English are comparable to the English performance while those languages which are low-resource and dissimilar to English suffer.

Performance of extracted models greatly improves with a fraction of real data. We now consider the case when the adversary has access to some real labeled data. Here, we sample 1, 5, or 10% of the MNLI (English) data and investigate two ways of using it: during extraction by adding it to the gibberish data, or after extraction as another fine-tuning stage similar to supplementary training (Phang et al., 2018). The results show that even a small fraction of real data can significantly improve zero-shot performance. In particular, 5% of the MNLI English training dataset is enough to lift the performance of extraction to that of XLMR-Base for all languages. Further, the results show that presenting data after extraction is better than mixing it during extraction. This is in line with results from Phang et al. (2018); Keskar et al. (2019).

4 Analysis

The dynamics of model extraction are hypothesized to be similar to that of model distillation (Krishna et al., 2020). NLP models ascribe high confidence to gibberish data (Feng et al., 2018). By distilling a model from such queries, the stolen model's decision boundary approximates that of the victim's.

We further validate this hypothesis by demonstrating that the embeddings of pre-trained language models show similar behavior whether the input data is real or gibberish. We compute representations for each example of the MNLI dataset and the gibberish dataset by max-pooling the outputs of the last layer of pre-trained RoBERTa. For 1000 examples from the MNLI development and 1000 gibberish samples, we compute the minimum Inner-Product distance between each example and the MNLI training data. We plot this nearest distance in Figure 2. Overlap in the distribution suggests the distinction between real and fake is difficult to make by embeddings alone. Though gibberish samples appear random, they sufficiently mimic the input distribution to allow distillation from the victim-

teacher model into the local-extracted model.

Finally, we demonstrate that extraction depends heavily on the vocabulary used for random sequence generation and not only on the properties of the models. Instead of using the vocabulary from WikiText-103, we use vocabulary of a dataset derived from papers on COVID-19[1]. The extraction performance drops from 78.6% to random chance. This suggests that model extraction is unlikely to succeed if the domain of the victim model and the input sampling distribution are different. The most common words of the COVID-19 dataset included *influenza, RNA, infection, respiratory, patients, viral* which substantially differ from the more common terms in WikiText-103 such as *television, family, government, military, system*. Whereas our earlier experiments demonstrated domain extension is possible by extracting into a multilingual model, this transfer requires input queries to reasonably mimic the domain of the victim model.

5 Conclusion

We study the problem of extracting multilingual models by stealing from a monolingual model. We query the monolingual victim model with gibberish data. We then use the victim's labels as ground-truth to fine-tune a separate multilingual. This extracts the task-specific knowledge from the victim and transfers it to languages seen by the multilingual model during its own self-supervised pre-training. We show that high accuracy can be obtained on several languages using this approach, and that this performance improves when the extractor has access to a small fraction of real data. We also show that post-hoc fine-tuning on real data is better than mixing real and gibberish data during extraction. We present results underscoring the importance of vocabulary on the extraction performance, and we provide preliminary evidence to support the hypothesis that the dynamics of model extraction are similar to that of model distillation. Our work prompts a deeper investigation into associated topics such as theoretical similarities to distillation, defenses against such multilingual extractions, and improving performance on out-of-domain vocabulary.

Abstract

We address hypernymy detection, *i.e.,* whether an `is-a` relationship exists between words (x, y), with the help of large textual corpora. Most conventional approaches to this task have been categorized to be either *pattern-based* or *distributional*. Recent studies suggest that *pattern-based* ones are superior, if large-scale Hearst pairs are extracted and fed, with the sparsity of unseen (x, y) pairs relieved. However, they become invalid in some specific sparsity cases, where x or y is not involved in any pattern. For the first time, this paper quantifies the non-negligible existence of those specific cases. We also demonstrate that distributional methods are ideal to make up for pattern-based ones in such cases. We devise a complementary framework, under which a pattern-based and a distributional model collaborate seamlessly in cases which they each prefer. On several benchmark datasets, our framework achieves competitive improvements and the case study shows its better interpretability.

1 Introduction

A taxonomy is a semantic hierarchy of words or concepts organized *w.r.t.* their *hypernymy* (*a.k.a.* `is-a`) relationships. Being a well-structured resource of lexical knowledge, taxonomies are vital to various tasks such as question answering (Gupta et al., 2018), textual entailment (Dagan et al., 2013; Bowman et al., 2015; Yu et al., 2020b), and text generation (Biran and McKeown, 2013). When automatically building taxonomies from scratch or populating manually crafted ones, the *hypernymy detection* task plays a central role. For a pair of queried words (x_q, y_q), hypernymy detection requires inferring the existence of a hyponym-hypernym relationship between x_q and y_q. Due to the good coverage and availability, free-text corpora are widely used to facilitate hypernymy detection, resulting in two lines of approaches: *pattern-based* and *distributional*.

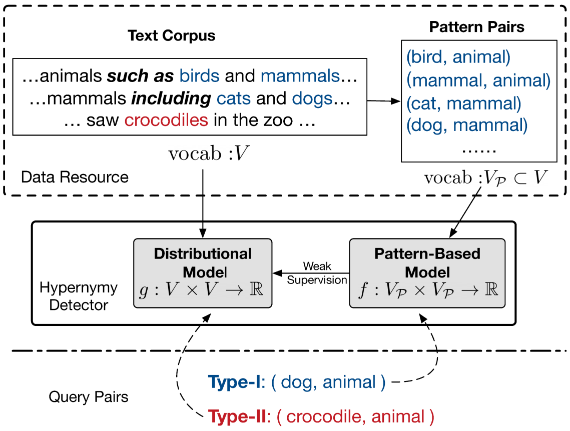

Figure 1: The overall framework of complementary methods for hypernymy detection from corpus. Different sparsity types of queried pairs are handled with pattern-based and distributional models respectively.

Pattern-based approaches employ pattern pairs (x, y) extracted via *Hearst-like patterns* (Hearst, 1992), *e.g.,* "*y such as x*" and "*x and other y*". An example of extracted pattern pairs from corpus are shown in Figure 1. Despite their high precision, the extracted pairs suffer from sparsity which comes in two folds *i.e.,* **Type-I**: x_q and y_q separately appear in some extracted pairs, but the pair (x_q, y_q) is absent *e.g.,* (dog, animal); or **Type-II**: either x_q or y_q is not involved in any extracted pair *e.g.,* (crocodile, animal).

Although matrix factorization (Roller et al., 2018) or embedding techniques (Vendrov et al., 2016; Nickel and Kiela, 2017; Le et al., 2019) are widely adopted to implement pattern-based approaches, they only relieve the **Type-I** sparsity and cannot generalize to unseen words appearing in the **Type-II** pairs. On the other hand, distribu-

tional ones follow, or are inspired by, the *Distributional Inclusion Hypothesis* (DIH; Geffet and Dagan 2005), *i.e.,* the set of the hyponym's contexts should be roughly contained by the hypernym's. Although applicable to any word in a corpus, they are suggested to be inferior to pattern-based ones fed with sufficient extracted pairs (Roller et al., 2018; Le et al., 2019).

Since pattern-based methods have unresolved sparsity issues, while distributional ones are more broadly applicable but globally inferior, neither of them can dominate the other in every aspect. In this light, we are interested in two questions:

- Is the **Type-II** sparsity severe in practice?
- If so, how to complement pattern-based approaches with distributional ones where the former is invalid?

To answer the first question, we conduct analyses involving estimations on real-world corpora as well as statistics of common hypernymy detection datasets. Results from both resources indicate that the likelihood of encountering the **Type-II** sparsity in practice could even reach up to more than 50%, which is thus non-negligible.

For the second question, we present ComHyper, a complementary framework (Sec. 4.1) which takes advantage of both pattern-based models' superior performance on **Type-I** cases and the broad coverage of distributional models on **Type-II** ones. Specifically, to deal with **Type-II** sparsity, instead of directly using unsupervised distributional models, ComHyper uses a training stage (Sec. 4.3) to sample from output space of a pattern-based model to train another supervised distribution model implemented by different context encoders (Sec. 4.2). In the inference stage, ComHyper uses the two models to separately handle the type of sparsity they are good at, as illustrated in Figure 1. In this manner, ComHyper relies on the partial use of pattern-based models on **Type-I** sparsity to secure performance no lower than distributional ones, and further attempts to lift the performance by fixing the former's blind spots (**Type-II** sparsity) with the latter. On several benchmarks and evaluation settings, the distributional model in ComHyper proves effective on its targeted cases, making our complementary approach outperform a competitive class of pattern-based baselines (Roller et al., 2018). Further analysis also suggests that ComHyper is robust when facing different mixtures of **Type-I** and **-II** sparsity.

Our contributions are summarized as : **1)** We confirm that a specific type of sparsity issue of current pattern-based approaches is non-negligible. **2)** We propose a framework of complementing pattern-based approaches with distributional models where the former is invalid. **3)** We systematically conduct comparisons on several common datasets, validating the superiority of our framework.

2 Related Work

Pattern-Based Approaches. Taxonomies from experts (*e.g.,* WordNet (Miller, 1995)) have proved effective in various reasoning applications (Song et al., 2011; Zhang et al., 2020). Meanwhile, Hearst patterns (Hearst, 1992) make large corpora a good resource of explicit `is-a` pairs, resulting in automatically built hypernymy knowledge bases (Wu et al., 2012; Seitner et al., 2016) of large scales. The coverage of both words and hypernymy pairs in those resources are far from complete.

To infer unknown hypernymies between known words, *e.g.,* implicit `is-a` pairs in transitive closures, pattern-based models are proposed. Roller et al. (2018) and Le et al. (2019) show that, on a broad range of benchmarks, simple matrix decomposition or embeddings on pattern-based word co-occurrence statistics provide robust performance. On Probase (Wu et al., 2012) - a Hearst-pattern-based taxonomy, Yu et al. (2015) use embeddings to address the same sparsity problem. Some methods (Vendrov et al., 2016; Athiwaratkun and Wilson, 2018; Nickel and Kiela, 2017, 2018; Ganea et al., 2018) embed WordNet in low-dimensional space. Depending on vectors of words learnt from known `is-a` pairs, the above pattern-based methods cannot induce more hypernymy pairs whose words do not appear in any pattern.

Distributional Approaches. Distributional models are inspired by DIH (Geffet and Dagan, 2005). They work on only word contexts rather than extracted pairs, thus are applicable to any word in a corpus. Early unsupervised models typically propose asymmetric similarity metrics over manual word feature vectors for entailment (Weeds et al., 2004; Clarke, 2009; Santus et al., 2014). In Chang et al. (2018) and Nguyen et al. (2017), the authors inject DIH into unsupervised embedding models to yield latent feature vectors with hypernymy information. Those feature vectors, manual or latent, may serve in unsupervised asymmetric metrics or to train supervised hypernymy classifiers. Shwartz et al. (2017) explore combinations of manual features and (un)supervised predictors, and suggest that unsupervised metrics are more robust *w.r.t.* the distribution change of training instances. Projection learning (Fu et al., 2014; Ustalov et al., 2017; Wang and He, 2020) has been used for supervised hypernymy detection.

Other Improved Methods. Due to weak generalization ability of Hearst patterns, Anh et al. (2016) and Shwartz et al. (2016) relieve the constraints from strict Hearst patterns to co-occurring contexts or lexico-syntactic paths between two words. They encode the co-occurring contexts or paths using word vectors to train hypernymy embeddings or classifiers. Although leading to better recall than Hearst patterns (Washio and Kato, 2018), they limit the trained embeddings or models from generalizing to every word in a corpus. Nevertheless they have no ability to cope with the **Type-II** sparsity, which is the main focus of our work.

Another line of retrofitting methods (Vulić et al., 2018; Vulić and Mrkšić, 2018), *i.e.,* adjusting distributional vectors to satisfy external linguistic constraints, has been applied to hypernymy detection. However, they strictly require more additional resources *e.g.,* synonym and antonym to achieve better performance (Kamath et al., 2019). To the best of our knowledge, we are the first to propose complementing the two lines of approaches to cover every word in a simple yet efficient way, with extensive analysis of the framework's potential and evaluation of performances.

3 Preliminaries

We formally define the aforementioned two types of sparsity, and provide some statistical insights about their impacts on pattern-based methods.

3.1 Notations and Definitions

Let V be the vocabulary of a corpus $\mathcal{C}$. By applying Hearst patterns on $\mathcal{C}$, a set of *extracted pairs* $\mathcal{P} \subseteq V \times V$, *i.e.,* `is-a` relationships $\{(x, y)\}$ $(x, y \in V)$, is obtained. As in Section 2, pattern-based approaches usually use $\mathcal{P}$ to perform matrix factorization or embedding learning. Due to their nature, only words "seen" in $\mathcal{P}$, or $V_{\mathcal{P}} = \{x \mid (x, y) \in \mathcal{P} \vee (y, x) \in \mathcal{P}\}$, will have respective columns/rows or embeddings. We refer to them by *in-pattern* (or IP for short) words. We refer to words without columns/rows or embeddings, *i.e.,* $V \setminus V_{\mathcal{P}}$, by *out-of-pattern* (or OOP) words.

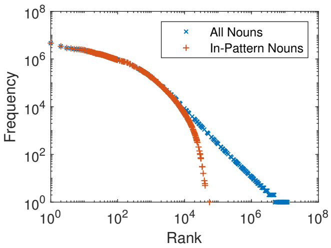

Figure 2: Corpus frequency of all nouns and IP nouns.

Suppose a pair of words $q = (x_q, y_q)$ is queried for potential hypernymy. We say q is an IP pair if both x_p and y_p are IP words, or an OOP pair if either of them is OOP. Due to the need of explicit columns/rows or embeddings for both x_q and y_q, pattern-based approaches may only make inferences on IP pairs, but are infeasible on OOP ones.

3.2 Observations and Motivation

Given the infeasibility of pattern-based methods on OOP pairs, we are interested in what extent pattern-based methods are limited, *i.e.,* the rough likelihood of encountering OOP pairs in practice. At first sight, Hearst patterns may have very sparse occurrences in a corpus. Nevertheless, words with higher frequencies tend to be covered by Hearst patterns and be IP words. Therefore, the possibility of encountering OOP pairs is not obvious to assess.

To shed light upon the OOP issue of pattern-based methods, we conduct an analysis on the corpora and extracted pairs in Roller et al. (2018). Considering that nouns tend to be queried more for potential hypernymy than, say, verbs, we only focus on nouns. In Figure 2, we show the corpus frequency of all nouns and in-pattern nouns, and draw the following observations.

1) $V_{\mathcal{P}}$ covers well the most frequent nouns in V. For the top-10^4 frequent nouns, the two lines of dots overlap well, indicating that common nouns are very likely to be involved in Hearst patterns.

2) Due to the limited size of $V_{\mathcal{P}}$, it is unable to cover the tail of V. With the frequency rank below 10^4, the two lines begin to separate. Comparing their intersections with the x-axis, it is understandable that a limited number of IP nouns cannot cover both frequent and tail nouns in a vocabulary, whose size is several orders of magnitudes larger.

3) The likelihood of a noun being OOP is non-negligible. The two lines enclose a triangular region, corresponding to the likelihood of a randomly drawn noun being OOP. According to our statistics,

Dataset	OOP (Hyper/All)	Total	OOP Rate
BLESS	44 / 1,829	14,542	12.58%
EVAL	694 / 3,903	13,450	29.02%
LEDS	105 / 209	2,770	7.55%
SHWARTZ	7,209 / 35,266	52,577	67.07%
W(BI)BLESS	0 / 46	1,668	2.76%
HYPERLEX	n/a / 107	2,163	4.95%

Table 1: Statistics of OOP pairs *w.r.t.* extracted pairs $\mathcal{P}$. OOP (All) is the number of OOP pairs while OOP (Hyper) is the number of OOP with true labels.

this region accounts for a non-negligible proportion of 19.9% of the total area.

With the likelihood of OOP nouns at hand, we are ready to roughly estimate the likelihood of encountering OOP pairs in practice. Suppose the two words in q are nouns independently sampled from the corpus distribution. Then the probability of q being OOP, *i.e.,* infeasible for pattern-based methods, is $1-(1-0.199)^2 = 35.8\%$. Even if y_q tends to bias towards more common words, the optimistic estimation is still above 19.9%.

Table 1 lists the actual portions of OOP pairs in several commonly used datasets *w.r.t.* $\mathcal{P}$ in Roller et al. (2018). Note that neither the datasets nor $\mathcal{P}$ are created in favor of the other. These actual rates may be above or below the estimated interval of 19.9%-35.8%, but are all at considerable levels. Considering the above analyses, we confirm that OOP pairs are non-negligible in practice and give a positive answer to the first question in Section 1.

Motivation of the Study. OOP pairs are problematic for pattern-based methods. Despite their non-negligible existence, former pattern-based methods (Roller et al., 2018; Le et al., 2019) boldly classify them as non-hypernymy in prediction. However, distributional methods are applicable as long as the two queried words have contexts. Thus, they are ideal to complement pattern-based methods on the non-negligible minority of OOP pairs.

4 Our Approach

4.1 Framework

Our framework is illustrated in Figure 1. It consists of a *pattern-based model* and a *distributional model* cooperating on the *data resource* to answer an arbitrarily queried pair of words $q \in V \times V$.

Data Resource. To train a pattern-based model using prior solutions, our data resource includes extracted pairs $\mathcal{P}$ from some text corpus $\mathcal{C}$. Unlike pattern-based approaches that depend solely on $\mathcal{P}$, our data resource also involves the corpus $\mathcal{C}$ for the sake of the distributional model.

Pattern-Based Model. The pattern-based model works on the extracted pairs $\mathcal{P}$ to serve in two roles. On the one hand, it is responsible for generalizing from statistics on $\mathcal{P}$ to score any in-pattern pair $q \in V_\mathcal{P} \times V_\mathcal{P}$ to reflect the plausibility of a hypernymy relationship. To this end, it is sufficient to adopt matrix-factorization-based (Roller et al., 2018) or embedding models (Le et al., 2019). On the other hand, the pattern-based model also provides supervision signals via a *sampler* for training the distributional model. We will specify this role later. Formally, we denote the pattern-based model by $f : V_\mathcal{P} \times V_\mathcal{P} \to \mathbb{R}$.

Distributional Model. Different from the pattern-based model defined on IP pairs $V_\mathcal{P} \times V_\mathcal{P}$, the distributional model has a form of $g : V \times V \to \mathbb{R}$, *i.e.,* it should be capable of predicting on any word pair in $V \times V$. This invalidates the model's dependency on extracted pairs involving x_q or y_q. The separate contexts of x_q and y_q in corpus $\mathcal{C}$ turn out to serve as the basis and input of the distributional model, respectively. Given the superior performance of pattern-based models on IP pairs (Roller et al., 2018), the distributional model g is only responsible to answer OOP pairs.

Various choices exist to implement the distributional model. We may apply unsupervised metrics (Weeds et al., 2004; Clarke, 2009; Santus et al., 2014) on manual features extracted from contexts of x_q and y_q, which are robust to the distribution change of training data (Shwartz et al., 2017). However, the scores of those metrics are not necessarily in the same scale with those output by the pattern-based model f for IP pairs. Such inconsistency will harm downstream systems which involve the scores for ranking or calculation.

Given sufficient supervision signals from f and the inherent noise of natural language, we implement the distributional model g by a supervised neural-network-based approach. Specifically, the network encodes the contexts of x and y in $\mathcal{C}$, *i.e.,* $\mathcal{C}(x)$ and $\mathcal{C}(y)$, to be $\mathbf{x}_h$ and $\mathbf{y}_H$, respectively, and makes predictions by a dot product, *i.e.,*

$$g(x, y) = \langle \mathbf{x}_h, \mathbf{y}_H \rangle.$$

Note that hypernymy is essentially asymmetric, so we distinguish $\mathbf{x}_h$ and $\mathbf{y}_H$ by the subscripts to reflect the asymmetry. In practice, we adopt networks with separate parameters for $\mathcal{C}(x)$ and $\mathcal{C}(y)$, which is detailed in the next section.

4.2 Encoding Queried Words

To implement the distributional model, we encode $\mathcal{C}(x)$ and $\mathcal{C}(y)$ into hypernymy-specific representations $\mathbf{x}_h$ and $\mathbf{y}_H$, respectively. There are various off-the-shelf models to encode sentential contexts. We take the following four approaches.

Transformed Word Vector. Instead of working directly on the original contexts $\mathcal{C}(x)$ and $\mathcal{C}(y)$, this approach takes as input the pre-trained word vectors (Mikolov et al., 2013; Pennington et al., 2014) $\mathbf{x}$ and $\mathbf{y}$ of x and y, and apply two Multi-Layer Perceptrons (MLPs), respectively:

$$\mathbf{x}_h = \mathbf{MLP}_h(\mathbf{x}), \quad \mathbf{y}_H = \mathbf{MLP}_H(\mathbf{y}).$$

The intuition is that word vectors roughly depend on the contexts and encode the distributional semantics. To make the MLPs generalize to V rather than $V_{\mathcal{P}}$, the word vectors are fixed during training. Inspired by the *post specialization* in Vulić et al. (2018), it also takes a similar approach to generalize task-specific word vector transformations to unseen words, though their evaluation task is not hypernymy detection.

NBoW with Mean-Pooling. Given words $\{c_j\}_{j=1}^{n}$ in a context $c \in \mathcal{C}(x)$, the Neural Bag-of-Words (NBoW for short) encoder looks up and averages their pre-trained vectors $\mathbf{c}_j$ as $\mathbf{c}$, transforms $\mathbf{c}$ through a MLP, and averages the resulted vectors through a Mean-pooling layer as $\mathbf{x}_h$:

$$\mathbf{x}_h = \frac{1}{|\mathcal{C}(x)|}\sum_{c\in\mathcal{C}(x)} \mathbf{MLP}_h(\mathbf{c}), \quad \mathbf{c} = \frac{1}{n}\sum_{j=1}^{n}\mathbf{c}_j.$$

To obtain $\mathbf{y}_H$, a similar network is applied, though the two MLPs do not share parameters to reflect the asymmetry of hypernymy. We fix the embeddings of context word vectors during training because satisfactory performance is observed. Due to its simplicity, NBoW is efficient to train. However, it ignores the order of context words and may not well reserve semantics.

context2vec with Mean-Pooling. To study the impacts of positional information within the context, we also attempt to substitute the NBoW with the context2vec encoder (Melamud et al., 2016). In context2vec, two LSTMs are used to encode the left and right contexts $\overrightarrow{c}$ and $\overleftarrow{c}$ of an occurrence of x, respectively. The two output vectors are concatenated as the final context representation $\mathbf{c}$ for the same transformation and averaging as for NBoW. Formally,

$$\mathbf{c} = \left[\,\overrightarrow{\mathbf{LSTM}}(\overrightarrow{c});\ \overleftarrow{\mathbf{LSTM}}(\overleftarrow{c})\,\right].$$

Note that the encoder for y still has separate parameters from those of x.

Hierarchical Attention Networks. NBoW and context2vec with Mean-Pooling both aggregate every context word's information into $\mathbf{x}_h$ and $\mathbf{y}_H$. Given several long contexts and the fixed output dimension, it is vital for encoders to capture the most useful information. Inspired by Yang et al. (2016), we incorporate attention on different words and contexts. We use a feed-forward network to estimate the importance, and combine the information, of each context word to obtain $\mathbf{c}$:

$$\alpha_j = \operatorname{softmax}\Big(\mathbf{w}_a^{\top}\tanh(\mathbf{W}_a\mathbf{c}_j)\Big), \mathbf{c} = \sum_{j=1}^{n}\alpha_j\mathbf{c}_j.$$

Then, another similar network is applied to all $\mathbf{c}^{(i)} \in \mathcal{C}(x)$ to obtain the representation of $\mathbf{x}_h$:

$$\beta_i = \operatorname{softmax}\Big(\mathbf{w}_b^{\top}\tanh(\mathbf{W}_b\mathbf{c}^{(i)})\Big), \mathbf{x}_h = \sum_{i=1}^{|\mathcal{C}(x)|}\beta_i\mathbf{c}^{(i)}.$$

For word y, the encoder is similar but still has separate parameters from those of x.

4.3 Training the Distributional Model

We train the distributional model g's parameters $\mathbf{\Phi}$ with supervision signals from the pattern-based model f. To make output scores of f and g comparable, we adopt the square error between the two scores as the loss on a pair (x, y), *i.e.*,

$$l(x, y; \mathbf{\Phi}) = \Big(g(x, y; \mathbf{\Phi}) - f(x, y)\Big)^2.$$

Compared with the potentially large size of the output space, a set of random samples from it suffices to train the parameters $\mathbf{\Phi}$. For each IP word $x \in V_{\mathcal{P}}$, we uniformly sample k entries from Δ_x, the column and row involving x in the output space $V_{\mathcal{P}} \times V_{\mathcal{P}}$:

$$\Delta_x = \{(x, y) \mid y \in V_{\mathcal{P}}\} \cup \{(y, x) \mid y \in V_{\mathcal{P}}\}.$$

The sample for x is done on P_x, a uniform distribution over Δ_x. Finally, our objective is

$$\min \sum_{x\in V_{\mathcal{P}}} \mathcal{L}(x; \mathbf{\Phi}),$$

where $\mathcal{L}(x; \mathbf{\Phi})$ is the expected loss related to x:

$$\mathcal{L}(x; \mathbf{\Phi}) = \sum_{i=1}^{k}\mathbb{E}_{(x^{(i)}, y^{(i)})\sim P_x}\, l(x^{(i)}, y^{(i)}; \mathbf{\Phi}).$$

5 Experimental Setup

We adopt the widely-used comprehensive evaluation framework[1] provided by Roller et al. (2018); Le et al. (2019). To make experimental results comparable, we align the settings as much as possible.

5.1 Corpora and Evaluation

Corpora. We used the 431k `is-a` pairs (243k unique) released by Roller et al. (2018). We substitute the Gigaword corpus they used by uKWac (Ferraresi, 2007) because the former is not complimentary. This decision does not affect reproducing pattern-based approaches in Roller et al. (2018).

Evaluation Tasks. The three sub-tasks include **1)** ranked hypernym detection: given (x_q, y_q) decide whether y_q is a hypernym of x_q. Five datasets *i.e.,* BLESS (Baroni and Lenci, 2011), EVAL (Santus et al., 2015), LEDS (Baroni et al., 2012), SHWARTZ (Shwartz et al., 2016) and WBLESS (Weeds et al., 2014) are used. The positive predictions should be ranked higher over negative ones and *Average Precision* (AP) is used for evaluation. **2)** hypernymy direction classification: determine which word in a pair has a broader meaning. Besides BLESS and WBLESS, we also use BIBLESS (Kiela et al., 2015) and *Accuracy* (Acc.) is reported for binary classification. **3)** graded entailment: predict scalar scores on HYPERLEX (Vulić et al., 2017). Spearman's correlation ρ between the labels and predicted scores is reported.

The statistics of datasets are shown in Table 1. The three tasks require algorithms to output scores unsupervisedly, which indicate the strength of hypernymy relationships. Note no external training data is available in the evaluation. Only extracted Hearst pattern pairs may be used for supervision.

5.2 Compared Methods

Pattern-Based Approaches. We reproduce four pattern-based methods *i.e.,* Count, PPMI, SVD-Count, and SVD-PPMI. As in Roller et al. (2018), SVD-PPMI is generally the most competitive.

Distributional Approaches. We compare with unsupervised distributional baselines in Roller et al. (2018), *i.e.,* Cosine, Weeds Precision (WP), invCL, and SLQS. For supervised distributional baseline, we adopt the strongest model SDSN in Rei et al. (2018) and take the probability scores of binary classifier as hypernymy predictions. All the 431k extracted pairs serve as true hypernymy pairs and false ones are generated by replacing one of the terms in true pairs with a random term.

	Detection (AP)				**Dir.**(Acc.)	**Graded**(ρ)
	BLESS	EVAL	LEDS	SHWARTZ	BLESS	HYPERLEX
Cosine	.106	.172	.736	.175	.000	-0.107
WP	.100	.251	.880	.283	.636	0.147
invCL	.096	.211	**.887**	.220	.636	0.062
SLQS	.020	.166	.423	.240	.341	-0.130
W2V	.292	.255	.712	.453	.767	0.313
NBOW	.124	**.258**	.617	.500	**.975**	0.264

HAN	**.346**	.250	.602	**.574**	**.975**	0.309

Table 2: Experimental results on OOP pairs.

Complementary Approaches. We adopt SVD-PPMI as the pattern-based model in our framework. We pre-train 300-dimensional word embeddings with Skip-Gram (Mikolov et al., 2013) on our corpus for the use of the distributional model. Specifically, we compare transformed word vector (W2V), NBOW/CONTEXT2VEC with MEAN-Pooling (NBOW/C2V), and Hierarchical Attention Networks (HAN)[2]. The output dimension of our four encoders is set to 300. The batch size is set to 128 and learning rate to 10^{-3}. We tuned the sampling size k in $\{1, 3, 5, 10, 100, 200, 400, 800\}$ on the validation set. We did not tune other hyperparameters since the default settings work well. Our code is available at `https://github.com/ccclyu/ComHyper`.

6 Experimental Results

We aim to answer: **1)** Are our distributional models supervised well by the pattern-based model? **2)** Do they improve our complementary methods over the pattern-based ones? **3)** Are complementary methods robust *w.r.t.* fewer extracted pairs?

6.1 Performance on OOP Pairs

To ensure that our supervised distributional models are working effectively on OOP pairs, we evaluate on only OOP pairs under the aforementioned settings. Because pattern-based approaches trivially give the lowest scores to OOP pairs, we only compare with distributional approaches.

---

[1] `https://github.com/facebookresearch/hypernymysuite`

[2] Heavy contextualized encoders based on the pretrain-finetune framework did not yield considerable improvement and we focus on efficient traditional encoders which already outperform the baselines. Though we include the BERT encoders in our released code, we suggest to make tradeoffs when choosing encoders as discussed in Xia et al. (2020).

		Detection (AP)					**Direction** (Acc.)			**Graded** (ρ)

	Oracle	.801	.666	.876	.861	.959	.992	n/a	n/a	n/a

Table 3: Experimental results on all queried pairs. Best ones are marked bold while second-best ones underlined.

Table 2 demonstrates the results. Note that the 46 OOP pairs in WBLESS and BIBLESS are all labeled false, causing undefined AP and perfect Acc. scores, so we omit the corresponding columns to save space. Observing from Table 2, except on LEDS, our distributional models generally achieve higher scores than unsupervised approaches. Especially, on the BLESS dataset, Cosine even gets a zero Accuracy score because it is symmetric and cannot suggest the right direction. The higher AP and Accuracy scores suggest that, supervised by the pattern-based model, our distributional models can generate better relative rankings within the scope of OOP pairs.

6.2 Main Results and Case Study

When facing both IP and OOP pairs, it is not enough to rank both types of pairs separately, since downstream systems usually require comparable scores or a unified ranking. We evaluate on the entire datasets under the aforementioned settings. We only compare with pattern-based methods and supervised distributional models because they generally outperform unsupervised ones.

Table 3 provides the main results. Best results are marked bold, and second-best ones are underlined. To better interpret the results, we also provide "Oracle" scores, *i.e.,* the upper-bounds that complementary methods can achieve. For the Detection task, Oracle scores are obtained by assigning OOP pairs having hypernymy relationships (See Table 1) the maximum score and other ones the minimum. For BLESS of Direction, the Oracle score is computed by assuming perfect predictions for OOP pairs. The Oracle scores for WBLESS/BIBLESS of the Direction task and HYPERLEX of Graded Entailment are not straightforward to estimate, thus are omitted.

In Table 3, complementary methods lead to superior results on Detection and Direction tasks. In eight out of nine columns, the best and second best scores are both achieved by complementary methods. Especially, large improvements (up to 25.9%) are observed on SHWARTZ with a higher OOP rate and thus a higher Oracle. In general, the HAN encoder achieves better performances. By attending to the most informative contexts and words, the HAN encoder potentially captures distributional semantics that are relevant to hypernymy relationships between queried words. Note that the relative performances between different context encoders are not necessarily consistent with those in Table 2. This is because the overall performance is not only sensitive to the relative ranking of OOP pairs, but also to their absolute scores.

In addition, with the same extracted $\mathcal{P}$ as supervision signals, our proposed methods show a great superiority over the supervised method (SDSN in Table 3). Both SDSN and our complementary approaches could be regraded as *combining pattern-based and distributional model.* The key difference is that complementary methods solve Type-I sparsity with a pattern-based model, which proved to be better than distributional ones on this case, while SDSN uses a distributional model (though supervised) uniformly on both cases.

Case Study. To explain the superiority of the HAN encoder, we exemplify with two true-hypernymy OOP pairs from two Detection datasets, respectively. Here, the two hyponyms are both uncommon and OOP words. Therefore, pattern-based models such as SVD-PPMI simply assign the pairs with minimum scores and rank them at the bottom. But by examining their contexts in the textual cor-

pus, the hypernymy relationships could have been inferred, and they could have been scored higher.

In Figure 3, we show the two OOP pairs, as well as their rank according to HAN and the OOP rates of the corresponding datasets. We also demonstrate the Top-3 contexts scored by HAN and visualize the context- and word-level attention weights. We observe that HAN can attend to informative contexts and words that help capture the semantics of the OOP word. For example, in LEDS, **vicarage** is OOP. HAN suggests three contexts that imply its meaning well. By reading the context words and phrases highlighted by HAN, *e.g., commodious residence*, and *collegiate church*, even people not knowing the word may guess it is a type of building. With our HAN-based distributional model, the pair is successfully promoted to top 50% in the ranking, well out of and above the bottom 7.55% of OOP pairs. Similar observations are drawn for the other pair, *i.e.,* (**kinetoscope**, device) with contexts *moving picture viewer*, and *movie projector system*.

We also observe that wrong predictions may be caused by extremely sparse contexts in the corpus such as *famicom* in the dataset SHWARTZ.

6.3 Impacts of Reduced Pairs

To analyze our complementary framework's robustness *w.r.t.* sparser extracted pairs $\mathcal{P}$, we randomly sample {95%,75%,55%,35%,15%} of all 243k `is-a` pairs, and rerun SVD-PPMI, the best pattern-based approach and our complementary approaches. In Figure 4, we only illustrate the results on LEDS for Detection and BLESS for Direction. Observations on the other datasets are similar, thus are omitted. We have the following observations. First, with fewer extracted pairs, the OOP rates increase quickly, and all models generally perform worse. This is not surprising since a sparser $\mathcal{P}$ leads to a less informative SVD-PPMI matrix and less supervision on distributional models. Second, despite the increased OOP rates, our complementary methods consistently outperform SVD-PPMI and suffer less from increasing OOP rates especially on BLESS. Finally, among the four context encoders, HAN performs better than the others when the sampled rate is higher than 75%. However, with lower sampled rates, W2V is more robust than the others on BLESS but fails to exceed HAN on EVAL.

7 Conclusion and Future Work

We propose complementing pattern-based and distributional methods for hypernymy detection. As far as we know, this is the first work along this line. We formally depict two types of sparsity that extracted pairs face, and indicate that pattern-based methods are invalid on the **Type-II**, *i.e.,* out-of-pattern pairs. By analyzing common corpora and datasets, we confirm that OOP pairs are non-negligible for the task. To this end, we devise a complementary framework, where a pattern-based and distributional model handle IP and OOP pairs separately, while collaborating seamlessly to give unified scores. Oracle performance analysis shows that our framework has high potentials on several datasets. Supervised by the pattern-based model, the distributional model shows robust capability of scoring OOP pairs and pushing the overall performance towards the oracle bounds.

In the future, we will extend the similar approach to multilingual (Yu et al., 2020a) or cross-lingual (Upadhyay et al., 2018) lexical entailment tasks. Moreover, one interesting direction is to use hyperbolic embeddings (Le et al., 2019; Balazevic et al., 2019) for pattern-based models due to their inherent modeling ability of hierarchies.

Interpreting Open-Domain Modifiers: Decomposition of Wikipedia Categories into Disambiguated Property-Value Pairs

Marius Paşca

Abstract

This paper proposes an open-domain method for automatically annotating modifier constituents (*"20th-century"*) within Wikipedia categories (*"20th-century male writers"*) with properties (*"date of birth"*). The annotations offer a semantically-anchored understanding of the role of the constituents in defining the underlying meaning of the categories. In experiments over an evaluation set of Wikipedia categories, the proposed method annotates constituent modifiers as semantically-anchored properties, rather than as mere strings in a previous method. It does so at a better trade-off between precision and recall.

1 Introduction

Motivation: As Web search moves towards returning structured answers rather than flat sets of document links in response to users' queries, the need for high-quality, wide-coverage knowledge to support such answers is growing stronger. The largest of the existing knowledge repositories (Bizer et al., 2009; Hoffart et al., 2013; Nastase and Strube, 2013), whether publicly available (Bollacker et al., 2008; Vrandečić and Krötzsch, 2014) or restricted to commercial access (Wu et al., 2012), uniformly rely on data in Wikipedia for their core sets of topics and knowledge assertions. In addition to its role in Web search and information retrieval (Chen et al., 2017; Ensan and Bagheri, 2017; Ma et al., 2018; Zhang and Balog, 2018), Wikipedia and the knowledge repositories derived from it are useful in a growing variety of tasks. Such tasks pertain to text analysis (Ratinov et al., 2011; Murty et al., 2018) and, specifically, knowledge acquisition from text (Nastase and Strube, 2013; Wu et al., 2012; Hoffart et al., 2013; Gupta et al., 2019).

Millions of Wikipedia articles are connected to parent categories, which are in turn connected to their own, iteratively broader categories. For example, the article *"art:Gary Oldman"* is connected to parent categories such as *"ctg:20th-century English male actors"*, *"ctg:Alumni of Rose Bruford College"*, which are in turn connected to their own, broader categories such as *"ctg:Actors"*, *"ctg:Acting"*, *"ctg:Language"*. Some categories really correspond to individual topics, e.g., *"ctg:Rose Bruford College"*. Many other categories in Wikipedia - hundreds of thousands, by our estimates - each corresponds to a fine-grained class that groups together individual articles sharing common properties. For example, the category *"ctg:20th-century English male actors"* groups articles such as *"art:Gary Oldman"* and *"art:Jude Law"*, which conceptually share properties that could be described as *"born or living in the 20th-century"*, *"born in England"*, *"being a male"* and *"being actors"*. That Wikipedia organizes topics into hundreds of thousands of potential fine-grained classes is remarkable. Comparatively, topics in other knowledge repositories are organized into only hundreds of types, in DBpedia (Bizer et al., 2009); or thousands of collections, in Freebase (Bollacker et al., 2008). Existing applications (Ma et al., 2018) that take advantage of Wikipedia categories include the creation of large, deep, fine-grained hierarchies out of Wikipedia articles and their categories (Flati et al., 2014; Gupta et al., 2018). Unfortunately, in both Wikipedia and downstream applications, Wikipedia categories are represented as nothing more than mere strings. Their meaning is otherwise not captured. Understanding and annotating the meaning of Wikipedia categories would make them more useful and increase their impact.

Contributions: The main contributions of this paper are as follows. First, it provides a precise, semantically-anchored understanding of the role of the constituents in defining the underlying meaning of Wikipedia categories. For this purpose, it pro-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6218–6228,
November 16–20, 2020.

poses an open-domain method for annotating modifier constituents within categories with properties and values referred to by modifier constituents. Previous work (Paşca, 2017) annotates categories with isolated, ambiguous strings such as *"century"* for the constituent *"20th-century"* within the category *"ctg:20th-century English male actors"*. In contrast, the method proposed here annotates categories with non-ambiguous values that are Wikipedia articles or Wikidata topics, such as *"val:20th century"* for the same constituent *"20th-century"* within *"ctg:20th-century English male actors"*. More importantly, it also annotates categories with properties with well-defined descriptions and semantic meaning in Wikidata (Vrandečić and Krötzsch, 2014), thus annotating the same constituent *"20th-century"* with the property *"prp:P569 (date of birth)"* from Wikidata. Second, the paper is the first to investigate the role of Wikidata in automatically enriching Wikipedia categories. In contrast, previous methods for open-domain information extraction mostly rely on unstructured or semi-structured text (Sun et al., 2018), Wikipedia (Tsurel et al., 2017) and repositories other than Wikidata (Hoffart et al., 2013; Qu et al., 2018; Moniruzzaman et al., 2019) with few exceptions (Chisholm et al., 2017). Third, in experiments over the gold set of Wikipedia categories, in comparison to a previous method (Paşca, 2017), the proposed method automatically annotates constituent modifiers as semantically-anchored properties and topics, rather than mere strings. It does so at a better trade-off between precision and recall.

2 Annotating Categories

Notations: The following prefixes distinguish among the various kinds of items: <u>*art*</u> as in *"art:Gary Oldman"*, for a Wikipedia article (http://en.wikipedia.org/wiki/Gary_Oldman); <u>*ctg*</u> as in *"ctg:20th-century English male actors"*, for a Wikipedia category (http://en.wikipedia.org/wiki/Category:20th-century_English_male_actors); <u>*tpc*</u> as in *"tpc:Gary Oldman"*, for a Wikidata topic (http://www.wikidata.org/wiki/Q83492), which often has an equivalent Wikipedia article (*"art:Gary Oldman"*); <u>*prp*</u> as in *"prp:P569 (date of birth)"*, for a Wikidata property (http://www.wikidata.org/wiki/Property:P569); <u>*val*</u> as in *"val:20th century"*, for the value of a property of a topic in Wikidata.

Goal: Finer-grained categories in Wikipedia often take the form of compositional noun phrases. Within such categories, individual modifier constituents refer to values that implicitly allude to explicit properties applying to, and shared by, the descendant Wikipedia articles located under the categories. For example, the modifier constituent *"English"* alludes to an explicit property regarding the *place of birth* applying to *"art:Gary Oldman"*, *"art:Jude Law"* and other descendant Wikipedia articles located under the category *"ctg:20th-century English male actors"*. Categories are represented simply as strings in Wikipedia. Understanding the role played by as many of their individual constituents as possible, by accurately identifying the explicit properties to which their constituents implicitly refer, would go a long way in understanding the overall meaning of the categories. It is the main goal of this paper.

Sources of Annotations: As suggested in (Paşca, 2017), Wikipedia itself can serve as the source for annotations of modifier constituents within Wikipedia categories. If Wikipedia connects a child category *"ctg:20th-century English male actors"* to a parent category *"ctg:English male actors by century"*, such a connection can be taken as evidence that the modifier *"20th-century"* within the child category plays a certain role *"century"*. Relying on data within Wikipedia itself is elegant but has shortcomings. First, the extracted annotations are strings. They are ambiguous. Whether the annotation *"century"* refers to a unit of measuring time, a 1981 novel or a cruise ship launched in 1995 is not encoded or clarified. Second, generic or underspecified annotations, like the string *"type"* for *"Zoology"* in *"ctg:Zoology museums"*, do not add much towards understanding the meaning of categories. Third, the annotations often reveal only the type of the value of the property alluded to by the modifier constituent, which is insufficient for understanding the explicit property. To illustrate, the annotation *"century"* for the modifier *"20th-century"* is arguably insufficient; *lived during* or *born in* would be more desirable.

As an alternative to reliance of previous work on Wikipedia itself, a novel aspect of the method proposed here is taking advantage of data available within Wikidata. Like Wikipedia, Wikidata is an actively developed, growing resource that benefits from editing by human contributors. For millions of topics, many of which are explicitly mapped to a corresponding Wikipedia article, Wikidata asserts knowledge about the topics as property-value

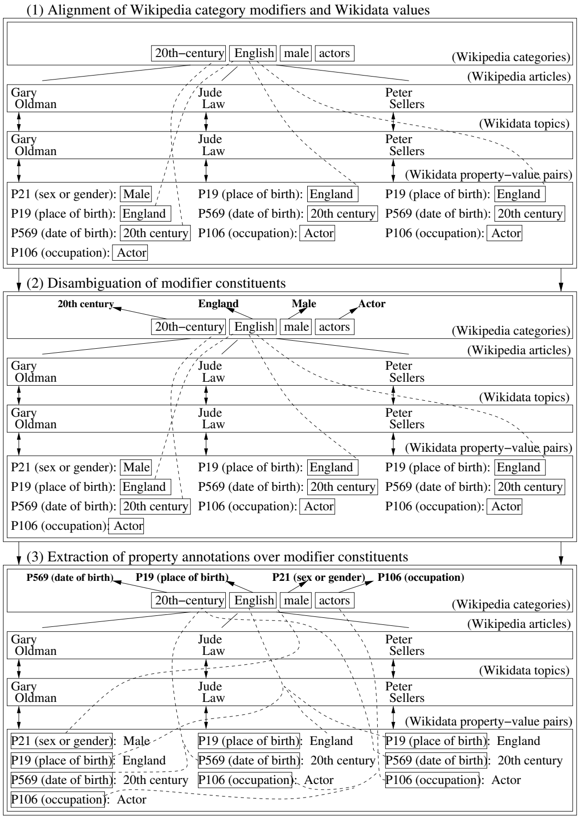

Figure 1: Overview of annotation of modifier constituents within Wikipedia categories based on Wikidata properties and values

pairs. Examples are the pairs *"prp:P19 (place of birth)"* and *"tpc:England"*; or *"prp:P21 (sex or gender)"* and *"tpc:Male"*, for the Wikidata topic *"tpc:Gary Oldman"* mapped to the Wikipedia article *"art:Gary Oldman"*. Values are usually other Wikidata topics. Properties (or predicates) are themselves special topics with explicit semantics in Wikidata. For example, *"prp:P19 (place of birth)"* is described in Wikidata as *"[..] birth location of a person, animal or fictional character"*. Unlike strings, Wikidata properties are semantically-anchored and therefore preferable as annotations over Wikipedia categories.

Acquisition from Wikidata: As illustrated in Figure 1, the proposed method annotates Wikipedia categories with Wikidata-based properties and values in three stages: (1) align arbitrary ngrams from Wikipedia categories, on one hand, to values of Wikidata properties of descendant Wikipedia articles, on the other hand; (2) as a side effect of the alignment, disambiguate the aligned ngram (string) to the aligned value (which, in most cases, is a Wikidata topic that also has an equivalent Wikipedia article); and (3) among Wikidata properties whose values were aligned to ngrams, extract one property per ngram, as a property annotation for the modifier constituent represented by the ngram.

(1) **Alignment of Modifiers and Values**: Rather than requiring modifier constituents of a Wikipedia category to be separately identified in advance, modifier constituents are identified and extracted simultaneously along with the annotations (first box from the top in Figure 1). The set of all contiguous spans (ngrams) within a Wikipedia category constitutes the initial, very noisy set of candidate modifier constituents of the category. Candidate alignments for each ngram come from the Wikidata property-value pairs of descendant Wikipedia articles of the category. The ngram is compared to the name of each value. In the first (top) box in Figure 1, one of the descendant Wikipedia articles of the category *"ctg:20th-century English male actors"* is *"art:Gary Oldman"*. It has the property *"prp:P21 (sex or gender)"* in Wikidata, whose value *"tpc:Male"* matches (after string normalization) the ngram *"male"* from the category.

In case of a match between a category ngram and a Wikidata value, the Wikidata property of the matched value becomes a candidate property annotation of the category ngram. Simultaneously, the category ngram becomes a candidate modifier constituent of the category. For the category *"ctg:20th-century English male actors"*, the property *"prp:P21 (sex or gender)"* becomes a candidate property annotation of the modifier constituent *"male"* from the category.

(2) **Disambiguation of Modifier Constituents**: The values of Wikidata properties are usually Wikidata topics which, in turn, have equivalent Wikipedia articles. A side effect of the alignment is the disambiguation of the category's modifier constituents (aligned ngrams) in terms of unambiguous Wikidata topics. For example, the ambiguous ngram *"English"* from the category *"ctg:20th-century English male actors"* is aligned to the value *"tpc:England"*, in the second box from the top in Figure 1. The value is a Wikidata topic. Therefore, the ambiguous modifier constituent *"English"* from the category is effectively disambiguated to the Wikidata topic *"tpc:England"* and its equivalent Wikipedia article *"art:England"*.

(3) **Extraction of Property Annotations**: The alignment may produce multiple candidate properties for the same modifier constituent of a category. For each modifier constituent, the candidate prop-

erty with the largest article support set is selected as the preferred property annotation (third box from the top in Figure 1). The article support set is the set of descendant Wikipedia articles of the category that, based on the alignment of their Wikidata values, contribute towards extracting a particular Wikidata property for a given modifier constituent. For example, the candidate properties for the modifier constituent *"Armin van Buuren"* of *"ctg:Armin van Buuren albums"* are *"prp:P676 (lyrics by)"*, *"prp:P162 (producer)"* and *"prp:P175 (performer)"*. The last is extracted via alignment to values of more descendant Wikipedia articles (e.g., *"art:Imagine (Armin van Buuren album)"*, *"art:10 Years (Armin van Buuren album)"*, *"art:Intense"*) than the other candidates. It is selected as the property annotation for *"Armin van Buuren"*.

Overall Annotations of Modifier Constituents: Given a category from Wikipedia, the method and its associated stages described above produce annotations for zero or more of its modifier constituents. If a modifier constituent is annotated, it is annotated with a topic that disambiguates it; and/or a property annotation. For the category *"ctg:20th-century English male actors"*, the modifier constituent *"20th-century"* is annotated with: the topic *"tpc:20th century"*, which disambiguates it; and the property *"prp:P569 (date of birth)"*. Note that the method is not limited to annotating modifier constituents. Depending on data available in Wikidata, the method might also annotate head constituents (without distinguishing them as such), although less frequently. For example, the method successfully annotates *"novels"* and *"women"* in *"ctg:Zombie novels*" and *"ctg:17th-century Norwegian women"* with *"prp:P136 (genre)"* and *"prp:P21 (sex or gender)"* respectively. But it fails to annotate *"games"* in *"ctg:Zombie Studios games"*.

3 Experimental Setting

Data Sources: The experiments operate over English snapshots of Wikipedia and Wikidata from June 2018. As in previous work (Ponzetto and Strube, 2007; Paşca, 2017), Wikipedia articles are automatically discarded if they are disambiguation or redirect pages. Similarly to (Ponzetto and Strube, 2007; Piccardi et al., 2018), Wikipedia categories are automatically discarded if they are meant for Wikipedia's internal bookkeeping, as approximated by the presence of the subphrases *article(s)*, *category(ies)*, *infobox(es)*, *pages*, *redirects*, *stubs*, *templates*, *wikiproject*, *use mdy dates*, *lists*, *stubs* or *wikidata* in their names. Finally, as in (Hoffart et al., 2013; Paşca, 2017; Gupta et al., 2018), categories are automatically discarded if they likely correspond not to classes but rather to individual topics. In this case, such categories are approximated by the absence of any plural-form tokens (based on lemmatization data in WordNet), thus discarding, e.g., *"ctg:Rose Bruford College"*. Alternatively, previous work on distinguishing Wikipedia articles that are classes (Paşca, 2018) could be extended to Wikipedia categories. The filtered Wikipedia snapshot connects 5,101,643 articles to 1,124,679 categories.

By traversing chains of Wikidata property-value pairs whose property is *"prp:P131 (located in the administrative territorial entity)"*, some of the existing location-based data in Wikidata is automatically expanded. For example, given the existing property-value pair *"prp:P19 (place of birth)"* and *"tpc:London"* for some Wikidata topic, additional property-value pairs like *"prp:P19 (place of birth)"* and *"tpc:Greater London"*, or *"prp:P19 (place of birth)"* and *"tpc:London"*, are added to the same Wikidata topic. Some of the temporal values in Wikidata are also automatically expanded. For any property-value pairs whose values are encoded as dates in Wikidata, additional property-value pairs are generated by a) selecting only the years; and also b) replacing the years with corresponding decades and centuries. For example, additional values generated starting from the value *"21 March 1958"* include *"tpc:1958"*, *"tpc:1950s"* and *"tpc:20th century"*.

Extraction Parameters: Property annotations extracted by the proposed method are discarded if they are one of the two properties used in Wikidata for organizing topics hierarchically, namely *"prp:P31 (instance of)"* or *"prp:P279 (subclass of)"*. During the alignment of modifier constituents from categories to values of properties from Wikidata, the two strings being compared are considered to match if, after conversion to lowercase, their lemmas (Fellbaum, 1998) or stems are either identical or one is an adjectival form and the other is the corresponding nominal form in WordNet, e.g., *"English"* vs. *"England"*.

Experimental Runs: The method from (Paşca, 2017) exploits the Wikipedia category network. It is a method available specifically for annotating modifier constituents within Wikipedia categories. Based on connections in Wikipedia from a child category of the form *"Z X"* to a parent category of the form *"X by Y"*, it extracts the annotation *"Y"* for the modifier constituent *"Z"* in the child category. It serves as a baseline run (denoted $\mathbf{B}_{wcn}$) in our experiments. For example, the modifier constituent *"20th-century"* in the child category *"ctg:20th-century actors"* is annotated as *"century"*, based on the presence of the parent category *"ctg:Actors by century"*. Besides the baseline run B_{wcn}, the method proposed here is evaluated through an experimental run denoted $\mathbf{R}_{prp}$. It extracts Wikidata properties such as *"prp:P569 (date of birth)"*, as property annotations.

Evaluation Set: The gold evaluation set for our experiments is a random sample of 700 target Wikipedia categories that are classes rather than individual topics. The set is created by inspecting random Wikipedia categories manually and either discarding them, if they correspond not to classes but instead to individual topics such as *"ctg:Association for Computing Machinery"* and *"ctg:Mille Lacs County, Minnesota"*; or retaining them, until the desired number of categories have been retained. Choosing the number of categories to retain is a balance between the desire to create a large evaluation set, on one hand; and the reality of the high cost (duration) of manual assignment of gold annotations, on the other hand. The retained target categories form the evaluation set for which modifier constituents and associated gold annotations must be compiled. The evaluation set covers a diverse range of domains of interest including art and entertainment for *"ctg:12 Stones albums"*, sports for *"ctg:Bulgarian arm wrestlers"*, religion for *"ctg:Buddhist temples in Southeast Asia"* or technology for *"ctg:3D platform games"*.

The manual assignment of annotations to Wikipedia categories from scratch would be a daunting task. It would require the analysis of hundreds of candidate Wikidata topics (properties), in order to select the correct or best annotation for each possible modifier constituent within each category. Even assuming unlimited human annotation resources of the highest quality, the task would be cumbersome and time-consuming, if not infeasible.

Label	Score	Ignored?		Description
		Ip?	Ir?	
c	1.0	No	No	Correct annotation
i	0.0	No	No	Incorrect annotation
s	0.0	No	Yes	Incorrectly identified modifier
d	0.0	Yes	No	Modifier with unspecified annotation

Table 1: Correctness labels assigned to triples of a target Wikipedia category, modifier constituent and annotation in the evaluation set (Label=correctness label; Score=score of correctness label; Ip?=ignored during computation of precision?; Ir?=ignored during computation of recall?)

Target Category: Modifier Constituent→Annotation	Label
19th-century French politicians: French→country	i
19th-century French politicians: French→P27 (country of citizenship)	c
19th-century French politicians: politicians→profession	c
Plautdietsch-language films: Plautdietsch-language→P364 (original language of work)	c
Artists from Liverpool: Liverpool→city	i
Artists from Liverpool: Liverpool→P19 (place of birth)	c
Courts in Sweden: Sweden→P27 (country of citizenship)	i
People from Yozgat Province: Yozgat→city	s
People from Yozgat Province: Yozgat Province→(unspecified annotation)	d

Table 2: Examples of entries from the evaluation set. An entry is tuple of a target category, a modifier constituent, an extracted (or unspecified) annotation and a correctness label (Label=correctness label)

In information retrieval, it is not uncommon to assess the relevance of documents selected not from the entire underlying document collection, but rather from documents automatically retrieved by any of the retrieval methods being evaluated. Similarly, the practical alternative pursued here is to manually label the correctness of automatically extracted annotations. For each of the target categories in the evaluation set, the annotations extracted for its modifier constituents by the experimental runs are manually labeled with one of a set of correctness labels, according to the perceived correctness of the annotations. Shown in Table 1, the correctness labels quantify the correctness of an annotation extracted for a modifier constituent within a category. They assess whether an annotation captures a property and, if so, whether it does so correctly. Table 2 illustrates correctness labels assigned to a sample of extracted annotations from the evaluation set. Each entry in the evaluation set is a tuple of a target category, a modifier constituent, an extracted (or unspecified) annotation and its correctness label. In the evaluation set, annotations that capture the desired property correctly are assigned the correctness label *c* (*Correct annotation*). Correct annotations by run B_{wcn} must capture the desired property lexically, such as the string *"profession"* for the modifier *"politicians"* within *"ctg:19th-century French politicians"*. Comparatively, correct annotation by run R_{prp} must capture the desired property semantically, such as the Wikidata property *"prp:P106 (occupation)"* for the same modifier. It is not sufficient that the string name *occupation* of the Wikidata property lexically capture the desired property. Thus, the assignment of correctness labels is relatively more lenient for run B_{wcn} and comparatively stricter for run R_{prp}. Annotations deemed incorrect are assigned the correctness label *i*. For example, the annotation *"country"* extracted for *"French"* in *"ctg:19th-century French politicians"* is incorrect because it does not reveal whether the underlying property might be *visited* or perhaps *born in* or possibly *made in*.

Target categories from the evaluation set may contain relevant modifier constituents for which none of the experimental runs extract any annotations. Such modifier constituents do not receive any manual correctness label and do not become part of the evaluation set so far. The resulting evaluation set would still be well suited for computing relative recall among the various experimental runs; but less suited for computing absolute recall. To alleviate the problem, modifier constituents that should have some (unspecified) annotation that has not yet been extracted by any of the experimental runs are annotated as such. For this purpose, a special "unspecified" annotation is added in the evaluation set for those modifier constituents. They are assigned the correctness label *d* from Table 1. An example is the modifier constituent *"Yozgat Province"* in *"ctg:People from Yozgat Province"* in Table 2. Consequently, the evaluation set can be used to compute not just the precision but also the recall of a given experimental run. Overall, the evaluation set contains one or more annotations for each of 1,316 unique pairs of a target category and a modifier constituent. Note that the count is larger than the number of entries in evaluation sets previously introduced for the evaluation of tasks related to compositionality analysis (Hendrickx et al., 2013; Paşca and Buisman, 2015; Paşca, 2017). The target categories in the evaluation set each consist of just above 4 tokens on average. Entries containing annotations extracted by different experimental runs are merged and sorted alphabetically, before being presented to two human annotators. The annotators manually assign correctness labels to the entries in the evaluation set. The agreement is 84%, when computed as a percentage of entries annotated by both annotators being assigned identical correctness labels; and 0.525, when computed as Cohen's Kappa coefficient.

Fraction of Categories with Extracted Annotations		
Reference Set	Run	
	B_{wcn}	R_{prp}
All Wiki	0.553	0.765
Gold Wiki	0.498	0.722

Table 3: Fraction of Wikipedia categories for which various runs extract some annotations for at least one modifier constituent. Computed as a fraction of the reference sets of all Wikipedia categories (All Wiki) and also of all Wikipedia categories from the gold evaluation set (Gold Wiki)

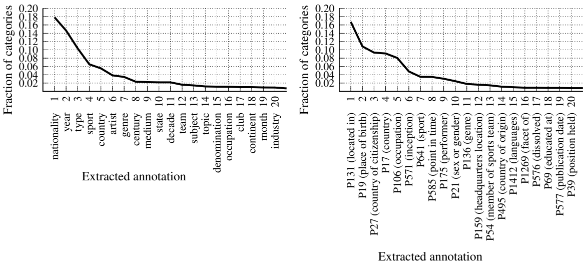

Figure 2: Most frequent annotations extracted over all categories from Wikipedia by run B_{wcn} (left graph) and by run R_{prp} (right graph). Computed as the fraction of Wikipedia categories for which a particular annotation is extracted for one of its modifier constituents

4 Evaluation Results

Coverage: When coverage is measured as the fraction of Wikipedia categories for which some annotations are extracted, the proposed method outperforms the baseline run B_{wcn} in Table 3. Figure 2 shows the annotations extracted most frequently by run B_{wcn} and by the proposed method. The horizontal axis represents the extracted annotations, sorted from most to least frequently extracted. There are 1,612 unique annotations extracted by B_{wcn} but virtually all of them are really type annotations rather than capturing any property annotations. In comparison, the proposed method extracts as many as 519 unique property annotations.

Evaluation Metrics: To automatically assess the annotations extracted by an experimental run, over the target categories in the evaluation set, their cor-

Run	Scores					
	Macro-Averaged			Micro-Averaged		
	P	R	F	P	R	F
B$_{wcn}$	0.526	0.007	0.013	0.526	0.008	0.015
R$_{prp}$	0.925	0.517	0.663	0.919	0.514	0.659

Table 4: Precision (P) and recall (R) (F=F$_1$-score)

rectness labels are retrieved from the evaluation set. The correctness labels are converted to individual correctness scores shown in the earlier Table 1. Micro- and macro-averaged precision and recall scores are computed out of individual correctness scores. Micro-averaged scores are computed as an average over all annotations extracted by an experimental run. Macro-averaged scores are first computed separately for each target category, then averaged over all target categories.

Precision and Recall: Table 4 compares the performance of the extraction methods. The baseline run B$_{wcn}$ has low macro-averaged recall and limited precision. In comparison, the properties extracted by the proposed method are more numerous and more accurate than the properties (really, types) extracted by the baseline. The proposed method gives uniformly higher F$_1$-scores than the baseline.

Table 5 gives examples of annotations extracted by the baseline run B$_{wcn}$ vs. the proposed method R$_{prp}$. Although not shown in the table, annotations are ambiguous strings for run B$_{wcn}$, vs. disambiguated properties or topics from Wikidata or Wikipedia for run R$_{prp}$. Annotations are extracted for modifier constituents that are ambiguous strings for run B$_{wcn}$, e.g., *"Indian"*, *"Jain"*; vs. disambiguated topics for run R$_{prp}$, e.g., the Wikipedia articles *"art:India"*, *"art:Jainism"*.

In Table 5, the baseline run B$_{wcn}$ can only annotate modifier constituents such as *"Indian"*, *"Jain"* in *"ctg:20th-century Indian Jain politicians"*. In contrast, the proposed method may also annotate head constituents, such as *"politicians"*. An additional experiment quantifies the role of annotations extracted for head constituents in increasing the recall of the proposed method. For each of a subset of 200 of the target categories from the evaluation set, the annotations extracted by R$_{prp}$ are manually inspected in order to identify and temporarily discard annotations of head (rather than of modifier) constituents. For example, annotations extracted by R$_{prp}$ for *"platform games"* in *"ctg:3D platform games"* or for *"Artists"* in *"ctg:Artists from Liverpool"* are temporarily discarded. Temporarily discarding the annotations extracted for head constituents causes recall scores of R$_{prp}$ over the subset of 200 target categories to decrease by 12.9%. Therefore, the ability of the proposed method to also annotate head constituents plays only a limited part in its superior recall relative to the baseline B$_{wcn}$ in Table 4.

Table 5: Examples of annotations extracted by runs B$_{wcn}$ vs. R$_{prp}$ for a sample of target categories (B=run B$_{wcn}$; R=run R$_{prp}$; prp=Property)

Classes of Errors: Among the errors affecting the quality of extracted properties, the most frequent is the non-optimal selection of a property, out of several available candidate properties. Since many of the descendant articles of the category *"ctg:1890s comics"* are topics introduced in that decade, the property *"prp:P571 (inception)"* is extracted, which is acceptable but may not be ideal. Similarly, the property *"prp:P20 (place of death)"* is extracted for *"Mongol"* in *"ctg:Mongol khans"*, because of evidence in Wikidata that individual khans not only led but also often died in that territory. For *"ctg:1990s Serbian television series endings"* and *"ctg:Thai historical films"*, most if not all individual descendant articles are about works (series or movies) in that language. Yet the two Wikipedia categories are primarily about works from that territory and not about works in that language, which means that the property extracted for *"Serbian"* and *"Thai"* should ideally be *"prp:P495 (country of origin)"* or similar; and not *"prp:P364 (original language of work)"*, which is actually extracted. This is also an infrequent case where annotating the same modifier constituent with more than one, instead of at most one, property might be useful. Among the small number of descendant articles available in Wikipedia for the category *"ctg:Carolina Panthers broadcasters"*, Wikidata properties and values do not mention *"Carolina Panthers"*, for some of them (*"art:Tim Brando"*, *"art:Roman Gabriel"*); and mention it occasionally (for *"art:Eugene Robinson"*) but with the property *"prp:P54 (member of sports team)"*. While it is not unusual for retired players to subsequently provide news coverage of their former teams, the property is strictly incorrect. A similar phenomenon causes the annotation *"prp:P19 (place of birth)"* to be extracted for *"Yozgat"* in *"ctg:People from Yozgat Province"*. Such errors are arguably more serious, since not only is the annotation incorrect but the modifier constituent (*"Yozgat"*) is also incorrectly selected. The occurrence of errors does not preclude correct annotations from being extracted for other modifier constituents: *"Yozgat Province"* is simultaneously and correctly annotated as *"prp:P19 (place of birth)"*.

Table 6 shows modifier constituents from the gold evaluation set annotated only by run B_{wcn}, in the upper portion; or only by R_{prp}, in the lower portion. More modifier constituents are annotated by run R_{prp} alone than by run B_{wcn} alone. The most common cause of R_{prp} failing to extract any annotations are missing properties and values in Wikidata, particularly when the categories have only a small number of descendant articles in Wikipedia. For the category *"ctg:Probinsya Muna Development Initiative politicians"*, none of the Wikidata properties of the few descendant articles in Wikipedia (e.g., *"art:Antonio Cuenco"*) refer to the relevant political party, namely to *"Probinsya Muna Development Initiative"*.

Run (Cnt): Examples of Modifier Constituents
B_{wcn} (175): 1672 treaties; 3 ft 6 in gauge railways in Sierra Leone; Agriculture companies of Spain; Charleston AlleyCats players; Earl Scruggs songs; Fossil fuel power stations in Pakistan; Hittite dictionaries; Probinsya Muna Development Initiative politicians; South Sudanese people in sports; Verve Records remix albums
R_{prp} (401): Oregon elections, 1882; Arab architects; People from Bangalore Urban district; Rivers of Cascade County, Montana; Crawley Down Gatwick F.C. players; Songs written by Irving Gordon; Later Yan people; Melodic death metal albums; Mercyhurst Lakers women's ice hockey; Philadelphia Police Department officers; Renaissance Revival architecture in Indiana

Table 6: Examples of modifier constituents (underlined) within categories from the gold evaluation set, for which some annotation(s) are extracted only by B_{wcn} vs. only by R_{prp} (Cnt=total count of unique such modifier constituents from the gold evaluation set, for the respective run)

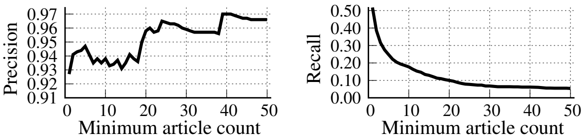

Figure 3: Macro-averaged precision (left graph) and recall (right graph) of run R_{prp}, as a function of the minimum count of supporting Wikipedia articles. An annotation is extracted for a Wikipedia category only when the number of supporting Wikipedia articles exceeds a given minimum on the horizontal axis.

Impact of More Supporting Articles: The article *"art:Gary Oldman"* is a descendant of the category *"20th-century English male actors"*. Since the article has the property-value pair *"prp:21 (sex or gender)"* and *"tpc:Male"* in Wikidata, it is in the article support set for assigning the property *"prp:21 (sex or gender)"* as an annotation of the modifier *"male"* within the category. When multiple candidate properties are available for a modifier constituent of a category, the candidate property with the largest article support set is selected as the property annotation. Intuitively, the selection of the property annotation is expected to be more vs. less reliable, depending on whether the counts of Wikipedia articles supporting the various candidate properties are larger or smaller.

Figure 3 investigates the phenomenon, by requiring the count of supporting Wikipedia articles of a candidate property to be larger than a minimum count, in order for the candidate property to be considered for extraction. In the figure, increasing the minimum count leads to more reliable candidate property annotations and higher precision in the left graph. As expected, increasing the minimum count also causes significant loss in recall in the right graph. As more data is gradually added to Wikidata over time, the proposed method is likely to select from among candidate properties with gradually more supporting Wikipedia articles, which could lead to gradually higher precision of extracted annotations, according to Figure 3.

Extraction in Other Languages: Extending the proposed method to languages other than English depends on the availability of resources in those languages. First, alternative names of Wikidata topics in other languages would be useful, to align ngrams of modifiers and values, as described in Section 2. Possible sources of such alternative names are titles of non-English Wikipedia articles equivalent to the Wikidata topics; and non-English topic names and aliases, if any, already available in Wikidata. Second, flexible ngram matching in other languages would be useful, similarly to how lemmas or stems are useful in English, as described in Section 3. Stemming and lemmatization may be available in some languages. In others, flexible ngram matching pairs could be collected from hyperlinks internal to Wikipedia. For example, "canadienne" and "canadien" are the anchor text of hyperlinks within the French articles titled *"Deborah Ellis"* and *"Yann Martel"* respectively. Both hyperlinks point to the French article titled *"Canada"*. Being able to flexibly match the resulting ngram pairs *"canadienne"* vs. *"canada"*, or *"canadien"* vs. *"canada"*, would be useful in the annotation of categories such as *"ctg:Écrivain canadien"*.

5 Related Work

As it extracts semantic annotations over open-domain concepts (namely, over categories from Wikipedia), the proposed method falls under the area of open-domain information extraction (Ernst et al., 2018; Qu et al., 2018; Sun et al., 2018; Zhu et al., 2019; Zhan and Zhao, 2020; Dash et al., 2020; Cao et al., 2020). Previous work in that area often uses Wikipedia data (Tsurel et al., 2017; Konovalov et al., 2017; Korn et al., 2019; Bornemann et al., 2020).

In previous work, annotations for modifier constituents within compositional noun phrases may be extracted out of an unbound set of ambiguous strings, with no explicit semantics and possibly redundant (*"from"*, *"born in"*, *"born at"*) (Hendrickx et al., 2013; Nakov and Hearst, 2013). Alternatively, when annotations are selected out of a small, manually-created set of candidate annotations (Tratz and Hovy, 2010; Shwartz and Waterson, 2018), they are too coarse-grained to be equivalent to *born in* or *headquartered in* etc. The method introduced in (Paşca and Buisman, 2015) decomposes compositional Wikipedia articles into constituent Wikipedia articles. For example, it decomposes *"art:Swiss passport"* into *"art:Switzerland"*, *"art:Passport"*. It does not attempt to otherwise understand or annotate the semantics of the constituents. It is applicable only to Wikipedia articles, although many more Wikipedia categories are compositional.

The method in (Paşca, 2017) extracts annotations over child categories based on their parent categories in Wikipedia. The method produces superior annotations to previous efforts (Nastase and Strube, 2013) to annotate categories based on data within Wikipedia itself. It extracts annotations that are strings without any associated descriptions or disambiguation. In contrast, the method proposed here extracts annotations as properties (*"prp:P569 (date of birth)"*) with defined descriptions and semantic meaning in Wikidata. It also disambiguates modifier constituents to the corresponding Wikidata topics or, if available, to corresponding Wikipedia articles. Such annotations and disambiguation add a layer of semantic understanding to hierarchies of articles and categories extracted from Wikipedia (Flati et al., 2014; Gupta et al., 2018), wherein categories are otherwise represented only as strings.

6 Conclusions

This paper takes advantage of data from Wikidata, to extract annotations for understanding the role played by various constituents in determining the meaning of Wikipedia categories. Unlike in previous work, the annotations are semantically-anchored properties and values, rather than ambiguous strings. They offer a better trade-off between precision vs. recall. Current work explores the utility of alternative sources besides Wikidata, in increasing the coverage of the annotations; and the role of the annotations in generating plausible categories for Wikipedia articles.

A Synset Relation-enhanced Framework with a Try-again Mechanism for Word Sense Disambiguation

Ming Wang[1] and **Yinglin Wang**[2, *]

Abstract

Contextual embeddings are proved to be overwhelmingly effective to the task of Word Sense Disambiguation (WSD) compared with other sense representation techniques. However, these embeddings fail to embed sense knowledge in semantic networks. In this paper, we propose a Synset Relation-Enhanced Framework (SREF) that leverages sense relations for both sense embedding enhancement and a try-again mechanism that implements WSD again, after obtaining basic sense embeddings from augmented WordNet glosses. Experiments on all-words and lexical sample datasets show that the proposed system achieves new state-of-the-art results, defeating previous knowledge-based systems by at least 5.5 F1 measure. When the system utilizes sense embeddings learned from SemCor, it outperforms all previous supervised systems with only 20% SemCor data.

1 Introduction

Word Sense Disambiguation (WSD) is an ongoing research area in Natural Language Processing community. It is aimed at determining the correct meaning (sense) of a word in its context given a list of potential or competing senses in a sense inventory. According to Navigli (2009), most of WSD solutions can be categorized into supervised and knowledge-based approaches. For supervised systems, they rely on sense-annotated data to train either word experts (Zhong and Ng, 2010) or a neural language model (Raganato et al., 2017a) for disambiguation and thus perform better than their knowledge-based counterparts (Banerjee and Pedersen, 2002; Basile et al., 2014; Agirre et al., 2014), which merely utilize sense knowledge in a sense inventory. However, knowledge-based approaches can better scale to a multilingual scenario or a specific domain where sense annotation is limited.

Contextual representations learned from neural language models (Peters et al., 2018) are proved to be beneficial to the task of WSD. Many recent systems (Loureiro and Jorge, 2019; Vial et al., 2019; Scarlini et al., 2020) utilize language models, especially BERT (Devlin et al., 2019), as a feature extraction tool to obtain contextual sense representations and outperform previous approaches by large margins. There are also systems (Luo et al., 2018; Kumar et al., 2019) that incorporate sense definitions into language models and achieve state-of-the-art performance. However, most of the systems are implemented in a supervised manner using a widely exploited sense-annotated corpus, SemCor (Miller et al., 1994), and merging knowledge from the sense inventory as a supplement. There is much space to explore regarding how to better exploit knowledge in a sense inventory such as different WordNet relations and super-sense that categorizes WordNet senses into 45 clusters.

In this paper, we present SREF, a knowledge-enhanced WSD approach that effectively exploits the sense definitions and relations in an inventory. First, we design a gloss augmentation for those synsets that have a short definition in WordNet so that each synset can learn a reliable sense embedding with features from BERT. Then, based on these embeddings, we explore the contribution of different synset relations in WordNet (Miller, 1995) to learn relation-enhanced sense embeddings. After the first WSD is conducted with a nearest neighbor approach against an

ambiguous word's context embedding and the relation-enhanced embeddings of the word's potential senses, we implement a try-again mechanism to the top 2 competing senses using synset relations and super-sense category. When applying the proposed strategy to tackle WSD, our system achieves state-of-the-art performance among knowledge-based systems. When we concatenate our sense embeddings with those learned from SemCor, new state-of-the-art performance in supervised category is achieved. We thus summarize our contributions as follows:

(1) We propose a fine-grained utilization of short WordNet sense glosses to retrieve web mentions to supplement sense embedding learning, and a method to create sense embeddings in a bag-of-sense manner by utilizing WordNet sense relations.

(2) We design a try-again mechanism that employs both synset relations and super-sense connections. To the best of our knowledge, this is the first attempt on employing WordNet relations to implement WSD again with sense relation knowledge.

(3) State-of-the-art performance is achieved in both all-words and lexical sample WSD datasets, surpassing previous systems by 5.5 F1 measure in knowledge-based all-words WSD. The supervised version of our system achieves state-of-the-art performance with only 20% SemCor data. The source code is available at: github.com/lwmlyy/SREF.

2 Related Work

In order to tackle WSD, approaches in two streams have been well developed over the last few decades, namely supervised and knowledge-based approaches. Their major difference is whether a sense-annotated corpus is employed.

2.1 Supervised Systems

Supervised systems originally regard WSD as a sense classification problem, building one classifier for each target word. IMS (Zhong and Ng, 2010), among others (Tsatsaronis et al., 2007, Iacobacci et al., 2016, Papandrea et al., 2017), is the most widespread system that leverages SVM to classify senses. In recent years, a more efficient supervised scheme has been proposed. Rather than training a few classifiers, it constructs a single neural architecture (Raganato et al., 2017a) with an annotated corpus and disambiguates words based on the output of the last layer. These methods have not outperformed traditional counterparts until sense definitions were incorporated (Luo et al., 2018). It has also become a trend that newly proposed systems (Kumar et al., 2019; Huang et al., 2019; Loureiro and Jorge, 2019; Vial et al., 2019; Scarlini et al., 2020) tend to exploit WordNet sense knowledge one way or another.

Despite the employment of sense knowledge, many systems still require a Most Frequent Sense (MFS) fallback since SemCor only covers a small proportion of WordNet lemmas. To address this issue, LMMS (Loureiro and Jorge, 2019) takes into account the synset and hypernymy relation in WordNet to extend sense embeddings to full coverage, utilizing BERT to contextualize the annotated senses in SemCor as a starting point. This approach achieves an unprecedented improvement in WSD tasks, although the synset relations are not adequately explored.

The recent development in contextual embeddings has injected much power into supervised WSD systems. Many of them rely on WordNet gloss to embed contextual information regarding a particular sense. However, a simple fact seems to be overlooked that many synset glosses are excessively short to deliver sufficient information. We thus propose a gloss augmentation method to relieve this issue. This is different from the previous gloss expanding methods (Ponzetto and Navigli, 2010; Miller et al., 2012), which expand glosses with either separate words or Wikipedia documents, rather than selected short sentences.

2.2 Knowledge-based Systems

Knowledge-based systems typically design some algorithms with which to operate on the semantic networks for disambiguation. One major branch is to consider the similarity between potential senses and the ambiguous word, including Lesk (Lesk, 1986) and other following researches (Banerjee and Pedersen, 2002; Basile et al., 2014). Another branch is to run graph algorithms (Agirre et al., 2014, Moro et al., 2014) on the semantic network and disambiguate based on sense connections in the network. There are also studies (McCarthy et al., 2007; Bhingardive et al., 2015) that focus on exploring how to learn or manipulate MFS given the fact that MFS is a highly competitive strategy.

Seeking language transferability, many knowledge-based methods (Basile et al., 2014; Camacho-Collados et al., 2016) rely on multilingual resources such as Wikipedia and BabelNet. A recent work (Scarlini, et al., 2020) follows the same idea by using BERT to learn contextual sense representations from retrieved mentions in both resources. Its supervised version is capable of beating many latest systems in noun disambiguation. However, both knowledge resources are constructed from a perspective of noun or entity relation, limiting the system's capability of disambiguating words in other part-of-speech (POS). In this paper, we augment the synset gloss (regardless of synset POS) of short length with retrieved mentions from the web so that the contextual representations can be more comprehensive for senses in all POS.

Although many previous similarity-based methods have explored the value of synset relations in WordNet, most of them utilize related synsets in a bag-of-word manner. For example, in enhanced Lesk (Basile et al., 2014), gloss words of related synsets are first merged into the gloss word set of a potential sense. Using the word set, a sense embedding is learned by summing all its word embeddings. This approach naturally neglects the word order in a sense gloss and weakens the difference between senses. In our approach, the sense embedding learning process is implemented in a bag-of-sense perspective so the weaknesses are relieved. Also, we propose a novel relation exploitation scheme to disambiguate again with not only the potential sense itself but also its related senses in WordNet. This is distinct from the methods in previous researches where relations are exploited to compress or cluster senses into coarse-grained senses (Miller and Iryna, 2015; Vial et al., 2019).

3 Preliminaries

In this section, we introduce WordNet and BERT, the contextual representation learning model.

3.1 WordNet

WordNet is a commonly used sense inventory for English WSD and it covers 117,659 synsets and 206,978 senses in its 3.0 version. A synset contains a set of senses that share the same meaning. For each synset, a definition (gloss) is provided to show what it means, or in some cases, to explain the synset less ambiguously. For example, *intend.v.01* (*intend* as its lemma), *mean.v.04* and *think.v.07* convey an identical meaning of *have in mind as a purpose* while *think.v.05* is defined as *imagine or visualize*. Also, many synsets are contextualized with one or more example sentences, e.g. *I mean no harm* for *mean.v.04*.

	N	**V**	**A**	**R**
gloss length	11.5	6.2	7.2	5.0
ambiguity	1.4	2.6	1.6	1.3

Table 1: Wordnet Synset Gloss Length (Number of Gloss Words per Synset) and Lemma Ambiguity (Number of Synsets per Lemma) in Different POS.

The synsets are organized into four groups according to their POS, namely noun (N), verb (V), adjective (A) and adverb (R). Synsets in each POS are connected by different relations separately in most cases. There are over 15 relations for synsets but many of them are defined for synsets in a particular POS. For instance, hypernymy and hyponymy relations are only available for nouns and verbs while entailment relation is valid for verbs alone. There is also a cross-POS relation in WordNet, defined as 'derivationally related form'. As an example, *intend.v.01* and *intention.n.03* are derivationally related.

WordNet defines a coarse-grained sense category named super-sense, which arranges senses into 45 clusters including *noun.person*, *noun.artifact* and others, 26 of which are for nouns, 15 for verbs, 3 for adjectives and 1 for adverbs. Senses in the same category have a weak connection to each other.

Despite the notable contribution of synset gloss to many WSD systems, synset relations are more valuable since they provide possibilities that machines could recognize synset connections. Here, we utilize WordNet relations for sense embedding enhancement (section 4.2) and a try-again mechanism (section 4.3).

3.2 BERT Utilization

BERT, a transformer-based language model, has attracted much attention from researchers of many NLP applications. In our research, we utilize BERT as a feature extraction model to learn a sense embedding for each WordNet sense using its gloss.

However, directly using synset gloss to learn a

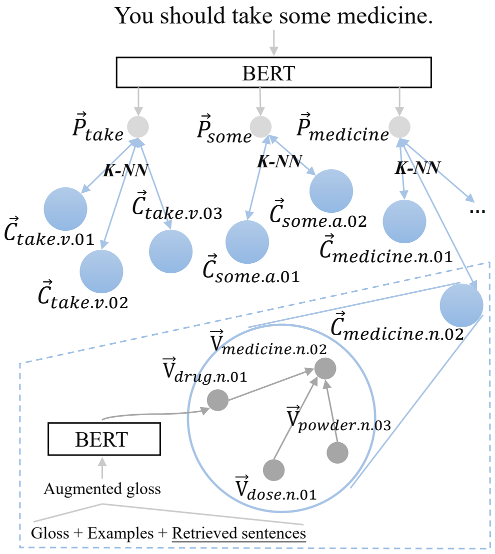

Figure 1: Knowledge-enhanced WSD Framework without the Try-again Mechanism

sense embedding is problematic since many synset glosses contain insufficient context for representation learning. Among others, the gloss for *think.v.05* is *imagine or visualize*, which is too short to carry adequate information. Table 1 presents the average synset gloss length and ambiguity of lemmas in four POS. It shows a relatively short gloss length for verb, adjective, and adverb synsets.

To address the above issue, we propose a gloss augmentation method (section 4.1) to bring in more context information regarding those poorly contextualized synsets.

In our final proposal, for each sense, we use BERT to learn its basic sense embedding from the concatenation of its gloss (and lemmas), example sentences and retrieved sentences from the web. In detail, we use $BERT_{LARGE\_CASED}$ as our feature extraction model and sum the output of the last 4 layers (a typical setting in previous researches such as LMMS, Loureiro and Jorge, 2019) at all output positions.

4 Method

Figure 1 demonstrates the overall concept of the framework without the try-again mechanism using an example. It relies on a K-NN algorithm to predict the correct sense of each word under disambiguation. The algorithm is implemented against a context representation ($\vec{P}$, lighter grey circle) directly from BERT at the position of the word under disambiguation and a knowledge-enhanced representation ($\vec{C}$, smaller blue circle) from BERT and WordNet knowledge. The big blue circle briefly illustrates how related senses are merged into one specific sense (section 4.2). In this big circle, the grey circles are basic sense embeddings ($\vec{V}$, grey circle) learned from the synset's augmented gloss (section 4.1) via BERT.

synset	gloss	queries
crash.v.05	break violently or noisily; smash	break violently, break noisily, smash
force.n.01	a powerful effect or influence	a powerful effect, a powerful influence

Table 2: Query Examples for Some Glosses.

4.1 WordNet Gloss Augmentation

In order to relieve the under-contextualization issue of many synsets, we propose a gloss augmentation approach to draw in more contextual information. Precisely, we simply use the short-length glosses as queries (words or phrases) to retrieve sequences from the web and combine the sequences with the original gloss and example sentences to learn a contextual representation from BERT. The whole process is built upon two hypotheses as follows.

(1) The words in the linguistic explanation of a synset tend to be less ambiguous and are often skewed to MFS/WordNet 1st sense. This is supported by the fact that more than 75% of the WordNet gloss words are labeled as MFS in the Princeton WordNet Gloss Corpus (Mihalcea and Moldovan, 2001).

(2) Word phrases in a synset gloss are even less ambiguous. Also, we calculate the proportion of polysemous phrase lemma in all phrase lemmas in WordNet. It shows a small proportion of those ambiguous phrase lemmas, 13.9% (4,922 out of 46,470).

Inspired by the above two hypotheses, we design a gloss augmentation method to retrieve sequences that contain gloss mentions. This is only operated on those synsets whose gloss has less than 6 words, which are easier to apply rules on. We detail the procedures as follows:

(1) For synsets whose gloss length is smaller than 6 words, cut each gloss or compose gloss words into one or more phrases under heuristic rules (split the gloss sentence with ';' into spans; segment each span based on the location of 'or'), see Table 2 for some

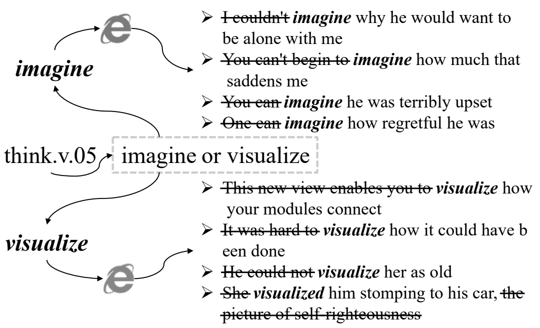

Figure 2: Gloss Augmentation for *think.v.05*

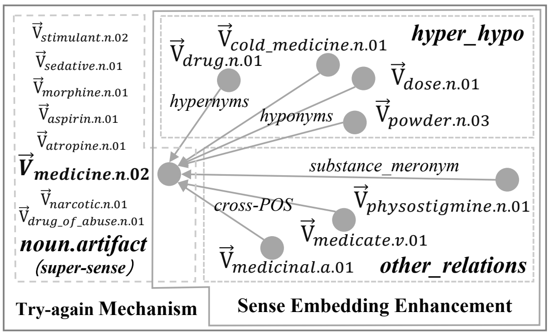

Figure 3: Synset Relation Exploitation for Sense Embedding Enhancement and Try-again Mechanism.

examples; For each query, retrieve sentences from *Baidu* translation website in its bilingual example section when each sentence contains the exact query;

(2) Filter out those sentences where query's POS is not the same as the synset's if the query is a word; extract the sub-sentence which includes the query but filters out the words before the query to reduce noise; Filter out those sentences that occur in more than one retrieved sentence sets of competing synsets (e.g. *think.v.01*, *think.v.02*) of a lemma to avoid overlap.

After the sequences (cf. Figure 2) are obtained, we combine them with each corresponding synset's gloss to learn a basic contextual representation.

4.2 Sense Embedding Enhancement

In this section, we introduce how to exploit WordNet relations for learning relation-enhanced sense embeddings. After each basic sense embedding is learned from its augmented gloss via BERT, it is further enhanced with a weighted sum of all its directly connected senses' basic sense embeddings. Here, we use all the relations except *verb_group* because this relation connects competing senses in many cases, weakening the difference between each other. The right proportion of Figure 3 reveals the process of sense embedding enhancement for *medicine.n.02*.

The relations are categorized into two classes named *hyper_hypo* (hypernymy and hyponymy) and *other_relations*. This is because the former class covers most of the connections in WordNet. We experiment on how the utilization of these two classes of relations benefit the task of WSD later.

Formula (1) details the sense embedding enhancement. Given all basic sense embeddings ($\vec{V}$), we enhance the embedding of sense s with the basic sense embedding ($\vec{V}_k$) of all its directly connected senses (R_s, including sense s) obtained with different WordNet relations. $d_{s,k}$ is the shortest path distance between sense s and sense k.

$$\vec{C}_s = \sum_k^{R_s} \frac{1}{1+d_{s,k}} * \vec{V}_k \qquad (1)$$

Given the above enhanced sense embeddings, we calculate the similarity (dot product) between an ambiguous word's context embedding $\vec{P}_w$ and the potential senses' enhanced embeddings $\vec{C}_s$ after normalization. The disambiguation at the first attempt (1st WSD) is completed by selecting the potential sense with the highest similarity. The lemma and POS are utilized when retrieving the potential senses from WordNet.

Algorithm 1: Try-again Mechanism

```
Input: context embedding $\vec{P}_w$ of an ambiguous word $w$
and enhanced sense embedding $\vec{C}_{s_{w,i}}$ of $w$'s ranked $i^{th}$
potential senses $s_{w,i}$ ($i = 1, 2$)
Output: $sim(w, s_{w,i})$ ($i = 1, 2$)
for $i = 1$ to 2 do
    $R_{s_{w,i}} = []$, $sim = []$;
    for relation in WordNet.all_relations do
        $R_{s_{w,i}}$.extend($s_{w,i}$.relation);
    if super-sense($s_{w,1}$) != super-sense($s_{w,2}$) then
        $R_{s_{w,i}}$.extend(super-sense($s_{w,i}$).synsets());
    for $s$ in $R_{s_{w,i}}$ do
        $sim$.append($\vec{C}_s \cdot \vec{P}_w$);
    $sim(w, s_{w,i}) = \vec{C}_{s_{w,i}} \cdot \vec{P}_w + \max(sim)$;
return $sim(w, s_{w,i})$ ($i = 1, 2$)
```

4.3 Try-again Mechanism

In this section, we introduce the try-again mechanism against the first and second most similar potential senses for every ambiguous word. This is based on the observation from the experimental result of the 1st WSD. It shows that after ranking potential senses according to the calculated similarity, 71.8% of the correct senses are ranked 1st, which represents the F1 score of the 1st WSD. Furthermore, 16% of the correct senses are ranked 2nd, which means our system's top 2 performance is 87.8%. This becomes a trigger to our experiment on whether synsets from different relations or the super-sense connection can benefit a 2nd WSD merely against the top 2 potential senses.

Algorithm 1 illustrates the detailed try-again mechanism, where both the 1st and 2nd WSD similarities are employed to select the final predicted sense. Precisely, for ambiguous word w ($\vec{P}_w$ as its contextual embedding), $\vec{C}_{s_{w,i}}$ is the enhanced sense embedding for one of its potential sense $s_{w,i}$. $R_{s_{w,i}}$ is all the directly connected senses from different WordNet relations except *verb_group*. In particular, if the top 2 potential senses belong to different super-sense categories, $R_{s_{w,i}}$ also contains all the senses that belong to the same super-sense as the potential sense. For instance, *medicine.n.01* belongs to *noun.cognition* while *medicine.n.02* is in *noun.artifact* category. In other words, the final WSD approach utilizes both the sense embedding of the potential sense itself and those of its related senses from WordNet relations and the super-sense category.

5 Experiment Setup

In this section, we evaluate our system using the evaluation framework provided by Raganato et al. (2017b). This framework includes five standard all-words WSD datasets: SensEval-2 (SE2, Palmer et al., 2001), SensEval-3 (SE3, Snyder and Palmer, 2004), SemEval-2007 (SE07, Pradhan et al., 2007), SemEval-2013 (SE13, Navigli et al., 2013) and SemEval-2015 (SE15, Moro and Navigli, 2015). We also show how our system performs on lexical sample datasets including SensEval-2 (SE2-LS, Kilgarriff, 2001) and SensEval-3 (SE3-LS, Mihalcea et al., 2004). We use the preprocessed datasets from UFSAC (Vial et al., 2018).

5.1 SREF

We have implemented both knowledge-based and supervised version of our system.

	ALL	N	V	A	R
SREF$_{kb}$	**73.5**	**78.5**	**56.6**	**79**	76.9
-w/o second_wsd	71.8 (-1.7)	77	54.4	77.2	76.3
-w/o gloss_augment	72.5 (-1.0)	77.7	55.4	76.8	77.7
-w/o other_relations	72.5 (-1.0)	77.5	**56.6**	75.2	**78.3**
-w/o hyper_hypo	70.7 (-2.8)	74.8	54.2	78.8	77.2

Table 3: Ablation Study on ALL (F1-%)

SREF$_{kb}$: the augmented gloss is utilized to learn a basic sense embedding from BERT by summing its last 4 layers at all output positions. Then synset relations are used to enhance each basic sense embedding. Finally, a nearest neighbor method is implemented against every ambiguous word's context embedding to its potential senses' enhanced embeddings before the try-again mechanism.

SREF$_{sup}$: Semcor is exploited to learn a supervised sense embedding for each labeled sense. The exact approach is proposed in LMMS (Loureiro and Jorge, 2019) but the learned sense embeddings are not extended with WordNet relations because we already have a knowledge-enhanced sense embedding learned from WordNet, detailed in section 4.2. Then we concatenate the **SREF**$_{kb}$ sense embedding with the corresponding one learned from SemCor if the sense is labeled in SemCor, otherwise itself. Each context embedding $\vec{P}_w$ is concatenated with itself for vector dimension matching because the vector dimension of each sense embedding has doubled.

5.2 Systems for Comparison

We compare our experimental results with the state-of-the-art in both knowledge-based and supervised categories.

Knowledge-based systems: Lesk$_{enhanced}$ (Basile et al., 2014), UKB (Agirre et al., 2018), Babelfy (Moro et al., 2014), WSD-TM (Chaplot and Sala-khutdinov, 2018) and KEF (Wang et al., 2020).

Supervised systems: EWISE (Kumar et al., 2019), GLU (Hadiwinoto et al., 2019), LMMS (Loureiro and Jorge, 2019), GlossBERT (Huang et al., 2019) and SENSEMBERT (Scarlini et al., 2020). We also include two systems that are available after the submission of this paper, namely BEM (Blevins and Zettlemoyer, 2020)

	Models	Test Datasets					Concatenation of all Test Datasets				
		SE2 (n=2282)	SE3 (1850)	SE07 (455)	SE13 (1644)	SE15 (1022)	ALL (7253)	N	V	A	R

Table 4: F1-% Performance on all-words WSD datasets, * represents those performance obtained (partially) as a development set. † denotes the systems that make use of the prior knowledge of MFS for unseen lemmas during testing. ‡ are systems proposed after this paper was submitted. **Bold** and underlined figures indicate the current (submission time) and previous state-of-the-art performance on the evaluation framework, respectively.

and EWISER (Bevilacqua and Navigli, 2020).

For lexical sample tasks, we compare our system with IMS+embeddings (Iacobacci et al., 2016), context2vec (Melamud et al., 2016), NN-CWEs (Wiedemann et al., 2019) and GLU (Hadiwinoto et al., 2019).

6 Results

In this section, an ablation study is first implemented to illustrate how the proposed factors contribute to the final WSD performance and a test set example is given regarding the try-again mechanism. Then, we compare our systems' performance on all-words and lexical sample datasets with state-of-the-art systems. Also, we demonstrate how the number of labeled sentences in SemCor affects the performance of SREF$_{sup}$ and LMMS. Finally, we experiment on how the knowledge-enhanced sense embeddings can benefit several similarity-calculating and ranking tasks with simple attempts.

6.1 Ablation Study

Table 3 shows the ablation analysis of SREF$_{kb}$ on the combined dataset and its POS portions, demonstrating the contribution of each proposed factor. In detail, gloss augmentation manages to boost the system's performance by 1 F1, equal to the contribution of *other_relations* which is manually defined in WordNet. This has revealed the potential of such a fine-grained WordNet gloss utilization, and the employment of more valuable resources such as Wikipedia rather than web mentions for further investigation. Another noteworthy observation is that the sense embedding enhancement damages adverb disambiguation performance.

Figure 4 provides an example about how the try-again mechanism in SREF$_{kb}$ selects the correct sense of *bell*. Here, the word is first falsely predicted to be *bell.n.03* which means *the sound of a bell* rather than *bell.n.01* that means *a hollow device made of metal*. The try-again mechanism manages to detect a more similar sense to the word's context, *fire_bell.n.01*, which is a hyponym of *bell.n.01*. In this case, the hyponymy relation helps the system to correctly disambiguate *bell*. There are also other cases where the super-sense relation contributes.

6.2 All-words WSD

Table 4 illustrates how different systems perform

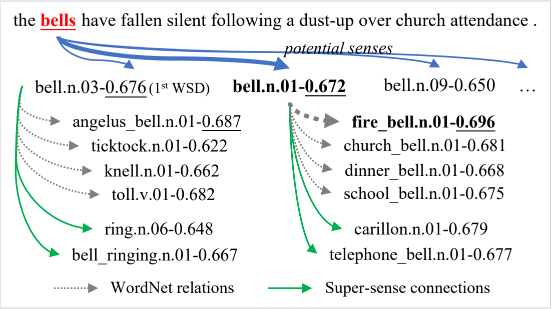

Figure 4: A Test Set Example of the Second WSD

Models	SE2-LS	SE3-LS	SE07
IMS+emb (2016)	69.9	75.2	62.6
context2vec (2016)	-	72.8	61.3
NN-CWEs (2019)	76.5	79.6	59.8
GLU (2019)	76.9	80.0	68.1
SREF$_{sup}$	**77.5**	**80.3**	**72.1**

Table 5: Performance on Lexical Sample Datasets

on standard WSD datasets separately (SE2, SE3, SE07, SE13, and SE15) and on their combined dataset (ALL). It has also shown those systems' performance on 'ALL' from POS perspectives.

For dataset-level performance, our relation-enhanced system, SREF$_{kb}$, achieves new state-of-the-art performance among the systems in the same category, surpassing the previous best system by 5.5 F1.

When our relation-enhanced sense embeddings are combined with the supervised sense embeddings learned from SemCor, our system (SREF$_{sup}$) also obtains new state-of-the-art performance among supervised systems, beating GlossBERT by 1 F1. GlossBERT utilizes SE07 as a developing set and tunes parameters on it. It is the first supervised system that performs over 70 F1 on SE07. SREF$_{sup}$, in contrast, requires no parameter tuning and reaches 72.1 F1 on SE07. It is also worth noting that SREF$_{sup}$ outperforms LMMS, a similar system, by almost 2.5 F1, revealing the tremendous benefits of explicit exploitation of WordNet sense relations.

Our systems also obtain state-of-the-art results in terms of POS disambiguation in both categories, achieving advantageous performance on more ambiguous word types (cf. Table 1) including verb, adjective and noun.

6.3 Lexical Sample WSD

We also conduct experiments on the English lexical sample tasks. For a fair comparison, we use the associated training dataset instead of SemCor to learn the supervised sense embeddings.

As is shown in Table 5, SREF$_{sup}$ obtains new state-of-the-art performance on lexical sample tasks, although the margin between previous best performance is relatively small. NN-CWEs and GLU are systems that employ BERT as a feature-extraction tool for their supervised learning framework but neglect WordNet sense knowledge. Therefore, although the systems can perform well on senses that are given sufficient labeled data for training, they do not have a good generalization ability to disambiguate rare or unseen senses. This is typically illustrated in their SE07 performance.

Models	MFS	LFS
WordNet S1	100	0
Lesk$_{enhanced}$	92.7	9.4
Babelfy	**93.9**	12.2
BiLSTM	93.4	22.9
EWISE	93.5	31.2
LMMS	87.6	52.6
SREF$_{kb}$	83.2	**55.2**
SREF$_{sup}$	91	53.2

Table 6: Performance on MFS and LFS against the 'ALL' dataset, where senses are partitioned into MFS and LFS according to their rank in WordNet.

6.4 Performance on Rare Senses

Except for the above regular experiments, we also set up an experiment regarding how our system performs on those synsets that are ranked first (MFS) in WordNet and the others (LFS, least frequent sense) in the 'ALL' dataset. We compare our results with those provided by EWISE, which is a zero-shot WSD system that makes use of sense gloss and relations in WordNet. EWISE has an overwhelming advantage of disambiguating unseen or rare senses and thus achieve much better results on LFS disambiguation. However, our systems (SREF$_{kb}$, SREF$_{sup}$) have better performance on LFS, although the margin between LMMS is not significant.

Table 6 demonstrates the performance on MFS and LFS for different systems. Although EWISE surpasses BiLSTM (Raganato et al., 2017a) on LFS disambiguation by a large margin, our supervised system still beats EWISE's performance by over 20 F1 while maintains a competitive performance on MFS disambiguation. This has shown our system's generalization ability of disambiguating rare sense.

6.5 Semcor Instance Utilization

Figure 5 demonstrates how the number of utilized Semcor sentences influences the performance of SREF$_{sup}$, LMMS and the sense embeddings learned from BERT and SemCor. For stable performance, we fix the sentence order in SemCor and incrementally extract a proportion of sentences to perform the experiments with a 10% step size. It is shown that even with 10% labeled data, SREF$_{sup}$ can outperform LMMS with full labeled data by 0.5 F1. Furthermore, SREF$_{sup}$

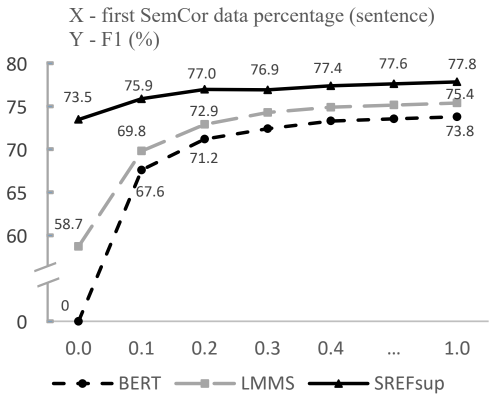

Figure 5: System Performance with Different Proportion of Semcor Sentences

obtains a new state-of-the-art result with only 20% labeled data.

6.6 Sense Embedding Application

In order to reveal the potential of SREF$_{sup}$ sense embeddings to other tasks, we experiment with three similarity-based tasks including SemEval-2017-Semantic Textual Similarity (Cer et al., 2017, SE17-STS-en-en), SemEval-2017 Task 3-SubtaskA and SubtaskB (Nakovet al., 2017, SE17-Task3-SubtaskA and SubtaskB). The similarity calculation is achieved by using merely BERT embeddings or concatenating them with the sum of SREF$_{sup}$ sense embeddings after disambiguating the text. The whole process is conducted in an unsupervised approach.

Table 7 shows that the utilization of sense embeddings is beneficial to these tasks. Nonetheless, a more plausible approach might be to utilize sense embeddings in a supervised framework, requiring further explorations.

6.7 Error Analysis

To implement the error analysis from a general perspective, we calculate the average ambiguity level (total number of potential senses divided by total number of ambiguous words) of those correctly and falsely disambiguated words by our system, 5.1 and 8.4 respectively. In a detail perspective, among the falsely disambiguated words, many competing senses are highly ambiguous and similar, and even their super-senses are hard to distinguish. For example, in '*The medicine can only be obtained with a prescription*' from SE15, the correct and predicted sense for *prescription* are so similar that algorithms that cannot spot the gloss focus (*instruction* or *drug*) would fail, requiring the sense embedding to carry separate information regarding what the object is and what features it has.

Tasks	BERT	SREF$_{sup}$
SE17-STS (Pearson correlation)	0.66	0.69
SE17-Task3-SubtaskA (MAP-%)	68.0	69.0
SE17-Task3-SubtaskB (MAP-%)	40.2	41.1

Table 7: Performance on Similarity-based Tasks

Correct - *written instructions from a physician or dentist to a druggist concerning the form and dosage of a drug to be issued to a given patient.*

Predicted - *a drug that is available only with written instructions from a dentist to a pharmacist.*

7 Conclusion

We have introduced SREF, a synset relation-enhanced framework with a try-again mechanism that takes into account WordNet relations and augments WordNet glosses with mentions from the web under simple hypotheses and rules. Empirical experiments have proved the effectiveness of SREF from both knowledge-based and supervised perspectives, obtaining major and minor improvements over previous state-of-the-art performance, respectively.

For future work, we intend to scale SREF$_{kb}$ to a multilingual version and explore the possibilities of using the multilingual WordNet so that abundant knowledge regarding English can be transferred to other languages. It is also worth investigating regarding how to better incorporate sense embedding into other downstream tasks.

Abstract

News headline generation aims to produce a short sentence to attract readers to read the news. One news article often contains multiple keyphrases that are of interest to different users, which can naturally have multiple reasonable headlines. However, most existing methods focus on the single headline generation. In this paper, we propose generating multiple headlines with keyphrases of user interests, whose main idea is to generate multiple keyphrases of interest to users for the news first, and then generate multiple keyphrase-relevant headlines. We propose a multi-source Transformer decoder, which takes three sources as inputs: (a) keyphrase, (b) keyphrase-filtered article, and (c) original article to generate keyphrase-relevant, high-quality, and diverse headlines. Furthermore, we propose a simple and effective method to mine the keyphrases of interest in the news article and build a first large-scale keyphrase-aware news headline corpus, which contains over 180K aligned triples of ⟨news article, headline, keyphrase⟩. Extensive experimental comparisons on the real-world dataset show that the proposed method achieves state-of-the-art results in terms of quality and diversity[1].

1 Introduction

News Headline Generation is an under-explored subtask of text summarization (See et al., 2017; Gehrmann et al., 2018; Zhong et al., 2019). Unlike text summaries that contain multiple context-related sentences to cover the main ideas of a document, news headlines often contain a single short sentence to encourage users to read the news. Since one news article typically contains multiple keyphrases or topics of interest to different users, it is useful to generate multiple headlines covering different keyphrases for the news article. Multi-headline generation aims to generate multiple independent headlines, which allows us to recommend news with different news headlines based on the interests of users. Besides, multi-headline generation can provide multiple hints for human news editors to assist them in writing news headlines.

However, most existing methods (Takase et al., 2016; Ayana et al., 2016; Murao et al., 2019; Colmenares et al., 2019; Zhang et al., 2018) focus on single-headline generation. The headline generation process is treated as an one-to-one mapping (the input is an article and the output is a headline), which trains and tests the models without any additional guiding information or constraints. We argue that this may lead to two problems. Firstly, since it is reasonable to generate multiple headlines for the news, training to generate the single ground-truth might result in a lack of more detailed guidance. Even worse, a single ground-truth without any constraint or guidance is often not enough to measure the quality of the generated headline for model testing. For example, even if a generated headline is considered reasonable by humans, it can get a low score in ROUGE (Lin, 2004), because it might focus on the keyphrases or aspects that are not consistent with the ground-truth.

In this paper, we incorporate the keyphrase information into the headline generation as additional guidance. Unlike one-to-one mapping employed in previous works, we treat the headline generation process as a two-to-one mapping, where the inputs are news articles and keyphrases, and the output is a headline. We propose a keyphrase-aware news multi-headline generation method, which contains two modules: (a) Keyphrase Generation Model, which aims to generate multiple keyphrases of interest to users for the news article. (b) Keyphrase-Aware Multi-Headline Generation Model, which

---

[1] The source code will be available at https://github.com/dayihengliu/KeyMultiHeadline.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6241–6250,
November 16–20, 2020.

takes the news article and a keyphrase as input and generates a keyphrase-relevant news headline. For training models, we build a first large-scale news keyphrase-aware headline corpus that contains 180K aligned triples of ⟨news article, headline, keyphrase⟩ .

As in years past, a lot of the food trends of the year were based on creating perfectly photogenic dishes. An aesthetically pleasing dish, however, doesn't mean it will stand the test of time. In fact, it's not uncommon for food trends to be all the hype one year and die out the next. From broccoli coffee to "bowl food," here are 10 food trends that you likely won't see in 2019.

...*[15 sentences with 307 words are abbreviated from here.]*

In 2018, restaurants all over the US decided it was a good idea to place gold foil on everything from ice cream to chicken wings to pizza resulting in an expensive food trend. For example, the Ainsworth in New York City sells $1,000 worth of gold covered chicken wings. It seems everyone can agree that this is a food trend that might soon disappear.

10 food trends that you likely won't see in 2019

place gold foil on foods resulting in an expensive food trend

"bowl food" became a trend this year

Is the glitter food the next trend?

Figure 1: Keyphrase-aware multi-headline generation

The proposed approach faces two major challenges. The first one is how to build the keyphrase-aware news headline corpus. To our best knowledge, no corpus contains the news article and headline pairs, which are aligned with a keyphrase of interest to users. The second is how to design the keyphrase-aware news headline generation model to ensure that the generated headlines are keyphrase-relevant, high-quality, and diverse. For the first challenge, we propose a simple but efficient method to mine the keyphrases of interest to users in news articles based on the user search queries and news click information that are collected from a real-world search engine. With this method, we build the keyphrase-aware news headline corpus.

For the second challenge, we design a multi-source Transformer (Vaswani et al., 2017) decoder to improve the generation quality and the keyphrase sensitivity of the model, which takes three source information as inputs: (a) keyphrase, (b) keyphrase-filtered article, and (c) original article. For the proposed multi-source Transformer decoder, we further design and compare several variants of attention-based fusing mechanism. Extensive experiments on real-world dataset have shown that the proposed method can generate high-quality, keyphrase-relevant, and diverse news headlines.

2 Keyphrase-Aware Headline Corpus

Our keyphrase-aware news headline corpus called **KeyAware News** is built by the following steps:

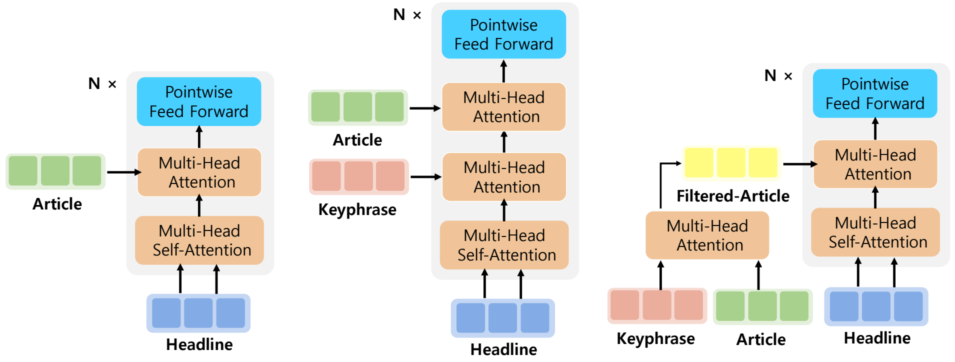
(1) **Data Collection**. We collect 16,000,000 raw samples which contain news articles with user search query information from Microsoft Bing News search engine[2]. Each sample can be presented as a tuple $\langle Q, X, Y, C\rangle$ where Q is a user search query, X is a news article that the search engine returns to the user based on the search query Q, Y is a human-written headline for X, and C represents the number of times the user clicks on the news under the search query Q. Each news article X has 10 different queries Q on average.

(2) **Keyphrase Mining**. We mine the keyphrase of interest to users with user search queries. We assume that if many users find and click on one news article through different queries containing the same phrase, such a phrase is the keyphrase for the article. For each article, we collect its corresponding user search queries and remove the stop words and special symbols from the queries. Then we find the common phrases (4-gram, 3-gram, or 2-gram) in these queries. These common phrases are scored based on how many times they appear in these queries and normalized by length. The score is also weighted by the user click number C, which means the phrases that appear in the queries have more users click on the article are more important. Finally, we use the n-gram with the highest score as the keyphrase Z of the article X.

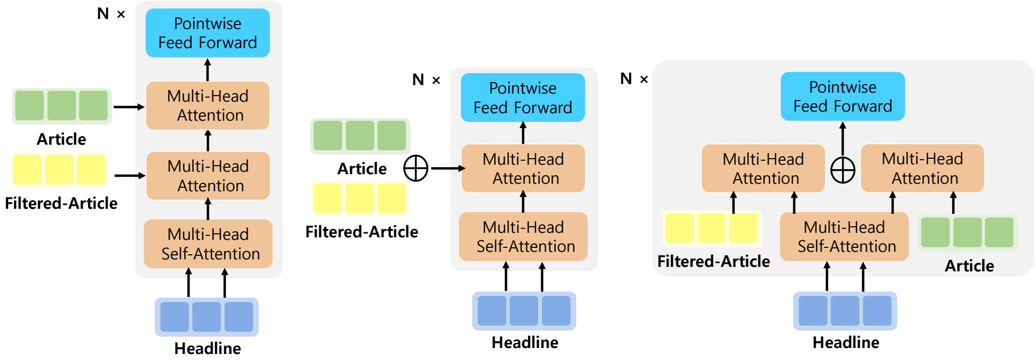
(3) **Article-Headline-Keyphrase Alignment**. In order to obtain the aligned article-headline-keyphrase tuple $\langle X, Y, Z\rangle$. We filter out the sample whose article or headline does not contain the Z. Moreover, we remove such pairs whose article length are greater than 600 or less than 100 tokens, or whose headline length are greater than 20 or less than 3 tokens. After the alignment and data cleaning, we obtain the **KeyAware News** which contains about 180K aligned article-headline-keyphrase triples. We split it into Train, Test, and Dev sets, each containing 165,913, 10,000, and 5,000 samples.

---

[2] All news articles are high-quality, real-world news and all the news headlines are written by humans.



(a) Article Only (b) Article + Keyphrase (c) Keyphrase-filtered Article



(d) Stack Fusing (e) Addition Fusing (f) Parallel Fusing

Figure 2: Visualization of the computational steps in each block of our multi-source Transformer decoders.

3 Methodology

3.1 Overview

The overall keyphrase-aware multi-headline generation procedure is shown in Figure 1, which involves two modules: (a) **keyphrase generation model** generates multiple keyphrases of interest to users for the news article. (b) **keyphrase-aware headline generation model** takes the news article and each generated keyphrase as input, and generates multiple keyphrase-relevant news headlines.

3.2 Headline Generation

The headline generation can be formalized as a sequence-to-sequence learning (Sutskever et al., 2014) task. Given an input news article X and a specific keyphrase Z, we aim to produce a keyphrase-relevant headline Y.

3.2.1 Headline Generation BASE Model

We first introduce the basic version of our headline generation model (we call BASE), which is keyphrase-agnostic. BASE is built upon the Transformer Seq2Seq model (Vaswani et al., 2017), which has made remarkable progress in sequence-to-sequence learning. Transformer contains a multi-head self-attention encoder and a multi-head self-attention decoder. As discussed in Vaswani et al. (2017), an attention function maps a query and a set of key-value pairs to an output as:

$$\textbf{Attention}(\bar{Q}, \bar{K}, \bar{V}) = \textbf{Softmax}(\frac{\bar{Q}\bar{K}^T}{\sqrt{d_k}})\bar{V},$$

where the queries $\bar{Q}$, keys $\bar{K}$, and values $\bar{V}$ are all vectors, and d_k is the dimension of the key vector. Multi-head attention mechanism projects queries, keys, and values to h different subspaces and calculates corresponding attention as:

$$\textbf{MultiHead}(\bar{Q}, \bar{K}, \bar{V}) = \textbf{Concat}(\mathrm{h_1}, ..., \mathrm{h_h})\mathrm{W^O},$$
$$\text{where } \mathrm{h_i} = \textbf{Attention}(\mathrm{\bar{Q}W_i^Q}, \mathrm{\bar{K}W_i^K}, \mathrm{\bar{V}W_i^V}).$$

The encoder is composed of a stack of N identical blocks. Each block has two sub-layers: multi-head self-attention mechanism and a position-wise fully connected feed-forward network. All sub-layers are interconnected with residual connections (He et al., 2016) and layer normalization (Ba et al., 2016).

Similarly, the decoder is also composed of a stack of N identical block. In addition to the two sub-layers in each encoder block, the decoder contains a third sub-layer which performs multi-head attention over the output of the encoder. Figure 2 (a) shows the architecture of the block in the decoder.

BASE uses the pre-trained BERT-base model (Devlin et al., 2018) to initialize the parameters of the encoder. Also, it uses the transformer decoder with a copy mechanism (Gu et al., 2016), whose hidden size, the number of multi-head h, and the number of blocks N are the same as its encoder.

3.2.2 Keyphrase-Aware Headline Generation Model

In order to explore more effective ways of incorporating keyphrase information into BASE, we design 5 variants of multi-source Transformer decoders.

Article + Keyphrase. The basic idea is to add the keyphrase into the decoder directly. The keyphrase X_{key} is represented as a sequence of word embeddings. As shown in Figure 2 (b), we add an extra sub-layer that performs multi-head attention over the X_{key} in each block of the decoder.

$$X_{dec}^{(n+1)} = \textbf{MultiHead}(X_{dec}^{(n)}, X_{key}, X_{key}), \quad (1)$$

where $X_{dec}^{(n)}$ is the output of the n-th block in the decoder. Since the original article has contained sufficient information for the model to learn to generate the headline, the model may tend to mainly use the article information and ignore the keyphrase and become less sensitive to keyphrases. As a byproduct, the generated headlines may lack diversity and keyphrase relevance.

Keyphrase-Filtered Article. Intuitively, when people read news articles, they tend to focus on the parts of the article that are matched to the keyphrases of their interests. Inspired by this, before inputting the original article representation into the decoder, we use the attention mechanism to filter the article with the keyphrase (see Figure 2 (c)).

$$\hat{X}_{enc} = \textbf{MultiHead}(X_{key}, X_{enc}, X_{enc}), \quad (2)$$

where X_{enc} is the output of the last block in the encoder. The resulting representation $\hat{X}_{enc}$ can be seen as the keyphrase-filtered article, which mainly keeps the article information that is related to the keyphrase. Since the decoder cannot directly access the representation of the original article, the model is forced to utilize the information of the keyphrase. Therefore, the sensitivity of the model to keyphrase is improved.

Fusing Keyphrase-Filtered Article and Original Article. Although feeding the keyphrase-filtered article representation $\hat{X}_{enc}$ instead of the original article representation X_{enc} to the decoder can improve the sensitivity of the model to keyphrase, some useful and global information in the original article may also be filtered out. It might reduce the quality of the generated headlines. To further balance the keyphrase sensitivity and headline quality of the model, we use X_{enc} and $\hat{X}_{enc}$ as two input sources for the decoder and fuse them. As shown in Figure 2 (d)-(f), we design three decoder variants based on different fusing mechanism to fuse the X_{enc} and the $\hat{X}_{enc}$.

(I) **Addition-Fusing Mechanism**. We directly perform a point-wise addition between the X_{enc} and the $\hat{X}_{enc}$. Then we feed it into the decoder.

(II) **Stack-Fusing Mechanism**. We perform a multi-head attention on $\hat{X}_{enc}$ and X_{enc} one by one in each block of the decoder. All of the sub-layers are interconnected with residual connections.

$$\hat{X}_{dec}^{(n)} = \textbf{MultiHead}(X_{dec}^{(n)}, \hat{X}_{enc}, \hat{X}_{enc}) \quad (3)$$
$$X_{dec}^{(n+1)} = \textbf{MultiHead}(\hat{X}_{dec}^{(n)}, X_{enc}, X_{enc}) \quad (4)$$

(III) **Parallel-Fusing Mechanism**. For each block of the decoder, we perform a multi-head attention in parallel on $\hat{X}_{enc}$ and X_{enc}. Then, we perform a point-wise addition between them. Similarly, all of the sub-layers are interconnected with residual connections.

$$\hat{X}_{dec}^{(n)} = \textbf{MultiHead}(X_{dec}^{(n)}, \hat{X}_{enc}, \hat{X}_{enc}) \quad (5)$$
$$\bar{X}_{dec}^{(n)} = \textbf{MultiHead}(X_{dec}^{(n)}, X_{enc}, X_{enc}) \quad (6)$$
$$X_{dec}^{(n+1)} = \bar{X}_{dec}^{(n)} + \hat{X}_{dec}^{(n)} \quad (7)$$

3.3 Keyphrase Generation

In this subsection, we show how to generate the keyphrases for a given news article X. Here we briefly describe three methods for keyphrase generation. It should be noted that in this paper, we mainly focus on news headline generation rather than keyphrase generation.

(1) **TF-IDF Ranking**. We use Term Frequency Inverse Document Frequency (TF-IDF) (Zhang et al., 2007) to weight all n-grams (n = 2, 3, and 4) in the news article X. Then we filter out n-grams with TF-IDF below the threshold or containing any punctuation or special character. For different n of the n-gram, we set different thresholds for filtering. We take this unsupervised method as a baseline.

Method	EM@1	EM@3	EM@5	R@1	R@3	R@5
TF-IDF	18.63	42.05	52.60	30.13	53.82	63.91
SEQ2SEQ	57.27	**78.45**	**84.26**	59.60	81.32	87.04
SLOT	**60.75**	76.94	83.18	**65.13**	**84.05**	**89.08**

Table 1: Keyphrase Generation Results

(2) **Seq2Seq**. Since our **KeyAware News** corpus contains the article-keyphrase pairs, we treat the keyphrase generation as a sequence-to-sequence learning task. We train the model BASE with article-keyphrase pairs. During inference, we use beam search with length penalty to generate n-grams ($n = 2$, 3, and 4) as the keyphrases.

(3) **Slot Tagging**. Because the keyphrases also appear in the news articles, we can formulate the keyphrase generation task as a slot tagging task (Zhang et al., 2016; Williams, 2019). We fine-tune the BERT-base model to achieve that. Concretely, we use the output sequence of the model to predict the beginning and end position of the keyphrase in the article. During inference, we follow the answer span prediction method used in Seo et al. (2017) to predict n-grams ($n = 2$, 3, and 4) with the highest probabilities as the keyphrases.

4 Experiments

4.1 Keyphrase Generation

In the first experiment, we evaluate the performance of three keyphrase generation methods: (a) unsupervised TF-IDF Ranking, (b) supervised sequence-to-sequence model (SEQ2SEQ), and (c) supervised slot tagging model (SLOT).

Implementation and Hyperparameters. The SEQ2SEQ has the same architecture hyperparameters as BASE model. And the architecture hyperparameters of SLOT are the same as those of the BERT-base[3]. We use article-keyphrase pairs in the train set of **KeyAware News** to train SEQ2SEQ and SLOT.

Metrics. For evaluation, each method generates top-K keyphrases for every news article in the test set. We use a top-K exact-match rate (EM@K) as an evaluation metric, which tests whether one of the K generated keyphrases matches the golden keyphrase exactly. Some of the generated key phrases may not exactly match the golden keyphrase but have overlapping tokens with it (it may be a sub-sequence of the golden keyphrase or vice versa). We thus report the Recall@K (R@K), which tests the percentage of the tokens in golden keyphrase covered by the K generated keyphrases.

Results. The results are shown in Table 1. We can see that the EM@1 of TF-IDF is only 18.63%, but SLOT achieves 60.75%. Both of SEQ2SEQ and SLOT significantly outperform the TF-IDF in all metrics. SEQ2SEQ achieves comparable performances in EM@K, but performs worse than SLOT in R@K. SLOT achieves 83.18% EM@5 and 89.08% R@5. In the following experiments, we use SLOT to generate keyphrases for our keyphrase-aware news headline generation models.

4.2 News Headline Generation

Baselines. In the following experiments, we compare various variants of the proposed keyphrase-aware models we introduced in Section 3.2.1 as follows: (1) **BASE**, as shown in Figure 2 (a), which is keyphrase-agnostic and only takes the news article as input. (2) **BASE + KEY**, as shown in Figure 2 (b), which takes keyphrase and article as input. (3) **BASE + Filter**, as shown in Figure 2 (c), which takes keyphrase-filtered article as input. (4) **BASE + StackFuse**, (5) **BASE + AddFuse**, and (6) **BASE + ParallelFuse** as shown in Figure 2 (d-f), which take the keyphrase-filtered article and the original article as inputs with stack-fusing, addition-fusing, and parallel-fusing mechanism, respectively. Based on **BASE + StackFuse**, **BASE + AddFuse**, and **BASE + ParallelFuse**, we further use the keyphrase as their additional inputs, like **BASE + KEY**. Then we obtain three additional variants (7) **BASE + StackFuse + KEY**, (8) **BASE + AddFuse + KEY**, and (9) **BASE + ParallelFuse + KEY**. In addition to **BASE**, We also compare four other keyphrase-agnostic baselines as follows. (10) **PT-NET**, the original pointer-generator network (See et al., 2017) , which are widely used in text summarization and headline generation tasks. (11) **SEASS** (Zhou et al., 2017b), the GRU-based (Cho et al., 2014) sequence-to-sequence model with selective encoding mechanism, which is widely used in text summarization. (12) **Transformer + Copy** (Vaswani et al., 2017; Gu et al., 2016), which has the same architecture hyperparameters as **BASE**, the only difference is that it does not use BERT to initialize the encoder. (13) **BASE + Diverse**, which applies diverse decoding (Li et al., 2016b) in beam search to **BASE** during inference to improve the generation diver-

Table 2: Multi-Headline Generation Results

sity for multiple headlines generation. To sum up, there are a total of 13 models to compare.

Implementation and Hyperparameters. The encoder and the decoder of BASE have the same architecture hyperparameters as BERT-base. All the variants of keyphrase-aware headline generation models also have the same architecture hyperparameters as BASE. The only difference among them is their computation steps of each block in the decoder, as shown in Figure 2. We follow the same training strategy in Vaswani et al. (2017) for training. And the implementation of them are based on Tensor2Tensor[4]. The implementations of PT-NET[5] and SEASS[6] are based on their open-source code.

4.2.1 Multi-Headline Generation

In this experiment, we only give models the news articles without the golden keyphrases. We use SLOT to generate top-K keyphrases for each article. Then each keyphrase-aware generation model using them to generates K different keyphrase-relevant headlines. For keyphrase-agnostic baselines, we apply the beam search to generate top k headlines for each article. We also apply the diverse decoding to BASE as a strong baseline (BASE + Diverse) for further comparison. The diversity penalty is set to be 1.0. It should be noted that we can also apply the diverse decoding to our keyphrase-aware models to further improve diversity.

Metrics. Following Li et al. (2016a), we use *Distinct-1* and *Distinct-2* (the higher the better) to evaluate diversity, which report the degree of the diversity by calculating the number of distinct unigrams and bigrams in generated headlines for each article. Since randomly generated headlines are also highly diverse, we measure the quality as well. As we discussed in Section 1, one news article can have multiple reasonable headlines. However, each article in our test set has only one human written headline, which may only focus on one keyphrase of the news article. We should emphasize that there may be only one generated headline that focuses on the same keyphrase of the human-written headline, while others focus on distinct keyphrases. It is thus not reasonable if we use the same human-written headline as the ground-truth to evaluate all generated headlines. We assume that if the headlines generated by the model are high-quality and diverse, there would be a higher probability that one of the headlines is closer to the single ground-truth. Therefore, we report the highest ROUGE score among the multiple generated headlines for each article. This criterion is similar to top-K errors (He et al., 2016) in image classification tasks. We report the results with K=1, 3, 5.

Results. Table 2 presents the results. For diversity, we can see that all of our keyphrase-aware generation models performs significantly better than other keyphrase-agnostic baselines in both *Distinct-1* and *Distinct-2* metrics for all K. After using the diverse decoding, BASE + Diverse achieves higher diversity. Nevertheless, the diversity is still lower than most keyphrase-aware generation models. As expected, BASE + Filter achieves the highest diversity, and BASE + KEY achieves the lowest diversity among the variants of our keyphrase-aware generation models. For quality, except BASE, there is still a big gap between other keyphrase-agnostic baselines and our keyphrase-aware generation models. Except for BASE + Filter, all of our keyphrase-aware generation models achieve higher ROUGE scores than BASE and BASE + Diverse (see the last 6 lines in Table 2). These results show that our keyphrase-aware generation models can effectively generate high-quality and diverse headlines.

Table 3: News Article Retrieval Results

4.2.2 News Article Retrieval

To further evaluate the quality and diversity of the generation, we design an experiment that uses a search engine to help us verify the diversity and quality of the generated headlines. It should be noted that the main purpose of this experiment is not to improve the performance of the search engine, but to measure the quality and diversity of the generated multiple headlines through a real-world search engine. We first collect the data pairs of the news article and its related user search query $\langle X, Q \rangle$ in the following way. If the article X is returned by the search engine based on a user query Q and the user clicks on the article X, then we take the query and the article as a data pair $\langle X, Q \rangle$. After collection, each article X in the test set has 10 different related user queries on average. The article X is used as the ground-truth for Q in the following evaluation. We replace the search key in the original search engine for each article with the K generated multi-headlines. Also, we re-build the indexes of the search engine that contains 10,000 news articles in the test set. Then we re-use the user search queries to retrieve the article. We believe that if the generated multi-headlines have high diversity and quality, then given different user queries, there should be a high probability that the golden article can be retrieved.

Metrics. We use the mean average precision (mAP), which is widely used for information retrieval as a metric. We report the results of mAP@N (N=1, 3, 5, and 10) which test the average probability that the golden article is ranked by the search engine to the top N. Using the human-written headline (HUMAN) as the search key is evaluated as a strong baseline. We also compare the performance of using a different number of headlines (K=1, 3, and 5). It should be noted that increasing the number of headlines as the search key does not ensure the improvement of the mAP, because the number of search keys of all other articles will also be increased. If the generated multi-headlines are not good enough, it will introduce noise and even cause mAP decreasing.

Results. Table 3 presents the results. Similarly, our models perform much better than other keyphrase-agnostic baselines. In most cases, BASE + Diverse outperforms BASE, but still performs worse than 7 keyphrase-aware generation models (see the last 7 lines in Table 3). Generally, with the number of headline K increases, we can see that the performance of our keyphrase-aware generation models improves much higher than other baselines. We find that the mAP@10 of BASE + ParallelFuse (K=5) achieves 76.08, which is even better than HUMAN. These results demonstrate that our keyphrase-aware generation models can generate high-quality and diversity headlines.

4.2.3 Human Evaluation

At a similar level of diversity, we want to investigate the quality of the headlines generated by our keyphrase-aware headline generation model compared to BASE + Diverse. Since the Distinct-1 and Distinct-2 of BASE + Diverse and BASE + StackFuse are close, we compare the quality of them through human evaluation. We randomly sample 100 articles from the test set, let each model generate 3 different headlines. We also mix a random headline and the golden headline for each article, and thus each article has 8 headlines. Three experts are asked to judge whether each headline could be used as the headline of the news. If more than two experts believe that it can be used as the headline of the news, then this headline is considered qualified. The results of the qualified rate of golden, BASE + Stack, BASE + Diverse, and random are 91.8%,

62.6%, 36.2%, and 0.0%, respectively. These results show that the quality of BASE + StackFuse is also higher than BASE + Diverse. We present some examples for comparison as shown in Figure 3.

5 Related Works

News headline generation is a subtask of summarization which has been extensively studied recently (Rush et al., 2015; Takase et al., 2016; Ayana et al., 2016; Tan et al., 2017; Zhou et al., 2017b; Higurashi et al., 2018; Zhang et al., 2018; Murao et al., 2019). With the rapid development of neural networks, various neural models have been successfully used in the headline generation task. Rush et al. (2015) propose an attention-based neural network for headline generation. Takase et al. (2016) propose a method based on encoder-decoder architecture and design an AMR encoder for headline generation. To take evaluation metrics into consideration, Ayana et al. (2016) apply minimum risk training method to the generation model. Tan et al. (2017) propose a coarse-to-fine method, which first extracts the salient sentences and then generates the headline based on these sentences. Zhou et al. (2017b) propose a method which divides the process of headline generation into three phases: a sentence encoder, a selective gate network for sentence selection, and a headline decoder. Higurashi et al. (2018) propose an extractive headline generation method, different from previous works that target the headline generation for the articles, this work focus on the task of headline generation for the community question answering forums. Due to lack of supervised training data, they propose a learning-to-rank based method to extract the essential substring from a question and use this substring as the headline of the forums. Zhang et al. (2018) propose a method for question headline generation, which designs a dual-attention seq2seq model.

However, most previous headline generation methods focus on one-to-one mapping, and the headline generation process is not controllable. In this work, we focus on the news multi-headline generation problem and design a keyphrase-aware headline generation method. Different information aware methods have been successfully used in natural language generation tasks (Zhou et al., 2017a, 2018; Wang et al., 2017), such as responses generation in the dialogue system. Similar to our task, responses generation in a dialogue system is also a one-to-many problem, Zhou et al. (2017a) propose a mechanism-aware seq2seq model for controllable response generation. They model different mechanisms as latent embeddings and learn the latent embeddings in their seq2seq model. Incorporating these mechanisms, their model can generate controllable responses. Zhou et al. (2018) propose a commonsense knowledge aware conversation generation method. More concretely, in the first stage, their model retrieves subgraphs from a knowledge base, and the model encodes the subgraphs using a dynamic graph neural network to facilitate better conversation generation in the second stage. Wang et al. (2017) propose an encoder-decoder based neural network for response generation. To our best knowledge, we are the first to consider keyphrase-aware mechanism on news headline generation and build the first keyphrase-aware news headline corpus.

6 Conclusion

In this paper, we demonstrate how to enable news headline generation systems to be aware of keyphrases such that the model can generate diverse news headlines in a controlled manner. We also build a first large-scale keyphrase-aware news headline corpus, which is based on mining the keyphrases of users' interests in news articles with user queries. Moreover, we propose a keyphrase-aware news multi-headline generation model that contains a multi-source Transformer decoder with three variants of attention-based fusing mechanisms. Extensive experiments on the real-world dataset show that our approach can generate high-quality, keyphrase-relevant, and diverse news headlines, which outperforms many strong baselines.

Abstract

Neural abstractive summarization systems have achieved promising progress, thanks to the availability of large-scale datasets and models pre-trained with self-supervised methods. However, ensuring the factual consistency of the generated summaries for abstractive summarization systems is a challenge. We propose a post-editing corrector module to address this issue by identifying and correcting factual errors in generated summaries. The neural corrector model is pre-trained on artificial examples that are created by applying a series of heuristic transformations on reference summaries. These transformations are inspired by an error analysis of state-of-the-art summarization model outputs. Experimental results show that our model is able to correct factual errors in summaries generated by other neural summarization models and outperforms previous models on factual consistency evaluation on the CNN/DailyMail dataset. We also find that transferring from artificial error correction to downstream settings is still very challenging[1].

1 Introduction

Self-supervised methods have achieved success in a wide range of NLP tasks, and automatic summarization is no exception (Liu and Lapata, 2019; Lewis et al., 2019; Zhang et al., 2019a; Shi et al., 2019; Fabbri et al., 2019). These state-of-the-art abstractive summarization models typically finetune pre-trained transformer-based models on a summarization dataset (Vaswani et al., 2017). Despite significant improvements over previous methods in terms of automatic evaluation scores such as ROUGE (Lin, 2004), ensuring factual consistency of the generated summary with respect to the source remains challenging. For example, Cao et al. (2018) claims that about 30% of summaries generated by abstractive models contain factual errors, which greatly limits their practicality.

Source:
Jerusalem (CNN)The flame of remembrance burns in Jerusalem, and a song of memory haunts Valerie Braham as it never has before. This year, Israel's Memorial Day commemoration is for bereaved family members such as Braham. "Now I truly understand everyone who has lost a loved one," Braham said. (...)
Original: **France's** memorial day commemoration is for bereaved family members as braham. *(inconsistent)* *After Correction*: **Israel's** memorial day commemoration is for bereaved family members as braham. *(consistent)*

Table 1: An example of an inconsistent system-generated summary and the output summary from our correction model. In this case, "France" is successfully corrected as "Israel".

Different approaches have been proposed to detect or ensure the factual consistency of generated summaries, including using fact extraction or applying attention on fact triples (Cao et al., 2018; Zhang et al., 2019b; Goodrich et al., 2019), applying natural language inference or question answering models for consistency checking (Falke et al., 2019; Li et al., 2018; Wang et al., 2020) and training the model on artificial datasets (Kryściński et al., 2019). Most of these approaches either require a high-quality fact extraction model or they only focus on factual consistency *evaluation*. Improving factuality *correction* by editing inconsistent parts in generated summaries is a direction that has not been explored much.

In this work, we propose a model to improve the factual consistency of system summaries with *post-editing correction* (Table 1). Our model takes a draft summary that is generated by an abstractive summarization model and produces a corrected final summary, conditioned on the source document. In addition, our trained corrector can be

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6251–6258,
November 16–20, 2020.

used as an evaluation model for factual consistency of abstractive summaries, with the assumption that a generated summary is inconsistent if our corrector decides to make edits. To teach the model to correct errors, we train it with artificial data that has factual errors introduced using heuristics proposed by Kryściński et al. (2019).

The empirical results based on automatic and human evaluations indicate that our model not only corrects factual errors in summaries, it is also a better and more reliable factuality evaluation model than FactCC (Kryściński et al., 2019), a recent proposed factuality evaluation method. In a downstream setting where we apply the corrector to the output of an abstractive summarizer, we find that our corrector is able to accurately correct errors in the generated summaries. However, the overall recall on correcting factual errors in real system summaries remains low, suggesting the errors introduced by heuristics have a different distribution than errors made by abstractive summarization systems.

2 Background and Related Work

Previous work on factual consistency in abstractive summarization can be divided into two categories: abstractive summarization models tailored towards factual consistency (Cao et al., 2018; Zhang et al., 2019b; Li et al., 2018), and evaluation models for factual consistency in abstractive summarization (Goodrich et al., 2019; Falke et al., 2019; Kryściński et al., 2019; Wang et al., 2020).

Cao et al. (2018) proposed a dual attention module in an abstractive summarizer that attends to both the source document and to relation triples extracted from the document. Zhang et al. (2019b) propose to improve their abstractive summarization model by optimizing fact scores defined in radiology reports with reinforcement learning methods. Li et al. (2018) jointly train their model's encoder on summarization and NLI tasks. Guo et al. (2018) train an abstractive summarization system with the auxiliary tasks of question and entailment generation and show that their generated summaries are less likely to produce extraneous facts. Kumar and Cheung (2019) show that neural abstractive summarizers often assign higher posterior likelihood to perturbed contrastive summaries that are inconsistent with the source text than to human-written gold-standard ones. Concurrently to our work, Zhu et al. (2020) recently proposed a fact-aware summarization model that uses a knowledge graph. They use a pre-trained corrector module to modify generated summaries. Concurrent to our work, Dong et al. (2020) proposes factual correction models that leverages knowledge learned from question answering models via span selection. Their models employ single or multi-masking strategies to either iteratively or auto-regressively replace entities.

In terms of evaluating abstractive summarization models for factual consistency, Goodrich et al. (2019) proposed a metric to check factual consistency by checking the overlapped fact triples between a source document and generated text on Wikidata. Falke et al. (2019) shows that factual error detection is a difficult task on its own and adapting entailment models for factual error detection do not offer the desired performance. Kryściński et al. (2019) finetune a BERT model on heuristically-created data with six types of rule-based text transformations for factual consistency checking. Wang et al. (2020) propose a framework for measuring inconsistencies in abstractive summarization by answering questions based on both generated summaries and documents.

3 Proposed Approach

In this section, we describe our procedure of introducing artificial errors in the datasets for training and propose our end-to-end error corrector model.

3.1 Dataset of Artificial Corruptions

Inspired by a recent study of error types made by state-of-the-art summarization system, we artificially created a weakly-supervised training dataset based on the text transformations proposed by Kryściński et al. (2019).

Given a source text d and the reference summary s, we corrupt the reference summary into an inconsistent summary s' with a randomly sampled corruption rule (described below) with probability α; otherwise, we keep $s' = s$ with probability $1-\alpha$. We set $\alpha = 0.3$ to match the factuality error rate in real abstract summaries based on a recent study (Cao et al., 2018). The training data consists of triplets (s', s, d).

Error Corruptions Four types of errors are used to create the inconsistent summaries: *Entity*, *Number*, *Date*, and *Pronoun* errors. They are the most common types of errors in abstractive summaries based on our manual inspection of

Source: (CNN) Gastrointestinal illness has gripped 100 people on the cruise ship Celebrity Infinity, according to a report from the Centers for Disease Control. Of the ship's 2,117 passengers, 95 have suffered from vomiting, diarrhea and other symptoms, the CDC said. (...)
Reference Summary: **100** passengers and crew members have been sickened on Celebrity Infinity. The ship, which is based on the West Coast, left San Diego in late March . **Corrupted Summary**: **95** passengers and crew members have been sickened on Celebrity Infinity. The ship, which is based on the West Coast, left San Diego in late March .

Table 2: An example of a *Number* corruption in the training set. The incorrect number "95" also appears in the source document.

	Overall Acc.	**Consistency checking**		
		Prec.	Recall	F1
Corrupted	84.38%	0.79	0.95	0.86
Clean		0.93	0.74	0.82

Table 3: Performance of our model on consistency checking on our test set of artificial corruptions. Corrupted and clean refer to the subsets of the test set that were artificially perturbed or not perturbed, respectively.

100 abstractive system-generated summaries that are sampled from the dataset of Kryściński et al. (2019) (henceforth, the K2019 dataset). Unlike Kryściński et al. (2019), we corrupt the reference summary rather than sentences sampled from the source document.

In the first four types of error constructions, we utilize a swapping strategy to introduce errors. For *Entity*, *Number*, and *Date* swapping, one entity in the reference summary is selected and swapped with another random entity of the same type[2] in the source document. For *Pronoun* swapping, one pronoun was extracted and swapped with another one of a matching syntactic case. Table 2 shows one example of a corruption.

3.2 Training Objective and Models

With the artificial training data consisting of triplets (s', s, d), the goal of the corrector is to generate the correct summary s based on the inconsistent summary s' and the source d. This can be expressed as a problem of maximizing the likelihood of $P(s|s', d)$ in an encoder-decoder model. We concatenate s' and d as input to the encoder (s' and d are separated by a separation token) and train the decoder to generate s.

We use BART (Lewis et al., 2019) as the basis of our summary corrector because of its demonstrated level of performance on conditional text generation tasks. BART is a sequence-to-sequence auto-regressive transformer model that is pre-trained as a denoising auto-encoder. One appealing aspect about BART is that it is pre-trained on a denoising task. Specifically, given an input sentence that is corrupted by text infilling, token deletion as well as other text transformations, BART is trained to output the original sentence. This pre-training task is similar to our summary correction task in which we can regard the corrupted or generated summary as the noisy input and in this case the noise is the inconsistent content in the summary.

4 Experiments

4.1 Evaluation Tasks and Measures

We evaluate our model on two tasks: factual consistency checking and error correction.

Factual consistency checking For this task, the model needs to classify each original input summary as *consistent* or *inconsistent* with respect to the source text. It is thus a binary classification task for which we report **accuracy**, as well as **precision**, **recall**, and **F1**.

We interpret the output of our corrector model as a classification decision as follows. If the corrector makes any change to the original input summary, we consider this to be a prediction of the *inconsistent* class. Otherwise, the corrector makes no change and we consider this a prediction of the *consistent* class.

Error correction For this task, the model must correct inconsistencies in the original summary (in any) with respect to the source text.

We define **correction accuracy** as the proportion of original summaries that are correctly changed by our corrector. On our artificial test set, an input summary is considered successfully corrected if the corrected summary matches the reference summary exactly. For the K2019 dataset, no reference corrections are available. We instead

---

[2] All the entities are extracted using a pre-trained NER model in spaCy `https://spacy.io/`.

conducted a human evaluation to check the consistency of the corrected output. We read the original and corrected summaries as well as the source document to determine whether a summary is successfully corrected by our model.

4.2 Datasets

We use two datasets for our experiments. The first is the dataset of artificial corruptions described in Section 3.1, which we create by taking samples from the CNN/DailyMail dataset. There are in total 287,227 samples in the training set, and we corrupted 30% of them (85,583). This results in 16,858/35,113/13,408/20,204 date/entity/number/pronoun corrupted samples respectively. We refer the other 201,644 training samples as clean samples. We also create artificial validation and test set for model selection and evaluation. In the test set, there are 5,780 corrupted samples and 5,710 clean samples.

The second dataset we use is the K2019 test set of Kryściński et al. (2019). This dataset contains 503 summaries generated by different recent neural abstractive summarizers, which have been manually labeled for whether they contain an inconsistency.

We evaluate our model on both datasets. We did not use baselines for the artificial test set since it is simply used as a check to demonstrate our model's performance in the artificial setting. The more meaningful evaluations are on K2019 consistency checking and error correction.

4.3 Corrector Training Details

We use the BART implementation from fairseq as the basis of our corrector.[3] The pre-trained BART model is fine-tuned on our training dataset for 10 epochs as described in Section 3.2. The learning rate is set to 3e-5. All our experiments is done on 4 NVIDIA Tesla V100 GPUs. The training process takes about 12 hours.

5 Results

Artificial corruptions Table 3 shows the consistency checking performance of our corrector model on our artificial test set. The high classification accuracy and F1 scores indicate that our model is able to identify these artificially injected errors.

Model	**Accuracy**	**Macro F1**
BERT+MNLI	51.51%	0.0882
BERT+FEVER	52.07%	0.0857
FactCC	74.15%	0.5106
FactCCX	72.88%	0.5005
Our model	**83.10%**	**0.6121**

Table 4: Factual consistency checking performance on the K2019 test set. Macro F1 is the macro-average of the F1 between the two classes.

For error correction, among the 5780 corrupted summaries in the test set, 62.13% are corrected by the model to exactly match the reference summary. For the 5710 clean summaries, the model made changes to 26.27% of them, which results in 73.73% correction accuracy on clean summaries. These results show that the model is able to correct majority of the test samples even under our strict evaluation measure.

K2019 Table 4 shows the consistency checking results on the K2019 test set. Compared with FactCC, our model improves performance by more than 10% higher in accuracy and 0.11 in macro F1-score. This result is interesting considering that the model is trained on a generation task rather than on classification.

As for correction performance, Table 6 shows the evaluation result of our human evaluation. Among 62 inconsistent summaries in the test set, the corrector model made changes to 19 summaries, of which 11 were successfully corrected and 7 remained inconsistent. For the remaining 441 consistent summaries in the test set, changes are made to 39 summaries and the model changed the meaning of 5 samples. In conclusion, with 17.74% probability that our model can successfully correct an inconsistent summary and 1.13% probability that it will corrupt a consistent one. Compared with the correction rate of 62.13% on the artificial test set, much lower correction rate on the real test set suggests that there is still a gap between the two settings. The error types in the training set are not able to represent the diverse errors made by summarization systems.

Output Analysis Table 5 shows several input and output summaries of our corrector model together with the source document fragments. In the

		cons.	*incons.*
consistent	441	436	5
inconsistent	62	11	51

Table 6: Human evaluation results on error correction on the K2019 dataset.

second example, the model correctly replaced 147 with 19, but was not able to correctly remove "including 142 students", which is a larger modification to the original summary. More examples can be found in the Appendix.

6 Conclusions

In this paper, we proposed a novel approach to correct inconsistent content in summaries generated by abstractive summarization models. We train an end-to-end correction model with artificial examples created by corrupting reference summaries. Our model achieved promising performance on our artificial test set and outperformed previous models on the manually annotated test set by wide margins. Our human evaluation indicates that our model is able to correct some factually inconsistent summaries generated by abstractive summarization model. However, low recall on the inconsistent summaries and false positive samples remain as challenges.

Abstract

Compressive summarization systems typically rely on a crafted set of syntactic rules to determine what spans of possible summary sentences can be deleted, then learn a model of what to actually delete by optimizing for content selection (ROUGE). In this work, we propose to relax the rigid syntactic constraints on candidate spans and instead leave compression decisions to two data-driven criteria: plausibility and salience. Deleting a span is *plausible* if removing it maintains the grammaticality and factuality of a sentence, and spans are *salient* if they contain important information from the summary. Each of these is judged by a pre-trained Transformer model, and only deletions that are both plausible and not salient can be applied. When integrated into a simple extraction-compression pipeline, our method achieves strong in-domain results on benchmark summarization datasets, and human evaluation shows that the plausibility model generally selects for grammatical and factual deletions. Furthermore, the flexibility of our approach allows it to generalize cross-domain: our system fine-tuned on only 500 samples from a new domain can match or exceed an in-domain extractive model trained on much more data.[1]

1 Introduction

Compressive summarization systems offer an appealing tradeoff between the robustness of extractive models and the flexibility of abstractive models. Compression has historically been useful in heuristic-driven systems (Knight and Marcu, 2000, 2002; Wang et al., 2013) or in systems with only certain components being learned (Martins and Smith, 2009; Woodsend and Lapata, 2012; Qian and Liu, 2013). End-to-end learning-based compressive methods are not straightforward to train: exact derivations of which compressions should be applied are not available, and deriving oracles based on ROUGE (Berg-Kirkpatrick et al., 2011; Durrett et al., 2016; Xu and Durrett, 2019; Mendes et al., 2019) optimizes only for content selection, not grammaticality or factuality of the summary. As a result, past approaches require significant engineering, such as creating a highly specific list of syntactic compression rules to identify permissible deletions (Berg-Kirkpatrick et al., 2011; Li et al., 2014; Wang et al., 2013; Xu and Durrett, 2019). Such manually specified, hand-curated rules are fundamentally inflexible and hard to generalize to new domains.

In this work, we build a summarization system that compresses text in a more data-driven way. First, we create a small set of high-recall constituency-based compression rules that cover the space of legal deletions. Critically, these rules are merely used to propose candidate spans, and the ultimate deletion decisions are controlled by two data-driven models capturing different facets of the compression process. Specifically, we model *plausibility* and *salience* of span deletions. Plausibility is a domain-independent requirement that deletions maintain grammaticality and factuality, and salience is a domain-dependent notion that deletions should maximize content selection (from the standpoint of ROUGE). In order to learn plausibility, we leverage a pre-existing sentence compression dataset (Filippova and Altun, 2013); our model learned from this data transfers well to the summarization settings we consider. Using these two models, we build a pipelined compressive system as follows: (1) an off-the-shelf extractive model highlights important sentences; (2) for each sentence, high-recall compression rules yield span candidates; (3) two pre-trained Transformer models (Clark et al., 2020) judge the plausibility and salience of spans, respectively, and only spans

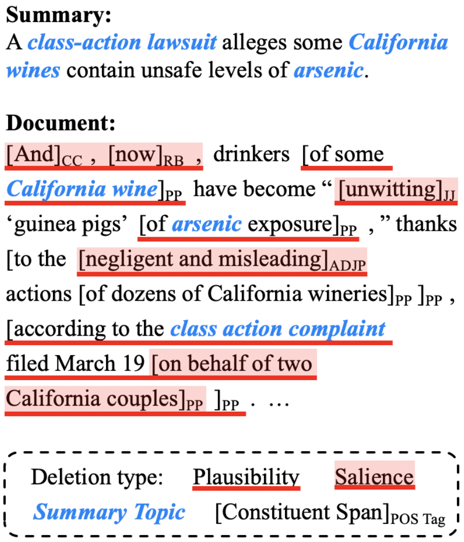
which are both plausible and not salient are deleted.

We evaluate our approach on several summarization benchmarks. On CNN (Hermann et al., 2015), WikiHow (Koupaee and Wang, 2018), XSum (Narayan et al., 2018), and Reddit (Kim et al., 2019), our compressive system consistently outperforms strong extractive methods by roughly 2 ROUGE-1, and on CNN/Daily Mail (Hermann et al., 2015), we achieve state-of-the-art ROUGE-1 by using our compression on top of MatchSum (Zhong et al., 2020) extraction. We also perform additional analysis of each compression component: human evaluation shows plausibility generally yields grammatical and factual deletions, while salience is required to weigh the content relevance of plausible spans according to patterns learned during training.

Furthermore, we conduct out-of-domain experiments to examine the cross-domain generalizability of our approach. Because plausibility is a more domain-independent notion, we can hold our plausibility model constant and adapt the extraction and salience models to a new setting with a small number of examples. Our experiments consist of three transfer tasks, which mimic real-world domain shifts (e.g., newswire → social media). By fine-tuning salience with only 500 in-domain samples, we demonstrate our compressive system can match or exceed the ROUGE of an in-domain extractive model trained on tens of thousands of document-summary pairs.



Summary:

Document:
[And]$_{CC}$, [now]$_{RB}$, drinkers [of some *California wine*]$_{PP}$ have become " [unwitting]$_{JJ}$ 'guinea pigs' [of *arsenic* exposure]$_{PP}$, " thanks [to the [negligent and misleading]$_{ADJP}$ actions [of dozens of California wineries]$_{PP}$]$_{PP}$, [according to the *class action complaint* filed March 19 [on behalf of two California couples]$_{PP}$]$_{PP}$ . ...

Deletion type: Plausibility Salience
Summary Topic [Constituent Span]$_{POS\ Tag}$

Figure 1: Decomposing span-based compression into plausibility and salience (§2). Plausible compressions (underlined) must maintain grammaticality, thus [to the ... wineries]$_{PP}$ is not a candidate. Salience identifies low-priority content from the perspective of this dataset (highlighted). Constituents both underlined *and* highlighted are deleted.

2 Plausible and Salient Compression

Our principal goal is to create a compressive summarization system that makes linguistically informed deletions in a way that generalizes cross-domain, without relying on heavily-engineered rules. In this section, we discuss our framework in detail and elaborate on the notions of plausibility and salience, two *learnable* objectives that underlie our span-based compression.

2.1 Plausibility

Plausible compressions are those that, when applied, result in grammatical and factual sentences; that is, sentences that are syntactically permissible, linguistically acceptable to native speakers (Chomsky, 1956; Schütze, 1996), and factually correct from the perspective of the original sentence. Satisfying these three criteria is challenging: acceptability is inherently subjective and measuring factuality in text generation is a major open problem (Kryściński et al., 2020; Wang et al., 2020; Durmus et al., 2020; Goyal and Durrett, 2020). Figure 1 gives examples of plausible deletions: note that *of dozens of California wineries* would be grammatical to delete but significantly impacts factuality.

We can learn this notion of plausibility in a data-driven way with appropriately labeled corpora. In particular, Filippova and Altun (2013) construct a corpus from news headlines which can suit our purposes: these headlines preserve the important facts of the corresponding article sentence while omitting minor details, and they are written in an acceptable way. We can therefore leverage this type of supervision to learn a model that specifically identifies plausible deletions.

2.2 Salience

As we have described it, plausibility is a domain-*independent* notion that asks if a compression maintains grammaticality and factuality. However, depending on the summarization task, a compressive system may not want to apply all plausible compressions. In Figure 1, for instance, deleting all plausible spans results in a loss of key information. In addition to plausibility, we use a domain-*dependent* notion of **salience**, or whether a span should be included in summaries of the form we want to produce.

Labeled oracles for this notion of content relevance (Gillick and Favre, 2009; Berg-Kirkpatrick et al., 2011, *inter alia*) can be derived from gold-standard summaries using ROUGE (Lin, 2004). We compare the ROUGE score of an extract with and without a particular span as a proxy for its importance, then learn a model to classify which spans improve ROUGE if deleted. By deleting spans which are both plausible and salient in Figure 1, we obtain a compressed sentence that captures core summary content with 28% fewer tokens, while still being fully grammatical and factual.

2.3 Syntactic Compression Rules

The base set of spans which we judge for plausibility and salience comes from a recall-oriented set of compression rules over a constituency grammar; that is, they largely cover the space of valid deletions, but include invalid ones as well.

Our rules allow for deletion of the following: (1) parentheticals (PRN) and fragments (FRAG); (2) adjectives (JJ) and adjectival phrases (ADJP); (3) adverbs (RB) and adverbial phrases (ADVP); (4) prepositional phrases (PP); (5) appositive noun phrases (NP_1–[,–NP_2–,]); (6) relative clauses (SBAR); and (7) conjoined noun phrases (e.g., NP_1–[CC–NP_2]), verb phrases (e.g., VP_1–[CC–VP_2]), and sentences (e.g., S_1–[CC–S_2]). Brackets specify the constituent span(s) to be deleted, e.g., CC–NP_2 in NP_1–[CC–NP_2].

Much more refined rules would be needed to ensure grammaticality: for example, in *She was [at the tennis courts]$_{PP}$*, deletion of the PP leads to an unacceptable sentence. However, this base set of spans is nevertheless a good set of building blocks, and reliance on syntax gives a useful inductive bias for generalization to other domains (Swayamdipta et al., 2018).

3 Summarization System

We now describe our compressive summarization system that leverages our notions of plausibility and salience. For an input document, an off-the-shelf extractive model first chooses relevant sentences, then for each extracted sentence, our two compression models decide which sub-sentential spans to delete. Although the plausibility and salience models have different objectives, they both output a posterior over constituent spans, and thus use the same base model architecture.

We structure our model's decisions in terms of separate sentence extraction and compression decisions. Let $S_1, \ldots, S_n$ denote random variables for sentence extraction where $S_i = 1$ indicates that the ith sentence is selected to appear in the summary. Let $C^{\mathrm{PL}}_{11}, \ldots, C^{\mathrm{PL}}_{nm}$, denote random variables for the plausibility model, where $C^{\mathrm{PL}}_{ij} = 1$ indicates that the jth span of the ith sentence is plausible. An analogous set of C^{SAL}_{ij} is included for the salience model. These variables are modeled independently and fully specify a compressive summary; we describe this process more explicitly in Section 4.4.

3.1 Preprocessing

Our system takes as input a document D with sentences $s_1, \cdots, s_n$, where each sentence s_i has words $w_{i1}, \cdots, w_{im}$. We constrain n to be the maximum number of sentences that collectively have less than 512 wordpieces when tokenized. Each sentence has an associated constituency parse T_i (Kitaev and Klein, 2018) comprised of constituents $c = (t, i', j')$ where t is the constituent's part-of-speech tag and (i', j') are the indices of the text span. Let $R(T_i)$ denote the set of spans proposed for deletion by our compression rules (see Section 2.3).

3.2 Extraction

Our extraction model is a re-implementation of the BERTSum model (Liu and Lapata, 2019), which predicts a set of sentences to select as an extractive summary. The model encodes the document sentences $s_1, \cdots, s_n$ using BERT (Devlin et al., 2019), also preprending `[CLS]` and adding `[SEP]` as a delimiter between sentences.[2] We denote the token-level representations thus obtained as: $[\mathbf{h}^{\mathrm{doc}}_{11}, \cdots, \mathbf{h}^{\mathrm{doc}}_{nm}] = \mathrm{Encoder}([s_1, \cdots, s_n])$

During fine-tuning, the `[CLS]` tokens are treated as sentence-level representations. We collect the `[CLS]` vectors over all sentences $\mathbf{h}^{\mathrm{doc}}_{i1}$, dot each with a weight vector $\mathbf{w} \in \mathbb{R}^d$, and use a sigmoid to obtain selection probabilities: $P(S_i = 1|D) = \sigma(\mathbf{h}^{\mathrm{doc}\top}_{i1}\mathbf{w})$

3.3 Compression

Depicted in Figure 2, the compression model (instantiated twice; once for plausibility and once for salience) is a sentence-level model

---

[2] BERT can be replaced with other pre-trained encoders, such as ELECTRA (Clark et al., 2020), which we use for most experiments.

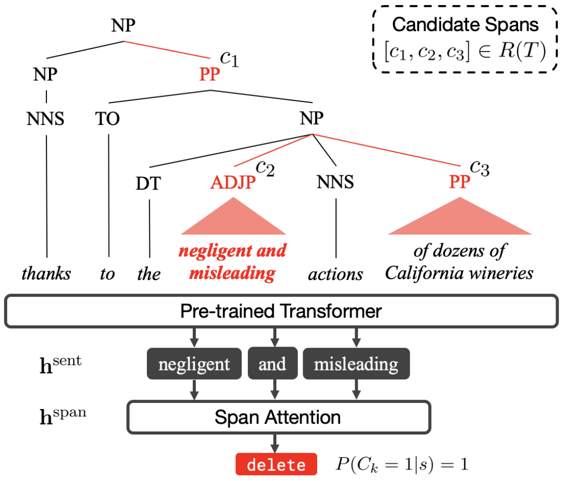

Figure 2: Compression model used for plausibility and salience modeling (§3.3). We extract candidate spans $c_i \in C(T)$ to delete, then compute span embeddings with pre-trained encoders (only one span embedding shown here). This embedding is then used to predict whether the span should be kept or deleted.

that judges which constituent spans should be deleted. We encode a single sentence s_i at a time, adding `[CLS]` and `[SEP]` as in the extraction model. We obtain token-level representations using a pre-trained Transformer encoder:[3]

$$[\mathbf{h}^{\text{sent}}_{i1}, \cdots, \mathbf{h}^{\text{sent}}_{im}] = \text{Encoder}([s_i])$$

We create a span representation for each constituent $c_k \in C(T_i)$. For the kth constituent, using its span indices (i', j'), we select its corresponding token representations $[\mathbf{h}^{\text{sent}}_{ii'}, \cdots, \mathbf{h}^{\text{sent}}_{ij'}]_k \in \mathbb{R}^{(j'-i') \times d}$. We then use span attention (Lee et al., 2017) to reduce this span to a fixed-length vector $\mathbf{h}^{\text{span}}_k$. Finally, we compute deletion probabilities using a weight vector $\mathbf{w} \in \mathbb{R}^d$ as follows: $P(C^X_k = 1|s_j) = \sigma(\mathbf{h}^{\text{span}\top}_k \mathbf{w})$, where C^X_k is either a plausibility or salience random variable.

3.4 Postprocessing

As alluded to in Section 2.3, there are certain cases where the syntactic compression rules license deleting a chain of constituents rather than individual ones. A common example of this is in conjoined noun phrases (NP_1–[CC–NP_2]) where if the second noun phrase NP_2 is deleted, its preceding coordinating conjunction CC can also be deleted without affecting the grammaticality of the sentence. To avoid changing the compression model substantially, we relegate secondary deletions to a post-processing step, where if a primary constituent like NP_2 is deleted at test-time, its secondary constituents are also automatically deleted.

4 Training and Inference

The extraction and compression models in our summarization system are trained separately, but both used in a pipeline during inference. Because the summarization datasets we use do not come with labels for extraction and compression, we chiefly rely on structured oracles that provide supervision for our models. In this section, we describe our oracle design decisions, learning objectives, and inference procedures.[4]

4.1 Extraction Supervision

Following Liu and Lapata (2019), we derive an oracle extractive summary using a greedy algorithm that selects up to k sentences in a document that maximize ROUGE (Lin, 2004) with respect to the reference summary.[5]

4.2 Compression Supervision

Because plausibility and salience are two different views of compression, as introduced in Section 2.3, we have different methods for deriving their supervision. However, their oracles share the same high-level structure, which procedurally operate as follows: an oracle takes in as input an uncompressed sentence x, compressed sentence or paragraph y, and a similarity function f. Using the list of available compression rules $R(T_x)$ for x, if x without a constituent $c_k \in R(T_x)$ results in $f(x \backslash c_k, y) > f(x, y)$, we assign c_k a positive "delete" label, otherwise we assign it a negative "keep" label. Intuitively, this oracle measures whether the deletion of a constituent causes x to become closer to y. We set f to ROUGE (Lin, 2004), primarily for computational efficiency, although more complex similarity functions such as BERTScore (Zhang et al., 2020b) could be used without modifying our core approach. Below, we elaborate on the nature of x and y for plausibility and salience, respectively.

Plausibility. We leverage labeled, parallel sentence compression data from news headlines to

---

[3] The encoders between the extraction and compression modules are fine-tuned separately; in other words, our modules do not share any parameters.

[4] See Appendices B and C for training and inference hyperparameters, respectively.

[5] We found that using beam search to derive the oracle yielded higher oracle ROUGE, but also a significantly harder learning problem, and the extractive model trained on this oracle actually performed worse at test time.

learn plausibility. Filippova and Altun (2013) create a dataset of 200,000 news headlines and the lead sentence of its corresponding article, where each headline x is a compressed extract of the lead sentence y. Critically, the headline is a subtree of the dependency relations induced by the lead sentence, ensuring that x and y will have very similar syntactic structure. Filippova and Altun (2013) further conduct a human evaluation of the headline and lead sentence pairs and conclude that, with 95% confidence, annotators find the pairs "indistinguishable" in terms of readability and informativeness. This dataset therefore suits our purposes for plausibility as we have defined it.

Salience. Though the sentence compression data described above offers a reasonable prior on span-level deletions, the salience of a particular deletion is a domain-dependent notion that should be learned from in-domain data. One way to approximate this is to consider whether the deletion of a span in a sentence x_i of an extractive summary increases ROUGE with the reference summary y (Xu and Durrett, 2019), allowing us to estimate what types of spans are *likely* or *unlikely* to appear in a summary. We can therefore derive salience labels directly from labeled summarization data.

4.3 Learning

In aggregate, our system requires training three models: an extraction model (θ_{E}), a plausibility model (θ_{P}), and a salience model (θ_{S}).

The extraction model optimizes log likelihood over each selection decision S_j in document D_i, defined as $\mathcal{L}_{\text{EXT}} = -\sum_{i=1}^{n}\sum_{j\in D_i}\log P(S_j^{(i)} = S_j^{(i)*}|D_i)$ where $S_j^{(i)*}$ is the gold label for selecting the jth sentence in the ith document.

The plausibility model optimizes log likelihood over the oracle decision $C_{jk}^{\text{PL}(i)*}$ for each constituent $c_k \in R(T_j)$ in sentence j, defined as $\mathcal{L}_{\text{CMP}} = -\sum_{j=1}^{m}\sum_{c_k\in R(T_j)}\log P(C_{jk}^{\text{PL}(i)} = C_{jk}^{\text{PL}(i)*}|s_j^{(i)})$. The salience model operates analogously over the C^{SAL} variables.

4.4 Inference

While our sentence selection and compression stages are modeled independently, structurally we need to combine these decisions to yield a coherent summary, recognizing that these models have not been optimized directly for ROUGE.

Our pipeline consists of three steps: (1) For an input document D, we select the top-k sentences with the highest posterior selection probabilities: $\text{argmax}_k P(S_i = 1|D;\theta_{\text{E}})$. (2) Next, for each selected sentence j, we obtain plausible compressions $Z_{\text{P}} = \{c_k|P(C_{jk}^{\text{PL}} = 1|s_j;\theta_{\text{P}}) > \lambda_{\text{P}}, \forall c_k \in R(T_j)\}$ and salient compressions $Z_{\text{S}} = \{c_k|P(C_{jk}^{\text{SAL}} = 1|s_j;\theta_{\text{S}}) > \lambda_{\text{S}}, \forall c_k \in R(T_j)\}$, where λ_{P} and λ_{S} are hyperparameters discovered with held-out samples. (3) Finally, we only delete constituent spans licensed by both the plausibility and salience models, denoted as $Z_{\text{P}} \cap Z_{\text{S}}$, for each sentence. The remaining tokens among all selected sentences form the compressive summary.[6]

We do not perform joint inference over the plausibility and salience models because plausibility is a necessary precondition in span-based deletion, as defined in Section 2.1. If, for example, a compression has a low plausibility score but high salience score, it will get deleted during joint inference, but this may negatively affect the well-formedness of the summary. As we demonstrate in Section 6.3, the plausibility model enforces strong guardrails that prevent the salience model from deleting arbitrary spans that result in higher ROUGE but at the expense of syntactic or semantic errors.

5 Experimental Setup

We benchmark our system first with an automatic evaluation based on ROUGE-1/2/L F_1 (Lin, 2004).[7] Our experiments use the following English datasets: CNN/DailyMail (Hermann et al., 2015), CNN (subset of CNN/DM), New York Times (Sandhaus, 2008), WikiHow (Koupaee and Wang, 2018), XSum (Narayan et al., 2018), and Reddit (Kim et al., 2019).[8]

We seek to answer three questions: (1) How does our compressive system stack up against our own extractive baseline and past extractive approaches? (2) Do our plausibility and salience modules successfully model their respective phenomena? (3) How can these pieces be used to improve cross-domain summarization?

---

[6] Our pipeline overall requires 3x more parameters than a standard Transformer-based extractive model (e.g., BERTSum). However, our compression module (which accounts for 2/3 of these parameters) can be applied on top of any off-the-shelf extractive model, so stronger extractive models with more parameters can be combined with our approach as well.

[7] Following previous work, we use `pyrouge` with the default command-line arguments: `-c 95 -m -n 2`

[8] See Appendix A for dataset splits.

Systems for Comparison. We refer to our full compressive system as **CUPS**[9], which includes CUPS$_{\text{EXT}}$ and CUPS$_{\text{CMP}}$, the extraction and compression components, respectively. CUPS$_{\text{EXT}}$ is a re-implementation of BERTSum (Liu et al., 2019) and CUPS$_{\text{CMP}}$ is a module consisting of both the plausibility and salience models. The pre-trained encoders in the extraction and compression modules are set to ELECTRA$_{\text{BASE}}$ (Clark et al., 2020), unless specified otherwise.

Because our approach is fundamentally extractive (albeit with compression), we chiefly compare against state-of-the-art extractive models: **BERTSum** (Liu et al., 2019), the canonical architecture for sentence-level extraction with pre-trained encoders, and **MatchSum** (Zhong et al., 2020), a summary-level semantic matching model that uses BERTSum to prune irrelevant sentences. These models outperform recent compressive systems (Xu and Durrett, 2019; Mendes et al., 2019); updating the architectures of these models and extending their oracle extraction procedures to the range of datasets we consider is not straightforward.

To contextualize our results, we also compare against a state-of-the-art abstractive model, **PEGASUS** (Zhang et al., 2020a), a seq2seq Transformer pre-trained with "gap-sentences." This comparison is not entirely apples-to-apples, as this pre-training objective uses very large text corpora (up to 3.8TB) in a summarization-specific fashion. We expect our approach to stack with further advances in pre-training.

Extractive, abstractive, and compressive approaches are typed as `ext`, `abs`, and `cmp`, respectively, throughout the experiments.

6 In-Domain Experiments

6.1 Benchmark Results

Table 1 (CNN, WikiHow, XSum, Reddit) and 2 (CNN/DM) show ROUGE results. From these tables, we make the following observations:

Compression consistently improves ROUGE, even when coupled with a strong extractive model. Across the board, we see improvements in ROUGE when using CUPS. Our results particularly contrast with recent trends in compressive summarization where span-based compression (in joint and pipelined forms) *decreases* ROUGE over sentence extractive baselines (Zhang et al., 2018; Mendes et al., 2019). Gains are especially pronounced on datasets with more abstractive summaries, where applying compression roughly adds +2 ROUGE-1; however, we note there is a large gap between extractive and abstractive approaches on tasks like XSum due to the amount of paraphrasing in reference summaries (Narayan et al., 2018). Nonetheless, our system outperforms strong extractive models on these datasets, and also yields

competitive results on CNN/DM. In addition, Table 3 includes representative summaries produced by our compressive system. The summaries are highly compressive: spans not contributing to the main event or story are deleted, while maintaining grammaticality and factuality.

Our compression module can also improve over other off-the-shelf extractive models. The pipelined nature of our approach allows us to replace the current BERTSum (Liu and Lapata, 2019) extractor with any arbitrary, black-box model that retrieves important sentences. We apply our compression module on system outputs from MatchSum (Zhong et al., 2020), the current state-of-the-art extractive model, and also see gains in this setting with no additional modification to the system.

6.2 Plausibility Study

Given that our system achieves high ROUGE, we now investigate whether its compressed sentences are grammatical and factual. The plausibility model is responsible for modeling these phenomena, as defined in Section 2.1, thus we analyze its compression decisions in detail. Specifically, we run the plausibility model on 50 summaries from each of CNN and Reddit, and have annotators judge whether the predicted plausible compressions are grammatical and factual with respect to the original sentence.[10] By nature, this evaluates the *precision* of span-based deletions.

Compression Rules	87.9	75.7	73.5	60.8
+ Plausibility Model	**96.0**	**89.7**	**93.1**	**66.7**

Table 4: Human evaluation of grammaticality (G) and factuality (F) of summaries, comparing the precision of span deletions from our compression rules (§2.3) before and after applying the plausibility model (§2.1).

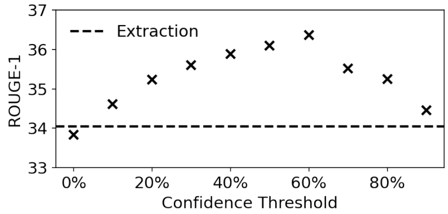

Figure 3: Varying the salience threshold $\lambda_{\text{S}} \in [0, 1)$ (depicted as % confidence) and its impact on ROUGE upon deleting spans $Z_{\text{P}} \cap Z_{\text{S}}$.

Because the plausibility model uses candidate spans from the high-recall compression rules (defined in Section 2.3), we compare our plausibility model against the baseline consisting of simply the spans identified by these rules. The results are shown in Table 4. On both CNN and Reddit, the plausibility model's deletions are highly grammatical, and we also see evidence that the plausibility model makes more semantically-informed deletions to maintain factuality, especially on CNN.

Factuality performance is lower on Reddit, but incorporating the plausibility model on top of the compression rules results in a 6% gain in precision. There is still, however, a large gap between factuality in this setting and factuality on CNN, which we suspect is because Reddit summaries are different in style and structure than CNN summaries: they largely consist of short event narratives (Kim et al., 2019), and so annotators may disagree on the degree to which deleting spans such as subordinate clauses impact the meaning of the events described.

---

[10] See Appendix D for further information on the annotation task and agreement scores.

6.3 Compression Analysis

The experiments above demonstrate the plausibility model generally selects spans that, if deleted, preserve grammaticality and factuality. In this section, we dive deeper into how the plausibility and salience models work together in the final trained summary model, presenting evidence of typical compression patterns. We analyze (1) our default system CUPS, which deletes spans $Z_{\text{P}} \cap Z_{\text{S}}$; and (2) a variant CUPS-NoPl (*without* plausibility but *with* salience), which only deletes spans Z_{S}, to specifically understand what compressions the salience model makes without the plausibility model's guardrails. Using 100 randomly sampled documents from CNN, we conduct a series of experiments detailed below.

On average, per sentence, 16% of candidate spans deleted by the salience model alone are not plausible. For each sentence, our system exposes a list of spans for deletion, denoted by $Z_{\text{P}} \cap Z_{\text{S}}$ and Z_{S} for CUPS and CUPS-NoPl, respectively. Because Z_{S} is identical across both variants, we can compute the plausibility model's *rejection rate* (16%), defined as $|Z_{\text{S}} \cap Z_{\text{P}}^{C}|/|Z_{\text{S}}|$. Put another way, how many compressions does the plausibility model *reject* if partnered with the salience model? On average, per sentence, the plausibility model rejects 16% of spans approved by the salience model alone, so it does non-trivial filtering of the compressions. We observe a drop in the token-level compression ratio, from 26% in CUPS to 24% in CUPS-NoPl, which is partially a result of this. From a ROUGE-1/2 standpoint, the slight reduction in compression yields a peculiar effect: on this subset of summaries, CUPS achieves 36.23/14.61 while CUPS-NoPl achieves 36.1/14.79, demonstrating the plausibility model trades off some salient deletions (-R1) for overall grammaticality (+R2) (Paulus et al., 2018).

Using salience to discriminate between plausible spans increases ROUGE. With CUPS, we perform a line search on $\lambda_{\text{S}} \in [0, 1)$, which controls the confidence threshold for deleting non-salient spans as described in Section 4.4.[11] Figure 3 shows ROUGE-1 across multiple salience cutoffs. When $\lambda_{\text{S}} = 0$, all plausible spans are deleted; in terms of ROUGE, this setting underperforms the extractive baseline, indicating we end up deleting spans that contain pertinent information. In contrast, at the peak when $\lambda_{\text{S}} = 0.6$, we delete non-salient spans with at least 60% confidence, and obtain considerably better ROUGE. These results indicate that the spans selected by the plausibility model are fundamentally good, but the ability to weigh the content relevance of these spans is critical to end-task performance.

7 Out-of-Domain Experiments

Additionally, we examine the cross-domain generalizability of our compressive summarization system. We set up three source → target transfer tasks guided by real-world settings: (1) NYT → CNN (one newswire outlet to another), (2) CNN → Reddit (newswire to social media, a low-resource domain), and (3) XSum → WikiHow (single to multiple sentence summaries with heavy paraphrasing).

For each transfer task, we experiment with two types of settings: (1) **zero-shot** transfer, where our system with parameters $[\theta_{\text{E}}; \theta_{\text{P}}; \theta_{\text{S}}]$ is directly evaluated on the target test set; and (2) **fine-tuned** transfer, where $[\theta_{\text{E}}; \theta_{\text{S}}]$ are fine-tuned with 500 target

---

[11] Our assumption is that posterior probabilities are calibrated, which holds true for various pre-trained Transformers across a range of tasks (Desai and Durrett, 2020).

samples, then the resulting system with parameters $[\theta'_{\mathrm{E}}; \theta_{\mathrm{P}}; \theta'_{\mathrm{S}}]$ is evaluated on the target test set. As defined in Section 2.1, plausibility is a domain-independent notion, thus we do not fine-tune θ_{P}.

Table 5 shows the results. Our system maintains strong zero-shot out-of-domain performance despite distribution shifts: extraction outperforms the lead-k baseline, and compression adds roughly +1 ROUGE-1. This increase is largely due to compression improving ROUGE precision: extraction is adept at retrieving content-heavy sentences with high recall, and compression helps focus on salient content within those sentences.

More importantly, we see that **performance via fine-tuning on 500 samples matches or exceeds in-domain extraction ROUGE.** On NYT → CNN and CNN → Reddit, our system outperforms in-domain extraction baselines (trained on tens of thousands of examples), and on XSum → WikiHow, it comes within 0.3 in-domain average ROUGE. These results suggest that our system could be applied widely by crowdsourcing a relatively small number of summaries in a new domain.

8 Related Work

Compressive Summarization. Our work follows in a line of systems that use auxiliary training data or objectives to learn sentence compression (Martins and Smith, 2009; Woodsend and Lapata, 2012; Qian and Liu, 2013). Unlike these past approaches, our compression system uses *both* a plausibility model optimized for grammaticality and a salience model optimized for ROUGE. Almeida and Martins (2013) leverage such modules and learn them jointly in a multi-task learning setup, but face an intractable inference problem in their model which needs sophisticated approximations. Our approach, by contrast, does not need such approximations or expensive inference machinery like ILP solvers (Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Durrett et al., 2016). The highly decoupled nature of our pipelined compressive system is an advantage in terms of training simplicity: we use only simple MLE-based objectives for extraction and compression, as opposed to recent compressive methods that use joint training (Xu and Durrett, 2019; Mendes et al., 2019) or reinforcement learning (Zhang et al., 2018). Moreover, we demonstrate our compression module can stack with state-of-the-art sentence extraction models, achieving additional gains in ROUGE.

One significant line of prior work in compressive summarization relies on heavily engineered rules for syntactic compression (Berg-Kirkpatrick et al., 2011; Li et al., 2014; Wang et al., 2013; Xu and Durrett, 2019). By relying on our data-driven objectives to ultimately perform compression, our approach can rely on a leaner, much more minimal set of constituency rules to extract candidate spans.

Gehrmann et al. (2018) also extract sub-sentential spans in a "bottom-up" fashion, but their method does not incorporate grammaticality and only works best with an abstractive model; thus, we do not compare to it in this work.

Discourse-based Compression. Recent work also demonstrates elementary discourse units (EDUs), spans of sub-sentential clauses, capture salient content more effectively than entire sentences (Hirao et al., 2013; Li et al., 2016; Durrett et al., 2016; Xu et al., 2020). Our approach is significantly more flexible because it does not rely on an a priori chunking of a sentence, but instead can delete variably sized spans based on what is contextually permissible. Furthermore, these approaches require RST discourse parsers and in some cases coreference systems (Xu et al., 2020), which are less accurate than the constituency parsers we use.

9 Conclusion

In this work, we present a compressive summarization system that decomposes span-level compression into two learnable objectives, plausibility and salience, on top of a minimal set of rules derived from a constituency tree. Experiments across both in-domain and out-of-domain settings demonstrate our approach outperforms strong extractive baselines while creating well-formed summaries.

A Summarization Datasets

Table 1 lists training, development, and test splits for each dataset used in our experiments.

Dataset	k	Train	Dev	Test
CNN/Daily Mail	3	287,084	13,367	11,489
CNN	3	90,266	1,220	1,093
New York Times	3	137,772	17,222	17,220
XSum	2	203,028	11,273	11,332
WikiHow	4	168,126	6,000	6,000
Reddit	2	41,675	645	645

Table 1: Training, development, and test dataset sizes for CNN/Daily Mail (Hermann et al., 2015), CNN (subset of CNN/DM), New York Times (Sandhaus, 2008), XSum (Narayan et al., 2018), WikiHow (Koupaee and Wang, 2018), and Reddit (Kim et al., 2019). For each dataset, the extraction model selects the top-k sentences to form the basis of the compressive summary.

B Training Details

Table 2 details the hyperparameters for training the extraction and compression models. These hyperparameters largely borrowed from previous work (Devlin et al., 2019), and we do not perform any additional grid searches in the interest of simplicity. The pre-trained encoders are set to either `bert-base-uncased` or `google/electra-base-discriminator` from HuggingFace Transformers (Wolf et al., 2019). Following previous work (Liu et al., 2019; Zhong et al., 2020), we use the best performing model among the top three validation checkpoints.

C Inference Details

Our system uses two hyperparameters at test-time to control the level of compression performed by the plausibility and salience models. Table 3 shows the BERT- and ELECTRA-based system hyperparameters, respectively. We sweep the salience model threshold $\lambda_S \in [0.1, 0.9]$ with a granularity of 0.05; across all datasets used in the in-domain experiments (CNN/DM, CNN, WikiHow, XSum, and Reddit), this process takes roughly 8 hours on a 32GB NVIDIA V100 GPU.

Furthermore, there are certain cases where the syntactic compression rules license deleting a chain of constituents rather than individual ones. A common example of this is in conjoined noun phrases (NP_1–[CC–NP_2]) where if the second noun phrase NP_2 is deleted, its preceding coordinating conjunction CC should also be deleted. To avoid changing the compression model substantially, we relegate secondary deletions to a postprocessing step, where if a primary constituent like NP_2 is deleted at test-time, its secondary constituents are also automatically deleted.

Hyperparameter	Extraction	Compression
Train Steps	10,000	10,000
Eval Steps	1,000	1,000
Eval Interval	1,000	1,000
Batch Size	16	16
Learning Rate	1e-5	1e-5
Optimizer	AdamW	AdamW
Weight Decay	0	0
Gradient Clip	1.0	1.0
Max Sequence Length	512	256
Max Spans	—	50

Table 2: Training hyperparameters for the extraction and compression models (§3).

Encoder	CNN/DM	CNN	WikiHow	XSum	Reddit
Hyperparameter: Plausibility (λ_P)					
BERT	0.6	0.6	0.6	0.6	0.6
ELECTRA	0.6	0.6	0.6	0.6	0.6
Hyperparameter: Salience (λ_S)					
BERT	0.7	0.5	0.4	0.55	0.65
ELECTRA	0.7	0.5	0.45	0.6	0.7

Table 3: BERT- and ELECTRA-based system hyperparameters for the plausibility (§2.1) and salience models (§2.2). We fix the plausibility threshold at 0.6 and only optimize the salience thresold.

D Plausibility Study

Study	CNN	Reddit
Grammaticality	0.24	0.17
Factuality	0.28	0.34

Table 4: Annotator agreement for grammaticality and factuality studies on CNN and Reddit. Values displayed are computed using Krippendorff's α (Krippendorff, 1980).

We conduct our human evaluation on Amazon Mechanical Turk, and set up the following requirements: annotators must (1) reside in the US; (2) have a HIT acceptance rate $\geq 95\%$; and (3) complete at least 50 HITs prior to this one. Each HIT comes with detailed instructions (including a set of representative examples) and 6 assignments. One of these assignments is a randomly chosen example from the instructions (the *challenge* question), and the other five are samples we use in our actual

		CNN/DM			CNN			WikiHow			XSum			Reddit

ext	CUPS_{EXT}	43.16	20.10	39.52	32.41	13.59	28.93	30.45	8.74	28.34	23.59	4.55	17.81	23.87	5.84	19.27
cmp	CUPS	**43.55**	**20.11**	**39.93**	**34.54**	**13.67**	**31.00**	**31.98**	**8.95**	**29.88**	**25.59**	**4.93**	**19.67**	**25.24**	**6.12**	**20.60**

Table 5: Results on CNN/DM, CNN, WikiHow, XSum, and Reddit with initializing the pre-trained encoders in CUPS to $\text{BERT}_{\text{BASE}}$ as opposed to $\text{ELECTRA}_{\text{BASE}}$.

		WikiHow			XSum			Reddit		
Type	Model	R1	R2	RL	R1	R2	RL	R1	R2	RL
cmp	CUPS	32.43	**9.44**	30.24	26.04	**5.36**	**19.90**	25.99	6.57	21.08
cmp	MatchSum + CUPS_{CMP}	**32.83**	9.24	**30.53**	**26.42**	5.09	19.76	**26.60**	**6.60**	**21.43**

Table 6: Results on WikiHow, XSum, and Reddit with replacing CUPS_{EXT} with MatchSum (Zhong et al., 2020), a state-of-the-art extractive model.

study. In each assignment, annotators are presented with the original sentence and a candidate span, and asked if deleting the span negatively impacts the grammaticality and factuality of the resulting, compressed sentence. Each annotator is paid 50 cents upon completing the HIT; this pay rate was calibrated to pay roughly $10/hour.

After all assignments are completed, we filter low-quality annotators according to two heuristics. An annotator is removed if he/she completes the assignment in under 60 seconds or answers the challenge question incorrectly. We see a substantial increase in agreement for both the grammaticality and factuality studies among the remaining annotators. The absolute agreement scores, as measured by Krippendorff's α (Krippendorff, 1980), are shown in Table 4. Consistent with prior grammaticality evaluations in summarization (Xu and Durrett, 2019; Xu et al., 2020), agreement scores are objectively low due to the difficulty of the tasks, thus we compare the annotations with expert judgements. An expert annotator (one of the authors of this paper uninvolved with the development of the plausibility model) performed the CNN annotation task; we find, by using the majority vote among the crowdsourced annotations, the regular and expert annotators concur 80% of the time on grammaticality and 60% of the time on factuality; this establishes a higher degree of confidence in the crowdsourced annotations when aggregated.

E System Results with BERT

Table 5 (CNN/DM, CNN, WikiHow, XSum, Reddit) shows results using $\text{BERT}_{\text{BASE}}$ as the pre-trained encoder. While the absolute ROUGE results with $\text{BERT}_{\text{BASE}}$ are lower than with $\text{ELECTRA}_{\text{BASE}}$, we still see a large improvement compared to the sentence extractive baseline.

F Extended MatchSum Results

On WikiHow, XSum, and Reddit, we additionally experiment with replacing the sentences extracted from CUPS_{EXT} with MatchSum (Zhong et al., 2020) system outputs. From the results (see Table 6), we see that our system with MatchSum extraction achieves the most gains on Reddit, but its average performance on WikiHow and XSum is more comparable to the standard CUPS system.

G Plausibility Ablation

Table 7 shows results on CNN, WikiHow, XSum, and Reddit with removing the plausibility model in CUPS_{CMP}. Consistent with the analysis in Section 6.3, we see the plausibility model is primarily responsible for gains in ROUGE-2, but in its absence, the salience model can delete arbitrary spans, resulting in gains in ROUGE-1 and ROUGE-L. This ablation demonstrates the need to analyze summaries outside of ROUGE since notions of grammaticality and factuality cannot easily be ascertained by computing lexical overlap with a reference summary.

H Out-of-Domain Results

In Tables 8, 9, and 10, we show ROUGE results with standard deviations across 5 independent runs, for the fine-tuning experiments on NYT → CNN, CNN → Reddit, and XSum → WikiHow, respectively. Despite fine-tuning with a random batch of 500 samples each time, we consistently see low

variance across the runs, demonstrating our system does not have an affinity towards particular samples in an out-of-domain setting.

Furthermore, we present an ablation of salience for the aforementioned transfer tasks in Table 11. On NYT → CNN, salience only helps increase ROUGE-L, but we see consistent increases in average ROUGE on CNN → Reddit and XSum → WikiHow. We can expect larger gains by fine-tuning salience on more samples, but even with 500 out-of-domain samples, our compression module benefits from the inclusion of the salience model.

I Reproducibility

Table 12 shows system results on the development sets of CNN/DM, CNN, WikiHow, XSum, and Reddit to aid the reproducibility of our system; both CUPS_{EXT} and CUPS are included. Furthermore, in Table 13, we report several metrics to aid the training of the extraction and compression models. These specific metrics recorded by training models on a 32GB NVIDIA V100 GPU with the hyperparameters listed in Table 2.

Understanding Neural Abstractive Summarization Models via Uncertainty

Abstract

An advantage of seq2seq abstractive summarization models is that they generate text in a free-form manner, but this flexibility makes it difficult to interpret model behavior. In this work, we analyze summarization decoders in both blackbox and whitebox ways by studying on the entropy, or uncertainty, of the model's token-level predictions. For two strong pre-trained models, PEGASUS (Zhang et al., 2020) and BART (Lewis et al., 2020) on two summarization datasets, we find a strong correlation between low prediction entropy and where the model copies tokens rather than generating novel text. The decoder's uncertainty also connects to factors like sentence position and syntactic distance between adjacent pairs of tokens, giving a sense of what factors make a context particularly selective for the model's next output token. Finally, we study the relationship of decoder uncertainty and attention behavior to understand how attention gives rise to these observed effects in the model. We show that uncertainty is a useful perspective for analyzing summarization and text generation models more broadly.[1]

1 Introduction

Recent progress in abstractive summarization has been fueled by the advent of large-scale Transformers pre-trained on autoregressive language modeling objectives (Hoang et al., 2019; Khandelwal et al., 2019; Lewis et al., 2020; Zhang et al., 2020). Despite their strong performance on automatic metrics like ROUGE (Lin, 2004), abstractive models are not as straightforward and interpretable as their extractive counterparts. Free-form generation in these models also leads to serious downstream errors, such as factual inconsistencies with the input document (Cao et al., 2018; Kryściński et al., 2020; Wang et al., 2020; Durmus et al., 2020; Goyal and Durrett, 2020). Although the interpretability of NLU models has been extensively studied (Ribeiro et al., 2016; Ghaeini et al., 2018; Jain and Wallace, 2019; Desai and Durrett, 2020), summarization models specifically have not received similar attention, with analysis efforts often focused on datasets and evaluation (Kryscinski et al., 2019).

In this work, we focus on interpreting and understanding abstractive summarization models through the lens of decoder uncertainty, or the entropy of decisions during generation. While uncertainty in generation has been studied from the perspective of data (Ott et al., 2018), sampling (Fan et al., 2018; Holtzman et al., 2019), and training (Correia et al., 2019; Kang and Hashimoto, 2020), it is underutilized as a technique for analysis and inspection of generation systems. We study two prominent summarization models, PEGASUS (Zhang et al., 2020) and BART (Lewis et al., 2020), fine-tuned on two English summarization datasets, CNN/Daily Mail (Hermann et al., 2015) and XSum (Narayan et al., 2018), to understand model behavior in each setting.

First, by comparing n-grams between the input document and generated summaries, we establish two coarse types for decoded tokens, *copy* and *generate* (See et al., 2017). We find that the entropy of the generation decision correlates with whether the model is copying or generating, as well as where in the sentence the token is. This paints a picture of certain contexts being more restrictive from the standpoint of generation, particularly early in sentences where a model has not "decided" what to copy yet, and illustrates the interaction of content selection and lexical choice. Second, we extend this analysis by looking at how uncertainty relates to the syntax of the generated sentence: whether uncertainty connects to syntactic notions of surprisal (Roark et al., 2009) and how the entropy

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6275–6281,
November 16–20, 2020.

varies across certain syntactic productions. Finally, we derive a way to quantify decoder attention by aggregating distinct self-attention heads, revealing the correlation between the attention entropy and prediction entropy, and investigating the correspondence between the prediction entropy and the fraction of the past and future decoded tokens.

Taking this analysis together, we find that the abstractiveness of reference summaries fundamentally changes model behavior: the extractive nature of CNN/DM makes most of its decisions low entropy and copy-oriented while the model maintains higher uncertainty on XSum, yielding more abstractive summaries. More broadly, we show that uncertainty is a simple but effective tool to characterize decoder behavior in text generation.

2 Model and Experimental Setup

Our experiments use PEGASUS (Zhang et al., 2020) and BART (Lewis et al., 2020), two state-of-the-art seq2seq pre-trained models. We use the *large* version of these two models, which have 16 and 12 Transformer layers, respectively. Both models have pre-training objectives tailored somewhat to this problem domain: seq2seq modeling for denoising (BART) or infilling of masked-out sentences (PEGASUS). We directly use the pre-trained models from Wolf et al. (2019).[2]

As reported in the original papers and measured by ROUGE-1/2/L (Lin, 2004), PEGASUS achieves 44.17/21.47/41.11 on CNN/DM (Hermann et al., 2015) and 47.21/24.56/39.25 on XSum (Narayan et al., 2018), and BART achieves 44.16/21.28/40.90 and 45.14/22.27/37.25.

Entropy. Entropy is a standard measure of uncertainty in a probabilistic distribution. Given a discrete random variable X with all possible outcomes $x_1, \cdots, x_n$, the entropy of X is defined as $H(X) = -\sum_{i=1}^{n} P(x_i) \log P(x_i)$.

For pre-trained Transformers, the domain of the predictions (the vocabulary) is large and also differs between models. The vocabulary sizes for PEGASUS and BART are 96,103 and 50,265,[3] and the prediction distribution is usually long-tailed. To combat this, nucleus sampling (Holtzman et al., 2019) is used to sample from only the top $1-p$ most probable outcomes (the nucleus) to avoid generating very unlikely tokens. To more fairly compare models with different vocabulary sizes, and to better reflect the actual sampling distribution, we therefore compute all entropy values in this work over the nucleus distribution. That is, we sort the prediction distribution $P(x_i)$ in descending order and get a minimal set of tokens where $V^{\min} = \{x | \sum_{x_i \in V^{\min}} P(x_i) \geq p\}$. Then we renormalize the distribution as follows:

$$P'(x_i) = \begin{cases} \frac{P(x_i)}{p'} & \text{if } x_i \in V^{\min} \\ 0 & \text{otherwise.} \end{cases} \tag{1}$$

where the cumulative probability $p' = \sum_{x_i \in V^{\min}} P(x_i)$. We use $p = 0.95$ for all experiments. The entropy $H(X)$ is computed based on the new distribution $P'(x_i)$.

3 Model Uncertainty during Generation

In this section, we analyze and compare the prediction uncertainty from different models and different datasets by inspecting entropy values during generation, allowing us to localize uncertainty to certain positions in a decoded sentence. A principle factor that past work has investigated is the amount of copying in abstractive summarization models (See et al., 2017; Paulus et al., 2018). We first aim to understand how decisions to copy document content or generate new text are reflected in the model's uncertainty.

One complicating factor is that while BART and PEGASUS both exhibit a mix of copying and novel generation, they do not have an explicit copy operation like in past models and so these behaviors are more difficult to define. We first separate generation decisions by bigrams that appear in the input document (existing bigrams) or whether they are free-form generations (novel bigrams).[4]

Figure 1 shows a histogram of model entropies broken down by these two categories. Most notably, **there is a strong correlation between copy-like behavior and the entropy of the model's prediction distribution**. On CNN/DM, we see that low entropy decisions are largely those generating existing bigrams, and conversely, existing bigrams are usually generated with low entropy. New bigrams are generated with a broad range of high

---

[2] Specifically, `google/pegasus-cnn_dailymail`, `google/pegasus-xsm`, `facebook/bart-large-cnn`, and `facebook/bart-large-xsum` for PEGASUS and BART on these two datasets.

[3] Note that entropy generally increases as the variable's domain grows: a uniform distribution over 10,000 outcomes has entropy 9.21, while a uniform distribution over 100,000 outcomes has entropy 11.51.

[4] Bigrams are defined based on tokens rather than wordpieces, and so may consist of more than two generation steps.

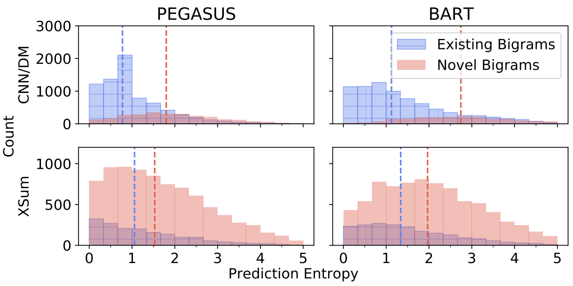

Figure 1: Next token entropies computed on 10K generation steps from $\text{PEGASUS}_{\text{CNN/DM}}$, $\text{PEGASUS}_{\text{XSUM}}$, $\text{BART}_{\text{CNN/DM}}$ and $\text{BART}_{\text{XSUM}}$ respectively, broken into two cases: an *Existing Bigram* means the bigram just generated occurs in the input document, while a *Novel Bigram* is an organic model generation. These cases are associated with low entropy and high entropy actions, respectively. The x-axis shows the entropy (truncated at 5), and the y-axis shows the count of bigram falling in each bin. The dashed lines indicate the median of each distribution.

entropy values, and are much more frequent on XSum. These results align with our manual analysis of these summaries: $\text{PEGASUS}_{\text{CNN/DM}}$ and $\text{BART}_{\text{CNN/DM}}$ summaries largely consist of spans from the input document with minor compression while $\text{PEGASUS}_{\text{XSUM}}$ and $\text{BART}_{\text{XSUM}}$ summaries involve stitching together disparate concepts and paraphrasing key details. This reflects a corresponding divergence in the gold summaries, where CNN/DM summaries are far more extractive than those in XSum.

Critically, though the entropy distributions are dissimilar across the two datasets, we see regularities among the approximate *copy* and *generate* operations: on CNN/DM and XSum, the median entropy values of using existing bigrams are 0.95 and 1.20, respectively, and for generating new bigrams, 2.27 and 1.75.

With this connection between entropy and copying behavior, we make the following additional observations based on Figures 1 and 2:

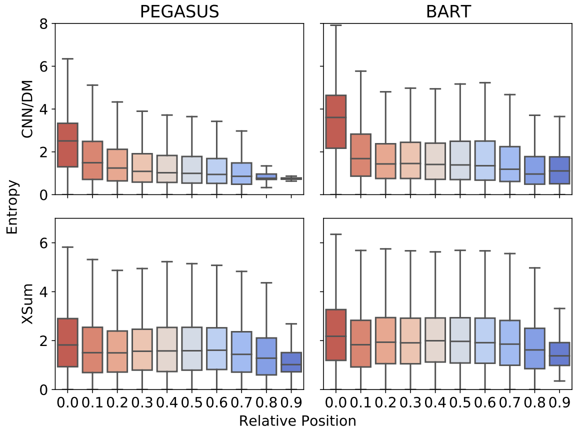

Figure 2: Prediction entropy values by relative sentence positions. For example, 0.0 indicates the first 10% of tokens in a sentence, and 0.9 is the last 10% of tokens. $\text{PEGASUS}_{\text{CNN/DM}}$ and $\text{BART}_{\text{CNN/DM}}$ make highly uncertain decisions to start, but then entropy decreases, suggesting that these models may be copying based on a sentence prefix. Entropies on XSum are more constant across the sentence.

Entropy varies across token positions, especially on CNN/DM. In Figure 2, we depict a different view of entropy, looking at the decoding process as it progresses through each sentence. Across both CNN/DM and XSum, models are most uncertain at the beginning of the sentence and least uncertain at the end of the sentence. However, the rate at which entropy drops off is quite different: on CNN/DM, the entropy after decoding 20% of tokens falls below 2, while the entropies on XSum only begin to considerably drop after decoding 80% of tokens. Our manual analysis suggests the following characterization: **to generate each sentence on CNN/DM, the model makes some high-entropy decisions to identify a sentence and begin to copy its prefix, followed by a series of low entropy decisions to copy that sentence's content.** On XSum, which is highly abstractive and features single sentence summaries, content planning and generation are less clearly decoupled.

PEGASUS copies and generates more tokens with entropy < 1. BART and PEGASUS report similar ROUGE results on CNN/DM, but these models do not place the same distributions over summaries. PEGASUS has more low-entropy copying decisions, and its start-of-sentence entropies are also significantly lower (Figure 2). This suggests that it is more confident than BART in selecting content to discuss next. There are also more low-entropy generation decisions, particularly on XSum.

4 Entropies of Syntactic Productions

Having observed connections between sentence position and entropy, we now flesh out this analysis from the lens of syntax, focusing in particular on uncertainty at constituent boundaries. From our PEGASUS generations on CNN/DM and XSum,

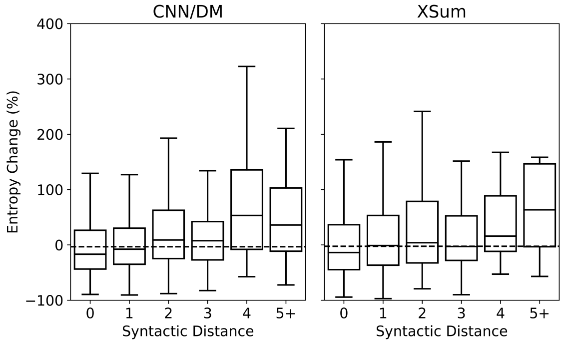

Figure 3: Correlating syntactic distance between neighboring tokens with the entropy change in those tokens' generation decisions for PEGASUS summaries. The median entropy change is depicted as a dashed black line. At points of high syntactic distance, the model's behavior is less restricted by the context, correlating with higher entropy.

we obtain constituency parses for each summary sentence using the Berkeley Neural Parser (Kitaev and Klein, 2018) and explore connections between syntax and uncertainty in more depth.

Low and high entropy decisions can be localized to constituent span boundaries. Parsing has long been used to explain psycholinguistic notions of surprisal (Hale, 2001; Roark et al., 2009, inter alia), which are in turn related to uncertainty under a language model. In our case, uncertainty about *generating* a text is a different notion than uncertainty when a reader is *processing* it. Hence, rather than looking at an incremental parser's behavior, we instead look at a simpler notion of syntactic distance (Shen et al., 2018), or the number of left and right parentheses between w_t and w_{t+1} in a linearized constituency tree. Our hypothesis is that when these words exhibit high syntactic distance, this word boundary is a "choice point" where the model may be less restricted in what it can choose to generate next.

Figure 3 shows the correlation between syntactic distance and the percent change in entropy between the adjacent tokens. On both CNN/DM and XSum, we see two patterns emerge: generating a token within the same immediate parent constituent (i.e., zero syntactic distance) is typically a *certain* decision, while generating a token belonging to a new constituent is an increasingly *uncertain* decision. From these results, we can draw a parallel to the copy vs. generate behavior established in Section 3; for example, generating *York* after *New* might be straightforward, perhaps due to a direct copy from the document, but generating a prepositional phrase might be more challenging due to the large search space of possible constructions or the higher chance that the model might delete this constituent.

Production Rule	Example
`NP → NP : NP`	[Arsenal vs Reading]$_{1.2}$ [:]$_{0.6}$ [the game that changed the game]$_{3.1}$
`NP → NP , SBAR ,`	[driver]$_{0.5}$ [,]$_{0.4}$ [who has not been identified]$_{2.2}$ [,]$_{0.1}$
`NP → CD NN NNS`	[16]$_{0.07}$ [felony]$_{0.05}$ [counts]$_{0.01}$
`NP → NNP CD`	[April]$_{0.04}$ [3]$_{0.1}$

Table 1: Examples of specific NP productions with high entropy (top) and low entropy (bottom). The notation $[\mathrm{Y}]_{H(Y)}$ implies the constituent Y is generated with entropy $H(Y)$.

Low entropy spans are often short, specific units of information. We also investigate the average entropy of spans within a rule production to uncover what types of spans are likely to elicit certainty or uncertainty during generation. In Table 1, we see qualitatively that productions with low average entropy productions are short extracts of document content, such as *16 felony counts*. These are largely factual, often containing cardinal values, and more likely to be copied. Within these constituents, the model is very certain about what to generate next, supporting the connection with low syntactic distance.

5 Understanding Decoder Self-Attention

While we have analyzed the model's predictions, we have not yet determined *how* the different behaviors we see emerge from the context. Our goal is to explore what the encoder attention places its emphasis during generation and how it correlates with the prediction entropy.[5]

Blocking Low-information Tokens. Analyzing the inner workings of attention in Transformers is challenging (Clark et al., 2019; Kovaleva et al., 2019), particularly because many heads are useless, redundant, or noisy, and they frequently attend to

---

[5] In PEGASUS and BART models, the encoder and decoder attention during decoding are two separate distributions where the encoder attention looks at the encoding context and the decoder attention attends to the previously decoded tokens. In this paper we chiefly examine the encoder attention to understand how the model references the input document.

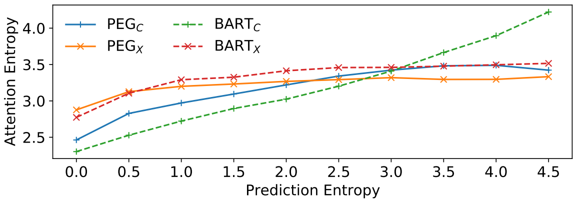

Figure 4: Correlation between attention entropy and prediction entropy of PEG(ASUS) and BART on C(NN/DM) and X(Sum). We compute the mean value of the attention entropy within each bucket of prediction entropy. The uncertainty of attention strongly correlates with the entropy of the model's prediction.

low-information tokens such as end-of-sentence markers or periods. Inspired by tf-idf (Joachims, 1997), we propose a method to compute a set of tokens most meaningfully attended to by the model. If a token in the encoding document is attended to across many time steps (like a word appearing in many documents in tf-idf), we want to disregard it in our analysis.

Let T denote the number of decoder timesteps and L be the length of the source document. We compute an aggregate attention matrix $S \in \mathbb{R}^{T \times L}$ by summing the attentions across all heads and all layers. We then compute a count of how often each token is attended to above a threshold q: $f_l = \sum_{t=1}^{T} [\mathbb{1}(s_{tl} \geq q)]$ and discard the attention values on tokens with the highest f score. In practice we discard 5% of tokens from the source document.

Attention Entropy. One natural question we can ask is whether there is a connection between entropy of the attention distribution and entropy of the decoder's prediction. This relationship is shown in Figure 4, where each point represents the mean attention entropy within the corresponding prediction entropy bucket. The attention entropy is especially low where the prediction entropy ranges from 0 to 0.5. For cases with prediction entropy greater than 1.5, the attention entropy saturates and no longer grows with the prediction entropy except the BART$_{\text{CNN/DM}}$. While attention entropy is probably not "causing" the low decoder entropy per se, nevertheless decoder entropy provides a lens into the inner workings of the Transformer model.

Projecting Attention to Vocabulary. We hypothesize that low decoder entropies may arise if the model is heavily attending to certain relevant tokens, particularly the (about to be predicted) token y_t of time step t and the input token of this time step x_t, equivalent to y_{t-1}. For the predicted token y_t, we compute the vocabulary projected attention value $\sum_{l=1}^{L} \mathbb{1}[\text{token}_l = y_t] s_{tl}$ where we accumulate the attention of all of the occurrences of the specified token y_t in the document. The higher the value, the more attention put to the encoding token(s) which are predicted for this time step during decoding. We can define the value for last time step input y_{t-2}, current time step input y_{t-1}, and the not-yet-decoded token y_{t+1} for next time step.

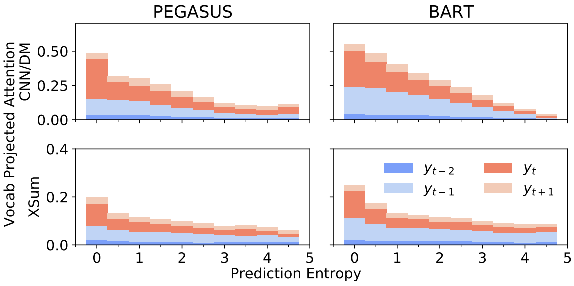

Figure 5: Vocabulary projected attention attending to the last input y_{t-2}, current input y_{t-1}, current output y_t, and next output y_{t+1}. When the prediction entropy is low, the attention mostly focus a few tokens including the current input y_{t-1} and current output y_t.

We show the relationship between the vocabulary projected attention and the prediction entropy in Figure 5. Visualizations for both models and both datasets show that when the prediction entropy is low, the attention focuses heavily on a few tokens including the current input token and the current token to predict. This suggests a potential mechanism where the model indexes into the source document by attending to y_{t-1}, then strongly identifies and "reads off" y_t as the next token to generate.

6 Conclusion

This work analyzes pre-trained summarization models via uncertainty, or the entropy of decoding decisions. We pursue several lines of inquiry: uncertainty can help us understand copying document spans vs. generating novel text, the behavior of models in different syntactic environments, and coarse properties of the model's attention distribution. All of these give insight into what conditions most heavily restrict the model's generation: generating an observed bigram (copying), low syntactic distance, and attention which can easily identify decoder context in the source document. We believe this approach can power future analyses of pre-trained text generation systems.

Abstract

Amongst the best means to summarize is *highlighting*. In this paper, we aim to generate summary highlights to be overlaid on the original documents to make it easier for readers to sift through a large amount of text. The method allows summaries to be understood in context to prevent a summarizer from distorting the original meaning, of which abstractive summarizers usually fall short. In particular, we present a new method to produce *self-contained* highlights that are understandable on their own to avoid confusion. Our method combines determinantal point processes and deep contextualized representations to identify an optimal set of sub-sentence segments that are both important and non-redundant to form summary highlights. To demonstrate the flexibility and modeling power of our method, we conduct extensive experiments on summarization datasets. Our analysis provides evidence that highlighting is a promising avenue of research towards future summarization.

1 Introduction

A summary is reliable only if it is true-to-original. Abstractive summarizers are considered to be less reliable despite their impressive performance on benchmark datasets, because they can hallucinate facts and struggle to keep the original meanings intact (Kryscinski et al., 2019; Lebanoff et al., 2019). In this paper, we seek to generate summary highlights to be overlaid on the original documents to allow summaries to be understood in context and avoid misdirecting readers to false conclusions. This is especially important in areas involving legislation, political speeches, public policies, social media, and more (Sadeh et al., 2013; Kornilova and Eidelman, 2019). Highlighting is most commonly used in education to make important information stand out and bring attention of readers to the essential topics (Rello et al., 2014).

Original Document and Summary Highlights
Afghan opium kills 100,000 people every year worldwide – more than any other drug – and the opiate heroin kills five times as many people in NATO countries each year than the eight-year total of NATO troops killed in Afghan combat, *the United Nations said Wednesday.* About 15 million people around the world use heroin, opium or morphine, fueling a $65 billion market for the drug and also fueling terrorism and insurgencies... *Drug money is funding insurgencies* in Central Asia, which has huge energy reserves, Costa said... Europe and Russia together consume just under half of the heroin coming out of Afghanistan, the United Nations concluded, and *Iran is by far the single largest consumer of Afghan opium.*

Table 1: An example of sub-sentence highlights overlaid on the original document; the highlights are self-contained.

The characteristics of summary highlights are: *saliency*, i.e., highlights must give the main points of the documents, and *non-redundancy*, suggesting that redundant content should not appear in a summary (Nenkova and McKeown, 2011). Importantly, a highlighted text should be *self-contained*, i.e., understandable on its own, without the need for specific information from surrounding context. Table 1 provides an example of sub-sentence highlights. In contrast, "*New Jersey is located in*" hardly constitutes a good highlight because the information it contains is incomplete and may confuse readers. To date, there has not been any unified framework to account for all these characteristics to generate highlights. We overcome the challenge by identifying self-contained sub-sentence segments from the documents, then combining determinantal point processes and deep contextualized representations to produce highlights.

Determinantal point process belongs to a class of optimization methods that have had considerable success in summarizing text and video (Kulesza and Taskar, 2012; Gong et al., 2014; Sharghi et al., 2018). It selects a diverse subset from a ground set of items, where an item is a candidate text segment in the context of generating summary highlights. An item is characterized by a *quality* score that indicates the salience of the segment and a *diversity*

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6282–6300,
November 16–20, 2020.

score that models *pairwise repulsion*, suggesting that two segments carrying similar meaning cannot both be included in the summary to avoid redundancy. The quality and diversity decomposition of DPP allows it to identify an optimal subset from a collection of candidate segments.

We study sub-sentence segments as they strike a balance between the quality and amount of highlights. Whole sentences often contain excessive or unwanted details; keywords are succinct but less informative. We conjecture that sub-sentence segments can be identified from a document similar to salient objects are identified from an image using bounding boxes (Girshick et al., 2014). To best estimate the size of segments, we present a novel method to "overgenerate" a rich set of self-contained, partially-overlapping sub-sentence segments from any sentence based on contextualized representations (Yang et al., 2019; Devlin et al., 2019), then leverage determinantal point processes to identify an essential subset based on saliency and non-redundancy criteria. Our contributions of this work are summarized as follows.

- We propose to generate sub-sentence summary highlights to be overlaid on source documents to enable users to quickly navigate through content. Comparing to keywords or whole sentences, sub-sentence segments allow us to attain a good balance between quality and amount of highlights.
- Importantly, sub-sentence segments are designed to be self-contained, and for which we introduce a new algorithm based on deep contextual representations to obtain self-contained text segments. All candidate segments are fed to determinantal point processes to identify an optimal subset containing informative, non-redundant, and self-contained sub-sentence highlights.
- We perform experiments on benchmark summarization datasets to demonstrate the flexibility and modeling power of our approach. Our analysis provides further evidence that highlighting offers a promising avenue of research.[1]

2 Related Work

An abstract failing to retain the original meaning poses a substantial risk of harm to applications. Abstractive summarizers can copy words from source documents or generate new words (See et al., 2017; Tan et al., 2017; Chen and Bansal, 2018; Narayan et al., 2018; Gehrmann et al., 2018; Liu and Lapata, 2019; Laban et al., 2020). With greater flexibility comes increased risk. Failing to accurately convey the original meaning can hinder the deployment of summarization techniques in real-world scenarios, as inaccurate and untruthful summaries can lead the readers to false conclusions (Cao et al., 2018; Falke et al., 2019; Lebanoff et al., 2019). We aim to produce summary highlights in this paper, which will be overlaid on source documents to allow summaries to be interpreted in context.

Original Sentence

- Some interstates are closed and hundreds of flights have been canceled as winter storms hit during one of the year's busiest travel weeks.

Self-Contained Segments

- Some interstates are closed
- hundreds of flights have been canceled as winter storms hit
- flights have been canceled as winter storms hit
- winter storms hit during one of the year's busiest travel weeks

Non-Self-Contained Segments

- Some interstates are
- closed and hundreds of flights have been
- been canceled as winter storms hit during one of
- hit during one of the year's

Table 2: Examples of self-contained and non-self-contained segments extracted from a document sentence.

Generation of summary highlights is of crucial importance to tasks such as producing informative snippets from search outputs (Kaisser et al., 2008), summarizing viewpoints in opinionated text (Paul et al., 2010; Amplayo and Lapata, 2020), and annotating website privacy policies to assist users in answering important questions (Sadeh et al., 2013). Determining the most appropriate textual unit for highlighting, however, has been an understudied problem. Extractive summarization selects whole sentences from documents; a sentence can contain 20 to 30 words on average (Kamigaito et al., 2018). Keyphrases containing two to three words are much less informative (Hasan and Ng, 2014). Neither are ideal solutions. There is a rising need for other forms of highlighting, and we explore sub-sentence highlights that strike a balance between the amount and quality of emphasized content.

It is best for highlighted segments to remain self-contained. In fact, multiple partially-overlapping and self-contained segments can exist in a sentence, as illustrated in Table 2. Identifying self-contained segments has not been thoroughly investigated in previous studies. Woodsend and Lapata (2010) propose to generate story highlights by selecting and combining phrases. Li et al. (2016) explore elemen-

tary discourse units generated using an RST parser as selection units. Spala et al. (2018) present a crowdsourcing method for workers to highlight sentences and compare systems. Arumae et al. (2019) propose to align human abstracts and source articles to create ground-truth highlight annotations. Importantly, and distinguishing our work from earlier literature, we make a first attempt to generate self-contained highlights, drawing on the successes of deep contextualized representations and their extraordinary ability of encoding syntactic structure (Clark et al., 2019; Hewitt and Manning, 2019). We next discuss our method in greater detail.

3 Our Method

We present a new method to identify self-contained segments, then select important and non-redundant segments to form a summary, as text fragments containing incomplete and disorganized information are hardly successful summary highlights.

3.1 Self-Contained Segments

A self-contained segment is, in a sense, a miniature sentence. Any text segment containing incomplete or ungrammatical constructions is incomprehensible to humans. Table 2 presents examples of self-contained and non-self-contained segments. Since its very inception (Vladutz, 1983), the concept of "semantically self-contained segment" has not been sufficiently examined in the literature and lacks an universal definition. We assume in this paper that a self-contained segment shall conform to certain syntactic validity constraints and there exists only weak dependencies between words that belong to the segment and those do not.

The automatic identification of self-contained segments requires more than segmentation or parsing sentences into tree structures (Dozat and Manning, 2018). Self-contained segments do not necessarily correspond to constituents of the tree and further, there is no guarantee that tree constituents are self-contained. In this paper, we define a segment to be a consecutive sequence of words, excluding segments formed by concatenating non-adjacent words from consideration. We perform exhaustive search to analyze every segment of a given sentence to determine if it is self-contained or not.

Let $\mathbf{x} = [x_1, \dots, x_\mathsf{N}]$ be a document sentence. We present a method to estimate whether an arbitrary segment $\mathbf{x}_{i:j}$ of the sentence is semantically self-contained or not. Our method is inspired by XLNet (Yang et al., 2019) that introduces a novel architecture with two-stream attention mechanism for autoregressive language modeling. Pretrained contextualized representations such as BERT and XLNet have demonstrated remarkable success on language understanding tasks. We expect the representations to encode the syntactic validity of segments, as similar findings are seen in recent structural probings (Hewitt and Manning, 2019).

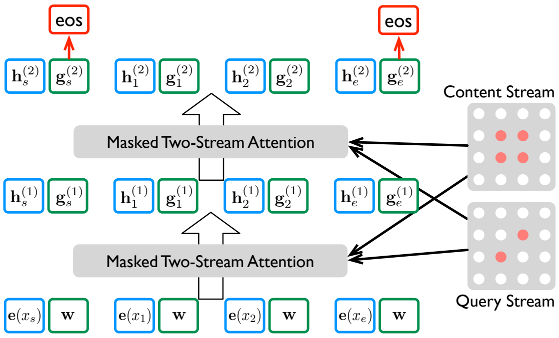

Figure 1: The XLNet architecture with two-stream attention mechanism is leveraged to estimate whether a segment is self-contained or not. A self-contained segment is assumed to be preceded and followed by end-of-sentence markers (`eos`).

We hypothesize that a self-contained segment, similar to a miniature sentence, can be preceded and followed by end-of-sentence (`eos`) markers without sacrificing grammatical correctness. We follow the convention of Clark et al. (2019) to define end-of-sentence markers (`eos`) to include periods and commas. Our method inserts hypothetical tokens x_s and x_e to the beginning and end positions of a segment $\mathbf{x}_{i:j}$, then constructs contextualized representations for these positions, denoted by $\mathbf{g}(\mathbf{x}_{i:j}, p_\text{start})$ and $\mathbf{g}(\mathbf{x}_{i:j}, p_\text{end})$, based on which we estimate how likely x_s is an end-of-sentence marker $p(x_\text{s}{=}\texttt{eos}|\mathbf{x}_{i:j})$, similarly for $p(x_\text{e}{=}\texttt{eos}|\mathbf{x}_{i:j})$. Their average probability indicates self-containedness. A higher score of $p(z|\mathbf{x}_{i:j})$ suggests $\mathbf{x}_{i:j}$ has a higher likelihood of being self-contained.

$$p(z|\mathbf{x}_{i:j}) = \frac{1}{2}\Big(p(x_\text{s}{=}\texttt{eos}|\mathbf{x}_{i:j}) + p(x_\text{e}{=}\texttt{eos}|\mathbf{x}_{i:j})\Big)$$

$$p(x_\text{s}{=}\texttt{eos}|\mathbf{x}_{i:j}) = \frac{\exp(\mathbf{e}(x_\text{s})^\top \mathbf{g}(\mathbf{x}_{i:j}, p_\text{start}))}{\sum_{x'} \exp(\mathbf{e}(x')^\top \mathbf{g}(\mathbf{x}_{i:j}, p_\text{start}))}$$

It is important to induce contextualized representations for the augmented segment *without* using the content of hypothetical tokens x_s and x_e. We leverage XLNet with two-stream attention mechanism for this purpose, as illustrated in Figure 1. For the k-th position (k={i:j, start, end}) of the l-th layer, a *content* stream builds representation $\mathbf{h}_k^{(l)}$

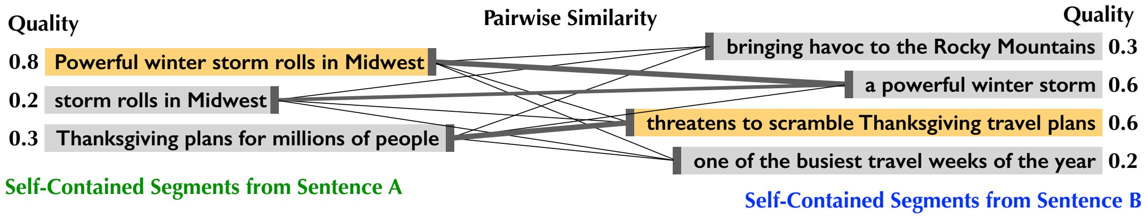

Figure 2: DPP selects a set of summary segments (marked yellow) based on the *quality* and *pairwise dissimilarity* of segments.

by attending to all tokens of the segment, whereas a *query* stream builds representation $\mathbf{g}_k^{(l-1)}$ simultaneously without incorporating the content of the current token x_k, following the equations given below. Our method builds on the pretrained XLNet model without fine-tuning. It relies on two-stream attention to construct deep contextualized representations $\mathbf{g}(\mathbf{x}_{i:j}, p_{\text{start}})$ and $\mathbf{g}(\mathbf{x}_{i:j}, p_{\text{end}})$, respectively for the beginning and end positions.

$$\mathbf{h}_k^{(l)} = \text{Attention}(\text{Q} = \mathbf{h}_k^{(l-1)}, \text{KV} = \mathbf{h}_{i:j}^{(l-1)})$$
$$\mathbf{g}_k^{(l)} = \text{Attention}(\text{Q} = \mathbf{g}_k^{(l-1)}, \text{KV} = \mathbf{h}_{i:j\setminus k}^{(l-1)})$$

Our method is the first attempt to extract semantically *self-contained* segments from whole sentences. Segments that do not resemble "miniature sentences" will be given low probabilities by the method. E.g., "*closed and hundreds of flights have been*" is scored low, not only because an end-of-sentence marker rarely occurs after "have been," but also the syntactic structure of the segment does not resemble that of a well-formed sentence.

We split a sentence at punctuation and extract a number of segments from each sentence chunk. A segment is discarded if its start (or end) probability is lower than the upper quartile value, indicating an inappropriate start (or end) point. The remaining segments are ordered according to the average probability. This process produces a collection of self-contained and partially-overlapping segments from a set of documents. Next, we assess the informativeness of the segments and leverage DPP to identify a subset to form the summary highlights.

3.2 Segment Selection with DPP

We employ the modeling framework proposed by Cho et al. (2019a) for modeling determinantal point processes. DPP (Kulesza and Taskar, 2012) defines a probability measure $\mathcal{P}$ over all subsets ($2^{|\mathcal{Y}|}$) of a ground set containing a collection of N segments $\mathcal{Y} = \{1, 2, \cdots, \mathsf{N}\}$. The probability of an extractive summary, containing a subset of the segments $Y \subseteq \mathcal{Y}$, is defined by Eq. (1), where $\det(\cdot)$ is the determinant of a matrix; $L \in \mathbb{R}^{\mathsf{N}\times\mathsf{N}}$ is a positive semi-definite matrix and L_{ij} indicates the correlation between segments i and j; L_Y is a submatrix of L containing only entries indexed by elements in Y; I is the identity matrix. This definition suggests that the probability of a summary $\mathcal{P}(Y; L)$ is proportional to the determinant of L_Y.

$$\mathcal{P}(Y; L) = \frac{\det(L_Y)}{\det(L + I)}, \tag{1}$$

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{i=1}^{N} \log \mathcal{P}(\hat{Y}^{(i)}; L^{(i)}(\boldsymbol{\theta})) \tag{2}$$

A decomposition exists for the L-ensemble matrix: $L_{ij} = q_i \cdot S_{ij} \cdot q_j$ where $q_i \in \mathbb{R}^+$ is a quality score of the i-th segment and S_{ij} is a pairwise similarity score between segments i and j. If q and S are available, $\mathcal{P}(Y)$ can be computed using Eq. (1). Estimating the pairwise similarity S is trivial, we refer the reader to (Cho et al., 2019b) for details. In this paper, we present a *inverted pyramid* method to estimate the quality of segments q. The quality model is parameterized by $\boldsymbol{\theta}$, thus the L-ensemble is parameterized the same, denoted by $L^{(i)}(\boldsymbol{\theta})$ for the i-th instance of the dataset. $\hat{Y}^{(i)}$ represents the ground-truth summary (Eq. (2)). The model is optimized by maximizing the log-likelihood, where parameters $\boldsymbol{\theta}$ are learned during training. As illustrated in Figure 2, DPP allows us to identify a set of salient and non-redundant summary segments.

Inverted pyramid We describe a classifier to predict if a segment of text is summary-worthy or not according to the *inverted pyramid* principle.[2] It is a way of front loading a story so that the reader can get the most important information first. E.g., the most newsworthy information such as who, what, when, where, etc. heads the article, followed by important details, and finally other general and background information. The inverted pyramid explains the common observation that lead baselines consisting of the first few sentences of an article perform strongly in the news domain.

---

[2] `https://en.wikipedia.org/wiki/Inverted_pyramid_(journalism)`

Our classifier assigns a high score to a segment if its content is relevant to the lead paragraph, and a low score if its content overlaps with the bottom paragraph of a news article, which usually contains trivial details. Importantly, the classifier is trained using CNN/DM (See et al., 2017), rather than any multi-document summarization data.

During training, we obtain the ground-truth summary of each article. A summary sentence is paired with the lead paragraph of the article that contains the top-5 sentences to form a *positive* instance and similarly, with bottom-5 sentences to form a *negative* instance. If a summary sentence appears as-is in the top or bottom paragraph, we exclude the sentence from the paragraph to avoid overfitting the classifier. At test time, the classifier learns to distill the essential content of the segment and assigns a high score to it if its content is similar to the lead paragraph, indicating the segment is relevant and summary-worthy.

For each instance, we obtain deep contextualized representation for it using the BERT architecture, where a segment and a lead (or bottom) paragraph is used as the input and the top layer hidden vector of the `[CLS]` token is extracted as the representation. It is fed to a feedforward, a dropout and a softmax layer to predict a binary label for the segment. Once the model is trained, we apply it to a segment and its lead paragraph to produce a vector which is used as part of the features for computing q.

DPP training. We obtain feature representations for the i-th segment by concatenating the previous vector and a number of surface features extracted for segment i. The features include the length and position of the segment within a document, the cosine similarity between the segment and document TF-IDF vectors (Kulesza and Taskar, 2011). We abstain from using sophisticated features to avoid model overfitting. The feature parameters $\boldsymbol{\theta}$ are to be learned during DPP training.

DPP is trained on multi-document summarization data by maximizing log-likelihood. At each iteration, we project the L-ensemble onto the positive semi-definite (PSD) cone to ensure that it satisfies the PSD property (§3.2). This is accomplished in two steps, where L' is the new L-ensemble.

$$L = \sum_{i=0}^{n} \lambda_i v_i v_i^\top \quad \text{(Eigenvalue decomposition)}$$

$$L' = \sum_{i=0}^{n} \max\{\lambda_i, 0\} v_i v_i^\top \quad \text{(PSD projection)}$$

Table 3: Results on DUC-04 dataset evaluated by ROUGE.

4 Experiments

4.1 Data Sets

Our data comes from NIST. We use them to investigate the feasibility of the proposed multi-document summarization method. Particularly, we use DUC-03/04 (Over and Yen, 2004) and TAC-08/09/10/11 datasets (Dang and Owczarzak, 2008), which contain 60/50/48/44/46/44 document sets respectively. These datasets are previously used as benchmarks for multi-document summarization competitions.[3] Our task is to generate a summary of less than 100 words from a set of 10 news documents, where a summary contains a set of selected text segments. There are four human reference summaries for each document set, created by NIST evaluators.

A system summary is evaluated against human reference summaries using ROUGE (Lin, 2004)[4], where R-1, R-2, and R-SU4 respectively measure the overlap of unigrams, bigrams and skip bigrams (with a maximum gap of 4 words) between system and reference summaries. In the following sections, we report results on DUC-04 (trained on DUC-03) and TAC-11 (trained on TAC-08/09/10) as they are the standard test sets (Hong et al., 2014).

4.2 Experimental Settings

Our method of estimating self-containedness uses the pretrained XLNet-LARGE (Yang et al., 2019) to estimate the probability of end-of-sentence markers. We require a candidate segment to contain five or more words. Our classifier is based on the BERT-BASE model and it is fine-tuned for two epochs on

Human Abstract

- Exxon and Mobil discuss combining business operations.
- A possible Exxon-Mobil merger would reunite 2 parts of Standard Oil broken up by the Supreme Court in 1911.
- Low crude oil prices and the high cost of exploration are motives for a merger that would create the world's largest oil company.
- As Exxon-Mobil merger talks continue, stocks of both companies surge.
- The merger talks show that corporate mergers are back in vogue.
- Antitrust lawyers, industry analysts, and government officials say a merger would require divestitures.
- A Mobil employee worries that a merger would put thousands out of work, but notes that his company's stock would go up.

Highlighting (Tree Segments)

- Whether or not the talks between Exxon and Mobil lead to a merger or some other business combination, America's economic history is already being rewritten.
- The boards of Exxon Corp. and Mobil Corp. are expected to meet Tuesday to consider a possible merger agreement that would form the world's largest oil company, a source close to the negotiations said Friday.
- Exxon Corp. and Mobil Corp. have held discussions about combining their business operations, a person involved in the talks said Wednesday.
- News that Exxon and Mobil, two giants in the energy patch, were in merger talks last week is the biggest sign yet that corporate marriages are back in vogue. (Rest omitted.)

Highlighting (XLNet Segments)

- Whether or not the talks between Exxon and Mobil lead to a merger or some other business combination, America's economic history is already being rewritten.
- Still, it boggles the mind to accept the notion that hardship is driving profitable Big Oil to either merge, as British Petroleum and Amoco have already agreed to do, or at least to consider the prospect, as Exxon and Mobil are doing.
- Oil stocks led the way as investors soaked up the news of continuing talks between Exxon and Mobil on a merger that would create the world's largest oil company.
- Although the companies only confirmed that they were discussing the possibility of a merger, a person close to the discussions said the boards of both Exxon and Mobil were expected to meet Tuesday to consider an agreement.
- Analysts predicted that there would be huge cuts in duplicate staff from both companies, which employ 122,700 people. (Rest omitted.)

Table 4: Example system outputs for a topic in DUC-04. Our highlighting method is superior to sentence extraction as it allows readers to quickly skim through a large amount of text to grasp the main points. XLNet segments are better than tree segments. Not only can they aid reader comprehension but they are also self-contained and more concise.

the training data. The maximum sequence length of the model is 512 tokens and the batch size is set to 16. We use the Adam optimizer with an initial learning rate of $5e^{-5}$, a warm-up period of 24,400 steps, corresponding to 10% of the training data, and linear decay after that.

4.3 Ground-Truth Segments

Our DPP framework is fully supervised and ground-truth summary segments are required for training the DPP. In an ideal scenario, we would have human annotators to label the ground-truth summary segments for each document set. It is akin to label bounding boxes for objects, which allows an object detector to be trained on millions of training examples (Girshick et al., 2014). Nonetheless, human annotation is tedious, expensive and time-consuming. We cannot afford to have human annotators to label a large number of segments.

We introduce an approximation method instead. First, we greedily select a set of summary sentences from a document set that achieve the highest R-2 F-score with human reference summaries. Secondly, for every summary sentence, we identify a single segment from a collection of over-generated and self-contained segments (§3.1), such that the selected attains the highest R-2 F-score with human summaries. Such segments are labelled as positive. This two-step process allows for easy generation of ground-truth summary segments.

4.4 Summarization Results

We compare our method with strong extractive and abstractive summarization systems for multi-document summarization, results are shown in Tables 3 and 5. *DPP* (Kulesza and Taskar, 2012) and variant *DPP-BERT* (Cho et al., 2019b) use determinantal point processes to extract *whole sentences* from a set of documents. *SumBasic* (Vanderwende et al., 2007) is an extractive approach leveraging the

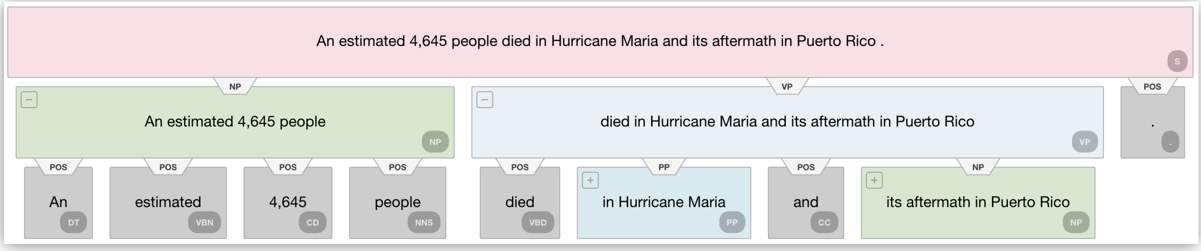

Figure 3: Example of a constituent parse tree, from which tree segments are extracted.

Segments and Scores of Self-Containedness		
1.	0.646	winter storms hit during one of the year's busiest travel weeks
2.	0.644	storms hit during one of the year's busiest travel weeks
3.	0.584	of the year's busiest travel weeks
4.	0.525	one of the year's busiest travel weeks
...	...	...
10.	0.132	and hundreds of flights have been canceled as winter storms hit during one of the year's busiest travel weeks
11.	0.122	and hundreds of flights have been canceled as winter storms hit
...	...	...
150.	0.0019	of flights have been canceled as winter
151.	0.0014	Some interstates are closed and hundreds of flights have been canceled as winter
152.	0.0013	hundreds of flights have been canceled as winter
153.	0.0008	are closed and hundreds of flights have been canceled as winter

Table 6: Examples of segments generated by XLNet and their scores of self-containedness.

fact that frequently occurring words are more likely to be included in the summary. *KL-Sum* (Haghighi and Vanderwende, 2009) is a greedy approach that iteratively adds sentences to the summary to minimize KL divergence. *LexRank* (Erkan and Radev, 2004) is a graph-based approach estimating sentence importance based on eigenvector centrality. All of these methods extract whole sentences rather than segments from a set of documents.

We further consider abstractive summarization methods. *Opinosis* (Ganesan et al., 2010) creates a word co-occurrence graph and searches for a graph path to generate an abstract. *PointerGen* (See et al., 2017) learns to reuse source words or predict new words. The documents are concatenated to serve as input. *CopyTrans* (Gehrmann et al., 2018) uses a 4-layer Transformer for the encoder and decoder. *Hi-MAP* (Fabbri et al., 2019) introduces an end-to-end hierarchical attention model to generate abstracts from multi-document inputs.

We explore two variants of our proposed method, called *HL-XLNetSegs* and *HL-TreeSegs*, focusing on highlighting summary segments. The former utilizes XLNet to extract a set of partially-overlapping segments from a sentence; the latter decomposes a sentence constituent parse tree into subtrees and collect text segments governed by the subtrees. An illustration is shown in Figure 3. Constituent parse trees are obtained using the Stanford parser (Manning et al., 2014). In both cases, the segments are passed to DPP, which identifies a set of important and non-redundant segments as highlights.

	DUC	TAC
# Words per XLNet segment	9.55	8.05
# XLNet segments per sentence	2.48	2.49
# Total segments per document set	398	352
# Summary segments per document set	9.62	9.09
# Words per tree segment	12.89	13.94
# Tree segments per sentence	3.31	3.33
# Total segments per document set	549	478
# Summary segments per document set	13.68	16.56

Table 7: Statistics of text segments generated by XLNet and the constituent parse tree method on DUC/TAC datasets.

As shown in Tables 3 and 5, we find both methods to perform competitively with state-of-the-art extractive and abstractive systems, while producing summary segments with simpler structure. Our *HL-XLNetSegs* method achieves the highest scores on DUC-04 and it performs comparable to other systems on TAC-11.[5] It is important to note that breaking a sentence into smaller segments dramatically increases the search space, making it a challenging task to accurately identify summary segments, yet extracting segments remains necessary as whole sentences may contain excessive and unwanted details. The degree of difficulty involved in generating sub-sentence highlights is thus beyond that of sentence selection. A similar finding is reported by (Cheng and Lapata, 2016).

Table 7 presents a direct comparison of XLNet and tree segments on DUC and TAC datasets. We find that XLNet segments are more concise than

---

[5] Our preliminary experiment comparing the quality classifier against that of Cho et al. (2019b) shows that our method obtains significantly better classification accuracy (70% vs. 96%) when evaluated on the CNN/DM test set with balanced positive/negative examples. With a new and improved quality classifier, we expect the current results to surpass that of running the Cho et al. system with self-contained segments.

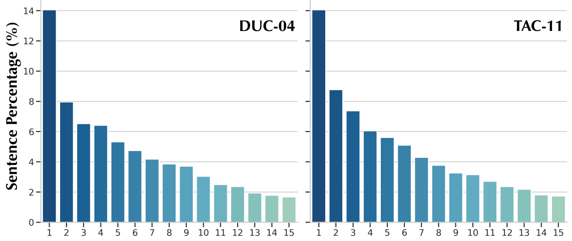

Figure 4: Absolute position of the whole sentence among all segments sorted by XLNet scores of self-containedness.

tree segments. A tree segment contains 13 tokens on average, while an XLNet segment contains 9.6 tokens on DUC-04. Both methods produce a large number of candidate segments, ranging from 350 to 550 segments per document set, with only 9 to 17 ground-truth summary segments per document set. The small ratio poses a substantial challenge for DPP. Not only must it identify salient content but it has to accurately identify the segments worthy of being included in the summary. In Table 4, we show example highlights produced by both methods; more examples are in supplementary.

Segments generated by XLNet are sorted according to their scores of self-containedness, $p(z|\mathbf{x}_{i:j})$. In Table 6, we provide examples of segments and their scores. The higher the score, the more likely the segment resembles a "miniature sentence." We are particularly interested in understanding where the original sentence is placed according to XLNet scores; results are shown in Figure 4. We observe that in 60% of the cases, the original sentence is placed among the top-10 candidates, suggesting the effectiveness of the XLNet model. As segments are shorter and occur more often in natural language texts, it is possible that they are considered more self-contained than the original sentence.

Segments extracted from subtrees are sorted by the depth of tree nodes. The higher nodes are informative constituents denoting complex noun phrases and sentential clauses (Hwa, 1999). An important caveat of the tree segments is their lack of *coverage*. E.g., "*4,645 people died*" is a valid self-contained segment, but it does not belong to a tree constituent, as seen in Figure 3. Given that drawback, we focus on segments created by XLNet in our experiments.[6]

	Self-Containedness Score			
XLNet	$\geq$3(%)	$\geq$4(%)	=5(%)	Average
All Segments	54.86	30.00	10.68	2.80
Top-5 Segments	55.25	30.24	10.78	2.81
Top-3 Segments	**61.04**	**34.04**	**12.42**	**2.95**

Table 8: Human evaluation of the self-containedness of text segments. The top-3 segments of XLNet exhibit a high degree of self-containedness: 61% of them have an average score of 3 or above, 34% have $\geq$4 score, and 12% receive the full score.

[Original Sentence] District Attorney David Roger agreed to drop charges including kidnapping, armed robbery, assault with a deadly weapon and conspiracy against both men.

- District Attorney David Roger agreed to drop charges including kidnapping, armed robbery, assault with a deadly weapon and conspiracy against both men. (4.0)
- District Attorney David Roger agreed to drop charges including kidnapping, armed robbery, assault with a deadly weapon and conspiracy against both men. (3.8)
- District Attorney David Roger agreed to drop charges including kidnapping, armed robbery, assault with a deadly weapon and conspiracy against both men. (3.6)

Table 9: Example text segments produced by the XLNet algorithm. Each segment is judged by five human evaluators on a scale of 1 (worst) to 5 (best) and we report their average scores. Human evaluation suggests that text segments generated by our model demonstrate a high degree of self-containedness.

4.5 Self-Containedness

We perform further analysis to investigate the effectiveness of our method on generating self-contained segments (§3.1). It is impractical to create a gold-standard by asking human annotators to judge all available sentence segments, as the number of segments is polynomial in sentence length. Instead, we perform post-hoc evaluation on segments generated by our XLNet algorithm, which are used as input to DPP. We sample 20 topics from TAC-11, extract 3 sentences from each document for a total of 585 sentences and 1,792 system-generated segments. A human annotator is given the original sentence and its segments and asked to score each segment on a Likert scale of 1 (worst) to 5 (best) for self-containedness. A Likert scale is necessary to accommodate potentially ambiguous cases. We employ 5 human annotators to judge each segment, their average scores are reported in Table 8.

We observe that 61% of top-3 segments have an average score of $\geq$3; 34% have a score $\geq$4; and 12% receive the full score. The human annotators are able to achieve a moderate level of agreement. The standard deviation of their scores is 0.95; 44% of the segments have their majority score agreed by three or more annotators. Table 9 presents example segments and their human assessment scores (more in supplementary). While our summary highlights

---

[6] Extracting propositions from a given sentence is beyond the scope of this paper, as proposition structures given by OpenIE (Banko et al., 2007) or PropS (Stanovsky et al., 2016) are often not consecutive segments of text. Instead, they are presented as relation tuples or directed graphs. Highlighting the proposition structures can cause hundreds of small text chunks to be highlighted in the documents, which may result in undesirable visual effects.

have been evaluated using both standard automatic metrics for assessing the informativeness of the summary and human assessment for judging the well-formedness of individual segments, we hope to explore other methods in future work, including human evaluation of highlights for the entire document set. The task is nontrivial. It requires a well-designed, intuitive graphical user interface for evaluators to read through all source documents and their accompanying summaries/highlights (Elhadad, 2006). Our method constitutes the preliminary step of generating summary highlights. This form of summarization allows readers to grasp the main points while remaining succinct and accessible, offering a promising avenue of research.

5 Conclusion

We make a first attempt to create sub-sentence summary highlights that are understandable and require minimum information from the surrounding context. Highlighting is important to help readers sift through a large amount of texts and quickly grasp the main points. We describe a novel methodology to generate a rich set of self-contained segments from the documents, then use determinantal point processes to identify summary highlights. The method can be extended to other text genres such as public policies to aid reader comprehension, which will be our future work to explore.

Acknowledgments

We are grateful to the anonymous reviewers for their insightful feedback. We thank Chris Wiggins for discussion on the inverted pyramid principle. This research was supported in part by the National Science Foundation grant IIS-1909603.

A Example System Outputs

We present example system outputs contrasting our highlighting method with traditional sentence extraction and human abstraction. Highlighting helps readers quickly skim through a large amount of text to grasp the main points. We observe that the XLNet segments are better than those obtained using the subtree method—not only can they aid reader comprehension but they are also self-contained and more concise. Further, we show example text segments produced by our XLNet algorithm, accompanied by their scores of self-containedness judged by five human evaluators, whose average scores are reported. Results of human evaluation suggest that text segments produced by our model demonstrate a high degree of self-containedness.

Human Abstract

- Exxon and Mobil discuss combining business operations.
- A possible Exxon-Mobil merger would reunite 2 parts of Standard Oil broken up by the Supreme Court in 1911.
- Low crude oil prices and the high cost of exploration are motives for a merger that would create the world's largest oil company.
- As Exxon-Mobil merger talks continue, stocks of both companies surge.
- The merger talks show that corporate mergers are back in vogue.
- Antitrust lawyers, industry analysts, and government officials say a merger would require divestitures.
- A Mobil employee worries that a merger would put thousands out of work, but notes that his company's stock would go up.

Extractive Summary

- The boards of Exxon Corp. and Mobil Corp. are expected to meet Tuesday to consider a possible merger agreement that would form the world's largest oil company, a source close to the negotiations said Friday.
- Exxon and Mobil, the nation's two largest oil companies, confirmed Friday that they were discussing a possible merger, and antitrust lawyers, industry analysts and government officials predicted that any deal would require the sale of important large pieces of such a new corporate behemoth.
- The reported talks between Exxon, whose annual revenue exceeds that of General Electric Co., and Mobil, the No. 2 U.S. oil company, came as oil prices sank to their lowest in almost 12 years.

Highlighting (Tree Segments)

- Whether or not the talks between Exxon and Mobil lead to a merger or some other business combination, America's economic history is already being rewritten.
- The boards of Exxon Corp. and Mobil Corp. are expected to meet Tuesday to consider a possible merger agreement that would form the world's largest oil company, a source close to the negotiations said Friday.
- Exxon Corp. and Mobil Corp. have held discussions about combining their business operations, a person involved in the talks said Wednesday.
- News that Exxon and Mobil, two giants in the energy patch, were in merger talks last week is the biggest sign yet that corporate marriages are back in vogue.
- Shares of Exxon, the biggest U.S. oil company, rose $1.6875, or 2.3 percent, to $74.375.
- Some analysts said that if the two giants reached an agreement, it was likely to be in the form of a takeover by Exxon of Mobil.
- Exxon was then known as Standard Oil of New Jersey, and Mobil consisted of two companies: Standard Oil of New York and Vacuum Oil.
- Which is why Mobil and Exxon are considering combining into the world's largest oil company.

Highlighting (XLNet Segments)

- Whether or not the talks between Exxon and Mobil lead to a merger or some other business combination, America's economic history is already being rewritten.
- Still, it boggles the mind to accept the notion that hardship is driving profitable Big Oil to either merge, as British Petroleum and Amoco have already agreed to do, or at least to consider the prospect, as Exxon and Mobil are doing.
- Oil stocks led the way as investors soaked up the news of continuing talks between Exxon and Mobil on a merger that would create the world's largest oil company.
- Although the companies only confirmed that they were discussing the possibility of a merger, a person close to the discussions said the boards of both Exxon and Mobil were expected to meet Tuesday to consider an agreement.
- Analysts predicted that there would be huge cuts in duplicate staff from both companies, which employ 122,700 people.
- They said the transaction would probably be an exchange of Mobil shares for Exxon shares.
- But this has been a particularly unsettling year for the oil industry, and there is little prospect that crude oil prices will recover soon.
- The merger discussions come against a backdrop of particularly severe pressure on Lucio Noto, the chairman, president and chief executive of Mobil, to find new reserves of oil and natural gas and to keep big projects profitable at a time of a deep decline in crude oil prices.
- If there is a reason this merger might get extra attention, it will be because Exxon and Mobil have not been terribly friendly toward either the Clinton administration's or the European Union's positions on global warming.

Table 10: Example system outputs for a topic in DUC-04. Highlighting allows readers to quickly sift through a large amount of text to grasp the main points. XLNet segments perform better than tree segments. Not only can they aid reader comprehension but they are also self-contained and more concise.

Human Abstract

- After years of civil war, Congo in October 1998 was again in turmoil as rebel forces fought to overthrow the government of President Kabila.
- The rebels, ethnic Tutsis, disenchanted members of Kabila's army and his political opponents, were said to be supported by Rwandan and Ugandan forces while Kabila was backed by Angola, Zimbabwe, Namibia, Sudan and Ugandan rebels.
- Ugandan forces while Kabila was backed by Angola, Zimbabwe, Namibia, Sudan and Ugandan rebels.
- At first the rebels advanced to the outskirts of the capital, Kinshasa, but foreign troops pushed them back to the extreme eastern part of the country.
- The rebels then launched a counter offensive but by mid-October it was not clear who would prevail.

Extractive Summary

- After a day of fighting, Congolese rebels said Sunday they had entered Kindu, the strategic town and airbase in eastern Congo used by the government to halt their advances.
- Rebels in eastern Congo on Saturday said they shot down a passenger jet ferrying 40 government soldiers into a strategic airport facing a rebel assault.
- A rebel defeat, on the other hand, would put the coalition of ethnic Tutsis, disenchanted members of the Congolese army and opposition politicians on the defensive and give a boost to Kabila's efforts to fend off the rebellion launched Aug. 2. Rebel commander Richard Mondo said troops had fired artillery rounds into Kindu Monday and early Tuesday, sending the population fleeing out of town.
- On Saturday, the rebels said they shot down a Congolese Boeing 727 which was attempting to land at Kindu air base with 40 troops and ammunition.

Highlighting (Tree Segments)

- Rebels attacked a village in western Uganda and killed six civilians before soldiers drove them off, a military spokesman said Thursday.
- Congolese rebels have taken their two-month campaign to oust President Laurent Kabila to the Internet.
- A day after shooting down a jetliner, Congolese rebels and their Rwandan allies pushed Sunday through government defense lines, showing the confidence of a victor in a week-old battle for a strategic air base.
- After a day of fighting, Congolese rebels said Sunday they had entered Kindu, the strategic town and airbase in eastern Congo used by the government to halt their advances.
- Rebels in eastern Congo on Saturday said they shot down a passenger jet ferrying 40 government soldiers into a strategic airport facing a rebel assault.
- A day after shooting down a jetliner carrying 40 people, rebels clashed with government troops near a strategic airstrip in eastern Congo on Sunday.
- Kabila has turned Kindu into a launching pad for a counteroffensive against rebel positions in eastern Congo.

Highlighting (XLNet Segments)

- Congolese rebels have taken their two-month campaign to oust President Laurent Kabila to the Internet.
- The bloody bandages of injured rebels trucked back to this rear base Wednesday offered evidence that the three-day battle for the strategic air base at Kindu was not going well for those fighting to oust Congolese President Laurent Kabila.
- Rebels in eastern Congo on Saturday said they shot down a passenger jet ferrying 40 government soldiers into a strategic airport facing a rebel assault.
- After trekking several hundred kilometers through dense tropical forest, thousands of rebel fighters have gathered 19 kilometers outside Kindu, where troops loyal to President Laurent Kabila have used an air base as a launching pad for offensives.
- On Saturday, the rebels said they shot down a Congolese Boeing 727 which was attempting to land at Kindu air base with 40 troops and ammunition.
- President Yoweri Museveni insists they will remain there until Ugandan security is guaranteed, despite Congolese President Laurent Kabila's protests that Uganda is backing Congolese rebels attempting to topple him.
- The rebels see Kindu as a major prize in their two-month revolt against President Laurent Kabila, whom they accuse of mismanagement, corruption and warmongering among Congo's 400 tribes.
- Both countries say they have legitimate security interests in eastern Congo and accuse Kabila of failing to rid the common border area of Rwandan and Ugandan rebels.
- The rebels say they now control one-third of Kindu and are poised to overrun the rest of the town.

Table 11: Example system outputs for a topic in DUC-04. Highlighting allows readers to quickly sift through a large amount of text to grasp the main points. XLNet segments perform better than tree segments. Not only can they aid reader comprehension but they are also self-contained and more concise. Our method further allows multiple segments, denoted by 🟪 and 🟩, to be selected from the same sentence.

Human Abstract

- Eleven countries were to adopt a common European currency, the euro, on Dec. 31, 1998.
- In November and December there were various reactions.
- France made moves toward a pan-European equity market.
- Ten of the countries quickly cut interest rates causing fear of overheating in some economies.
- In Denmark, which had earlier rejected the euro, a majority was now in favor.
- And in faraway China, the euro was permitted in financial exchanges.
- Whatever the outcome, the euro's birthday, Dec. 31, 1998, would be an historical date.
- Some saw it as a step towards political union while others already considered themselves as citizens of Europe.

Extractive Summary

- In a surprise move, nations adopting the new European currency, the euro, dropped key interest rates Thursday, effectively setting the rate that will be adopted throughout the euro zone on Jan. 1.
- The annual inflation rate in the 11 nations that adopt the euro as their shared currency on Jan. 1 fell to 0.9 percent in November, the European Union's statistics agency reported Wednesday.
- Wim Duisenberg, the head of the new European Central Bank, said in an interview published Wednesday that he won't step down after completing half his term as earlier agreed.
- Ten of the 11 countries adopting the euro dropped their interest rate to 3 percent.
- Duisenberg was named this spring as head of the new European Central Bank, which will govern the policies of the euro, the new single currency which goes into effect Jan. 1.

Highlighting (Tree Segments)

- Two days before the new euro currency goes into effect for 11 European Union members, a growing number of Danes believe their country should take part, according to a poll published Tuesday.
- Wim Duisenberg, the head of the new European Central Bank, said in an interview published Wednesday that he won't step down after completing half his term as earlier agreed.
- In a surprise move, nations adopting the new European currency, the euro, dropped key interest rates Thursday, effectively setting the rate that will be adopted throughout the euro zone on Jan. 1.
- Making their first collective decision about monetary policy, the 11 European nations launching a common currency on Jan. 1 cut interest rates Thursday in a surprise move that won market confidence.
- In a surprise move, nations adopting the new European currency, the euro, dropped key interest rates Thursday, effectively setting the rate that will be adopted throughout the euro zone on Jan. 1.
- China made trading in the euro official Monday, announcing authorization for the European common currency's use in trade and financial dealings starting Jan. 1.
- The annual inflation rate in the 11 nations that adopt the euro as their shared currency on Jan. 1 fell to 0.9 percent in November, the European Union's statistics agency reported Wednesday.
- The year 1999 is the official start-up date of the euro, the common European currency that will unite 11 countries monetarily.

Highlighting (XLNet Segments)

- Two days before the new euro currency goes into effect for 11 European Union members, a growing number of Danes believe their country should take part, according to a poll published Tuesday.
- Making their first collective decision about monetary policy, the 11 European nations launching a common currency on Jan. 1 cut interest rates Thursday in a surprise move that won market confidence.
- The annual inflation rate in the 11 nations that adopt the euro as their shared currency on Jan. 1 fell to 0.9 percent in November, the European Union's statistics agency reported Wednesday.
- French authorities said Thursday that the Paris stock exchange would join an alliance between London and Frankfurt that is seen as the precursor of a pan-European market.
- Ten of the 11 countries joining European economic union dropped their key interest rate to 3 percent, with Portugal making the most significant plunge, from 3.75 percent.
- Not only that, the notion of a Europe-wide exchange raises technical questions about the compatibility not just of trading systems but also of the regulations governing stock market operations in the countries that will use the euro beginning in January.

Human Abstract

- Boeing 737-400 plane with 102 people on board crashed into a mountain in the West Sulawesi province of Indonesia, on Monday, January 01, 2007, killing at least 90 passengers, with 12 possible survivors.
- The plane was Adam Air flight KI-574, departing at 12:59 pm from Surabaya on Java bound for Manado in northeast Sulawesi.
- There were three Americans on board, it is not know if they survived.
- The cause of the crash is not known at this time but it is possible bad weather was a factor.

Extractive Summary

- Three Americans were among the 102 passengers and crew on board an Adam Air plane which crashed into a remote mountainous region of Indonesia, an airline official said Tuesday.
- Rescue teams Tuesday found the smoldering wreckage of an Indonesian jetliner that went missing over Indonesia's Sulawesi island during a storm.
- The Indonesian rescue team Tuesday arrived at the mountainous area in West Sulawesi province where a passenger plane with 102 people onboard crashed Monday, finding at least 90 bodies at the scene.
- The Indonesian Navy (TNI AL) has sent two Cassa planes to carry the bodies of five of its members who were killed in a plane crash in the Indonesian island of Sulawesi late Monday.

Highlighting (Tree Segments)

- An Indonesian passenger plane carrying 102 people disappeared in stormy weather on Monday, and rescue teams were sent to search an area where military aviation officials feared the Boeing 737-400 aircraft may have crashed.
- Indonesian Transportation Ministry' s air transportation director general M. Ichsan Tatang said the weather in Polewali of Sulaweisi province was bad when the plane took off from Surabaya.
- Three Americans were among the 102 passengers and crew on board an Adam Air plane which crashed into a remote mountainous region of Indonesia, an airline official said Tuesday.
- An Indonesian passenger plane carrying 102 people disappeared in stormy weather on Monday, and rescue teams were sent to search an area where military aviation officials feared the Boeing 737-400 aircraft may have crashed.
- Rescue teams Tuesday found the smoldering wreckage of an Indonesian jetliner that went missing over Indonesia's Sulawesi island during a storm, officials said.
- Chinese Foreign Minister Li Zhaoxing on Tuesday sent a message of condolences to his Indonesian counterpart Hassan Wirayuda over Monday's plane crash.

Human Abstract

- Internet security needs a global approach because it is a global problem.
- Pakistan tried to block a riot-sparking video and accidentally blocked world YouTube access.
- Internet sabotage shut down digital infrastructure in Estonia and Bangladesh.
- Overseas hackers accessed confidential information from South Korea.
- China and Taiwan are both accused of Internet attacks to steal secret data.
- The U.S. considered including cyberspace regulation in rules of international warfare.
- South Korea's real-name system authenticates identity information on applications for online accounts.
- The UAE is establishing a computer emergency response team.
- Computer whizzes sell security vulnerability information to both software vendors and criminals.

Extractive Summary

- Telecoms and computer executives, legal officials and UN agencies on Friday warned that the world needs to take a global approach to tackling cybercrime and security issues on the Internet.
- Taiwan's Internet market has matured over the past 10 years, but the ratio of Internet users worried about Internet security has risen significantly, according the results of a telephone survey released Sunday by the Ministry of Transportation and Communications (MOTC).
- The National Security Bureau (NSB) has never permitted hacking activities nor any other attack on computer and Internet systems at home or abroad, the NSB said in a news release issued Thursday.
- Since the adoption by the South Korean government in 2005 of the Internet real- name system, people's privacy, reputation and economic rights are better protected, according to the Ministry of Information and Telecommunication.

Highlighting (Tree Segments)

- South Korea's presidential mansion, the Blue House, has come under cyber-attack from overseas hackers who accessed some confidential information, officials said Tuesday.
- The National Security Bureau (NSB) has never permitted hacking activities nor any other attack on computer and Internet systems at home or abroad, the NSB said in a news release issued Thursday.

- But just in the last month, a so-called Floating Eyeballs toy made in China was recalled after it was found to be filled with kerosene, sets of toy drums and a toy bear were also recalled because of lead paint and an infant wrist rattle was recalled because of a choking hazard. (1.4)
- But just in the last month, a so-called Floating Eyeballs toy made in China was recalled after it was found to be filled with kerosene, sets of toy drums and a toy bear were also recalled because of lead paint and an infant wrist rattle was recalled because of a choking hazard. (2.0)

Table 20: Example text segments produced by the XLNet model. The scores of *self-containedness* are shown in parentheses. Each segment is judged by five human evaluators on a scale of 1 (worst) to 5 (best) and we report their average scores. This example is among the worst cases; we use it to illustrate the difficulty of finding self-contained segments in a polynomial space.

Summarizing Text on Any Aspects:
A Knowledge-Informed Weakly-Supervised Approach

Bowen Tan[1], **Lianhui Qin**[2], **Eric P. Xing**[1,3], **Zhiting Hu**[1,4]

Abstract

Given a document and a target aspect (e.g., a topic of interest), aspect-based abstractive summarization attempts to generate a summary with respect to the aspect. Previous studies usually assume a small pre-defined set of aspects and fall short of summarizing on other diverse topics. In this work, we study summarizing on *arbitrary* aspects relevant to the document, which significantly expands the application of the task in practice. Due to the lack of supervision data, we develop a new weak supervision construction method and an aspect modeling scheme, both of which integrate rich external knowledge sources such as ConceptNet and Wikipedia. Experiments show our approach achieves performance boosts on summarizing both real and synthetic documents given pre-defined or arbitrary aspects.[1]

1 Introduction

Remarkable progresses have been made in generating *generic* summaries of documents (Nallapati et al., 2016; See et al., 2017; Narayan et al., 2018), partially due to the large amount of supervision data available. In practice, a document, such as a news article or a medical report, can span multiple topics or aspects. To meet more specific information need in applications such as personalized intelligent assistants, it is often useful to summarize a document with regard to a given aspect, i.e., *aspect-based* summarization.

Recent research has explored the problem of aspect-based abstractive summarization (Krishna and Srinivasan, 2018; Fremann and Klementiev, 2019). A key challenge of the task is the lack of direct supervision data containing documents paired with multiple aspect-based summaries. Previous studies have created synthetic data from generic news summarization corpora which have a small set of aspects (e.g., "sports", "health" and other 4 aspects in (Frermann and Klementiev, 2019)). As a result, models trained on these data tend to be restricted to the pre-defined set and fall short of summarizing on other diverse aspects.

This paper aims to go beyond pre-defined aspects and enable summarization on arbitrary aspects relevant to the document. The arbitrary aspect may not be explicitly mentioned but only implicitly related to portions of the document, and it can be a new aspect not seen during training. To this end, we develop a new approach that integrates rich external knowledge in both aspect modeling and weak supervision construction. Specifically, we derive weak supervisions from a generic summarization corpus, where the ConceptNet knowledge graph (Speer et al., 2017) is used to substantially expand the aspect scope and enrich the supervisions. To assist summarization model to better understand an aspect, especially a previously unseen one, we augment the model inputs with rich aspect-related information extracted from Wikipedia.

Our approach is compatible with any neural encoder-decoder architectures. In this work, we use the large pre-trained BART model (Lewis et al., 2019) and fine-tune with the proposed method. Experiments on real news articles show our approach achieves performance boosts over existing methods. When adapting to the previous synthetic domain, the BART model after fine-tuning with our weak supervisions becomes substantially more data efficient, and outperforms previous best-performing systems greatly using only 0.4% training examples.

2 Related Work

Aspect-based summarization as an instance of controllable text generation (Hu et al., 2017; Ficler and Goldberg, 2017) offers extra controllability compared to generic summarization to ensure concise

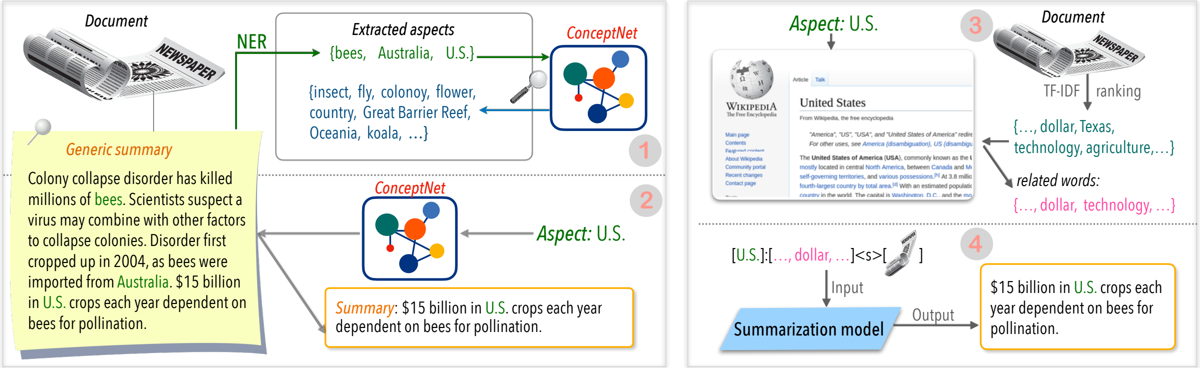
Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6301–6309,
November 16–20, 2020.



Colony collapse disorder has killed millions of bees. Scientists suspect a virus may combine with other factors to collapse colonies. Disorder first cropped up in 2004, as bees were imported from Australia. $15 billion in U.S. crops each year dependent on bees for pollination.

Summary: $15 billion in U.S. crops each year dependent on bees for pollination.

$15 billion in U.S. crops each year dependent on bees for pollination.

Figure 1: Illustration of our approach. **Left:** Constructing weak supervisions using ConceptNet, including (1) extracting aspects and (2) synthesizing aspect-based summaries. **Right:** Augmenting aspect information, including (3) identifying aspect related words in the document using Wikipedia and (4) feeding both aspect and related words into summarization model.

summaries of interest. Early work has studied topic-aware summarization in the multi-document setting, with (typically small) datasets containing multiple documents tagged with a relevant topic (Dang, 2005; Conroy et al., 2006). For single-document aspect-based summarization, *extractive* methods were used to extract related key sentences/words from the document (Lin and Hovy, 2000). Our work studies *abstractive* aspect-based summarization that generates summaries. Deutsch and Roth (2019) studied a sub-task of learning to select information in documents that should be included in the summary. Recent work (Fremann and Klementiev, 2019; Krishna and Srinivasan, 2018) on the problem synthesized training data that use news categories as the aspects and thus have a small pre-defined set of aspects available. We aim to enable summarization on any aspects, and develop new weak supervisions by integrating rich external knowledge.

Aspect-based summarization has also been explored in the customer reviews domain (Hu and Liu, 2004), where product aspects, customer sentiment, and sometimes textual summaries are extracted (Popescu and Etzioni, 2007; Wang and Ling, 2016; Angelidis and Lapata, 2018). Query-based summarization produces a summary in response to a natural language query/question (Daumé III and Marcu, 2006; Liu et al., 2012; Xie et al., 2020) which differs from abstract aspects.

Incorporating knowledge through weak supervision has primarily been studied in classification or extraction problems (Hu et al., 2016; Peng et al., 2016; Ratner et al., 2017). For example, (Hu et al., 2016) creates soft labels from a logical-rule enhanced teacher model to train neural classifiers. This work explores weak supervisions in the generation setting. Automatic creation of data supervisions also links our work to text data augmentation in either heuristic-based (Wei and Zou, 2019) or automated manner (Sennrich et al., 2016; Hu et al., 2019b). This work embeds rich structured knowledge in the data synthesis process.

3 Approach

Given a document and an aspect which can be a word or a phrase, the task aims to generate a summary that concisely describes information in the document that is relevant to the aspect. We present our approach that enables a neural summarization model to summarize on any aspects. The aspect can be any words relevant to (but not necessarily occurring in) the document. Our approach incorporates rich external knowledge sources, including ConceptNet for enriching weak supervisions in training (sec 3.1) and Wikipedia for advising the document-aspect relation to improve comprehension (sec 3.2). Figure 1 shows an overview of our approach.

An advantage of our approach is that it is compatible with any neural summarization architectures, such as the popular encoder-decoders. This enables us to make use of the large pre-trained network BART (Lewis et al., 2019), on which we apply our approach for fine-tuning and improved inference.

3.1 Knowledge-enriched Weak Supervisions

Usually no direct supervision data is available. We start with a generic summarization corpus. Specifically, in this work we use the CNN/DailyMail (Hermann et al., 2015) which consists of a set of *(document, summary)* pairs. Our approach constructs weakly supervised examples by automatically extracting potential aspects and synthesizing aspect-based summaries from the generic summary.

Each resulting aspect and its aspect-based summary are then paired with the document for training.

Extracting Aspects Given a generic summary, we want to extract as many aspects as possible so that the summarization model can see sufficient examples during training. On the other hand, the aspects must be relevant to the generic summary to facilitate synthesizing appropriate summary in the next step. To this end, we first apply a named entity recognition (NER) model[2] to extract a set of entities mentioned in the generic summary. These entities serve as a seed set of aspects. We then augment the seed set by collecting each entity's neighbor concepts on the ConceptNet knowledge graph, as these concepts are semantically closely related to the entity (and thus the generic summary). For example, in Figure 1(1), "insect" is a new aspect from ConceptNet given the seed entity "bees".

Synthesizing Aspect-based Summaries For each aspect, we synthesize a specific summary by extracting and concatenating all relevant sentences from the generic summary. We make use of ConceptNet in a similar way as above. Specifically, a sentence is considered relevant if it mentions the aspect or any of its neighbors on ConceptNet.

The use of ConceptNet greatly augments the supervisions in terms of both the richness of aspects and the informativeness of respective summaries.

3.2 Knowledge-aided Aspect Comprehension

The summarization model is required to precisely locate information in the document that matches the desired aspect. Such comprehension and matching can be challenging, especially with only noisy weak supervisions during training. Our approach facilitates the inference by informing the model with pre-computed document-aspect relations.

Concretely, we extract words from the document which are most *related* to the aspect (more details below), and feed those words into the model together with the aspect and document. In this way, the model is advised which parts of the document are likely to be aspect-related. For the BART architecture, we use an input format as:

`[aspect]:[related words]<s>[doc]`

where `<s>` is a special token for separation.

To determine the related words, the intuition is that the words should be describing or be associated with the aspect. We use the Wikipedia page of the aspect for filtering the words. Besides, we want to select only salient words in the document for a concise summary. Thus, we first rank all words in the document by TF-IDF scores, and select top words that occur in the aspect's Wikipedia page[3].

4 Experiments

Setup We construct weak supervisions from 100K out of 280K (doc, summary) pairs in the training set of the CNN/DailyMail dataset (Hermann et al., 2015). We use the CNN/DailyMail-pretrained BART (Lewis et al., 2019) provided by Fairseq (Ott et al., 2019) as our base summarization model, and fine-tune with our approach implemented using Texar (Hu et al., 2019a). We use Adam optimizer with an initial learning rate of 3e-5, and beam search decoding with a width of 4.

4.1 Studies on Synthetic Domain

We first study on the synthetic data, **MA-News**, introduced in (Frermann and Klementiev, 2019). Although its aspects are restricted to only 6 coarse-grained topics, the synthetic domain facilitates automatic evaluation, providing a testbed for (1) comparison with the previous models and (2) studying the generalization ability of our weak-supervision approach when adapting to the new domain.

Specifically, MA-News is synthesized from CNN/DailyMail by interleaving paragraphs of original documents belonging to different aspects. The assembled document is paired with each component's aspect and generic summary to form an aspect-based summary instance. The dataset has 280K/10K/10K examples in train/dev/test sets, respectively, and contains 6 pre-defined aspects including {"sport", "health", "travel", "news", "science technology", "tv showbiz"}.

Comparisons with previous methods We first compare our approach with the previous summarization models, as shown in Table 1. **(1)** In the first block, `SF` is the best model in (Frermann and Klementiev, 2019) with a customized neural architecture and is trained with the full MA-News training set. **(2)** In the second block, we also train the large BART model with the MA-News training set, either using the full 280K instances or only 1K instances. BART trained with the full set unsurprisingly shows much better results than `SF`, yet the one with the 1K subset falls behind `SF`. **(3)** The third block evaluates our method. `BART Weak-Sup` is fine-tuned only with our

---

[2] https://spacy.io/models/xx

[3] We select $\leq$ 10 words. If the Wikipedia API does not find any page of the aspect, the related word is set to empty.

Models	R-1	R-2	R-L
Lead-3 (2019)	21.50	6.90	14.10
PG-Net (2017)	17.57	4.72	15.94
SF (2019)	28.02	10.46	25.36
BART MA-News-Sup 280K	41.90	20.46	39.06
BART MA-News-Sup 1K	24.58	8.82	22.74
BART Weak-Sup (Ours)	28.56	10.53	25.93
+ MA-News-Sup 1K (Ours)	35.62	15.80	33.01

Table 1: Results (ROUGE) on the MA-News test set. The results of `Lead-3`, `PG-Net` and `SF` are from (Frermann and Klementiev, 2019), where `SF` is the previous best model. Our approach trains with only weak supervisions (sec 3.1) or with additional 1K MA-News supervised training data.

Models	R-1	R-2	R-L
Weak-Sup only	28.56	10.53	25.93
MA-News-Sup 1K	24.58	8.82	22.74
+ Weak-Sup	**35.62**	**15.80**	**33.01**
MA-News-Sup 3K	29.13	11.89	27.02
+ Weak-Sup	**37.17**	**16.84**	**34.40**
MA-News-Sup 10K	39.49	18.71	36.67
+ Weak-Sup	**39.82**	**18.81**	**36.92**

Table 2: Fine-tuning BART on the synthetic domain, evaluated on MA-News test set. `Weak-Sup only` trains BART only with our weak supervisions. `MA-News-Sup 1K` trains with 1K MA-News supervised examples. `+Weak-Sup` trains first with weak supervisions and then supervisedly on MA-News.

weak supervisions (sec 3). Even without using any direct supervision examples in MA-News, the model performs slightly better than `SF`. More interestingly, by further using only 1K MA-News instances to continue fine-tuning the model, we achieve performance boosts compared to both `SF` and `BART MA-News-Sup 1K`. This shows our proposed knowledge-informed method provides rich information that helps with the task.

Efficiency of adapting to the domain We continue to study how our weakly supervised method can help with efficient adaptation of BART to the synthetic domain. As shown in Table 2, by fine-tuning BART using more MA-News training data (i.e., `MA-News-Sup 1K`, `3K`, and `10K`), the test performance improves reasonably, as is also shown by the blue curve in Figure 2. However, if we add our proposed weak supervisions (i.e., `+Weak-Sup`), the performance improves much faster, as is also shown by the orange curve in the figure. The enhanced data efficiency validates the effectiveness of the weakly supervised method.

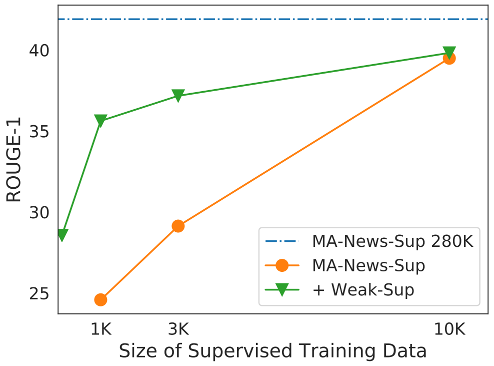


Figure 2: Visualizing the ROUGE-1 results in Table 2. The green dashed line marks the performance of BART fine-tuned on the whole MA-News training set.

Models	Accu.	Info.	Fluency
MA-News-Sup 280K	2.19	3.44	4.44
Weak-Sup (Ours)	**4.59**	**4.36**	**4.87**
+ MA-News 3K (Ours)	4.14	4.07	4.80

Table 3: Human evaluation using 5-point Likert scale. `MA-News 280K` trains BART with the whole MA-News set. `Weak-Sup` trains with our weak supervisions. `+MA-News 3K` further fine-tunes with 3K MA-News instances.

4.2 Summarizing Real News on Any Aspects

We next study summarization of a document on arbitrary aspects. To evaluate the generalization of the methods, we test on real news articles from the *All The News* corpus (Kaggle, 2020) where we randomly extract 50 articles from different publications other than CNN (so that no articles are included in the weak supervision). We ask human annotators to label an arbitrary relevant aspect for each article. We then collect aspect-based summaries by the models, and present each to 3 annotators to rate.

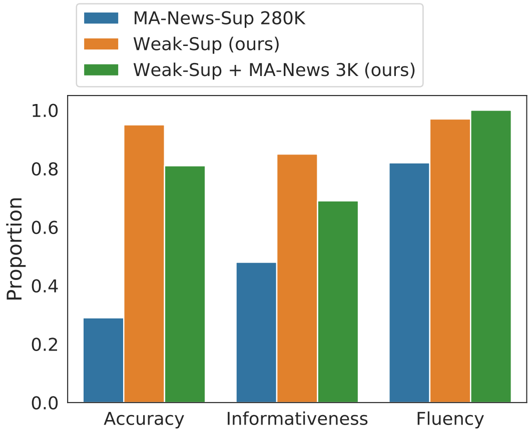

Figure 3: Proportions of model outputs that get a human score ≥ 4. For example, around 95% of summaries by `Weak-Sup (ours)` are scored 4 or 5 in terms of accuracy.

Document In an exclusive interview with Breitbart News, Republican presidential nominee Donald Trump blasted Bill **Clinton**'s suggestion that the United States use **Syrian refugees** to rebuild Detroit. The populist **billionaire** denounced **Clinton**'s suggested proposal as "**crazy**" and "unfair" to **American** workers who are already living there and are in need of **jobs**. "It's very unfair to the **people** that are living there. I think it's crazy," Trump told Breitbart on Thursday. "I mean, these people ... ... "There are plenty of people in Detroit who you could almost look at as refugees," Carson said. "I mean, we need to take care of our own people. We need to create jobs for them. " **Clinton**'s suggestion that the U. S. ought to give Detroit jobs to foreign **refugees** came during a February discussion at the Clinton Global Initiative with Chobani **billionaire** and mass migration enthusiast, Hamdi Ulukaya. "The truth is that the big loser in this over the long run is ... ... a pretty good deal. " During the discussion, **Clinton** praised Ulukaya for his efforts to fill his **yogurt** plants with **imported** foreign **refugees**. Ulukaya suggested that the U. S. ought to be taking in more **refugees** and said that he was "proud" of Turkey's decision to accept 2 million **Syrian refugees**. Ulukaya told **Clinton** that **Syrian refugees** "bring **flavors** to the community just like in . . . Twin Falls, [Idaho]" where Ulukaya's **yogurt** factory is based. Clinton's controversial suggestion that ... ... millions of more illegal immigrants, thousands of more violent crimes, and total chaos and lawlessness. **According** to Pew **polling** data, Hillary Clinton's plan to expand immigration is opposed by at least 83 **percent** of the **American electorate** — **voters** whom Clinton has **suggested** are racist for opposing immigration. **According** to a September 2015 Rasmussen survey, 85 **percent black voters** oppose Clinton's refugee agenda to admit more than 100, 000 Middle Eastern refugees — with less than one **percent** of **black voters** (. 56 **percent**) in **favor** of her refugee plan.

Aspect: Donald Trump

Summary: Presidential nominee Donald Trump calls suggestion that the u.s. use Syrian refugees to rebuild Detroit "crazy" and "unfair" to American workers who are already living there and in need of jobs.

Aspect: Hamdi Ulukaya

Summary: Chobani billionaire and mass migration enthusiast, Hamdi Ulukaya, suggested that the U.S. should take in more refugees to fill jobs like in his yogurt plant in Twin Falls, Idaho, where his factory is based.

Aspect: vote

Summary: Polls show that at least 83 percent of the U.S. electorate is opposed to expanding immigration and that 85 percent of black voters oppose the plan to admit more than 100,000 middle eastern refugees to the country.

Table 4: Generated summaries of a document on different aspects. Document content relevant to specific aspects is highlighted in respective colors. "Related words" identified through Wikipedia (sec 3.2) are highlighted in **bold**.

As in previous work (Kryscinski et al., 2019; Frermann and Klementiev, 2019), the criteria include *accuracy* (coherence between the aspect and the summary), *informativeness* (factual correctness and relevance of the summary with regard to the document), and *fluency* (language quality of individual sentences and the whole summary). The Pearson correlation coefficient of human scores is 0.51, showing moderate inter-rater agreement. Table 3 shows the averaged scores, and Figure 3 shows the proportions of model outputs receiving high scores in terms of the three criteria. We can see our weakly supervised method performs best. The model trained on the 280K MA-News examples, though performs well on the MA-News test set (Table 1), fails to generalize to the broader set of diverse aspects, showing the importance of introducing rich knowledge in supervisions and inference process for generalization. Interestingly, fine-tuning our model with 3K MA-News instances results in inferior performance, showing the previous synthetic data with limited aspects could restrict generalization to other aspects.

Table 4 shows example summaries by our `Weak-Sup` model. Given an arbitrary aspect (e.g., an entity or a word), the model correctly identifies the related portions in the document and generates a relevant short summary. It is also noticeable that our approach identifies meaningful "related words" using Wikipedia as described in sec 3.2, which help with precise summarization.

5 Conclusions

This paper studies the new problem of summarizing a document on arbitrary relevant aspects. To tackle the challenge of lacking supervised data, we have developed a new knowledge-informed weakly supervised method that leverages external knowledge bases. The promising empirical results motivate us to explore further the integration of more external knowledge and other rich forms of supervisions (e.g., constraints, interactions, auxiliary models, adversaries) (Hu and Xing, 2020; Ziegler et al., 2019) in learning. We are also interested in extending the aspect-based summarization in more application scenarios (e.g., summarizing a document corpus).

A More Experimental Details

We use Adam optimizer with $\beta = (0.9, 0.999)$, $\epsilon = 10^{-8}$, a weight decay of 0.01, and an initial learning rate of 3e-5. For generation, we use beam search decoding with a width of 4 and a length penalty of 2. All experiments are conducted on 4 GTX 1080Ti GPUs.

B More Generation Examples

We provide more generated summaries from our weakly supervised model.

Document In an exclusive interview with Breitbart News, Republican presidential nominee Donald Trump blasted Bill Clinton's suggestion that the United States use Syrian refugees to rebuild Detroit. The populist billionaire denounced Clinton's suggested proposal as "crazy" and "unfair" to American workers who are already living there and are in need of jobs. "It's very unfair to the people that are living there. I think it's crazy," Trump told Breitbart on Thursday. "I mean, these people are getting started — I think it's a very, very hard place to get your start. " "We shouldn't have them [i. e. Syrian refugees] in the country," Trump added. "We don't know who these people are. We have no idea. This could be the all time great Trojan horse. We have no idea who they are. The whole thing is ridiculous. Number one: we should build safe zones over in Syria, that's what we should have, and we should have the Gulf states fund them. It's just crazy. We ought to be building safe zones in Syria and not taking these people in — whether it's Detroit or anywhere else. " and former GOP presidential contender Ben Carson echoed Trump's sentiment in a Friday interview on Breitbart News Daily on SiriusXM Patriot Channel 125. Carson explained that "we need to take care of our own people" and noted that the policies of Democrat politicians have turned many Americans living in Detroit into refugees in their own country. "There are plenty of people in Detroit who you could almost look at as refugees," Carson said. "I mean, we need to take care of our own people. We need to create jobs for them. " Clinton's suggestion that the U. S. ought to give Detroit jobs to foreign refugees came during a February discussion at the Clinton Global Initiative with Chobani billionaire and mass migration enthusiast, Hamdi Ulukaya. "The truth is that the big loser in this over the long run is going to be Syria. This [i. e. the Syrian migrant crisis] is an enormous opportunity for Americans," Clinton said in February. "Detroit has 10, 000 empty, structurally sound houses — 10, 000. And lot of jobs are to be had repairing those houses. Detroit just came out of bankruptcy and the mayor's trying to do an innovative sort of urban homesteading program there. But it just gives you an example of what could be done. And I think any of us who have ever had any personal experience with either Syrian Americans or Syrian refugees think it's a pretty good deal. " During the discussion, Clinton praised Ulukaya for his efforts to fill his yogurt plants with imported foreign refugees. Ulukaya suggested that the U. S. ought to be taking in more refugees and said that he was "proud" of Turkey's decision to accept 2 million Syrian refugees. Ulukaya told Clinton that Syrian refugees "bring flavors to the community just like in … Twin Falls, [Idaho]" where Ulukaya's yogurt factory is based. Clinton's controversial suggestion that U. S. give Detroit jobs to imported foreign refugees has received virtually no media coverage outside of Breitbart News. During his Wednesday immigration policy address, Trump challenged the media to begin asking Hillary Clinton to explain her "radical" immigration platform. The media needs to begin demanding to hear Hillary Clinton's answer on how her policies will affect Americans and their security … These are matters of for our country and its people, and we deserve answers from Hillary Clinton … What we do know, despite the total lack of media curiosity, is that Hillary Clinton promises a radical amnesty combined with a radical reduction in immigration enforcement. The result will be millions of more illegal immigrants, thousands of more violent crimes, and total chaos and lawlessness. According to Pew polling data, Hillary Clinton's plan to expand immigration is opposed by at least 83 percent of the American electorate — voters whom Clinton has suggested are racist for opposing immigration. According to a September 2015 Rasmussen survey, 85 percent black voters oppose Clinton's refugee agenda to admit more than 100, 000 Middle Eastern refugees — with less than one percent of black voters (. 56 percent) in favor of her refugee plan.

Aspect: Donald Trump

Summary: Presidential nominee Donald Trump calls suggestion that the u.s. use Syrian refugees to rebuild Detroit "crazy" and "unfair" to American workers who are already living there and in need of jobs.

Aspect: Hamdi Ulukaya

Summary: Chobani billionaire and mass migration enthusiast, Hamdi Ulukaya, suggested that the U.S. should take in more refugees to fill jobs like in his yogurt plant in Twin Falls, Idaho, where his factory is based.

Aspect: vote

Summary: Polls show that at least 83 percent of the U.S. electorate is opposed to expanding immigration and that 85 percent of black voters oppose the plan to admit more than 100,000 middle eastern refugees to the country.

Document the palestinian authority officially became the 123rd member of the international criminal court on wednesday, a step that gives the court jurisdiction over alleged crimes in palestinian territories. the formal accession was marked with a ceremony at the hague, in the netherlands, where the court is based. the palestinians signed the icc's founding rome statute in january, when they also accepted its jurisdiction over alleged crimes committed "in the occupied palestinian territory, including east jerusalem, since june 13, 2014." later that month, the icc opened a preliminary examination into the situation in palestinian territories, paving the way for possible war crimes investigations against israelis. as members of the court, palestinians may be subject to counter-charges as well. israel and the united states, neither of which is an icc member, opposed the palestinians' efforts to join the body. but palestinian foreign minister riad al-malki, speaking at wednesday's ceremony, said it was a move toward greater justice. "as palestine formally becomes a state party to the rome statute today, the world is also a step closer to ending a long era of impunity and injustice," he said, according to an icc news release. " indeed, today brings us closer to our shared goals of justice and peace." judge kuniko ozaki, a vice president of the icc, said acceding to the treaty was just the first step for the palestinians. "as the rome statute today enters into force for the state of palestine, palestine acquires all the rights as well as responsibilities that come with being a state party to the statute. these are substantive commitments, which cannot be taken lightly," she said. rights group human rights watch welcomed the development. "governments seeking to penalize palestine for joining the icc should immediately end their pressure, and countries that support universal acceptance of the court's treaty should speak out to welcome its membership," said balkees jarrah, international justice counsel for the group. "what's objectionable is the attempts to undermine international justice, not palestine's decision to join a treaty to which over 100 countries around the world are members." in january, when the preliminary icc examination was opened, israeli prime minister benjamin netanyahu described it as an outrage, saying the court was overstepping its boundaries. the united states also said it "strongly" disagreed with the court's decision. "as we have said repeatedly, we do not believe that palestine is a state and therefore we do not believe that it is eligible to join the icc," the state department said in a statement. it urged the warring sides to resolve their differences through direct negotiations. "we will continue to oppose actions against israel at the icc as counterproductive to the cause of peace," it said. but the icc begs to differ with the definition of a state for its purposes and refers to the territories as "palestine." while a preliminary examination is not a formal investigation, it allows the court to review evidence and determine whether to investigate suspects on both sides. prosecutor fatou bensouda said her office would "conduct its analysis in full independence and impartiality." the war between israel and hamas militants in gaza last summer left more than 2,000 people dead. the inquiry will include alleged war crimes committed since june. the international criminal court was set up in 2002 to prosecute genocide, crimes against humanity and war crimes. cnn's vasco cotovio, kareem khadder and faith karimi contributed to this report.

Aspect: palestinian
Summary: palestinian foreign minister: "the world is also a step closer to ending a long era of impunity and injustice". the palestinian authority becomes the 123rd member of the international criminal court. the move gives the court jurisdiction over alleged crimes committed in palestine since june.

Aspect: israel
Summary: israel and the u.s. opposed the palestinians' efforts to join the court, which is based in the netherlands. palestinian foreign minister: "today brings us closer to our shared goals of justice and peace" the court has jurisdiction over alleged crimes committed in the occupied territories since june.

Document Around 1980, Bill Gates gave Microsoft, the company he founded, a : ”A computer on every desk and in every home. ”’ ”But Microsoft CEO Satya Nadella, who in 1992 and rose to the top job in 2014, thinks Gates' famous mission had a big flaw.” ’”When I joined the company in 1992, we used to talk about our mission as putting a PC in every home, and by the end of the decade we have done that, at least in the developed world,” Nadella told published on Monday. ”It always bothered me that we confused an enduring mission with a temporal goal. ”’ ”In other words, Nadella is saying that Gates' vision for the future of Microsoft had a logical stopping point and did not consider what the company's direction would be once the goal was achieved. In the 2000s, under former CEO Steve Ballmer, Microsoft became better known for its efforts to than for innovating.” ’Nadella believes in making Microsoft more driven by a sense of purpose — in 2015, he said was ”to empower every person and every organization on the planet to achieve more.” And he has encouraged the company .’ ”Under Nadella, Microsoft has taken the focus off Windows and the PC and pinned its hopes to the rise of its Azure and Office 365 products, as the company's older businesses stagnate. While this approach hasn't translated to huge revenue growth, it has revitalized the company's image.” ”Gates told USA Today that he enjoys working with Nadella, serving his successor as a special adviser and helping guide the company's investments in technology as it competes with Apple, Google, and Amazon.”

Aspect: innovation
Summary: In the 2000s, under former CEO Steve Ballmer, Microsoft became better known for its efforts to than for innovating. under Nadella, Microsoft has taken the focus off Windows and the PC and pinned its hopes to the rise of its Azure and Office 365 products.

Aspect: apple
Summary: Gates says he enjoys working with Nadella, serving as a special adviser and helping guide the company's investments in technology as it competes with Apple, Google, and Amazon. ‘it always bothered me that we confused an enduring mission with a temporal goal,’ he said.

Document Officials have discovered that Islamic State jihadis have been using a chemistry laboratory at Mosul University to make bombs used by ISIS jihadists throughout the region. “The University of Mosul is the best Daesh research center in the world,” Gen. Hatem Magsosi, Iraq’s main explosives officer, told The Wall Street Journal. “Trainees go to Raqqa, [Syria] then to Mosul university to use the existing facilities. ” ISIS hijacked university chemistry lab in Mosul for making bombs: https: . by @MargaretWSJ @BKesling pic. twitter. — WSJ Think Tank (@WSJThinkTank) April 1, 2016, They have found “ chemical bombs and suicide bomb vests like the ones used in the Brussels attacks and by at least some of the Paris attackers. ” The lab also contained “ explosives and chemical weapons. ” However, officials told the outlet they do not know how much of the facility remains intact currently. The United coalition bombed the university in March. Alumni said the university boasted “a strong reputation around Iraq for its science departments. ” A year ago, the Islamic State established “a research hub in the chemistry lab. ” The terrorist group kept the staff at the university, many who “specialized in organic, industrial and analytical chemistry. ” A raid in Syria in March killed Islamic State’s Abd Mustafa also known as Haji Imam. He taught physics in Iraq before he joined in 2004. Officials put him in prison, but released him in 2012. Then he traveled to Syria, where he eventually joined the Islamic State. Gen. Magsosi said the group places Imam as “the top expert at the Mosul bomb lab. ” The sources told the Journal that the Islamic State used one part of the university for explosives and another for suicide bombs. The Wall Street Journal reports: During the same time frame, there has been a surge in Islamic State’s use of bombs that mix chemical precursors into an explosive powdery substance known as triacetone triperoxide, or TATP, both in Iraq and Europe. It isn’t clear how many of these weapons, if any, can be traced to research or training conducted in Mosul. Gen. Magsosi says that his units called explosives the “Satan Recipe” because they are very hard to detect and they are usually so lethal. The Islamic State captured Mosul, Iraq’s second largest city, in June 2014. Since then, they have destroyed libraries and buildings at the university. Kurdish outlet Rudaw reported last October that the group destroyed the university’s Faculty of Agriculture buildings. In December 2014, ISIS raided the Central Library of Mosul to destroy all books. ‘These books promote infidelity and call for disobeying Allah,” announced a militant to the residents. “So they will be burned. ” The library was “the biggest repository of learning the northern Iraqi town. ” The terrorists destroyed “Iraq newspapers dating to the early 20th century, maps and books from the Ottoman Empire, and book collections contributed by about 100 of Mosul’s establishment families. ” After that raid, the ISIS militants targeted the library at the University of Mosul. They burned science and culture textbooks in front of the students. According to the Boston Globe: A University of Mosul history professor, who spoke on condition he not be named because of his fear of the Islamic State, said the extremists started wrecking the collections of other public libraries last month. He reported particularly heavy damage to the archives of a Sunni Muslim library, the library of the Latin Church and Monastery of the Dominican Fathers, and the Mosul Museum Library with works dating back to 5000 BC. Citing reports by the locals who live near these libraries, the professor added that the militants used to come during the night and carry the materials in refrigerated trucks with license plates. Militants also targeted the public library, which was home to more than 8, 000 rare books and manuscripts. Elderly residents begged the men not to burn the building.

Aspect: chemistry
Summary: Chemistry lab at Mosul University used to make bombs used by ISIS jihadists throughout the region, officials say. Officials say they do not know how much of the facility remains intact currently after coalition bombed the university in March. ISIS used one part of the university for explosives and another for suicide bombs, sources say.

Aspect: europe
Summary: Officials have found chemical bombs and suicide bomb vests like the ones used in the Brussels attacks and by at least some of the Paris attackers. the lab also contained “ explosives and chemical weapons. It is not clear how many of these weapons, if any, can be traced to research or training conducted in the university.

Aspect: book
Summary: Book collections destroyed in front of students at university library in Mosul, Iraq. ISIS has destroyed libraries and buildings at the university since it captured the city in June 2014, including one with works dating back to 5000 BC. Officials say they do not know how much of the facility remains intact currently.

BERT-enhanced Relational Sentence Ordering Network

Abstract

In this paper, we introduce a novel BERT-enhanced Relational Sentence Ordering Network (referred to as BERSON) by leveraging BERT for capturing a better dependency relationship among sentences to enhance the coherence modeling for the entire paragraph. In particular, we develop a new Relational Pointer Decoder (referred as RPD) by incorporating the relative ordering information into the pointer network with a Deep Relational Module (referred as DRM), which utilizes BERT to exploit the deep semantic connection and relative ordering between sentences. This enables us to strengthen both local and global dependencies among sentences. Extensive evaluations are conducted on six public datasets. The experimental results demonstrate the effectiveness and promise of BERSON, showing a significant improvement over the state-of-the-art by a wide margin.

1 Introduction

Coherence modeling is one of the essential aspects of natural language processing (Xu et al., 2019; Mesgar et al., 2019; Moon et al., 2019; Farag and Yannakoudakis, 2019). A coherent text can facilitate understanding and avoid the confusion for reading comprehension. The Sentence Ordering task (Barzilay and Lapata, 2008) aims to reconstruct a coherent paragraph from an unordered set of sentences and has shown to be beneficial to improve the coherence in many NLP tasks including multi-document summarization (Barzilay and Elhadad, 2002; Nallapati et al., 2017), conversational analysis (Zeng et al., 2018), and text generation (Konstas and Lapata, 2013; Holtzman et al., 2018). Table 1 shows an example of this task.

An unordered set of sentences		Coherent paragraph	
1	Dan was walking during the night.	1	Dan was walking during the night.
3	They tried to steal his book bag.	2	A group of thieves surrounded him.
4	A bystander noticed them.	3	They tried to steal his book bag.
2	A group of thieves surrounded him.	4	A bystander noticed them.
5	But she continued to walk away.	5	But she continued to walk away.

Table 1: Illustration of the sentence ordering task. It aims to reorganize an unordered set of sentences into a coherent paragraph.

In recent years, several approaches based on ranking or sorting frameworks have been developed to deal with this task. RankTxNet (Kumar et al., 2020) computes a score for each sentence and sorts these scores with ranking based loss functions. Pairwise Model (Chen et al., 2016) adopts a pairwise ranking algorithm to learn the relative order of each sentence pair. B-TSort (Prabhumoye et al., 2020) predicts the constraint between two sentences and uses the topological sort technique to find the ordering.

On the other hand, to better capture the global coherence, pointer network (Vinyals et al., 2015) has been gradually used for the decoder of the ordering model. It is able to capture the paragraph-level contextual information for generating an ordered sequence with the highest coherence probability (Gong et al., 2016; Logeswaran et al., 2018; Cui et al., 2018; Yin et al., 2019). Further, HAN (Wang and Wan, 2019) and TGCM (Oh et al., 2019) introduce the attention mechanism (Vaswani et al., 2017), and FUDecoder (Yin et al., 2020) proposes pairwise ordering prediction modules to enhance the traditional pointer network.

Despite having achieved great successes, pairwise ranking and pointer network-based ordering approaches have a few problems. The former focuses on learning the local relationship between sentence pairs, but may have trouble in capturing the global interactions among all the sentences. The latter overlooks the importance of learning relative order between sentence pairs through the encoder-decoder, and lacks enough local interac-

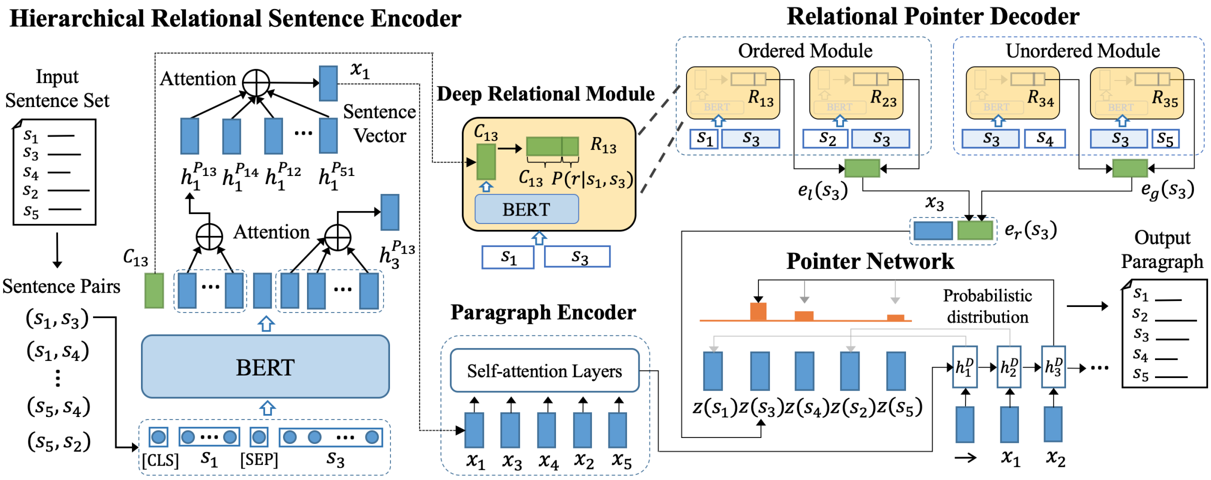

Figure 1: The architecture of the proposed BERSON. Given an unordered set of sentences, our BERT-based Hierarchical Relational Sentence Encoder first builds the high-level representation for each input sentence. Then, a self-attention based paragraph encoder is employed for paragraph encoding. Finally, the proposed Relational Pointer Decoder generates an ordered out sequence. For the sentence generation at the 3rd timestep in the decoder, s_1 and s_2 are the previous sorted sentences, and s_3, s_4, and s_5 are the unsorted ones. Here, we use the candidate sentence s_3 as an example to illustrate how to encode the relative ordering information for it in the pointer network based on Deep Relational Module. Please refer to Section 2.4 for more details of the decoder.

tions among sentences.

To address the above limitations, in this paper, we propose a novel BERT-enhanced Relational Sentence Ordering Network (referred to as BERSON) by integrating BERT (Devlin et al., 2019) with the pointer network to fully exploit the pairwise relationships between sentences for a better coherence modeling. Specifically, we first introduce a BERT-based Hierarchical Relational Sentence Encoder, which uses sentence pairs as the input to the model and learns the high-level representation for each sentence. Next, a Self-Attention based Paragraph Encoder is adopted for paragraph encoding.

Building upon the above pairwise sentence and paragraph encoding, a novel Relational Pointer Decoder (referred to as RPD) is developed by incorporating the informative relative ordering information into the pointer network with a Deep Relational Module (referred to as DRM). This module leverages the Next Sentence Prediction objective of BERT to learn the relative ordering between sentences and constructs a pairwise relationship representation for each sentence pair, which helps RPD not only exploit the global orientation information among unordered sentences but also consider the local coherence between the candidate sentence and the previously sorted ones. Thus, RPD is able to generate a more coherent order assignment for the input sentences. In addition, the pairwise ordering prediction loss is also added as the auxiliary objective to guide the coherence modeling in the training procedure. The overall architecture of our model is presented in Figure 1.

Extensive experiments are conducted on six public datasets in different domains to evaluate the performances of BERSON. The results show that BERSON significantly outperforms the existing approaches by a wide margin and achieves a state-of-the-art performance on all the datasets and under all the evaluation measurements.

2 Relational Sentence Ordering Network

In this section, we start by formulating the sentence ordering problem and then present the proposed model BERSON, which is composed of a BERT-based Hierarchical Relational Sentence Encoder, a Self-Attention based Paragraph Encoder, and a Relational Pointer Decoder enhanced by a new Deep Relational Module to model the text coherence in a more effective way.

2.1 Problem Definition

Given an out-of-order version set of N sentences $\mathbf{s} = [s_1, s_2, \cdots, s_N]$, and $s_i = [w_{i1}, w_{i2}, \cdots, w_{il_i}]$, where l_i is the number of words in sentence s_i. The model aims to recover the correct order $\mathbf{o} = [o_1, o_2, \cdots, o_N]$ for these sentences.

2.2 Hierarchical Relational Sentence Encoder

The sentence encoder is designed based on BERT with sentence pairs in the set as input, and further adopts two-level attention layers to encode the hierarchical semantic concepts and contextual information of the sentence.

Formally, for the given N sentences in the set, all the pair of sentences can be denoted as:

$$P = \left\{P_{ij} | i \in [1, N], j \in [1, N], i \neq j\right\} \tag{1}$$

where P_{ij} represents the sentence pair (s_i, s_j). The total number of sentence pairs is $|P| = A_N^2$. These sentence pairs are sent into BERT to not only learn the sentence representation but also capture the pairwise relationship between sentences.

As shown in the left part of Figure 1, given a sentence pair $P_{ij} = (s_i, s_j)$, the input sequence of this pair to the BERT model consists of a [CLS] token, the first sentence s_i in the pair, a separator token [SEP], and the second sentence s_j. The BERT model encodes the representation for this pair as:

$$\left\{C_{ij}, h_{i1}^{P_{ij}}, \cdots, h_{il_i}^{P_{ij}}, S_{ij}, h_{j1}^{P_{ij}}, \cdots, h_{jl_j}^{P_{ij}}\right\} \tag{2}$$

where C_{ij} and S_{ij} are the final hidden states of the [CLS] and [SEP] tokens, and $\left\{h_{i1}^{P_{ij}}, \cdots, h_{il_i}^{P_{ij}}\right\}$ and $\left\{h_{j1}^{P_{ij}}, \cdots, h_{jl_j}^{P_{ij}}\right\}$ are the output word representations of sentence s_i and s_j in this pair with the sequence length l_i and l_j respectively.

After the BERT encoder, we compose a fixed-dimensional representation for each sentence.

For sentence s_i in pair P_{ij}, the representations $\left\{h_{i1}^{P_{ij}}, \cdots, h_{il_i}^{P_{ij}}\right\}$ of each word are combined together with an attention mechanism to obtain its sentence representation $h_i^{P_{ij}}$:

$$u_{ik} = \tanh\left(W_w h_{ik}^{P_{ij}}\right), \alpha_{ik} = \frac{\exp(v_w u_{ik})}{\sum_{k=1}^{l_i} \exp(v_w u_{ik})}$$
$$h_i^{P_{ij}} = \sum\nolimits_{k=1}^{l_i} \alpha_{ik} h_{ik}^{P_{ij}} \tag{3}$$

where W_w and v_w are learnable parameters. Attention allows the model to concentrate on the informative words for coherence and helps build a better semantic representation. Similarly, we also compute the representation $h_j^{P_{ij}}$ for s_j in pair P_{ij}.

Further, all the sentence pairs related to sentence s_i can be described as: $P_i = \left\{P_{ij} | j \in [1, N], j \neq i\right\} \cup \left\{P_{ki} | k \in [1, N], k \neq i\right\}$. The number of pairs is $2N - 2$. The corresponding sentence representations of s_i obtained from these pairs are given as: $h_i = \left\{h_i^{P_{ij}} | j \in [1, N], j \neq i\right\} \cup \left\{h_i^{P_{ki}} | k \in [1, N], k \neq i\right\}$. We denote $h_i = \left\{h_i^1, \cdots, h_i^{2N-2}\right\}$ for simplification.

Since the sentence embeddings of s_i in different pairs capture different context features, to reward the most salient features that contribute highly to the overall contextual meaning of the sentence, a high-level attention mechanism is adopted to establish the final representation x_i for sentence s_i:

$$u_i^t = \tanh\left(W_s h_i^t\right), \alpha_i^t = \frac{\exp(v_s u_i^t)}{\sum_{t=1}^{2N-2} \exp(v_s u_i^t)}$$
$$x_i = \sum\nolimits_{t=1}^{2N-2} \alpha_i^t h_i^t \tag{4}$$

where W_s and v_s are also trainable weights. Essentially, as all the related sentence pairs are fairly considered, it is ensured that this representation being invariant to the input sentence order and being logically reliable to be used in our model.

2.3 Paragraph Encoder

After the sentence encoder, a self-attention based paragraph encoder is employed to capture the global dependency for all the sentences.

Specifically, the sentence representations obtained from the sentence encoder are packed together into a paragraph matrix $X = [x_1, \cdots, x_N]$ as $X^{(1)}$, which is then sent to L self-attention layers (Vaswani et al., 2017). For the l-th layer, the output matrix $X^{(l)}$ is computed as:

$$\widetilde{X}^{(l)} = \mathrm{LN}(X^{(l-1)} + \mathrm{MultiHead}(X^{(l-1)})) \tag{5}$$
$$X^{(l)} = \mathrm{LN}(\widetilde{X}^{(l)} + \mathrm{FFN}(\widetilde{X}^{(l)})) \tag{6}$$

where MultiHead$(\cdot)$ is multi-head attention function, FFN$(\cdot)$ denotes the fully-connected feed-forward network, and LN$(\cdot)$ is the layer normalization operation (Ba et al., 2016).

The final paragraph vector m is generated by averaging the output matrix $X^{(L)}$ from the last self-attention layer: $m = \frac{1}{N} \sum_{n=1}^{N} X_n^{(L)}$, where $X_n^{(L)}$ is the n-th row in $X^{(L)}$. This vector will then be used as the initial state of our decoder.

2.4 Relational Pointer Decoder

In this section, we propose a Relational Pointer Decoder (RPD), which utilizes the useful relative ordering information to enhance pointer network with a Deep Relational Module (DRM). In the following, we first describe the new module DRM and then incorporate it into the pointer network to strengthen the coherence modeling in the decoder.

2.4.1 Deep Relational Module

Our Deep Relational Module is based on BERT model, which aims to capture a better dependency relationship between sentences. The architecture of this module is shown in the middle part of Figure 1.

In particular, as illustrated in Section 2.2, given the sentence pair P_{ij}, the embedding of the [CLS] symbol from the top layer of BERT is denoted as C_{ij}. Owing to the Next Sentence Prediction pretraining objective of BERT, this vector C_{ij} is able to aggregate the semantic relations for the input sentence pair and is capable of identifying the relative order between two sentences. Therefore, we take full advantages of this vector to exploit the latent dependency for sentences.

Further, a probability distribution $P(r|s_i, s_j)$ is generated, $r \in \{\text{before}, \text{after}\}$, which measures the probability of s_i occuring before or after s_j:

$$P(r|s_i, s_j) = \text{softmax}(W_c C_{ij}) \tag{7}$$

where W_c denotes the learnable weights.

In order to obtain the richer pairwise relation information for the sentence pair, we combine the above semantic feature C_{ij} and the probability distribution together:

$$R_{ij} = \left[C_{ij}; P(r|s_i, s_j)\right] \tag{8}$$

This new vector R_{ij} is considered as the relational representation for this sentence pair (s_i, s_j), which is then leveraged to provide the relative order information for the pointer network. We compute such pairwise relational representation for all the sentence pairs in the paragraph, and utilize the subset of them at each step of the decoder.

Different from the previous method of using the learned sentence vectors to calculate the pairwise relationship between sentences (Yin et al., 2020), DRM employs the whole sequence of the sentence pair as the input to BERT. It allows us to directly relate words from different sentences together, which is more straightforward to exploit the intrinsic relations and coherence between sentences. Further, instead of relying on the modules trained from scratch to control the pairwise ordering predictions (Yin et al., 2020), DRM adopts BERT as the main building block to obtain a pairwise relationship representation for the sentence pair. Intuitively, being pre-trained on the large corpus in BERT, this representation encodes more reliable and accurate relative ordering information, and thus is more effective to help determine the pairwise ordering predictions in the decoder.

2.4.2 Integrating DRM with Pointer Network

As illustrated in the right part of Figure 1, Relational Pointer Decoder (RPD) incorporates Deep Relational Module into the pointer network to promote the coherence modeling among sentences.

Formally, the conditional coherence probability of a predicted order $\widehat{\mathbf{o}}$ for the given out-of-order sentence set $\mathbf{s}$ can be computed as:

$$P(\widehat{\mathbf{o}}|\mathbf{s}) = \prod_{i=1}^{N} P(\widehat{o}_i|\widehat{\mathbf{o}}_{<i}, \mathbf{s}) \tag{9}$$

A higher probability indicates a more coherent sentences assignment. We employ an LSTM-based pointer network as the basis of our decoder, and the mathematical formulation for the i-th step in the decoder is:

$$h_i^D = \text{LSTM}(h_{i-1}^D, x_{\widehat{o}_{i-1}}) \tag{10}$$
$$P(\widehat{o}_i|\widehat{\mathbf{o}}_{<i}, \mathbf{s}) = \text{softmax}(g^T \tanh(W_q h_i^D + W_k Z_i))$$

where g, W_q, and W_k are all learnable parameters, h_i^D is the hidden state in the decoder with size d, $h_0^D = m$, and $x_{\widehat{o}_{i-1}}$ is the embedding of the previous predicted sentence $s_{\widehat{o}_{i-1}}$ at step $i-1$. The softmax function produces an output distribution over all unordered sentences (candidate sentences). The one that yields the highest probability from the distribution will be selected at position i.

The matrix Z_i encodes the relationship representation information of the candidate sentence with the other sentences in the set. For one candidate sentence, the other sentences can be divided into two groups: previously sorted subset and unsorted subset. The relative ordering information between the candidate sentence and the two group sentences are captured by the proposed DRM with its two versions: *Ordered Module* and *Unordered Module*, respectively. On the one hand, such modeling helps evaluate the local coherence between the previously sorted sentences and the candidate sentence for investigating the rationality of each candidate choice. On the other hand, the global relative orientation information of other unsorted sentences with respect to the candidate one also provides further clues for the current prediction. Thus, both the local dependency information and the global orientation are fully exploited in RPD.

For the Ordered Module, the pairwise relationships between the predicted sentence $s_{\widehat{o}_{i-1}}$ at step $i-1$ and the candidate sentence s_c can be effectively measured by our deep relational module with the following relational representation:

$$R_{\widehat{o}_{i-1}c} = \left[C_{\widehat{o}_{i-1}c}; P(r|s_{\widehat{o}_{i-1}}, s_c)\right] \tag{11}$$

which not only encodes the semantic relations between two sentences, but also includes the probability of whether sentence s_c truly appears after $s_{\widehat{o}_{i-1}}$ or not. In similar ways, the relational embedding generated with the previous ordered sentences can be described as $\left\{R_{\widehat{o}_1 c}, \cdots, R_{\widehat{o}_{i-1}c}\right\}$. Then, we compose a high-level local coherence representation $e_l(s_c)$ for this candidate sentence by integrating these relational embeddings to summarize the overall local dependency for s_c.

For the Unordered Module, the relative orientation of another unordered sentence s_g with respect to the candidate sentence s_c can also be captured by our relational embedding as:

$$R_{cg} = \left[C_{cg}; P(r|s_c, s_g)\right] \tag{12}$$

Considering all the other unsorted sentences, a hierarchical global orientation representation $e_g(s_c)$ for s_c can be obtained, which is formulated as:

$$e_g(s_c) = \frac{1}{|S_c|} \sum\nolimits_{s_g \in S_c} R_{cg} \tag{13}$$

where S_c is the unordered sentence set except s_c.

Subsequently, to leverage the relative ordering information encoded by Ordered and Unordered Modules simultaneously, the representation $e_l(s_c)$ and $e_g(s_c)$ are integrated together, which allows us to build a more informative relational vector $e_r(s_c)$ for sentence s_c. Finally, a new representation for this candidate sentence s_c is obtained by combining its sentence embedding and relational vector $e_r(s_c)$ together:

$$z(s_c) = [x_c; e_r(s_c)] \tag{14}$$

Such representation is generated for all unsorted sentences, which are then packed into matrix Z_i for order predictions. During inference, we use beam search to select sentences sequentially.

2.5 Model Training

Assume that there are Q paragraphs in the training set $Q = \{(\mathbf{s}, \mathbf{o})\}$. Following the existing ordering networks (Gong et al., 2016; Oh et al., 2019), the model is trained to maximize the coherence probability by minimizing the loss function as follows:

Dataset	Length statistics		Data split			Vocabulary
	mean	max	train	valid	test	
NIPS abstract	6	15	2427	408	377	11505
AAN abstract	5	20	8569	962	2626	34485
NSF abstract	8.9	40	96070	10185	21580	334090
arXiv abstract	5.38	35	884912	110614	110615	64557
SIND	5	5	40155	4990	5055	30861
ROCStory	5	5	78529	9816	9817	33903

Table 2: Summary of datasets used in our experiments.

$$L_c = -\frac{1}{|Q|} \sum\nolimits_{(\mathbf{s},\mathbf{o}) \in Q} \log P(\mathbf{o}|\mathbf{s};\theta) + \frac{\lambda}{2} \|\theta\|_2^2 \tag{15}$$

where θ denotes all the trainable parameters.

To further exploit the correct relative order information, we add the Pairwise Ordering Prediction Loss (Ploss) as an auxiliary objective L_p. It is defined as the cross-entropy loss function optimized by minimizing the negative log-likelihood of each pair's ground-truth relative ordering label $y_{ij} \in [0, 1]$, given the networks prediction $\widehat{y}_{ij}$:

$$\begin{aligned} L_p = -\frac{1}{|Q|}\frac{1}{|P|} \sum_{(\mathbf{s},\mathbf{o}) \in Q} \sum_{P_{ij} \in P} & (-y_{ij} \log P(\widehat{y}_{ij}|P_{ij}) \\ & -(1-y_{ij}) P(1-\widehat{y}_{ij}|P_{ij})) \end{aligned}$$

The final training objective of our model can be formulated as:

$$L = L_C + \alpha L_p \tag{16}$$

where α is the coefficient that makes a balance between the influences of the two loss functions.

3 Experiments

In this section, we empirically evaluate the effectiveness of BERSON in the sentence ordering task.

3.1 Datasets

The experiments are conducted on six public datasets in different domains:

NIPS abstract, AAN abstract, NSF abstract, arXiv abstract: These datasets contain abstracts of research papers. NIPS abstract[1] is from conference papers in NIPS, where papers in years 2005-2013/2014/2015 for training/validation/testing (Logeswaran et al., 2018). AAN abstract (Logeswaran et al., 2018) is collected from ACL Anthology Network corpus. ACL papers published up to year 2010 for training, year 2011 for validation and 2012-2013 for testing. NSF abstract (Logeswaran et al., 2018) is from NSF Research Award abstract dataset, where abstracts in years 1990-1999/2000/2001-2003 for

SIND	2e-5	8	10	1.0
ROCStory	2e-5	16	10	0.6

Table 3: Hyper-parameter settings of our model on each dataset.

training/validation/testing. ArXiv abstract (Gong et al., 2016; Chen et al., 2016) is from arXiv website[2]. The validation and test sets of this dataset are the first and last 10% abstracts from the shuffled data, and the remaining data are for training.

SIND, ROCStory: SIND is a visual storytelling dataset[3] (Huang et al., 2016), which is released as training/validation/testing following the 8:1:1 split. ROCStory is a commonsense story dataset[4] (Wang and Wan, 2019; Mostafazadeh et al., 2016). It is randomly split by 8:1:1 for the training/validation/test sets. Both of two datasets consist of 5 sentences in each story text.

Table 2 shows the details of all the datasets.

3.2 Evaluation Metrics

Following the existing work (Oh et al., 2019), we employ the three most commonly used metrics[5] in this task to assess the model performance:

Accuracy (Acc): This metric calculates the ratio of sentences whose absolute positions are correctly predicted (Logeswaran et al., 2018).

Perfect Match Ratio (PMR): It measures the percentage of the exactly matching orders across all the paragraphs: PMR=$\frac{1}{Q}\sum_{i=1}^{Q}\mathbb{1}(\widehat{\mathbf{o}}^i = \mathbf{o}^i)$, where $\widehat{\mathbf{o}}^i$ and $\mathbf{o}^i$ are the predicted and correct order of the i-th paragraph respectively (Chen et al., 2016).

Kendall's tau (τ): For a paragraph containing N sentences, τ is defined as: $\tau = 1-2\times$ (# *inversions*) $/\binom{N}{2}$, where # *inversions* denotes the number of pairs in the predicted sequence with the incorrect relative order (Lapata, 2003). The score ranges from -1 (the worst) to 1 (the best).

A higher score indicates a better performance for all the metrics.

3.3 Experimental Setup

We adopt the BERT$_{\text{BASE}}$ in the experiment and fine-tune it on each dataset. The paragraph encoder has 2 self-attention layers with 8 heads. The hidden size is 768 and beam size is 16. Adam is employed as the optimizer. To search for the optimal hyper-parameters, we adopt the grid search strategy for learning rate from {2e-5, 5e-5}, batch size from $\{8, 16, 32\}$, the number of epochs from $\{5, 10, 20\}$, and the coefficient α in the loss function from $\{0.2, 0.4, 0.6, 0.8, 1.0\}$. The model with the best performance on the validation set is selected for each setting. The recommended hyper-parameter configuration of the model on each dataset are presented in Table 3. To diminish the effects of randomness in training, the results of our model are averaged with 5 random initializations. For data preprocessing, we use the tokenizer[6] from BERT to preprocess the sentences. The experiments are conducted on GeForce GTX 1080Ti GPU with PyTorch framework .

3.4 Baselines

To demonstrate that BERSON truly improves the sentence ordering performance, we compare it with the state-of-the-art methods in this task, which can be categorized into two classes:

(1) Ranking or Sorting frameworks: Pairwise Model (Chen et al., 2016); RankTxNet (Kumar et al., 2020); B-TSort (Prabhumoye et al., 2020).

(2) Pointer network based models: HAN (Wang and Wan, 2019); LSTM+PtrNet (Gong et al., 2016); V-LSTM+PtrNet (Logeswaran et al., 2018); ATTOrderNet (Cui et al., 2018); SE-Graph (Yin et al., 2019); FUDecoder (Yin et al., 2020); TGCM (Oh et al., 2019).

In addition to the above existing approaches, we also investigate three variants of BERSON.

BertSenPD: This model replaces the ranking module in RankTxNet with the traditional pointer network decoder (PD). Please note that it uses the single sentence rather than sentence pair as the input to BERT to obtain the sentence vector.

BertPairPD, HRSEPD: These two models employ the sentence pair encoding strategy with BERT and utilize PD instead of our RPD as the decoder. HRSEPD adopts the proposed Hierarchical Relational Sentence Encoder (HRSE), while BertPairPD does not have two-level attention layers in the encoder. They aim to investigate the impact of both the Hierarchical Relational Sentence Encoder and the Relational Pointer Decoder.

Table 4: Comparison results for different models on sentence ordering task. The best and second-best results are in bold and underlined respectively.

3.5 Main Results

The experimental results[7] are reported in Table 4. As we see, BERSON achieves the state-of-the-art-performance on all the datasets and under all the evaluation metrics.

The results show that BERSON significantly outperforms all the existing methods by a large margin. BERSON shows remarkable improvements over the existing best systems of 12.39% and 16.77% accuracy score on NIPS and arXiv datasets, and with 15.42%, 11.37%, and even 22.23% gains in PMR score on NIPS, SIND, and ROCStory datasets respectively, which strongly demonstrates the effectiveness of our model[8].

Compared with the existing ranking approaches, our BertSenPD baseline performs much better than RankTxNet with stable improvements, which confirms the superiority of the traditional pointer network to the ranking module used in their model. This could be due to that RankTxNet only computes a score for each sentence in parallel, which overlooks the coherence of the whole predicted sequence and may have trouble in generating a more coherent order assignment. Besides, although B-TSort outperforms RankTxNet with clear improvements, it only considers the sentence-pair interactions and does not take the entire paragraph into account. Therefore, B-TSort is limited by the lack of a global structure and falls behind other baselines for Acc and PMR scores on the large dataset NSF abstract. In contrast, BERSON not only captures the local coherence between every two sentences but also obtains the paragraph-level contextual information for the global dependency, hence being more competitive in the sentence ordering.

In addition, among the pointer network based ordering models, FUDecoder exhibits a better performance. However, the ordering prediction modules of FUDecoder are built based on two non-linear layers trained from scratch and with the learned sentence vectors as the input, which is still difficult to fully explore the latent dependency among sentences. Once these modules are not sufficiently trained especially on small datasets, they may mislead the decoder with the wrong relative orientation information. Our BERSON overcomes the limitation of FUDecoder by utilizing BERT model as the main building block of our DRM to improve the pairwise ordering strategy. As shown in Table 4, BERSON achieves to outperform FUDecoder with significant improvements of about 14.32% and 22.23% PMR score on SIND and ROCStory respectively, which proves the promise of incorporating more reliable ordering module into the decoder to ensure the more accurate relative ordering information.

Moreover, for the variants of our model, BertPairPD and HRSEPD perform better than BertSenPD on all the datasets. This shows that with the sentence pair instead of single sentence as the input to BERT, the model directly builds the inter-

---

[7] The validation results, average runtime, and the number of parameters are reported in Appendix.

[8] Ordering prediction examples from BERSON and several baselines are also shown in Appendix.

Models	arXiv abstract			ROCStory		
	Acc	PMR	τ	Acc	PMR	τ
BertPairPD	71.03	48.98	0.79	78.01	60.39	0.83
HRSEPD	71.65	49.91	0.80	79.81	61.93	0.84

- Ploss	73.99	54.89	0.82	81.63	66.92	0.87

Table 5: Ablation studies on arXiv and ROCStory datasets. We remove various modules and explore their influences to our model.

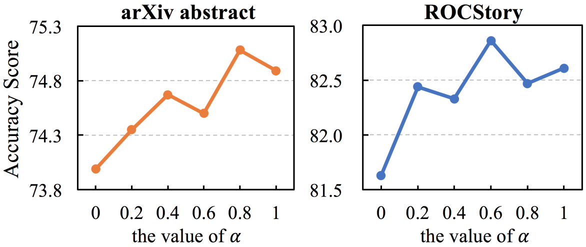

Figure 2: Results of varying the coefficient α for Pairwise Ordering Prediction Loss in our model.

actions between words from different sentences, which is capable of capturing the rich contextual information for each sentence and is more beneficial to modeling the relations among sentences. Besides, HRSEPD outperforms BertPairPD with stable improvements, which reflects the strength of our Hierarchical Relational Sentence Encoder. Furthermore, by adopting our Relational Pointer Decoder to replace the traditional pointer network, BERSON achieves further improvements across the datasets, which demonstrates the advantage of enhancing the pointer network with DRM to reach a superior performance.

3.6 Ablation Study

Further, to better understand the contributions of different components in our Relational Pointer Decoder, we conduct ablation study on arXiv and ROCStory datasets, which are both the largest datasets in the two domains for providing more reliable analysis. The results are reported in Table 5.

Effect of Ordered and Unordered Modules: It is observed that the removal of two modules hurts the model performance dramatically though they still outperform our baseline models BertPairPD and HRSEPD. Compared with Ordered Module, the lack of Unordered Module leads noticeable drops, which indicates that the relative orientations between unsorted sentences are more important for order predictions. The superior performance of BERSON over these two variants shows the necessity of having both modules in RPD to leverage the global orientation and local dependency information simultaneously for a better coherence model.

Models	arXiv abstract		SIND	
	head	tail	head	tail
Pairwise Model	84.85	62.37	-	-
LSTM+PtrNet	90.47	66.49	74.66	53.30
ATTOrderNet	91.00	68.08	76.00	54.42

RankTxNet	92.97	69.13	80.32	59.68
BertSenPD	93.38	72.57	81.46	61.02
BertPairPD	94.01	73.99	82.37	62.24
BERSON	**94.75**	**76.69**	**84.95**	**64.87**

Table 6: Accuracy of predicting the first and the last sentences on arXiv and SIND datasets.

Effect of Pairwise Ordering Prediction Loss: As shown in Table 5, removing the Pairwise Ordering Prediction Loss (Ploss) in the training procedure causes a performance degradation on both datasets. This proves the benefit of encouraging the accurate relative ordering information through the loss function. As the coefficient α in Equation 16 directly controls the impact of Ploss, we further study how the value of this coefficient affects the performance of BERSON. Figure 3 shows the results of accuracy score on arXiv and ROCStory datasets. It is shown that $\alpha = 0.8, 0.6$ is superior to other settings for arXiv and ROCStory respectively. Thus, it is essential to have an appropriate value to balance the importance of Ploss and the original training objective for BERSON.

3.7 Analysis

In this section, we delve into further analysis to investigate the stability and adaptability of the proposed model.

3.7.1 Prediction of First and Last Sentences

Previous studies (Oh et al., 2019; Yin et al., 2019) have mentioned that both the first and last sentences play crucial roles in a paragraph due to their special positions. Thus, we also report the performances of our models in correctly predicting these two sentences on arXiv and SIND datasets. As summarized in Table 6, both of the two variants BertSenPD and BertPairPD outperform the existing state-of-the-arts. BERSON achieves fur-

BERSON	**47.38**	**6.90**	**0.73**	**76.53**	**86.48**

Table 8: Performance for paragraphs containing more than 10 sentences in NIPS and AAN datasets.

ther boosts and reaches the best performances on both datasets. For identifying the last sentence, BERSON obtains significant improvements over RankTxNet of 7.56% and 5.19% gain on arXiv and SIND datasets respectively, which also indicates the benefits of the proposed model.

3.7.2 Sentence Displacement Analysis

Additionally, we analyze the displacement of sentences in the predicted orders by calculating the percentage of sentences whose predicted location is within one, two or three positions from their original location (Prabhumoye et al., 2020). The higher score is better, which denotes less displacement of sentences. As summarized in Table 7, BERSON also achieves a better performance than B-TSort across the datasets and on all the window sizes especially for the smaller ones. BERSON even reaches 99% percent when the window size is 3 on NIPS, AAN, and SIND datasets, which clearly demonstrates the promise of BERSON.

3.7.3 Performance on Longer Paragraphs

Following the prior approach (Prabhumoye et al., 2020), we also evaluate the model performance on paragraphs longer than 10 sentences, which are much challenging for the order prediction. In addition to the three metrics adopted in the previous sections, here we also utilize two other metrics: Longest Common Subsequence (LCS) and Rouge-S for a more comprehensive comparison[9]. Table 8 reports the results on NIPS and AAN datasets. BERSON significantly outperforms B-TSort with all the metrics, showing more than 10% gain in accuracy score on both datasets. Besides, the results of PMR score indicate that it is difficult for B-TSort to exactly match orders for all the sentences, while our BERSON consistently shows a good potential on these longer paragraphs, which proves the stronger ability of BERSON in modeling the long-range dependency across the sentences.

4 Conclusion

In this work, we develop a new BERT-enhanced Relational Sentence Ordering Network (BERSON) by integrating BERT with the pointer network for a better coherence modeling. In particular, a novel Relational Pointer Decoder is developed to incorporate the relative ordering information into the pointer network with a Deep Relational Module, which leverages BERT to fully exploit the pairwise relationships between sentences helping generate an ordered sequence. The experiments on six datasets demonstrate the superiority of BERSON to the baselines, which achieves the state-of-the-art performance across the datasets.

A Appendix

A.1 Case Study

Table 9 reports the sentence ordering results for two examples produced by different models. For the baseline FUDecoder and B-TSort, we ran the public code provided by the authors to generate the order predictions. As we see, in the first example, BERSON achieves to exact match orders for all the sentences while all the baseline methods have some incorrect order predictions. For the second input paragraph, BERSON is able to correctly predict the order for the most of sentences which also shows a better performance than the competing models.

A.2 Two other metrics used in the Analysis

Longest Common Subsequence (LCS): It calculates the percentage of longest correct subsequence between the predicted order and the gold order (Gong et al., 2016). The consecutiveness is not necessary for it[10].

Rouge-S: This metric (Chen et al., 2016; Gong et al., 2016) measures the fraction of pairs of sentences whose predicted relative order is the same as the ground truth order[11]. It allows for any arbitrary gaps between two sentences as long as their relative order is correctly identified.

A higher score is better for both metrics.

A.3 Discussion of Topic Shift Problem

BERSON captures both global and local coherence among sentences, which is effective in reorganizing texts with multiple topics. In particular, the paragraph encoder is able to model the global topic information for all the sentences, which helps guide the order prediction process for the decoder. In addition, building upon the Next Sentence Prediction pre-training objective of BERT, the Deep Relational Module captures the local dependency relationship between each pair of sentences and identifies the tight semantic connections for sentence ordering, especially identifying the sentences containing topic shift clues of the whole text and acting as a link between the preceding and the following topics. Further, the Relational Pointer Decoder leverages both the topical context flows from the previously predicted sequences and from the unsorted sentences to generate an accurate order prediction for these topic-linking sentences and their neighboring ones. Therefore, BERSON is capable of generating a logically consistent output sequence for texts including texts with topic shift.

Example 1	
(4) The reception began with the bride and groom dancing. (2) The bride and groom wrote their own wedding vows. (5) Then, family pictures were taken with the bride and groom. (1) We gathered at the church to celebrate the marriage. (3) They make a handsome couple.	
Ground Truth	(1) (2) (3) (4) (5)
FUDecoder	(1) (2) (5) (4) (3)

Online Conversation Disentanglement with Pointer Networks

Tao Yu¶ and **Shafiq Joty**¶†
¶Nanyang Technological University, Singapore
†Salesforce Research
`{tao003, srjoty}@ntu.edu.sg`

Abstract

Huge amounts of textual conversations occur online every day, where multiple conversations take place concurrently. Interleaved conversations lead to difficulties in not only following the ongoing discussions but also extracting relevant information from simultaneous messages. Conversation disentanglement aims to separate intermingled messages into detached conversations. However, existing disentanglement methods rely mostly on handcrafted features that are dataset specific, which hinders generalization and adaptability. In this work, we propose an end-to-end online framework for conversation disentanglement that avoids time-consuming domain-specific feature engineering. We design a novel way to embed the whole utterance that comprises timestamp, speaker, and message text, and propose a custom attention mechanism that models disentanglement as a pointing problem while effectively capturing inter-utterance interactions in an end-to-end fashion. We also introduce a joint-learning objective to better capture contextual information. Our experiments on the Ubuntu IRC dataset show that our method achieves state-of-the-art performance in both link and conversation prediction tasks.

1 Introduction

With the fast growth of Internet and mobile devices, people now commonly communicate in the virtual world to discuss events, issues, tasks, and personal experiences. Among the various methods of communication, text-based conversational media, such as Internet Relay Chat (IRC), Facebook Messenger, Whatsapp, and Slack, has been and remains one of the most popular choices. Multiple ongoing conversations seem to occur naturally in such social and organizational interactions, especially when the conversation involves more than two participants (Elsner and Charniak, 2010). For example, consider the excerpt of a multi-party conversation in Figure 1 taken from the Ubuntu IRC corpus (Lowe et al., 2015). Even in this small excerpt, there are 4 concurrent conversations (distinguished by different colors) among 4 participants.

Time	Sp	Message Text
02:26	system	===zelot joined the channel
02:26	zelot	hi, where can i get some help in regards to issues with mount?
02:26	TuxThePenguin	After taking it out
02:26	hannasanarion	TuxThePenguin, try booting with monitors connected to motherboard
02:26	pnunn	TuxThePonguin, sounds like there is on board graphics as well, so try that without the card
02:26	pnunn	Yeh, just one monitor though
02:27	hannasanarion	pnunn, right
02:27	TuxThePenguin	Makes sense to me :)
02:27	pnunn	process of elimination.
02:27	TuxThePenguin	Along with Occam's Razor
02:27	Bashing-om	zelot: If you are on a supported release of 'buntu, this is a good place to ask.
02:27	TuxThePenguin	Any solution is most likely the simplest one
02:28	wllrt	I'm a emacs newb and looking to prevent rsi.

Figure 1: An excerpt of a conversation from the Ubuntu IRC corpus (best viewed in color). Same color reflects same conversation. Mentions of names are highlighted.

Identifying or disentangling individual conversations is often considered as a prerequisite for downstream dialog tasks such as utterance ranking and generation (Lowe et al., 2017; Kim et al., 2019). It can also help building other applications such as search, summarization, and question answering over conversations, and support users by providing online help (Joty et al., 2019).

However, often there are no explicit structures or metadata to separate out the individual conversations. Naive heuristics to disentanglement often lead to sub optimal results as Kummerfeld et al. (2019) found that only 10.8% of the conversations

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6321–6330,
November 16–20, 2020.

in the widely used Ubuntu IRC dialog corpus were extracted correctly by the heuristics employed by Lowe et al. (2015, 2017).

Previous studies have therefore investigated traditional machine learning methods with statistical and linguistic features for conversation disentanglement, *e.g.,* (Shen et al., 2006), (Wang and Oard, 2009; Wang et al., 2011b,a), (Elsner and Charniak, 2010, 2011), to name a few. The task is generally solved by first finding links between utterances, and then grouping them into a set of distinct conversations. Recent work by Jiang et al. (2018) and Kummerfeld et al. (2019) adopt deep learning approaches to learn abstract linguistic features and compute message pair similarity. However, these methods heavily rely on hand-engineered features that are often too specific to the particular datasets (or domains) on which the model is trained and evaluated. For example, many of the features used in (Kummerfeld et al., 2019) are only applicable to the Ubuntu IRC dataset. This hinders the model's generalization and adaptability to other domains.

In this work, we propose a more general framework for conversation disentanglement while avoiding time-consuming and domain-specific feature engineering. In particular, we cast link prediction as a pointing problem, where the model learns to point to the parent of a given utterance (Figure 2). Each pointing operation is modeled as a multinomial distribution over the set of previous utterances. A neural encoder is used to encode each utterance text along with its speaker and timestamp. The pointing function implements a custom attention mechanism that models different interactions between two utterances. This results in an end-to-end neural framework that can be optimized with a simple cross entropy loss. During training, we jointly model the reply-to relationship and pairwise relationship (whether two utterances in the same conversation) under the same framework, so that more contextual and structural information can be learned by our model to further improve the disentangling performance.

Furthermore, the framework supports online decoding, which is naturally provided by the pointer network framework, disentangles a conversation as it unfolds, and can provide real-time help to participants in contributing to the right conversations.

We performed extensive experiments on the recently released Ubuntu IRC dataset (Kummerfeld et al., 2019) and demonstrate that our approach outperforms previous methods for both link prediction and conversation prediction tasks.[1] Ablation studies reveal the importance of different components of the model and special handling of self-links. Our framework is generic and can be applied to chat conversations from other domains.

2 Background

In this section, we give a brief overview of previous work on conversation disentanglement and the generic pointer network model.

2.1 Conversation disentanglement

Most existing approaches treat disentanglement as a two-stage problem. The first stage involves *link prediction* that models "reply-to" relation between two utterances. The second stage is a *clustering* step, which utilizes the results from link prediction to construct the individual conversation threads.

For link prediction, earlier methods used discourse cues and content features within statistical classifiers. Elsner and Charniak (2008, 2010) combine conversation cues like speaker, mention, and time with content features like the number of shared words to train a linear classifier.

Recent methods use neural models to represent utterances with compositional features. Mehri and Carenini (2017) pre-train an LSTM network to predict *reply* probability of an utterance, which is then used in a link prediction classifier along with other handcrafted features. Jiang et al. (2018) model high and low-level linguistic information using a siamese hierarchical convolutional network that models similarity between pairs of utterances in the same conversation. The interactions between two utterances is captured by taking element-wise absolute difference of the encoded sentence features along with other handcrafted features. Kummerfeld et al. (2019) uses feed-forward networks with averaged pre-trained word embedding and many hand-engineered features. Tan et al. (2019) used an utterance-level LSTM network, while Zhu et al. (2019) used a masked transformer to get a context-aware utterance representation considering utterances in the same conversation.

Finding a globally optimal clustering solution for conversation disentanglement has been shown to be NP-hard (McCallum and Wellner, 2005). Previous methods focus mostly on approximating the global

---

[1] `https://github.com/vode/onlinePtrNet_disentanglement`

optimal by either using greedy decoding (Wang and Oard, 2009; Elsner and Charniak, 2008, 2010, 2011; Jiang et al., 2018; Aumayr et al., 2011) or training multiple link classifiers to do voting (Kummerfeld et al., 2019). Mehri and Carenini (2017) trained additional classifiers to decide whether an utterance belongs to a conversation or not. Wang et al. (2020) use a multi-task topic tracking framework for conversation disentanglement, topic prediction and next utterance ranking.

Our work is fundamentally different from previous studies in that we treat link prediction as a pointing problem modeled by a multinomial distribution over the previous utterances (as opposed to pairwise binary classification). This formulation allows us to model the global conversation flow. Our method does not rely on any handcrafted features. Each utterance in our method is represented by the utterance text, its speaker and timestamp, which are generic to any conversation. The interactions between the utterances are effectively modeled within the pointer module. Moreover, our framework can work in an end-to-end online setup.

2.2 Pointer Networks

Pointer networks (Vinyals et al., 2015) are a class of encoder-decoder models that can tackle problems where the output vocabulary depends on the input sequence. They use attentions as pointers to the input elements. An encoder network first transforms the input sequence $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ into a sequence of hidden states $\boldsymbol{H} = (\boldsymbol{h}_1, \ldots, \boldsymbol{h}_m)$. At each time step t, the decoder takes the input from the previous step, generates a decoder state $\boldsymbol{d}_t$, and uses it to attend over the input elements. The attention gives a $\mathrm{softmax}$ (multinomial) distribution over the input elements as follows.

$$s_{t,i} = \sigma(\boldsymbol{d}_t, \boldsymbol{h}_i); \quad \boldsymbol{a}_t = \mathrm{softmax}(\boldsymbol{s}_t) \tag{1}$$

where $\sigma(.,.)$ is a scoring function for attention, which can be a neural network or simply a dot product operation. The model uses $\boldsymbol{a}_t$ to infer the output: $\hat{\mathrm{y}}_t = \arg\max(\boldsymbol{a}_t)$.

Similar to the standard pointer network, each pointing mechanism in our approach is modeled as a multinomial distribution over the indices of the input sequence. However, unlike the original pointer network where a decoder state points to an encoder state, in our approach, the current encoder state points to the previous states.

Pointer networks have recently yielded state-of-the-art results in constituency parsing (Nguyen et al., 2020), dependency parsing (Ma et al., 2018), anaphora resolution (Lee et al., 2017), and discourse segmentation and parsing (Lin et al., 2019). To the best of our knowledge, this is the very first work that utilizes a pointer network for conversation disentanglement. It is also a natural fit for online conversation disentanglement.

3 Our Disentanglement Model

Given a sequence of streaming utterances $\mathcal{U} = \{U_1, U_2, \ldots, U_i, \ldots\}$, our task in link prediction (§3.1) is to find the parent utterances $U_{p_i} \subset U_{\leq i}$ that the current utterance U_i replies to. Here, $U_{\leq i}$ refers to all the previous utterances until i, that is, $U_{\leq i} = (U_0, U_1 \ldots, U_i)$. An utterance can reply to itself (*i.e.,* $i = p_i$), for example, the initial message in a conversation or a system message. Besides, one utterance may have multiple parents, and one parent can be replied to by multiple (children) messages. For example, in Figure 1, both `pnunn` and `hannasanarion` reply to `TuxThePonguin`'s message. The case of one message replying to multiple parents is very rare in our corpus (see Table 1).

After link prediction, we employ a decoding algorithm (§3.3) to construct the individual threads.

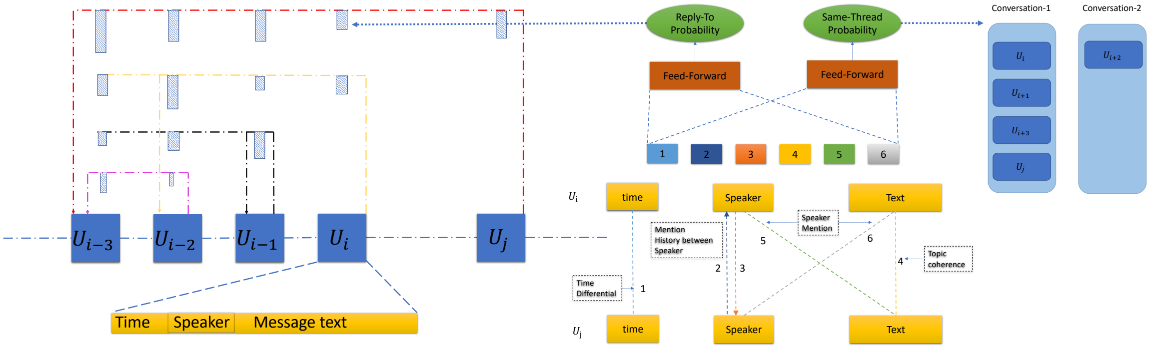
3.1 Link Prediction by Pointing

We propose a joint learning framework for conversation disentanglement based on pointing operations where Figure 2 shows the network architecture. It has three main components: (*a*) an utterance encoder and (*b*) a pointer module (*c*) a pairwise classification model. The job of the utterance encoder is to encode each utterance U_i as it comes, while the the pointer module implements a custom pointing mechanism to find the ancestor message $U_p \in U_{\leq i}$ that U_i replies to. The pairwise classification model is to determine whether two utterances U_i and U_j are in the same conversation or not.

3.1.1 Utterance Encoder

As shown in Figure 1, each utterance U_i has three components $<t_i, s_i, m_i>$: the timestamp t_i when the utterance was posted, the speaker s_i who posted it, and the message content m_i. We encode these three components separately.

Encoding timestamp. The timestamp `hour:min` is directly encoded as a two-dimensional vector $[hour, min]$. For example, timestamp `02:26` is encoded as $[02, 26]$.



(a) (b) (c)

Figure 2: (a) Overview of our Pointer Network joint learning framework for online conversation disentanglement. Each utterance U_i consists of three parts: time (t_i), speaker (s_i) and message text (m_i), which are encoded by the utterance encoder. (b) The Pointer module designs an effective attention mechanism that captures inter-utterance interactions through several features and models link prediction as a multinomial distribution over the previous utterances. (c) The pairwise classification model aims to capture higher-order contextual information. The whole model is trained end-to-end and can decode/disentangle the conversation in an online fashion.

Encoding speaker. In a multi-party conversation, participants mention each other's names to make disentanglement easier, compensating for the lack of visual cues normally present in a face-to-face conversation (O'Neill and Martin, 2003; Elsner and Charniak, 2010). Our goal is to capture the mention relation between utterances in the way we encode the speaker information. For this, each speaker is placed in the same vocabulary as the words, and encoded with a unique identifier (a discrete value).

Encoding message text. We utilize a Bidirectional LSTM or Bi-LSTM (Hochreiter and Schmidhuber, 1997) to encode the raw text message m_i into deep contextual representations of the words. We concatenate the hidden states from both forward and backward LSTM cells. Formally, for a message containing n words $m_i = (w_0, w_1, \dots, w_n)$, the Bi-LSTM gives $\boldsymbol{H} = (\overrightarrow{\boldsymbol{h}}_0 \oplus \overleftarrow{\boldsymbol{h}}_0, \overrightarrow{\boldsymbol{h}}_1 \oplus \overleftarrow{\boldsymbol{h}}_1, \dots, \overrightarrow{\boldsymbol{h}}_n \oplus \overleftarrow{\boldsymbol{h}}_n)$, where $\oplus$ denotes vector concatenation.

3.1.2 Pointer Module

Given the encoded representation of the current utterance U_i, our pointer module computes a probability distribution over the previous utterances $U_{\leq i}$ which represents the probability that U_i replies to an utterance $U_j \in U_{\leq i}$. The module implements an association function between U_i and U_j by incorporating different kinds of interactions. Figure 2(b) gives a schematic diagram of the module, which has five different components:

(*a*) Time difference: The time difference between U_i and U_j is computed as: $\boldsymbol{t}_{i,j} = [\boldsymbol{t}_i - \boldsymbol{t}_j]$.

(*b*) Mention: To determine whether U_i mentions s_j (speaker of U_j) in its message m_i, we compute:

$$mention_{i,j} = \sum_{w_k \in m_i} \mathbb{1}(s_j = \text{Index}(w_k)) \quad (2)$$

where $\mathbb{1}$ is the Indicator function that returns 1 if the index of w_k in m_i matches the speaker id s_j.

(*c*) Mention history: The pointer module also keeps track of mention histories between two speakers. It not only computes whether s_i mentions s_j in m_i, but it also keeps track of whether s_i, s_j mentioned each other in their previous messages and how often. It maintains an external memory $\boldsymbol{M}$ (a matrix) to record this. At each step, we compute both $mention_{i,j}$ and $mention_{j,i}$, and update the memory $\boldsymbol{M}$ to be used in the next step.

$$\boldsymbol{M}_{i,j} = \boldsymbol{M}_{i,j} + \text{mention}_{i,j} \quad (3)$$

$$\boldsymbol{M}_{j,i} = \boldsymbol{M}_{j,i} + \text{mention}_{j,i} \quad (4)$$

The memory $\boldsymbol{M}$ grows incrementally as the model sees new speakers during training and inference.

(*d*) Topic coherence: To model textual similarity between m_i and m_j, we use a similar method as Chen et al. (2016). Let $\boldsymbol{H}_i = (\boldsymbol{h}_{i,0}, \ldots, \boldsymbol{h}_{i,p})$ and $\boldsymbol{H}_j = (\boldsymbol{h}_{j,0}, \ldots, \boldsymbol{h}_{j,q})$ be the Bi-LSTM representations for m_i and m_j, respectively from the utterance encoder layer. We compute soft alignment between m_i and m_i as follows.

$$\boldsymbol{H}_i^{'} = \mathrm{softmax}(\boldsymbol{H}_i \boldsymbol{H}_j^T)\boldsymbol{H}_j \tag{5}$$

$$\boldsymbol{H}_j^{'} = \mathrm{softmax}(\boldsymbol{H}_j \boldsymbol{H}_i^T)\boldsymbol{H}_i \tag{6}$$

In Eq. 5, we use the vectors in $\boldsymbol{H}_i$ as the query vectors to compute attentions over the key/value vectors in $\boldsymbol{H}_j$, and compute a set of attended vectors $\boldsymbol{H}_i^{'} = (\boldsymbol{h}_{i,0}^{'}, \ldots, \boldsymbol{h}_{i,p}^{'})$, one for each $\boldsymbol{h}_i \in \boldsymbol{H}_i$. Eq. 6 does the same thing but uses $\boldsymbol{H}_j$ as the query vectors and $\boldsymbol{H}_i$ as the key/value vectors to compute the attended vectors, $\boldsymbol{H}_j^{'} = (\boldsymbol{h}_{j,0}^{'}, \ldots, \boldsymbol{h}_{j,q}^{'})$.

Then we enhance the interactions by applying difference and element-wise product between the original representation $\boldsymbol{H}$ and the attended representations $\boldsymbol{H}^{'}$ as follows.

$$\boldsymbol{h}_i^f = [\boldsymbol{h}_i; \boldsymbol{h}_i^{'}; \boldsymbol{h}_i - \boldsymbol{h}_i^{'}; \boldsymbol{h}_i \cdot \boldsymbol{h}_i^{'}] \tag{7}$$

$$\boldsymbol{h}_j^f = [\boldsymbol{h}_j; \boldsymbol{h}_j^{'}; \boldsymbol{h}_j - \boldsymbol{h}_j^{'}; \boldsymbol{h}_j \cdot \boldsymbol{h}_j^{'}] \tag{8}$$

The final representation $\boldsymbol{h}_{i,j}$ is computed as

$$\boldsymbol{h}_{i,j} = \boldsymbol{h}_i^f \oplus \boldsymbol{h}_j^f \tag{9}$$

where $\oplus$ denotes concatenation.

(*e*) Pointing: After computing the above four types of interactions between each pair of utterances, we concatenate them and feed them into a feed-forward network to compute the pointing distribution over all the previous utterances.

$$\begin{aligned} \boldsymbol{f}_{i,j} = \; & \boldsymbol{t}_{i,j} \oplus mention_{i,j} \oplus mention_{j,i} \\ & \oplus \boldsymbol{M}_{i,j} \oplus \boldsymbol{M}_{j,i} \oplus \boldsymbol{h}_{i,j} \end{aligned} \tag{10}$$

$$\begin{aligned} \mathrm{score}(U_i, U_j) &= \tanh(\boldsymbol{w}^T \boldsymbol{f}_{i,j}) \\ p(U_i, U_j) &= \frac{\exp(\mathrm{score}(U_i, U_j))}{\sum_{s=0}^{i} \exp(\mathrm{score}(U_i, U_s))} \\ & \text{for } j \in (0, ..., i) \end{aligned} \tag{11}$$

where $\boldsymbol{w}$ is a shared linear layer parameter. We use cross entropy (CE) loss for the pointer module.

$$\mathcal{L}_{\text{link}}(\theta) = -\sum_{j=0}^{i} y_{i,j} \log p(U_i, U_j) \tag{12}$$

where $y_{i,j} = 1$ if U_i replies to U_j, otherwise 0, and θ are the model parameters.

3.1.3 Pairwise Classification Model

In the above pointer module, we only consider first-order interaction between two utterances in an online fashion (*i.e.,* looking at only previous utterances). However, higher-order information derived from the entire conversation may provide more contextual information for the model to learn useful disentanglement features. We propose a joint learning framework to consider both first- and higher-order information simultaneously in a unified framework; see Figure 2(b)-(c).

For the higher-order information, we train a binary pairwise classifier that decides whether two utterances should be in the same conversation. For any two arbitrary utterances we use the same feature function from Eq. 10 (*i.e.,* the parameters are shared with the pointer module) and feed them into a binary logistic classifier. The probability of two utterances belongs to the same conversation is:

$$p_{\text{pair}}(U_i, U_j) = \mathrm{sigmoid}(\boldsymbol{w}^T \boldsymbol{f}_{i,j}) \tag{13}$$

where $\boldsymbol{w}$ is the classifier parameter. We use a binary cross entropy loss for this model.

$$\mathcal{L}_{\text{pair}}(\theta) = -y_{i,j} \log \hat{y}_{i,j} - (1 - y_{i,j}) \log(1 - \hat{y}_{i,j}) \tag{14}$$

where $\hat{y}_{i,j} = p_{\text{pair}}(U_i, U_j)$, $y_{i,j} = 1$ if U_i and U_j are in the same conversation, otherwise 0, and θ are the model parameters. Since the pairwise classifier is trained on all possible pairs of utterances in a conversation, it models higher-order information about the conversation clusters.

3.2 Training

The final training loss of our model is:

$$\mathcal{L}(\theta) = \mathcal{L}_{\text{link}}(\theta) + \lambda \mathcal{L}_{\text{pair}}(\theta) \tag{15}$$

where λ is the hyper-parameter for tuning the importance of the pairwise classification loss. We use Glove 128-dimensional word embedding (Pennington et al., 2014), pre-trained by Lowe et al. (2015) on the #Ubuntu corpus. The hidden layers in the Bi-LSTM are of 256 dimensions. We optimize our model using Adam (Kingma and Ba, 2014) optimizer with a learning rate of 1×10^{-5}. For regularization, we set the dropout at 0.2 and L_2 penalize weight with 1×10^{-7}.

3.3 Decoding

Our framework naturally allows us to disentangle the threads in an online fashion. As a new utterance

U_i arrives, the utterance encoder encodes it into a vector. The pointer module then computes a multinomial distribution over the previous utterances $U_{\leq i}$ (Eq. 11) by modelling pair-wise interactions, and then finds the parent message U_{p_i} as follows.

$$p_i = \underset{j=\{0,\dots,i\}}{\arg\max} \; p(U_i, U_j) \tag{16}$$

To the best of our knowledge, this is the first work using an end-to-end framework for online conversation disentanglement. In our analysis of several conversations, we found that the self-links (an utterance pointing to itself) play a crucial role in clustering performance. Mistakes in correctly identifying a self-link will result in two misclusterings. To address this, we did some simple adjustment to our decoding method. We raise the threshold for self-link prediction to make a more conservative prediction of self-links. In particular, during decoding we first find the parent with the highest probability, but if it turns out to be a self-link, we see if the probability passes the preset threshold, otherwise the utterance with the second highest probability will be predicted as the parent. The tuning of the threshold parameter for self-link is done on the development set.

4 Experiment

In this section, we present our experiments — the dataset used, the evaluation metrics, experimental setup, and the results with analysis.

4.1 Dataset

The dataset used for training and evaluation is from (Kim et al., 2019), which is the largest dataset available for conversation disentanglement (Kummerfeld et al., 2019). It consists of multi-party conversations extracted from the #Ubuntu IRC channel. A typical conversation starts with a question that was asked by one participant, and then other participants respond with either an answer or follow-up questions. This leads to a back-and-forth conversation between multiple participants. An example of the Ubuntu-IRC data is shown in Figure 1. We follow the same train, dev, test split as the Dialog System Technology Challenges 8 (DSTC8) (Kim et al., 2019).[2] Table 1 reports the dataset statistics.

	Train	Dev	Test
Total # links	52641	2145	4265
Total # conversations	6201	526	370
Avg link distance	8	8	7
Median link distances	3	3	3
Avg parents per utterance	1.03	1.05	1.04
Avg # of utterances per conv.	9	5	12
Median # of utterances per conv.	5	4	6

Table 1: Statistics of train, dev and test datasets.

4.2 Metrics

We consider two kinds of metrics to evaluate our disentanglement model: link level and conversation level. For link-level, we use precision, recall and F-1 scores. For cluster level evaluation, we use the same clustering metrics from DSTC8 and (Kummerfeld et al., 2019). This includes:

(*a*) Variation of Information (VI). This is a measure of information gain or loss when going from one clustering to another (Meilă, 2007). It is the sum of conditional entropies $H(Y|X) + H(X|Y)$, where X and Y are clusterings of the same set of items. We used the bound for n items that $VI(X;Y) \leq \log(n)$, and present $1 - VI$, so that the larger the value the better.

(*b*) Ajusted Random Index (ARI). A measure (also referred to as **1V1**) (Hubert and Arabie, 1985) between two clusterings by considering all links of samples and counting links that are assigned in the same or different clusters in the predicted and true clusterings. ARI is defined as:

$$\frac{\sum_{ij}\binom{n_{ij}}{2} - [\sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2}]/\binom{n}{2}}{\frac{1}{2}[\sum_i \binom{a_i}{2} + \sum_j \binom{b_j}{2}] - [\sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2}]/\binom{n}{2}}$$

where n_{ij} are number of overlapping links between predicted cluster i and ground truth cluster j, whereas a_i and b_j indicate row and column level summation over n_{ij}.

(*c*) Exact Match F-1. Calculated using the number of perfectly matching conversations, excluding conversations with only one message.

4.3 Models Compared

Feed Forward Model. We use the feed-forward model from (Kummerfeld et al., 2019) as the baseline model, which outperforms previously proposed disentanglement models. For the DSTC8

Table 2: Experimental results on the Ubuntu test set. "T" suffix means the model uses only utterance text. "−T" indicates the model excludes utterance text. "Joint Train" indicates the model is trained with the joint learning objective (Eq. 15), "Self Link" indicate the model is decoded with self-link threshold re-adjustment.

challenge, the author (one of the task organizers) provided a trained model[3], which has two feed-forward layers. The input is 77 hand-engineered features combined with 128 dimension word average embeddings from pre-trained Glove. We will denote this model as FF model below.

Pointer Network. This is our model. For computational simplicity, we did not compute the attention over all the previous utterances, rather we set a fixed window size of 50. This means for the current utterance, we will calculate the attention with itself and 50 previous utterances during training and decoding. In our training data, about 97% of the utterances' parents are located in this window. In the #Ubuntu Data, according to the statistic of Table 1, one utterance only have 1.03 parent utterances on average. So, given an utterance we only predict its most likely parent.

4.4 Results

We present our main results in Table 2. For analysis purposes, in the table we also show the results for two variants of the models: (*i*) when the models consider only the utterance texts, as denoted by (T) suffix; (*ii*) when the models exclude the utterance text, as denoted by (−T) suffix. In addition, we present how the models perform specifically on self-links predictions, as correctly identifying self-links turns out to be quite crucial for identifying the conversations, as we will explain later. We also report the performance of the Siamese hierarchical convolutional neural network (SHCNN) from (Jiang et al., 2018) on #Ubuntu dataset. However, SHCNN mainly focuses on modeling message content representations and only incorporates four context features: speaker identicality, absolute time difference, and the number of duplicate words. So the performance is not as good as the feed-forward model with many hand-engineered features.

Link Prediction. We can see that our Pointer Network has better **link prediction** accuracy compared to the baseline, when it uses the message texts. The reason that the baseline performs slightly better in the absence of message texts is because it uses several meta features from the whole thread that capture more structural information. On the other hand, our model has access to only time and speaker information in the absence of message texts. Thus, we can say that our model can capture textual similarity or topical coherence better compared to the baseline.

Cluster (or Conversation) Prediction. Now if we compare the performance at the **cluster-level**, we see that our model performs much better when it uses only textual information compared to the baseline. In the absence of textual information, it performs on par with the baseline. However, when we compare the full model, we notice that its results are lower in some cluster-level measures (see 'Ptr-Net' results in the last block), which we did not expect given that it has higher accuracy on link prediction. Therefore, we performed a case

Table 4: "+G" indicates replacing self-link prediction with ground truth labels.

study, and the study reveals that one particular kind of links, which we call "self-link", are very crucial to the cluster-level results.

Self-links. Kummerfeld et al. (2019) mention that most of the self-links are system messages like `"===zelot just join the channel"`. However, according to our statistics (shown in Table 3), only 41% self-links are system messages, and we have identified two other types of utterances that reply to themselves:

- *Start of a conversation:* These messages do not reply to any previous message but will be replied afterward.
- *Isolated Messages:* These are non-system messages, but reply to no previous message and never been replied afterwards.

Handling Self-links. To see how much our models get affected by inaccurate self-link predictions, we performed an experiment using ground truth self-links, where we replace those predictions with ground truth self-link. From Table 4, we see that although it shows only 3% improvement on overall link-prediction for our model, but for cluster prediction, it increases by 13% F1 for FF model and 19% for our model. The reason is if a self-link is predicted wrong and the utterance links to another conversation, it may destroy two true positive clusters. So the performance on self-link prediction could be a bottleneck for the clustering task.

Table 5 gives the detailed self-link prediction results for the FF model. This shows that the model can predict the system messages with almost 100% accuracy, but for other kinds of self-links, the performance is not that high. Experimental results in Table 2 show that our proposed Pointer Network has worse results on self-links compared to the FF model (compare "FF" and " Ptr-Net" in the forth and fifth block), which explains why our model does not perform well on clustering metrics.

Link Type	P	R	F1
System Messages	99.0	100	99.5
Start of Topic	75.0	80.0	77.5
Isolated Messages	66.7	80.0	73.3

Table 5: Self-link prediction results for the baseline model (Kummerfeld et al., 2019).

When we do the simple adjustment to our decoding method by raising the threshold for self-link prediction, we see significant improvements in clustering. Note that this adjustment also improves the performance of the baseline (FF+Self-Link).

Joint Learning. The results in Table 2 show that joint learning further improves the clustering result. Combined with joint training, our online decoding algorithm achieves state-of-the-art results.

Ablation Studies. To show the importance of encoding textual and non-texture features like speaker and time, we trained the models with only textual features and without textual features; see the (T) (−T) variants in Table 2.

Intuitively, it is hard for the models to come up with a good prediction with only textual features, since the utterances in the same conversation usually talk about similar topics. This makes it difficult for the models to identify the right parent. Therefore, the results in Table 2 show a huge drop in performance when no speaker and time information are used and only textual features are used (see the first block of results with (T) suffix). This indicates that time and speaker mention information play a crucial role in disentanglement.

Similarly, the performance also goes down for the models when they do not consider textual information; see (−T) variants in Table 2. Although compared to the text only, the drop is less.

5 Conclusion

In this paper, we have proposed a novel online framework for disentangling multi-party conversations. In contrast to previous work, our method reduces the effort of complicated feature engineering by proposing an utterance encoder and a pointer module that models inter-utterance interactions. Moreover, we propose a joint-training framework that enables the pointer network to learn more contextual information. Link prediction in our framework is modeled as a pointing function with a multinomial distribution over previous utterances. We also show that our framework supports online decoding. Extensive experiments have been conducted on the #Ubuntu dataset, which show that our method achieves state-of-the-art performance on both link and conversation prediction tasks without using any handcrafted features.

There are some possible future directions from our work. We have shown in our experiments that self-link predictions have a significant impact on clustering results. This reminds us that neither our and most of the existing methods took good advantage of graph information in disentangling conversations. This can be done in two ways, encoding, and decoding. From the encoding side, it would be ideal to encode an utterance within its context. One challenge for this problem is that conversations are tangled, so sequential encoding methods like the one of (Sordoni et al., 2015) would not be appropriate. From the decoding side, a promising direction would be to make global inference in a more efficient way.

Abstract

In this paper we tackle the task of definition modeling, where the goal is to learn to generate definitions of words and phrases. Existing approaches for this task are discriminative, combining distributional and lexical semantics in an implicit rather than direct way. To tackle this issue we propose a generative model for the task, introducing a continuous latent variable to explicitly model the underlying relationship between a phrase used within a context and its definition. We rely on variational inference for estimation and leverage contextualized word embeddings for improved performance. Our approach is evaluated on four existing challenging benchmarks with the addition of two new datasets, CAMBRIDGE and the first non-English corpus ROBERT, which we release to complement our empirical study. Our Variational Contextual Definition Modeler (VCDM) achieves state-of-the-art performance in terms of automatic and human evaluation metrics, demonstrating the effectiveness of our approach.[1]

1 Introduction

In most current NLP tasks, fixed-length vector representations of words, word embeddings, are used to represent some form of the meaning of the word. In the case of humans, however, oftentimes we will use a sequence of words known as a *definition* —a statement of the meaning for a term— to express meanings of terms (words, phrases, or symbols). It is with this in mind that the question of "Can machines define?" is aimed to be answered with the task of **definition modeling** (Noraset et al., 2017).

Definition modeling can be framed as a task of conditional generation, in which the definition $\mathbf{d}$ of the word or phrase is generated given a conditioning variable $\mathbf{w}$ such as a word's associated word embedding or other representations of context. Current approaches for this task (Noraset et al., 2017; Gadetsky et al., 2018; Ni and Wang, 2017; Ishiwatari et al., 2019) are mainly encoder-decoder based, in which one encodes a contextual representation for a word/phrase $\mathbf{w}$ using a variety of features such as context or character composition, and uses the contextual representation(s) to generate the definition $\mathbf{d}$.

Despite the relative success of existing approaches for definition modelling, their discriminative nature —where distributional-derived information is at one end of the model and lexical information is at the other— limits their power as the underlying semantic representations of the distributional and lexical information are learned in an implicit rather than direct way. For example, although Ishiwatari et al. (2019) successfully showed that both local and global contexts are useful to disambiguate meanings of phrases in certain cases, their approach heavily relies on an attention mechanism to identify semantic alignments between the input phrase and the output definition, which may introduce noise and ultimately be insufficient to capture the entire meaning of each phrase-definition pair.

To tackle this issue, we propose to explicitly model the underlying semantics of phrase-definition pairs by introducing a continuous latent variable $\mathbf{z}$ over a definition space, which is used in conjunction with $\mathbf{w}$ to guide the generation of definition $\mathbf{d}$. The introduction of this latent representation enables us to treat it as a global defining signal during the generation process, complementing existing alignment mechanisms such as the attention.

Although the latent definition variable enables us to explicitly model underlying semantics of context-definition pairs, the incorporation of it into the task renders the posterior intractable. In this paper we recur to variational inference to estimate this in-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6331–6344,
November 16–20, 2020.

tractable posterior, effectively making our model a Conditional Variational Autoencoder and evolving the generation process from $p(\mathbf{d}|\mathbf{w})$ to $p(\mathbf{d}|\mathbf{w}, \mathbf{z})$.

We also note that existing approaches for definition modelling heavily rely on word embeddings, which due to their fixed nature can only capture so much of the semantics, being known to offer limited capabilities when dealing with polysemy. Considering the success of pretrained deep contextualized word representations which by specifically addressing these limitations have been shown to improve performance on a variety of downstream NLP tasks (Peters et al., 2018; Devlin et al., 2018), in this paper we propose a mechanism to integrate deep contextualized word representations in the definition modelling task. Specifically, we successfully leverage BERT (Devlin et al., 2018) as our contextual encoder and our definition encoder to produce representations for $\mathbf{w}$ and $\mathbf{d}$ respectively.

Finally, we develop two new datasets for this task, one derived from the Cambridge Dictionary [2], and the other derived from Le Petit Robert[3]. In summary, our contributions are:

- **Model:** We propose a novel approach for the task of definition modeling, leveraging deep contextualized word representation and the variational encoder-decoder architecture. We achieve new state-of-the-art performance on the definition modeling task, outperforming the previous state-of-the-art by as much as 9 BLEU points on the OXFORD dataset and 22 BLEU points on the ROBERT dataset.
- **Datasets:** We develop two new datasets CAMBRIDGE and ROBERT for this task. With ROBERT, a French dataset, being the first non-English dataset developed for this task.

Datasets and pre-trained models will be publicly released to the greater NLP community to help facilitate further advances on this task upon acceptance of this paper.

2 Related Work

Our work is related to the seminal paper by Hill et al. (2016), who proposed using the definitions found in everyday dictionaries as a means of bridging existing gaps between lexical and phrasal semantics. Effectively, they train a language model to map dictionary definitions to lexical representations of words, presenting the task of reverse dictionaries, where the goal is to return the name of a concept given a definition.

Noraset et al. (2017) later introduced the task of definition modeling, in which a model is tasked with generating a definition for a given word, given its respective embedding. The authors argued that, compared to other related tasks such as word similarity or analogical relatedness, definition generation can be considered a more transparent view of the information captured by an embedding. However, this method does not incorporate contextual information, preventing it from generating appropriate definitions for polysemic words. Addresing this, Gadetsky et al. (2018) studied the problem of polysemy in definition modeling, introducing an attention-based model which uses contextual information determine components in the embedding which may refer to a relevant word meaning.

Ni and Wang (2017) explore a different but related problem, proposing an approach for automatically explaining non-standard English expressions (i.e. slang) in a given sentence. They present a hybrid word-character sequence-to-sequence model that directly explains unseen non-standard expression, garnering reasonable definitions of expressions given their context.

More recently, Ishiwatari et al. (2019) have tackled some of the limitations of previous works on definition modelling and non-standard English expression explanation. Concretely, they note that whenever it is not possible to figure out the meaning of a given expression from its immediate local context, it is common to consult dictionaries for definitions or search documents or the web to find other global context to help in interpretation. In light of this, they introduce the task of describing a given phrase in natural language, based on its local and global contexts. To tackle this the authors introduce a model which consists of two context encoders (one for the local context, and one for the global context) as well as a description decoder. Our proposed model, uses a more practical variational encoder-decoder framework, allowing us to take advantage of explicitly modeling the phrase-definition relationship, while also leveraging deep contextualized word representations for more informative context representations.

---

[2] `https://dictionary.cambridge.org/`

[3] `https://dictionnaire.lerobert.com/`

Finally, our model is also related to Sohn et al. (2015), in which Conditional Variational Autoencoders (CVAEs) —an extension of the original variational autoencoder (VAE) (Kingma and Welling, 2014)— were proposed for generating diverse structured output, mainly in the context of image generation, and visual object segmentation and labeling. Our work is also related to CVAE models that have been developed for the domain of natural language processing, specifically Zhang et al. (2016) who proposed a CVAE in the context of Neural Machine Translation (NMT). As the usage of VAEs has become relatively common, we will omit a detailed explanation of these models, referring readers to Kingma and Welling (2014).

3 Proposed Approach

In a way analogous to previous work (Noraset et al., 2017), our proposed approach is a generative probabilistic model for word definitions, in which the goal is to estimate the probability of generating a definition d, given an input w. Concretely, we propose to directly capture the joint semantics of the (w, d) pairs by introducing a latent variable $\mathbf{z}$ to model the underlying *definition space*. Our proposed generative process can be formulated as follows:

$$p(\mathrm{d}|\mathrm{w}) = \int_z p(\mathrm{d}, z|\mathrm{w}) d_z = \int_z p(\mathrm{d}|z, \mathrm{w}) p(z|\mathrm{w}) d_z \tag{1}$$

where the conditional probability $p(\mathrm{d}|\mathrm{w})$ evolves into $p(\mathrm{d}|\mathrm{w}, \mathrm{z})$, and the generation of the definition d is now conditioned on both the input variable w and our introduced continuous latent variable z.

Since the introduction of our latent variable makes posterior inference intractable, in this paper we resort to variational inference to perform posterior approximation. Effectively, this makes our proposed generative model a CVAE (Sohn et al., 2015) such that the variational lower bound can be formulated as follows:

$$\begin{aligned} \log p(\mathrm{d}|\mathrm{w}) \geq \mathbb{E}_{\mathrm{z} \sim q(\mathrm{z})} \big[\log p(\mathrm{d}|\mathrm{w}, \mathrm{z}) \big] \\ - D_{\mathrm{KL}} \big[q(\mathrm{z}) || p(\mathrm{z}|\mathrm{w}) \big] \end{aligned} \tag{2}$$

where $q(\mathrm{z})$ is the introduced variational approximation to the intractable posterior $p(\mathrm{z}|\mathrm{w}, \mathrm{d})$ and $p(\mathrm{z}|\mathrm{w})$ is the prior distribution. Following previous work (Sohn et al., 2015; Zhang et al., 2016) we let $\mathbf{z}$, $\mathbf{w}$ and $\mathbf{d}$ be random vectors associated to z, w and d respectively, and utilize neural networks to estimate the following components.

- $q(\mathrm{z}) \approx q_\phi(\mathbf{z}|\mathbf{w}, \mathbf{d})$ is our variational approximation for the intractable posterior (the *recognition network*), which we model with a neural network with parameters ϕ. This makes $q_\phi(\mathbf{z}|\mathbf{w}, \mathbf{d})$ a *neural definition inferer*.
- $p(\mathrm{z}|\mathrm{w}) \approx p_\theta(\mathbf{z}|\mathbf{w})$ is a *(conditional) prior network*, parameterized by θ, which in our case can be regarded as a *neural definition prior*.
- $p(\mathrm{d}|\mathrm{w}, \mathrm{z}) \approx p_\theta(\mathbf{d}|\mathbf{w}, \mathbf{z})$ is a *generation network*, parameterized by θ which acts as a *variational definition modeler*.

In the following subsections we give details on how we specifically model each one of these components. With this in mind, we develop the following architecture comprised of 3 major components:

- **Encoders** - This component is comprised of two encoders - one *context encoder* to produce a representation for $\mathbf{w}$ and another *definition encoder* to produce a representation for $\mathbf{d}$ (Section 3.1).
- **Neural Definition Inferer** - This component *infers* the latent representation $\mathbf{z}$ from the representation of the word/phrase —the explicitly modeled prior $p_\theta(\mathbf{z}|\mathbf{w})$— and in conjunction with the definition (the approximated posterior $q_\phi(\mathbf{z}|\mathbf{d}, \mathbf{w})$) (Section 3.2).
- **Variational Definiton Modeler** - This component can be viewed as a decoder which takes in latent representation $\mathbf{z}$ to guide the generation of the target sentence, essentially $p_\theta(\mathbf{d}|\mathbf{w}, \mathbf{z})$ (Section 3.3).

Notation For clarity when explaining the approach, we define the notation conventions we will follow, namely: d refers to dimensions, $\boldsymbol{c}$ refers to the context vectors produced by the attention mechanism, g refers to projections/activations, and $\boldsymbol{h}$ refers to sets of vectors.

3.1 Encoders

3.1.1 Context Encoder

To encode the sequence in which the word in question is used, we adopt the BERT (Devlin et al., 2018) architecture, which is comprised of multiple Transformer (Vaswani et al., 2017) encoder layers pretrained on a masked-language modeling task to encode deep contextual word representations for a given sequence. BERT has also shown to be able to model the relationship between two tasks on pair-wise natural language understanding tasks. It is to this end that we propose the construction of *phrase-context pairs* to leverage this property in the context encoding process.

Inspired by *context-gloss pairs* (Huang et al., 2019) for the task of Word-Sense Disambiguation (WSD), we construct *phrase-context pairs* for our task of definition modeling. Often, there are differences in the word or phrase that we aim to define, and the lexeme form that is used in the context sentence. For example, the lemma *run* has the following forms: *run*, *runs*, *ran* and *running*, which all represent the same lexeme. To account for these discrepancies between the lemma and the lexeme form, we construct the aforementioned *phrase-context pairs*, which are constructed by simply inserting a separator token, denoted as [SEP], between the word/phrase and the context sentence. Below we show how this process would work for an example taken from Cambridge dictionary dataset for the lemma *leave*:

> He *left* a wife and two children.
> ↪ *leave* [SEP] He *left* a wife and two children.

This form of construction for the *phrase-context pairs* comes with the added benefit of querying a sentence for a definition by simply prepending the word/phrase and a seperator token to the context sequence. As we use BERT as our encoder, we are able to leverage its self attentive nature to produce a representation of the word or phrase in question with respect to the context sentence.

As we initialize our context encoder with BERT, the phrase-context pair sequence $c = [w_t, \text{[SEP]}, c_2, \ldots c_{M_c}]$, containing word or phrase w_t, is prepended by a [CLS] token and is appended by a [SEP] token, making $c_0 =$ [CLS] and $c_{M_c} =$ [SEP].

We define this **context encoder** as T_c, which takes in the context sequence c, and returns a sequence of annotation vectors for each token in c. We denote these annotation vectors as as $\boldsymbol{h}_c$, where $\{\boldsymbol{h}_c^{(i)}\}_{i=0}^{M_c} \in \mathbb{R}^{d_c}$ and

$$\boldsymbol{r}_{w_t} = T_c(c)[t] \tag{3}$$

is the t^{th} representation in h_c, representing w_t. In the case that w_t is split into multiple subword tokens by the BERT tokenizer, we set the word representation to be the mean of each of its subword representations. Namely, in the case that w_t is comprised of the n^{th} to the m^{th} subtokens,

$$\boldsymbol{r}_{w_t} = \frac{1}{m-n} \textstyle\sum_{i=n}^{m} T_c(c)[i] \tag{4}$$

3.1.2 Definition Encoder

The definition encoder, which we denote as T_d, is also initialized with BERT. This encoder takes in the definition sequence $d = [d_0, d_1, \ldots, d_{M_e}]$ as input and represents d as:

$$\boldsymbol{r}_d = T_d(d)[0] \tag{5}$$

where $\boldsymbol{r}_d \in \mathbb{R}^{d_e}$. We take the representation (corresponding to the preprended [CLS] token) as a representation for the entire definition sequence.

3.2 Neural Definition Inferer

We formulate the posterior distribution $q_\phi(\mathbf{z}|\mathbf{d}, \mathbf{w})$ and prior distribution $p_\theta(\mathbf{z}|\mathbf{w})$ as multivariate Gaussians with a diagonal covariance matrices. To model these distributions we make use of neural networks, following Zhang et al. (2016).

3.2.1 Neural Definition Posterior

As modeling the true posterior $p(\mathbf{z}|\mathbf{d}, \mathbf{w})$ is generally intractable, to approximate this true posterior, we use a variational distribution, formulated as the following multivariate Gaussian:

$$q_\phi(\mathbf{z}|\mathbf{d}, \mathbf{w}) = \mathcal{N}(\mathbf{z}; \mu(\mathbf{d}, \mathbf{w}), \sigma(\mathbf{d}, \mathbf{w})^2 \mathbf{I}) \tag{6}$$

which is parameterized by the mean and $\mu(\mathbf{d}, \mathbf{w})$ standard deviation $\sigma(\mathbf{d}, \mathbf{w})$, both which are treated as functions of definition $\mathbf{d}$ and phrase $\mathbf{w}$ parameterized by neural networks.

From the neural encoding mechanisms, we gather the definition representation $\boldsymbol{r}_d$, and the context representation $\boldsymbol{r}_{w_t}$. We then concatenate $\boldsymbol{r}_d$ and $\boldsymbol{r}_{w_t}$ and project the resulting vector onto our latent space, setting $\boldsymbol{h}_z = g(\boldsymbol{W}_z[\boldsymbol{r}_{w_t}; \boldsymbol{r}_d] + \boldsymbol{b}_z)$, where $\boldsymbol{W}_z \in \mathbb{R}^{d_z \times (d_e + d_c)}$ is a trainable weight matrix, $\boldsymbol{b}_z \in \mathbb{R}^{d_z}$ is a trainable bias vector and $g(\cdot)$ represents a non-linearity activation. In our experiments we set $g(\cdot)$ to be the $tanh(\cdot)$ activation function, following previous work.

To attain the aforementioned mean and variance vectors parameterizing the variational distribution, setting $\boldsymbol{\mu} = \boldsymbol{W}_\mu \boldsymbol{h}_z + \boldsymbol{b}_\mu$ and $\log \boldsymbol{\sigma}^2 = \boldsymbol{W}_\sigma \boldsymbol{h}_z + \boldsymbol{b}_\sigma$, where $\boldsymbol{W}_\mu, \boldsymbol{W}_\sigma \in \mathbb{R}^{d_z \times d_z}$ are trainable weight matrices parameterizing the projection and $\boldsymbol{b}_\mu, \boldsymbol{b}_\sigma \in \mathbb{R}^{d_z}$ are bias vectors.

In order to make the parameters θ differentiable for gradient descent optimization, we use the "reparameterization trick" (Kingma and Welling, 2014) setting $\boldsymbol{z} = \boldsymbol{\mu} + \boldsymbol{\sigma} \cdot \boldsymbol{e}$, where $\boldsymbol{e} \sim \mathcal{N}(0, \boldsymbol{I})$ is a noise variable sampled from a multivariate Gaussian distribution to derive our latent vector $\boldsymbol{z}$.

3.2.2 Neural Definition Prior

Our prior is a conditional distribution formulated as the following multivariate Gaussian:

$$p_\theta(\mathbf{z}|\mathbf{w}) = \mathcal{N}(\mathbf{z}; \mu'(\mathbf{w}), \sigma'(\mathbf{w})^2 \mathbf{I}) \tag{7}$$

which is parameterized by $\mu'(\cdot)$, and $\sigma'(\cdot)$ which are both solely functions of phrase $\mathbf{w}$. In a similar fashion to the *neural definition posterior*, we make use of a linear projection to project $\boldsymbol{r}_{w_t}$ to the mean vector $\boldsymbol{\mu}'$ and another linear projection to derive the log variance vector. During inference (at test time) when sampling from $p_\theta(\mathbf{z}|\mathbf{w})$, we set our latent vector $\boldsymbol{z}$ to be the mean vector $\boldsymbol{\mu}'$.

To initialize the decoding procedure detailed in the next subsection, we feed the latent representation $\boldsymbol{z}$ and project it to the decoding space setting $\boldsymbol{h}'_d = g(\boldsymbol{W}_d \boldsymbol{z} + \boldsymbol{b}_d)$, where $\boldsymbol{W}_d \in \mathbb{R}^{d_d \times d_z}$ and $\boldsymbol{b}_d \in \mathbb{R}^{d_d}$.

3.3 Variational Definition Modeler

Given phrase $\mathbf{w}$ and latent representation $\mathbf{z}$, the process of definition modeling can be formulated as the following conditional language model:

$$p(\mathbf{d}|\mathbf{w}, \mathbf{z}) = \textstyle\prod_{j=1}^{M_d} p(d_j | d_{<j}, \mathbf{z}, \mathbf{w}) \tag{8}$$

$$p(d_j | d_{<j}, \mathbf{z}, \mathbf{w}) = g_d(\boldsymbol{s}_j, \boldsymbol{c}_j) \tag{9}$$

where g_d is a feed-forward neural network which returns a distribution over the elements in the decoder vocabulary given the context vector $\boldsymbol{c}_j$ (see Eq. 16) and decoder state $\boldsymbol{s}_j$.

During generation of the definition sequence, we want the decoder to rely on all of the encoded components at each timestep. We modify the LSTM Cell (Hochreiter and Schmidhuber, 1997) to encompass previous context vector $\boldsymbol{c}_{j-1}$, and the projected latent definition representation $\boldsymbol{h}'_d$.

Intuitively, at each timestep j, we want the generated token to have the ability to rely on each of these components in the case that the previous hidden state and/or generated token does not provide enough information or misleads the accurate generation of the next token. We refer to this modified cell as the Variational Contextual Definition Modeler (VCDM) Cell, and the resulting decoder as a VCDM-RNN. The VCDM Cell calculates the decoder hidden state $\boldsymbol{s}_j$ as follows[4]:

$$\boldsymbol{i}_j = \sigma(\boldsymbol{W} E_{d_j} + \boldsymbol{U} \boldsymbol{s}_{j-1} + \boldsymbol{A} c_{j-1} + \boldsymbol{V} \boldsymbol{h}'_d) \tag{10}$$

$$\boldsymbol{f}_j = \sigma(\boldsymbol{W}_f E_{d_j} + \boldsymbol{U}_f \boldsymbol{s}_{j-1} + \boldsymbol{A}_f \boldsymbol{c}_{j-1} + \boldsymbol{V}_f \boldsymbol{h}'_d) \tag{11}$$

$$\boldsymbol{o}_j = \sigma(\boldsymbol{W}_o E_{d_j} + \boldsymbol{U}_o \boldsymbol{s}_{j-1} + \boldsymbol{A}_o \boldsymbol{c}_{j-1} + \boldsymbol{V}_o \boldsymbol{h}'_d) \tag{12}$$

$$\tilde{\boldsymbol{C}}_j = g(\boldsymbol{W}_g E_{d_j} + \boldsymbol{U}_g \boldsymbol{s}_{j-1} + \boldsymbol{A}_g \boldsymbol{c}_{j-1} + \boldsymbol{V}_g \boldsymbol{h}'_d) \tag{13}$$

$$\boldsymbol{C}_j = \sigma(\boldsymbol{f}_j \cdot \boldsymbol{C}_{j-1} + \boldsymbol{i}_j \cdot \tilde{\boldsymbol{C}}_j) \tag{14}$$

$$\boldsymbol{s}_j = g(\boldsymbol{C}_j) \cdot \boldsymbol{o}_j \tag{15}$$

where $E_{d_j} \in \mathbb{R}^{d_w}$ is the embedding for the target word, $\boldsymbol{W}, \boldsymbol{W}_f, \boldsymbol{W}_o, \boldsymbol{W}_g \in \mathbb{R}^{d_d \times d_w}$, $\boldsymbol{U}, \boldsymbol{U}_f, \boldsymbol{U}_o, \boldsymbol{U}_g \in \mathbb{R}^{d_d \times d_d}$, $\boldsymbol{A}, \boldsymbol{A}_f, \boldsymbol{A}_o, \boldsymbol{A}_g \in \mathbb{R}^{d_d \times d_d}$, and $\boldsymbol{V}, \boldsymbol{V}_f, \boldsymbol{V}_o, \boldsymbol{V}_g \in \mathbb{R}^{d_d \times d_d}$ are trainable weight matrices parameterizing the RNN cell.

Additionally, at each decoder timestep j we attend to the set of annotation vectors $\boldsymbol{h}_c$ produced by the last layer of the context encoder. To compute context vector $\boldsymbol{c}_j$, we use general attention (Luong et al., 2015) shown below:

$$\boldsymbol{c}_j = \textstyle\sum_{i=1}^{T} \alpha_i \boldsymbol{h}_c^{(i)} \tag{16}$$

$$\alpha_i = \mathrm{softmax}(\boldsymbol{s}_j^\top \boldsymbol{W}_a \boldsymbol{h}_c^{(i)}) \tag{17}$$

where $\boldsymbol{W}_a \in \mathbb{R}^{d_d \times d_c}$, and α_i can be viewed as an alignment over $\boldsymbol{h}_c$ and $\boldsymbol{c}_j$ as a vector capturing the encoder hidden states scaled by this alignment.

3.4 Optimization challenges

Despite the VAE's appeal as a tool to learn unsupervised representations through the use of latent variables, these models are often found to ignore latent variables when using powerful generators. To overcome this issue of "posterior collapse" (Bowman et al., 2016), we incorporate the following heuristics: (1) annealing the KL term from 0 to 1 using a sigmoid annealing schedule, following Bowman et al. (2016) and (2) thresholding the KL term in the objective function with a constant λ using the "free bits" technique (Kingma et al., 2016). With these changes, our objective function is modified

---

[4] Note: For clarity, we omit the bias terms in Equations 10-15

CAMBRIDGE	Count		Length		
Partition	**Phrases**	**Examples**	**Phrase**	**Context**	**Definition**
Train	21,993	42,689	1.01	9.14 ± 4.27	11.64 ± 6.75

Overall	33,507	88,842	1.00	10.51 ± 7.38	7.97 ± 4.94

Table 1: Statistics for CAMBRIDGE and ROBERT. The number of individual phrases, number of examples, and the mean and s.d. of the lengths of each partition of the dataset are reported

to become the following:

$$\mathcal{L}(\theta,\phi) = -\mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{w},\mathbf{d})}\left[\log p_\theta(\mathbf{d}|\mathbf{w},\mathbf{z})\right] + \gamma\sum_i \max(\lambda, D_{\mathrm{KL}}(q_\phi(\mathbf{z}_i|\mathbf{w},\mathbf{d})||p(\mathbf{z}_i|\mathbf{w}))) \quad (18)$$

Where γ denotes the annealing term that follows the sigmoid schedule and λ denotes the *target rate*, and the sub-index i denotes the i^{th} dimension of the latent vector $\mathbf{z}$. In our experiments, we set the total $\lambda = 1$.

4 Empirical Study

4.1 Data

To evaluate our approach we make use of the following previously released datasets: OXFORD (Gadetsky et al., 2018) built from Oxford Dictionaries[5], URBAN built from the Urban Dictionary[6], and WIKIPEDIA (Ishiwatari et al., 2019) built from Wikipedia.

The task of definition modeling with respect to each of the aforementioned datasets can be regarded as three separate domains, in which (1) OXFORD can be viewed as a corpus of "traditional" dictionary definitions, where most common words in a given language are contained, (2) URBAN can be viewed as a corpus of "uncommon , slang words in which one often has to use context and subword information to decipher the meaning, and (3) WIKIPEDIA can be viewed almost as a description generation task of named entities, conditioned on the given context.

In addition to these datasets, we also develop the CAMBRIDGE (English) and ROBERT (French) dataset. We collect this data from the online version of the Cambridge Dictionary[7] and Le Petit Robert[8]. Following the spirit of previously released datasets, we include three components for each example: (1) the word or phrase being defined, (2) an example (context sentence) in which it is contained and (3) its corresponding definition. These datasets can be seen as an addition to the domain of "traditional" dictionary definitions, with ROBERT being the first non-English dataset. Please refer to Table 1 for statistics regarding these datasets.

4.2 Experiments

4.2.1 Our Model: VCDM

We initialize each of our encoders with BERT-base-uncased (or in the case of ROBERT, CamemBERT-base (Martin et al., 2019)), setting $d_e, d_c = 768$. We set latent dimension $d_z = 83$, and the LSTM decoder's hidden size $d_d = 512$ with an output vocabulary size of 10k, initializing embeddings with Word2Vec (Mikolov et al., 2013). We perform gradient descent using the Adam optimizer (Kingma and Ba, 2014) with its default hyperparameters. During decoding, we use the beam-search algorithm, setting the beam size to 5. We implement all models in PyTorch (Paszke et al., 2019).

4.2.2 Baselines

Local and Global Context-Aware Description generator (LoG-CAD): proposed by Ishiwatari et al. (2019), this model achieved the previous state-of-the-art on existing datasets for this task. The model makes use of a BiLSTM (Graves and Schmidhuber, 2005) to encode sentence-level context, a character-level CNN (Zhang et al., 2015) to encode character-level information, and pretrained Google CBOW[9](Mikolov et al., 2013) vectors (for ROBERT we use the French `fasttext` word vectors (Grave et al., 2018)). During decoding, this method makes use of a 2-layer attentional 300-dim LSTM decoder with an additional gating mechanism to combine all these sources of encoding information.

LSTM baseline (LSTM): To show the effect of continous latent variable modeling for this task,

[9] `https://code.google.com/archive/p/word2vec/`

and for a more direct comparison to LoG-CAD, we implement an LSTM version of our proposed architecture. Following LoG-CAD, use a 2-layer 300 dimensional BiLSTM as each encoder and use a 10k Byte-Pair tokenized (Sennrich et al., 2016) encoder vocabulary. The *neural definition inferer* and the *variational definition modeler* are kept the same as our proposed method.

BERT Baselines: This baseline is a single-layer attentional 512-dim LSTM-LM decoder conditioned on $\boldsymbol{r}_{w_t}$. We use two variants: (1) **BERT-fr** where $\boldsymbol{r}_{w_t}$ is produced by a a frozen BERT-base encoder and (2) **BERT-ft** where $\boldsymbol{r}_{w_t}$ is produced by a BERT-base encoder finetuned during training.

4.3 Evaluation

When comparing our approach to our baselines we make use of two automatic evaluation metrics, namely sentence-level BLEU (Papineni et al., 2002; Koehn et al., 2007) and the recently proposed BERTScore (Zhang et al., 2019). While the former is a well-known metric for machine translation, based mainly on n-gram matching between source and target, the latter is a rather new approach that leverages BERT's pretrained contextual embeddings, matching words in candidate and reference sentences by way of cosine similarity. Concretely, BERTScore computes 3 metrics, namely precision (denoted as P_{BERT}), recall (denoted as R_{BERT}) and F1 score (denoted as F_{BERT}).

Our interest in BERTScore sparks from the fact that it has been recently shown to correlate better with human judgement in system evaluations, and to address the potential issue of coherent definition generations being given low evaluation scores as a result of having zero or low n-gram overlap with the reference sentence.

Finally, in addition to our automatic evaluation we also performed a human study, where three different human annotators evaluated the output generated by our proposed approach, as well as by the LoG-CAD and BERT-ft baselines. We followed the approach by Ishiwatari et al. (2019) and used their 1-5 scale:

1. Completely wrong or self-definition
2. Correct topic with wrong information
3. Correct but incomplete
4. Small details missing
5. Correct

to evaluate 100 randomly sampled instances from Oxford.
