Link prediction accuracy Table 3 also compares link prediction accuracy before and after calibration. In most cases vector and matrix scaling

---

[3] https://github.com/thunlp/OpenKE/

improve accuracy, which is reminiscent of previous work showing that training KGE with softmax cross-entropy improves link prediction performance (Kadlec et al., 2017; Safavi and Koutra, 2020). We conclude that for relation prediction under the CWA, **vector scaling provides the best trade-off** between calibration, accuracy, and efficiency, as it consistently improves accuracy and calibration with only $O(k)$ extra parameters.

5 Open-world evaluation

We now address the more realistic **open-world assumption** (OWA), in which predictions not present in the knowledge graph are considered *unknown*, rather than false, until ground-truth labels are obtained. While the OWA is beneficial because it helps us assess KGE calibration under more realistic conditions, it is also challenging because it significantly changes the requirements for evaluation. Specifically, now we need a label for every triple considered, whereas with the CWA we only needed labels for a small group of positives.

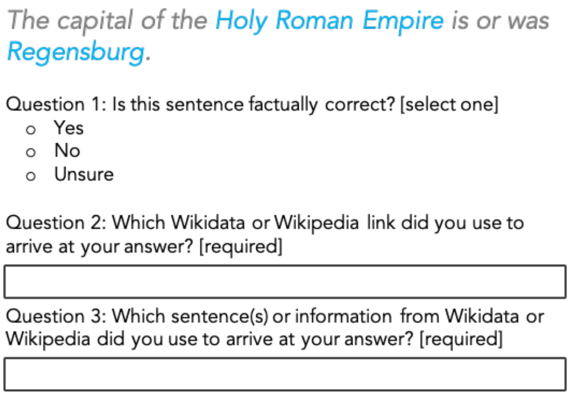
We emphasize that this is the reason the OWA is rarely used to evaluate KGE. Narrowing down the large space of unknowns to a manageable smaller set and labeling these triples can be difficult and costly. We thus contribute first steps toward evaluation strategies under the OWA.

5.1 Task and metrics

Similar to the link prediction task in § 4.1, we construct $(h, ?, t)$ queries from (h, r, t) knowledge graph triples. A KGE model then scores relations $r_i \in R$ to answer these queries. However, here we only consider completions $(h, r_i, t) \notin G$, those for which the *truth values are not known ahead of time*, which reflects how practitioners would use KGE to complete knowledge graphs in deployment settings. We use `FB15K-Wiki` as our dataset for this task because it is linked to Wikidata; we provide links to entities' Wikidata pages in our crowdsourced label collection process (§ 5.2).

Generating OWA predictions For each $(h, ?, t)$ query, we take the top-ranked $(h, \hat{r}, t)$ prediction made by a KGE model, and filter these predictions to unknowns $(h, \hat{r}, t) \notin G$.

To simulate how a practitioner might narrow down a large set of unknowns to a few promising candidates under resource constraints (i.e., the cost of collecting labels), we take only the predictions made with confidence level ≥ 0.80. In other words, we choose to obtain *many* judgments of a *few* high-confidence predictions rather than *few* judgments of *many* lower-confidence predictions. This helps us robustly compute agreement, maximize the probability of positives, and control quality.



The capital of the Holy Roman Empire is or was Regensburg.

Question 1: Is this sentence factually correct? [select one]
- ○ Yes
- ○ No
- ○ Unsure

Question 2: Which Wikidata or Wikipedia link did you use to arrive at your answer? [required]

Question 3: Which sentence(s) or information from Wikidata or Wikipedia did you use to arrive at your answer? [required]

Figure 3: Open-world annotation interface.

We run this generation process for each KGE model from § 3.1 trained on `FB15K-Wiki` before and after calibration. We use vector scaling as our calibrator because it yields the best results on `FB15K-Wiki` under the CWA (§ 4.3).

For evaluation, we use the same accuracy and calibration metrics as in § 4.1. However, since there is no "test set" in the open world, we must obtain ground-truth labels on predictions, discussed next.

5.2 Data annotation

We collect judgments of the unknown $(h, \hat{r}, t) \notin G$ predictions over `FB15K-Wiki` using the Figure 8 crowdsourcing platform.[4] In the task, crowd workers answer whether each prediction is factually correct (Figure 3). Triples are presented as sentences, converted via pre-defined relation templates, with links to the Wikidata entries of the head and tail entities. Appendix B gives sentence template examples, as well as more details on data preprocessing and the data annotation instructions.

Participants We limit the annotation task to the highest-trusted group of contributors on Figure 8, and require references from Wikidata or Wikipedia for answers. We also pre-label 20% of all triples and require participants to pass a 5-question "quiz" before starting the task and maintain 90% accuracy on the remaining gold questions. We gather judgments for 1,152 triples, and collect five judgments per triple, taking the majority label as ground-truth. The inter-annotator agreement using Fleiss'

Aggregate	0.548	0.296	0.295	0.549

kappa (Fleiss, 1971) is 0.7489 out of 1.

5.3 Results and discussion

Table 4 compares calibration error and link prediction accuracy before and after applying vector scaling. As shown in the table, the translational models do not make any uncalibrated predictions above a confidence level of 0.80 due to underconfidence, as dicussed in § 4.3. The bilinear models, DistMult and ComplEx, are much less calibrated off-the-shelf than under the CWA (c.f. Table 3).

Even after vector scaling, which reduces ECE significantly for both models and scales the scores of the translational models appropriately, **all models are overconfident**, collectively reaching around 50-60% accuracy at the 80-100% confidence level (Table 4 and Figure 4). This is consistent with observations of KGE overconfidence made by Pezeshkpour et al. (2020) for the task of triple classification, as well as observations on the general overconfidence of neural networks for vision and language processing (Guo et al., 2017).

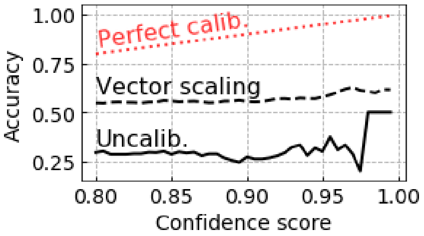

Figure 4: Reliability before and after calibration, aggregated across all four models.

We also do not observe any correlation between a model's level of exposure to a particular relation type and its calibration on that relation type. For example, all models achieve relatively low ECE ($< 4\%$) on the relation */language/human_language/countries_spoken_in*, which appears in only 0.148% of all triples in `FB15K-Wiki`. By contrast, for the relation */location/location/containedby*, which appears in 2.30% of all `FB15K-Wiki` triples (15× more frequent), all models are poorly calibrated both before and after vector scaling (ECE $> 10\%$). We discuss these results and behaviors in more detail next.

Challenges of the OWA Accurately calibrating KGE models (and evaluating calibration thereof) is challenging under the OWA for several reasons. First, in the CWA, all queries are known to have at least **one correct answer ahead of time**, whereas in the OWA we have no such guarantee. This highlights one of the fundamental challenges of the OWA, which is that of selecting predictions from a vast space of unknowns to maximize the probability of positives. It is likely that different strategies for selecting unknowns would lead to different observed levels of calibration.

In the OWA there is also a **mismatch between negatives** in the calibration and evaluation stages. Recall that in the calibration stage, we take completions not seen in the graph as negative samples (§ 3.3), which is essentially a closed-world assumption. By contrast, at evaluation time we make an open-world assumption. Higher-quality validation negatives may alleviate this problem; indeed, recent works have raised this issue and constructed new datasets toward this direction, albeit for the task of triple classification (Pezeshkpour et al., 2020; Safavi and Koutra, 2020).

Finally, our observation about the varying levels of calibration per relation suggests that **some relations are simply more difficult to** calibrate because of the knowledge required to accurately model them. Most popular "vanilla" KGE models do not explicitly make use of external knowledge that can help refine prediction confidences, such as entity types, compositional rules, or text.

Table 5 provides examples of high-scoring predictions made before and after calibration with corresponding labels. While most predictions are grammatically correct, it is perhaps not reasonable to expect KGE to capture certain types of semantics, logic, or commonsense using just the structure of the graph alone, for example that architects can design buildings but not video games (Table 5).

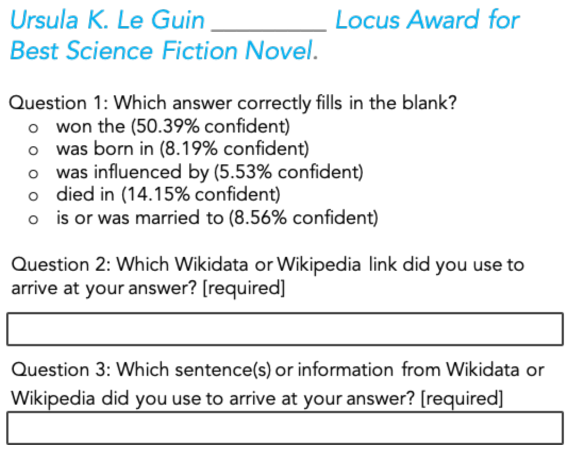
Link prediction accuracy As shown in Table 4, calibration with vector scaling on `FB15K-Wiki` improves OWA link prediction accuracy by 20-28 percentage points, which is significantly higher than under the CWA (c.f. Table 3), in which it improved accuracy by 1-5 percentage points on `FB15K-Wiki`. We conclude that from a practitioner's perspective, vector scaling is a **practical technique for making predictions more accurate and trustworthy** even if it does not perfectly calibrate models.

6 Case study

Finally, we conduct a case study of human-AI knowledge graph completion as a proof of concept on the benefits of KGE calibration for practitioners. In this experiment, given "fill-in-the-blank" sentences corresponding to incomplete knowledge graph triples, the task is to choose from multiple-choice answer lists generated by KGE to complete the sentences. We show that, compared to annotators *not* provided with confidence scores for this task, annotators provided with calibrated confidence scores for answer choices **more accurately and efficiently** complete triples.

6.1 Data

We construct a knowledge graph consisting of 23,887 entities, 13 relations, and 86,376 triples from Wikidata. We collect triples in which the head entity is categorized as a writer on Wikidata, and 13 people-centric relations (e.g., *born in*, *married to*). We extract our dataset directly from Wikidata to guarantee that all answers are resolvable using a single public-domain source of information. We choose writing as a domain because it is less "common knowledge" than, e.g., pop culture.



Ursula K. Le Guin _________ *Locus Award for Best Science Fiction Novel.*

Question 1: Which answer correctly fills in the blank?
○ won the (50.39% confident)
○ was born in (8.19% confident)
○ was influenced by (5.53% confident)
○ died in (14.15% confident)
○ is or was married to (8.56% confident)

Question 2: Which Wikidata or Wikipedia link did you use to arrive at your answer? [required]

Question 3: Which sentence(s) or information from Wikidata or Wikipedia did you use to arrive at your answer? [required]

Figure 5: Example completion task from our case study. The confidence scores shown in parentheses for Question 1 are presented to the confidence group only.

Task input After training and calibrating each KGE model from § 3.1 over the Wikidata graph, we use our best-calibrated model (ComplEx + Platt scaling, ECE < 0.01 under the CWA) to predict relations. Per triple, we take the top-five predicted relations $\{\hat{r}\}_{i=1}^{5}$ and their calibrated confidence scores $\{\hat{p}\}_{i=1}^{5}$. We filter these predictions to a sample of 678 triples by choosing only instances whose ground-truth relation r is in the top-five predictions $\{\hat{r}\}_{i=1}^{5}$, balancing class proportions, and discarding questions with answers that are easy to guess. Appendix C.1 provides more details.

6.2 Task setup

The task is to complete triples by choosing the correct relation among the top-five KGE-predicted relations $\{\hat{r}\}_{i=1}^{5}$, presented in natural language.

We conduct an A/B test whereby we vary how the confidence scores $\{\hat{p}\}_{i=1}^{5}$ for answer choices are presented to participants. We provide the **no-confidence (control) group** with multiple-choice answers in their natural language form without any accompanying confidence estimates, whereas the **confidence (treatment) group** is provided a calibrated confidence score along with each answer candidate in parentheses (Figure 5). We also provide the confidence group with an extra paragraph of instructions explaining that the confidence scores are generated by a computer system; Appendix C.2 provides the full task instructions.

To mitigate position bias, we randomize the pre-

Table 6: Case study results. ↑: Higher is better. ↓: Lower is better. **Bold**: Significant at $p < 0.05$. Underline: Significant at $p < 0.01$. *: p-value not applicable. Detailed explanations are given in § 6.3.

	Accuracy ↑			Sec. per triple ↓
	Overall	Per triple	Per person	
No-conf.	0.8977	0.8969	0.9120	36.88
Conf.	0.9175*	**0.9220**	**0.9478**	**31.91**
Abs. diff.	+0.0198	+0.0251	+0.0358	-4.97
Rel. diff.	+2.21%	+2.79%	+3.93%	-13.48%

sentation order of answer choices so that the answers are not necessarily ranked in order of confidence. The answer candidates are presented in the *same* randomized order for both groups.

Participants We recruit 226 participants for the no-confidence group and 202 participants for the confidence group from Figure 8. Participants are required to pass a 10-question "quiz" and maintain 50% minimum accuracy across all pre-labeled gold questions. We limit each participant to up to 20 judgments, and collect three judgments per triple.

6.3 Results and discussion

Table 6 summarizes the results of our case study. For the accuracy results, statistical significance is determined with the Wilcoxon rank-sum test (Wilcoxon, 1992) due to non-normality. For the efficiency results, statistical significance is determined with an independent two-sample t-test.

Accuracy The proportion of correct judgments in the no-confidence group was 0.8977 compared to 0.9175 in the confidence group, an improvement of 1.98 percentage points. In terms of the average judgment accuracy per triple, or the number of correct judgments divided by the number of judgments per triple, the no-confidence and confidence averages were 0.8969 and 0.9220 respectively, a significant difference ($p < 10^{-3}$). The average judgment accuracy per participant also differed significantly ($p < 10^{-6}$), again in favor of the confidence group.

Finally, model accuracy was 0.6268, meaning that for 62.68% (425/678) of triples seen by participants in the confidence group, the answer choice with the highest confidence score was the correct answer. Given that the confidence group's accuracy was much higher (0.9175 versus 0.6268), we can conclude that the participants in this group did not blindly trust the confidence scores.

Efficiency For this comparison we remove outliers with average judgment times more than two standard deviations away from the group mean. The mean time per judgment was 36.88 seconds in the no-confidence group (194 participants) versus 31.91 seconds in the confidence group (179 participants), a significant difference ($p = 0.010$). Note that we required sources and textual references for all answers across both groups (Questions 2 and 3 in the example in Figure 5). However, even with these quality control measures, the confidence group was significantly faster.

In conclusion, the results of our case study indicate that human-AI knowledge graph completion is more accurate and efficient with calibrated confidence scores generated by KGE. These findings suggest that calibrated probabilities are indeed trustworthy to practitioners, motivating the utility of calibration for human-AI tasks.

7 Conclusion

We investigate calibration as a technique for improving the trustworthiness of link prediction with KGE, and uniquely contribute both closed-world *and* open-world evaluations; the latter is rarely studied for KGE, even though it is more faithful to how practitioners would use KGE for completion. We show that there is significant room for improvement in calibrating KGE under the OWA, and motivate the importance of this direction with our case study of human-AI knowledge graph completion. As knowledge graphs are increasingly used as gold standard data sources in artificial intelligence systems, our work is a first step toward making KGE predictions more trustworthy.

A Implementation details

To select models, we grid search over the number of training epochs in {200, 300, 500}, the batch size in {100, 200, 500}, and the embedding dimension in {50, 100}. For training, we use random uniform negative sampling to speed up the training process. We search over the number of negative relations sampled per positive triple in {1, 5}.

We follow the original papers' choices of loss functions and optimizers. For loss functions, we use margin ranking for TransE, TransH, and DistMult and binary cross-entropy for ComplEx, and grid search over the margin hyperparameter in {1, 5, 10} for margin ranking. For optimizers, we use SGD for TransE and TransH, and Adagrad for DistMult and ComplEx, with a learning rate of 0.01.

We use the scikit-learn implementations of one-versus-all Platt scaling and isotonic regression[5], and implement vector and matrix scaling in Tensorflow with L-BFGS (Liu and Nocedal, 1989) limited to 2,000 iterations following the reference implementation provided by Guo et al. (2017).[6]

B Open-world evaluation

B.1 Data

To construct the set of triples for annotation, we discard relations pertaining to Netflix (e.g., */media_common/netflix_genre/titles*) to avoid disagreement due to crowd workers' countries of origin, since Netflix title availability varies widely by country. We convert all triples to sentences with a set of pre-defined relation templates. Because all relations can be reversed—e.g., (*Beyoncé*, *citizenOf*, *USA*) and (*USA*, *hasCitizen*, *Beyoncé*) express the same fact—we create two sentence templates for each relation and take the sentence that expresses the more plausible and/or grammatical statement per triple. Table 7 gives examples of sentence templates for relations in `FB15K-Wiki`.

B.2 Task instructions

This section gives the data annotation task instructions. Note that we conduct two separate annotation tasks: One with links to entities' Wikidata pages, and one with links to entities' IMDb pages for */film* relations only (Wikidata is linked to both Freebase and IMDb). The instructions are exactly the same between the two versions of the task, except that each instance of "Wikidata and/or Wikipedia" is replaced with "IMDb" in the latter.

Overview The goal of this task is to determine whether a given sentence is true or false.

Instructions Given a sentence that states a potentially true fact about the world, for example

> *Elizabeth Alexandra Mary Windsor is the queen of the Commonwealth.*

Read the sentence carefully and answer whether the sentence is factually correct by choosing one of *Yes*, *No*, or *Unsure*. To arrive at your answer, you **must use English-language Wikidata and/or Wikipedia**, even if you know the answer ahead of time. Each sentence already contains links to potentially relevant Wikidata pages; however, if you do not find an answer in the Wikidata page, you must check related Wikipedia pages. You **may not use any external data sources beyond English-language Wikidata or Wikipedia**. After you select your answer (Question 1), give the primary English-language Wikidata or Wikipedia URL (Question 2) and the text snippet or reasoning you used to arrive at your answer (Question 3).

Rules and Tips

- Read each sentence carefully and check both Wikidata and Wikipedia before choosing your answer.

---

[5] https://scikit-learn.org/stable/modules/generated/sklearn.calibration.CalibratedClassifierCV.html

[6] https://github.com/gpleiss/temperature_scaling

- **Question 1**: If a sentence is not grammatically correct, treat it as false. If a sentence is grammatically correct but you cannot find any information on Wikidata or Wikipedia supporting or disproving its claim, or you cannot reason about whether its claim is true or false, choose Unsure.
- **Question 2**: You must copy-paste the primary Wikidata or Wikipedia link that you used to arrive at your answer. **Only copy-paste the single link that contains the most complete answer to the question.** You may use the provided Wikidata links, but you **may also need to check related Wikipedia pages if you do not find what you are looking for. You may not use any external data sources beyond English-language Wikidata or Wikipedia.**
- **Question 3**: You may copy-paste relevant textual snippets from Wikidata or Wikipedia. If there is no relevant text to copy-paste, you may write a brief explanation of how you arrived at your answer.

Examples We give two examples presented to crowd workers in the task instructions.

1. *Nawaz Sharif is or was a leader of Pakistan.*
    - Is this sentence factually correct?
        - Yes
    - Which Wikidata or Wikipedia link did you use to arrive at your answer?
        - https://en.wikipedia.org/wiki/Nawaz_Sharif
    - Which sentence(s) or information from Wikidata or Wikipedia did you use to arrive at your answer?
        - "Mian Muhammad Nawaz Sharif is a Pakistani businessman and politician who served as the prime minister of Pakistan for three non-consecutive terms" - from the Wikipedia page of Nawaz Sharif
2. *The capital of France is or was Avignon.*
    - Is this sentence factually correct?
        - No
    - Which Wikidata or Wikipedia link did you use to arrive at your answer?
        - https://en.wikipedia.org/wiki/List_of_capitals_of_France
    - Which sentence(s) or information from Wikidata or Wikipedia did you use to arrive at your answer?
        - Avignon is not listed as a capital of France on the Wikipedia page about the capitals of France.

C Case study

C.1 Data

To convert all triples into natural language for the task, we map each relation in the dataset to a phrase: P19 (*was born in*), P20 (*died in*), P21 (*is of gender*), P26 (*is or was married to*), P101 (*works or worked in the field of*), P103 (*speaks or spoke the native language of*), P106 (*works or worked as a*), P119 (*is buried in*), P136 (*created works in the genre of*), P140 (*follows or followed the religion*), P166 (*was awarded the*), P551 (*lives or lived in*), and P737 (*was influenced by*).

We train each model on all triples that we collected from Wikidata, but limit the task input to a subset of triples for which the correct answer is unambiguous but also not easy to guess. To this end, we discard triples with relations that can be guessed via type matching: *Gender* (the tail entity is always *male* or *female* in our dataset), *award received* (the tail entity usually contains the word "award", "prize", etc.), and *place of burial* (the tail entity usually contains the word "cemetery"). We also discard triples with relations that can be interpreted as synonyms of one another (*occupation* and *genre*, e.g., "fiction writer"), and triples with the relation *field of work* for which the tail entity is synonymous with "writer" or "author", since all people in the dataset are categorized as authors or writers on Wikidata. Finally, we remove triples for which there is more than one correct answer in the top-five predicted relations.

C.2 Task instructions

This section gives the task instructions of the case study. Underline indicates that the enclosed text was presented to the confidence group only.

Overview The goal of this task is to complete a sentence so that it states a true fact about the world.

Instructions Given a partially complete sentence, fill in the blank with exactly one of the provided answer choices so that the sentence states a true fact about the world. To arrive at your answer, you **must use the provided Wikidata links**

in each sentence. You may not use any external data sources beyond the provided Wikidata links in each sentence. Please note that we have used a computer system to generate “confidence values” for each answer choice in order to help you with the task. These values signify our system’s belief about which answer is most likely to be correct. After you select your answer (Question 1), give the single Wikidata URL (Question 2) and the text snippet or reasoning you used to arrive at your answer (Question 3). You must provide all answers in English.

Rules and Tips

- **Question 1**: Choose the answer that makes the sentence grammatically correct and factual according to Wikidata. Every sentence has at least one correct answer. If you believe a sentence has multiple equally correct answers, choose any of them.
- **Question 2**: You must copy-paste the single, entire Wikidata link that you used to arrive at your answer. The link that you copy-paste **must contain the correct answer that fills in the blank in the sentence**. You must use the Wikidata links provided in each sentence. You may not use any external data sources beyond the provided Wikidata links.
- **Question 3**: You may copy-paste relevant textual snippets from Wikidata. If there is no relevant text to copy-paste, you must write a brief explanation of how you arrived at your answer. You must provide all answers in English.

Examples We give two examples presented to crowd workers in the task instructions.

1. *Anna Akhmatova* ________________ *Leo Tolstoy*.
   (a) was or is married to (40% confident)
   (b) **was influenced by** (45% confident)
   (c) was the academic advisor of (5% confident)
   (d) was the child of (5% confident)
   (e) was the parent of (5% confident)
   - Which Wikidata link did you use to arrive at your answer?
     - https://www.wikidata.org/wiki/Q80440
   - Which sentence(s) or information from Wikidata did you use to arrive at your answer?
     - Wikidata says that Anna Akhmatova was influenced by Leo Tolstoy.
2. *Ursula K. Le Guin* ________________ *Hugo Award for Best Short Story*.
   (a) **was awarded the (40% confident)**
   (b) was influenced by (0% confident)
   (c) created the (50% confident)
   (d) was or is married to (10% confident)
   (e) lives in (0% confident)
   - Which Wikidata link did you use to arrive at your answer?
     - https://www.wikidata.org/wiki/Q181659
   - Which sentence(s) or information from Wikidata did you use to arrive at your answer?
     - Wikidata says that Ursula K Le Guin won the Hugo Award for Best Short Story.

Text Graph Transformer for Document Classification

Haopeng Zhang **Jiawei Zhang**
IFM Lab, Department of Computer Science,
Florida State University, FL, USA
haopeng,jiawei@ifmlab.org

Abstract

Text classification is a fundamental problem in natural language processing. Recent studies applied graph neural network (GNN) techniques to capture global word co-occurrence in a corpus. However, previous works are not scalable to large-sized corpus and ignore the heterogeneity of the text graph. To address these problems, we introduce a novel *Transformer* based heterogeneous graph neural network, namely Text Graph Transformer (TG-Transformer). Our model learns effective node representations by capturing structure and heterogeneity from the text graph. We propose a mini-batch text graph sampling method that significantly reduces computing and memory costs to handle large-sized corpus. Extensive experiments have been conducted on several benchmark datasets, and the results demonstrate that TG-Transformer outperforms state-of-the-art approaches on text classification task.

1 Introduction

Text classification is a widely studied problem in natural language processing and has been addressed in many real-world applications such as news filtering, spam detection, and health record systems (Kowsari et al., 2019; Che et al., 2015; Zhang et al., 2018). The objective is to assign corresponding labels to textual units based on text representations.

Deep learning models like Convolutional Neural Networks (CNN) (Kim, 2014) and Recurrent Neural Networks (RNN) (Hochreiter and Schmidhuber, 1997) have been applied for text representation learning instead of traditional hand-crafted features, such as n-gram and bag-of-words (BoW) (Joulin et al., 2016). Researchers have recently turned to Graph Neural Network (GNN) to exploit global features in text representation learning, which learns node embedding by aggregating information from neighbors through edges. Defferrard et al. (2016) first generalized CNN to graph for text classification task. Then Yao et al. (2019) applied Graph Convolution Network (GCN) (Kipf and Welling, 2016) on a corpus level heterogeneous text graph and achieved state-of-the-art performance. Liu et al. (2020) further improved classification accuracy by expanding the text graph with semantic and syntactic contextual information.

However, these GCN-based models on heterogeneous text graphs suffer from two practical issues. Firstly, none of these models are scalable to large-sized corpus due to high computation and memory costs. Calculation of all the nodes in the graph is required at each layer during training. Secondly, all these models ignore the heterogeneity of the text graph, which consists of both document and word nodes. Distinguishing nodes of different types will benefit node representation learning.

To address the above problems, we propose a novel *Transformer*-based heterogeneous GNN model, namely Text Graph Transformer (TG-Transformer). Instead of learning based on the full text graph, we propose a text graph sampling method that enables subgraph mini-batch training. The significantly reduced computing and memory costs make the model scalable to large-sized corpus. Moreover, we utilize *Transformer* to aggregate information in subgraph batch with two proposed graph structural encodings. We also distinguish the learning process of different type nodes to fully utilize the heterogeneity of text graph. The main contributions of this work are as follows:

1. We propose Text Graph Transformer, a heterogeneous graph neural network for text classification. It is the first scalable graph-based method for the task to the best of our knowledge.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8322–8327,
November 16–20, 2020.

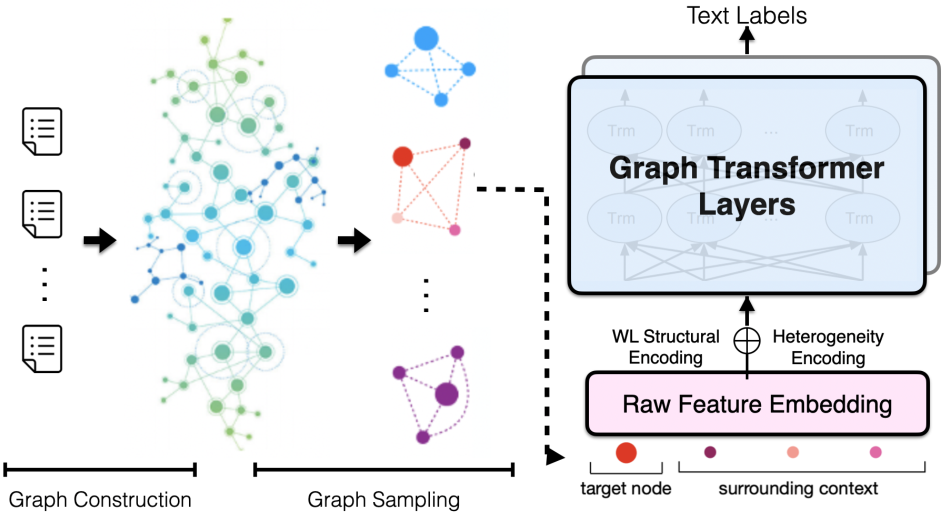

Figure 1: Overall Structure of TG-Transformer

2. We propose a novel heterogeneous text graph sampling method that significantly reduces computing and memory costs.
3. We perform experiments on several benchmark datasets, and the results demonstrate the effectiveness and efficiency of our model.

2 Methodology

In this section, we introduce TG-Transformer in great detail. First, we present how to construct a heterogeneous text graph for a given corpus. Then, we introduce our text graph sampling method, which can generate subgraph mini-batch from the text graph. These subgraph batches will be fed into TG-Transformer to learn efficient node representations for classification. The overall structure of our model is shown in Fig. 1.

2.1 Text Graph Building

To capture global word co-occurrence within corpus, we build a heterogeneous text graph $\mathcal{G} = (\mathcal{U}, \mathcal{V}, \mathcal{E}, \mathcal{F})$. The text graph contains two types of nodes: word nodes ($\mathcal{U}$) representing all documents in the corpus and document nodes ($\mathcal{V}$) representing all the words in the corpus vocabulary. The text graph also contains two types of edges: word-document edges ($\mathcal{E}$) and word-word edges ($\mathcal{F}$). Word-document edges are built based on word occurrence within documents with edge weights measured by the term frequency-inverse document frequency (TF-IDF) method. Word-word edges are built based on local word co-occurrence within sliding windows in the corpus, with edge weights measured by point-wise mutual information (PMI):

$$\text{PMI}(w_i, w_j) = \log \frac{p_{i,j}}{p_i p_j} = \log \frac{N_{i,j} N}{N_i N_j}, \qquad (1)$$

where $N_i, N_j, N_{i,j}$ are the number of sliding windows in a corpus that contain word w_i, word w_j and both w_i, w_j. N is the total number of sliding windows in the corpus.

2.2 Text Graph Sampling

To reduce computing and memory cost, we propose a text graph sampling method. Instead of learning based on the entire text graph, TG-Transformer is trained on sampled subgraph mini-batch, making it scalable to large-sized corpus. We separate sub-graph sampling as a pre-process step in an unsupervised manner for controlling the time costs in model learning.

We first calculate the intimacy matrix $\mathbf{S}$ of the text graph based on pagerank algorithm:

$$\mathbf{S} = \alpha \cdot (\mathbf{I} - (1 - \alpha) \cdot \overline{\mathbf{A}})^{-1}, \qquad (2)$$

where factor $\alpha \in [0, 1]$ is usually set as 0.15. $\overline{\mathbf{A}} = \mathbf{D}^{-\frac{1}{2}} \mathbf{A} \mathbf{D}^{-\frac{1}{2}}$ is the normalized symmetric adjacency matrix, $\mathbf{A}$ is the adjacency matrix of the text graph, and $\mathbf{D}$ is its corresponding diagonal matrix. Each entry $\mathbf{S}_{i,j}$ measures the intimacy score between node i and node j.

For any document target node $v_i \in \mathcal{V}$, we sample its context subgraph $\mathcal{C}(v_i)$ of size k by selecting its top k intimate neighbour word nodes $u_j \in \mathcal{U}$.

Meanwhile, for any word target node $u_i \in \mathcal{U}$, we first calculate the ratios of two type incident

Table 1: Statistics of the experiment datasets. V denotes the vocabulary size, C the number of classes, and W the average number of words per document.

Dataset	Train	Test	V	C	W
R8	5,485	2,189	7,688	8	65.72
R52	6,532	2,568	8,892	52	69.82
Ohsumed	3,357	4,043	14,157	23	135.82
IMDB	278,732	69,683	115,831	10	325.6
Yelp 2014	900,309	225,077	476,191	5	148.8

edge:

$$r_w(u_i) = \frac{|\mathcal{F}(u_i)|}{|\mathcal{F}(u_i)| + |\mathcal{E}(u_i)|}, \tag{3}$$

$$r_d(u_i) = \frac{|\mathcal{E}(u_i)|}{|\mathcal{F}(u_i)| + |\mathcal{E}(u_i)|}, \tag{4}$$

where $\mathcal{F}(u_i), \mathcal{E}(u_i)$ are the sets of word-word edges, word-document edges incident to u_i with intimacy score larger than threshold θ. We sample its context subgraph $\mathcal{C}(u_i)$ of size k by selecting its top $k \cdot r_w(u_i)$ intimate neighbour word nodes and its top $k \cdot r_d(u_i)$ intimate neighbour document nodes, respectively.

2.3 Text Graph Transformer

Based on the sampled subgraph mini-batch, TG-Transformer will update the text graph nodes' representations iteratively for classification. We build one model for each target node type (document/word) to model heterogeneity. The input of our model will be raw feature embeddings of nodes in subgraph batch injected by the following two extra structural encodings:

Heterogeneity Encoding The heterogeneity encoding can capture the document and word types in the text graph. Similar to the segment encoding in (Devlin et al., 2018), we use 0 and 1 to encode document nodes and word nodes, respectively.

Weisfeiler-Lehman Structural Encoding We adopt the WL Role Embedding by (Zhang et al., 2020a) to capture the structure of text graph. The Weisfeiler-Lehman (WL) algorithm (Niepert et al., 2016) can label nodes according to their structural roles in the graph. For node v_j (document or word node) in the sampled subgraph, we can denote its WL code as $WL(v_j) \in \mathbb{N}$, and the encoding is defined as:

$$\left[\sin\left(\frac{\mathrm{WL}(v_j)}{10000^{\frac{2l}{d_h}}}\right), \cos\left(\frac{\mathrm{WL}(v_j)}{10000^{\frac{2l+1}{d_h}}}\right)\right]_{l=0}^{\left\lfloor \frac{d_h}{2} \right\rfloor}. \tag{5}$$

These two encodings have the same dimension (i.e., d_h) as the original raw feature embeddings, so we add them together as the initial node representation for the input subgraph, which can be denoted as $\mathbf{H}^{(0)}$.

Graph Transformer Layer The D layer graph transformer will aggregate information from subgraph batch to learn the target node representation. Each graph transformer layer contains three trainable matrices: $\mathbf{W}_Q, \mathbf{W}_K, \mathbf{W}_v \in \mathbb{R}^{d_h \times d_h}$ and queries $\mathbf{Q}$, keys $\mathbf{K}$ and values $\mathbf{V}$ are generated by multiplying the input correspondingly:

$$\{\mathbf{Q}, \mathbf{K}, \mathbf{V}\} = \mathbf{H}^{(l-1)} \left\{\mathbf{W}_Q^{(l)}, \mathbf{W}_K^{(l)}, \mathbf{W}_V^{(l)}\right\}. \tag{6}$$

Then a TG-Transformer layer can be donated as:

$$\begin{aligned} \mathbf{H}^{(l)} &= \text{G-Transformer}\left(\mathbf{H}^{(l-1)}\right) \\ &= \operatorname{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{d_h}}\right)\mathbf{V} + \text{G-Res}, \end{aligned} \tag{7}$$

where G-res refers to the graph residual term in (Zhang and Meng, 2019) to solve the over-smoothing issue of GNNs. The output of the last layer $\mathbf{H}^{(D)}$ will be averaged as the final representations $\mathbf{z}$ of the target node and fed into a *softmax* classifier:

$$\mathbf{z} = \operatorname{softmax}(\operatorname{average}(\mathbf{H}^{(D)}) \in \mathbb{R}^{d_y \times 1}. \tag{8}$$

Based on the sampled subgraphs for all the nodes in the training set, e.g., $\mathcal{T}$, we can define the cross-entropy based loss function as:

$$\ell = -\sum_{n \in \mathcal{T}} \sum_{f=1}^{d_y} \mathbf{y}_n(f) \log \mathbf{z}_n(f), \tag{9}$$

Table 2: Text classification accuracy results. Models with "*" utilize pre-trained Glove word embeddings. For the scores not reported in the existing works, we mark them with '-' in the table.

Model	R8	R52	Ohsumed	IMDB	Yelp 2014
CNN*	95.7±0.5	87.6±0.4	58.4±1.0	42.7±0.4	66.1±0.6
LSTM*	96.1±0.2	90.5±0.8	51.1±1.5	52.1±0.3	68.4 ±0.1
fastText*	96.1±0.2	92.8±0.1	57.7±0.5	45.2±0.4	66.2±0.6
Text GCN	97.0±0.1	93.7±0.1	67.7±0.3	-	-
Text GNN*	97.8±0.2	94.6±0.3	69.4±0.6	-	-
Tensor GCN*	98.0±0.1	95.0±0.1	70.1±0.2	-	-
TG-Transformer*	98.1±0.1	95.2±0.2	70.4±0.4	53.4±1.2	69.8±0.6

where $n \in \mathcal{T}$ denotes the target word/document nodes in the training set, d_y is the label vector dimension, and $\mathbf{y}_n$ represents the ground-truth label vector of node n.

3 Experiment

3.1 Experimental Setup

Datasets We evaluate the effectiveness of our model on five benchmarked datasets: R52 and R8 Reuters dataset[1] for news documents classification, Ohsumed dataset[2] for medical bibliographic classification, and two large-scale review rating datasets: IMDB and Yelp 2014. Detailed statistics of the datasets are summarized in Table 1.

Baselines We compare our method with three classical baseline models: **CNN** in (Kim, 2014), **LSTM** in (Liu et al., 2016) and **fastText** in (Joulin et al., 2016) using the average of word/n-grams embeddings. In addition, we compare with three state-of-the-art GNN-based models: **TextGCN** in (Yao et al., 2019) using GCN, **Text GNN**[3] in (Huang et al., 2019) using text level graphs and **TensorGCN** in (Liu et al., 2020) using semantic and syntactic contextual information.

Implementation We set the node representation dimension as 300 and initialize with Glove word embeddings (Pennington et al., 2014). We train a 2-layer graph transformer with a hidden size 32 and 4 attention heads. We use mini-batch SGD with Adam optimizer (Kingma and Ba, 2014), and the dropout rate is set as 0.5. The initial learning rate as 0.001, and we decay it with weight decay $5e^{-4}$. 10 percent of the training set is randomly selected as validation set, and we stop training if the validation set loss does not decrease for 10 consecutive epochs.

Table 3: Training time per epoch of GNN-based models.

Model	R52	Ohsumed
Text GCN	2.64	3.48
Tensor GCN	4.32	5.13
TG-Transformer	0.83	1.17

3.2 Experiment Results

Table 2 presents the classification accuracy of our model compared with baseline methods. GNN-based models generally perform better than sequential and bag-of-word models due to its ability to model global word co-occurrence in the corpus, and TG-Transformer outperforms other graph models with much less memory and computing cost. This is likely due to the utilization of the text graph's heterogeneity and effective representing learning by Graph Transformer Layers. Moreover, TG-Transformer performs well on large-sized corpus such as IMDB and Yelp 14. We also evaluate model efficiency with training time per epoch, as shown in Table 3. It can be observed that our text graph sampling method reduces the computing cost significantly and makes our model scalable to large corpus, where previous GNN-based models such as Text GCN are not applicable due to computing power limit.

Hyperparameter Here we analyze the effects of subgraph sizes k in sampling. We notice parameter k has a large influence on the model performance since it defines the number of neighbor nodes used to update the target node representation. During parameter tuning, we notice the learning performance improves steadily as k increases from 1 to an optimal value (i.e.,23 for R8) and starts decreasing as

---

[1] https://www.cs.umb.edu/ smimarog/textmining/datasets/

[2] http://disi.unitn.it/moschitti/corpora.htm

[3] We give this name for simplicity.

Table 4: Ablation study results.

Settings	R52	Ohsumed
Original	95.2	70.4
(1) Without structural encodings	94.8	69.6
(2) Without pre-trained Emb.	93.5	66.9
(3) Simultaneous updating	94.7	69.3

k further increases. The same trend is noticed for all datasets. The computing cost to train the model also increases as k goes larger, but is still less than other GNN-based models.

Ablation Study We perform ablation studies to analyze our model further, as shown in Table 4. In (1), we remove the two structural encodings and only use raw feature embeddings as input. The decreased performance demonstrates that the structural encodings capture some useful heterogeneous graph structure information. In (2), we remove pre-trained word embeddings and initialize all the nodes with random vectors. Model performance has a larger decrease, demonstrating the significance of pre-trained word embeddings and initial node representations on our model. In (3), we train one model to update and learn both subgraph batch target node types. The slightly decreasing classification accuracy reflects the importance of modeling heterogeneity information of the text graph.

4 Related Work

4.1 Text Classification

Traditional text classification studies rely on handcrafted features like BoW (Zhang et al., 2010) and n-gram (Wang and Manning, 2012). With the development of deep learning, researchers applied CNN (Kim, 2014; Zhang et al., 2015), LSTM (Tai et al., 2015; Liu et al., 2016), word embedding techniques (Joulin et al., 2016; Pennington et al., 2014), attention mechanism (Yang et al., 2016; Wang et al., 2016) in text classification models and kept improving accuracy. Recently, graph based text classification models received growing attention due to its ability to model global information in corpus (Yao et al., 2019; Peng et al., 2018; Zhang et al., 2020b; Nikolentzos et al., 2019). Our paper follows this line of works on developing novel GNN for text classification.

4.2 Graph Neural Network

Representative examples of GNN models proposed by present include GCN (Kipf and Welling, 2016), Graph Attention Network (GAT)(Veličković et al., 2017) and Graph SAGE (Hamilton et al., 2017). GCN models are based on approximated graph convolutional operator while GAT relies on self-attention mechanism. Recently, *Transformer* (Vaswani et al., 2017) models have been applied in novel GNN designs (Hu et al., 2020; Zhang et al., 2020a).

5 Conclusion

In this paper, we proposed a scalable heterogeneous graph model, TG-Transformer, for text classification. Experimental results prove its effectiveness and efficiency compared to state-of-the-art methods. It also enables parallelization and pre-training in GNN models for further research.

Danai Koutra
University of Michigan
dkoutra@umich.edu

Abstract

We present CoDEx, a set of knowledge graph **CO**mpletion **D**atasets **EX**tracted from Wikidata and Wikipedia that improve upon existing knowledge graph completion benchmarks in scope and level of difficulty. In terms of scope, CoDEx comprises three knowledge graphs varying in size and structure, multilingual descriptions of entities and relations, and tens of thousands of *hard negative* triples that are plausible but verified to be false. To characterize CoDEx, we contribute thorough empirical analyses and benchmarking experiments. First, we analyze each CoDEx dataset in terms of logical relation patterns. Next, we report baseline link prediction and triple classification results on CoDEx for five extensively tuned embedding models. Finally, we differentiate CoDEx from the popular FB15K-237 knowledge graph completion dataset by showing that CoDEx covers more diverse and interpretable content, and is a more difficult link prediction benchmark. Data, code, and pretrained models are available at https://bit.ly/2EPbrJs.

1 Introduction

Knowledge graphs are multi-relational graphs that express facts about the world by connecting entities (people, places, things, concepts) via different types of relationships. The field of automatic knowledge graph completion (**KGC**), which is motivated by the fact that knowledge graphs are usually incomplete, is an active research direction spanning several subfields of artificial intelligence (Nickel et al., 2015; Wang et al., 2017; Ji et al., 2020).

As progress in artificial intelligence depends heavily on data, a relevant and high-quality benchmark is imperative to evaluating and advancing the state of the art in KGC. However, the field has largely remained static in this regard over the past decade. Outdated subsets of Freebase (Bollacker et al., 2008) are most commonly used for evaluation in KGC, even though Freebase had known quality issues (Tanon et al., 2016) and was eventually deprecated in favor of the more recent Wikidata knowledge base (Vrandečić and Krötzsch, 2014).

Indeed, KGC benchmarks extracted from Freebase like FB15K and FB15K-237 (Bordes et al., 2013; Toutanova and Chen, 2015) are questionable in quality. For example, FB15K was shown to have train/test leakage (Toutanova and Chen, 2015). Later in this paper (§ 6.2), we will show that a relatively large proportion of relations in FB15K-237 can be covered by a trivial frequency rule.

To address the need for a solid benchmark in KGC, we present **CoDEx**, a set of knowledge graph **CO**mpletion **D**atasets **EX**tracted from Wikidata and its sister project Wikipedia. Inasmuch as Wikidata is considered the successor of Freebase, CoDEx improves upon existing Freebase-based KGC benchmarks in terms of scope and level of difficulty (Table 1). Our contributions include:

Foundations We survey evaluation datasets in encyclopedic knowledge graph completion to motivate a new benchmark (§ 2 and Appendix A).

Data We introduce CoDEx, a benchmark consisting of three knowledge graphs varying in size and structure, entity types, multilingual labels and descriptions, and—unique to CoDEx—manually verified *hard negative* triples (§ 3). To better understand CoDEx, we analyze the logical relation patterns in each of its datasets (§ 4).

Benchmarking We conduct large-scale model selection and benchmarking experiments, reporting baseline link prediction and triple classification results on CoDEx for five widely used embedding models from different architectural classes (§ 5).

Comparative analysis Finally, to demonstrate the unique value of CoDEx, we differentiate

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8328–8350,

Table 1: Qualitative comparison of CoDEx datasets to existing Freebase-based KGC datasets (§ 2.1).

	Freebase variants (FB15K, FB15K-237)	CoDEx datasets
Scope (domains)	Multi-domain, with a strong focus on awards, entertainment, and sports (§ 6.1 and Appendix E)	Multi-domain, with focuses on writing, entertainment, music, politics, journalism, academics, and science (§ 6.1 and Appendix E)
Scope (auxiliary data)	Various decentralized versions of FB15K with, e.g., entity types (Xie et al., 2016), sampled negatives (Socher et al., 2013), and more (Table 8)	Centralized repository of three datasets with entity types, multilingual text, and manually annotated hard negatives (§ 3)
Level of difficulty	FB15K has severe train/test leakage from inverse relations (Toutanova and Chen, 2015); while removal of inverse relations makes FB15K-237 harder than FB15K, FB15K-237 still has a high proportion of easy-to-predict relational patterns (§ 6.2)	Inverse relations removed from all datasets to avoid train/test leakage (§ 3.2); manually annotated hard negatives for the task of triple classification (§ 3.4); few trivial patterns for the task of link prediction (§ 6.2)

CoDEx from FB15K-237 in terms of both content and difficulty (§ 6). We show that CoDEx covers more diverse and interpretable content, and is a more challenging link prediction benchmark.

2 Existing datasets

We begin by surveying existing KGC benchmarks. Table 8 in Appendix A provides an overview of evaluation datasets and tasks on a *per-paper* basis across the artificial intelligence, machine learning, and natural language processing communities.

Note that we focus on *data* rather than *models*, so we only overview relevant evaluation benchmarks here. For more on existing KGC models, both neural and symbolic, we refer the reader to (Meilicke et al., 2018) and (Ji et al., 2020).

2.1 Freebase extracts

These datasets, extracted from the Freebase knowledge graph (Bollacker et al., 2008), are the most popular for KGC (see Table 8 in Appendix A).

FB15K was introduced by Bordes et al. (2013). It contains 14,951 entities, 1,345 relations, and 592,213 triples covering several domains, with a strong focus on awards, entertainment, and sports.

FB15K-237 was introduced by Toutanova and Chen (2015) to remedy data leakage in FB15K, which contains many test triples that invert triples in the training set. FB15K-237 contains 14,541 entities, 237 relations, and 310,116 triples. We compare FB15K-237 to CoDEx in § 6 to assess each dataset's content and relative difficulty.

2.2 Other encyclopedic datasets

NELL-995 (Xiong et al., 2017) was taken from the Never Ending Language Learner (NELL) system (Mitchell et al., 2018), which continuously reads the web to obtain and update its knowledge. NELL-995, a subset of the 995th iteration of NELL, contains 75,492 entities, 200 relations, and 154,213 triples. While NELL-995 is general and covers many domains, its mean average precision was less than 50% around its 1000th iteration (Mitchell et al., 2018). A cursory inspection reveals that many of the triples in NELL-995 are nonsensical or overly generic, suggesting that NELL-995 is not a meaningful dataset for KGC evaluation.[1]

YAGO3-10 (Dettmers et al., 2018) is a subset of YAGO3 (Mahdisoltani et al., 2014), which covers portions of Wikipedia, Wikidata, and WordNet. YAGO3-10 has 123,182 entities, 37 relations, and 1,089,040 triples mostly limited to facts about people and locations. While YAGO3-10 is a high-precision dataset, it was recently shown to be too easy for link prediction because it contains a large proportion of duplicate relations (Akrami et al., 2020; Pezeshkpour et al., 2020).

2.3 Domain-specific datasets

In addition to large encyclopedic knowledge graphs, it is common to evaluate KGC methods on at least one smaller, domain-specific dataset, typically drawn from the **WordNet** semantic network (Miller, 1998; Bordes et al., 2013). Other choices include the Unified Medical Language System (**UMLS**) database (McCray, 2003), the **Alyawarra kinship** dataset (Kemp et al., 2006), the **Countries** dataset (Bouchard et al., 2015), and variants of a synthetic "**family tree**" (Hinton, 1986). As our focus in this paper is encyclopedic knowledge, we do not cover these datasets further.

---

[1] Some examples: (*politician:jobs*, *worksfor*, *county:god*), (*person:buddha001*, *parentofperson*, *person:jesus*)

Table 2: CoDEx datasets. (+): Positive (*true*) triples. (-): Verified negative (*false*) triples (§ 3.4). We compute multilingual coverage over all labels, descriptions, and entity Wikipedia extracts successfully retrieved for the respective dataset in Arabic (ar), German (de), English (en), Spanish (es), Russian (ru), and Chinese (zh).

	$\lvert E\rvert$	$\lvert R\rvert$	Triples $E \times R \times E$					Multilingual coverage					
			Train (+)	Valid (+)	Test (+)	Valid (-)	Test (-)	ar	de	en	es	ru	zh
CoDEx-S	2,034	42	32,888	1827	1828	1827	1828	77.38	91.87	96.38	91.55	89.17	79.36
CoDEx-M	17,050	51	185,584	10,310	10,311	10,310	10,311	75.80	95.20	96.95	87.91	81.88	69.63
CoDEx-L	77,951	69	551,193	30,622	30,622	-	-	67.47	90.84	92.40	81.30	71.12	61.06

3 Data collection

In this section we describe the pipeline used to construct CoDEx. For reference, we define a knowledge graph G as a multi-relational graph consisting of a set of entities E, relations R, and factual statements in the form of (*head*, *relation*, *tail*) triples $(h, r, t) \in E \times R \times E$.

3.1 Seeding the collection

We collected an initial set of triples using a type of snowball sampling (Goodman, 1961). We first manually defined a broad seed set of entity and relation types common to 13 domains: Business, geography, literature, media and entertainment, medicine, music, news, politics, religion, science, sports, travel, and visual art. Examples of seed entity types include *airline*, *journalist*, and *religious text*; corresponding seed relation types in each respective domain include *airline alliance*, *notable works*, and *language of work or name*. Table 9 in Appendix B gives all seed entity and relation types.

Using these seeds, we retrieved an initial set of 380,038 entities, 75 relations, and 1,156,222 triples by querying Wikidata for statements of the form (*head entity of seed type*, *seed relation type*, ?).

3.2 Filtering the collection

To create smaller data snapshots, we filtered the initial 1.15 million triples to k-cores, which are maximal subgraphs G' of a given graph G such that every node in G' has a degree of at least k (Batagelj and Zaveršnik, 2011).[2] We constructed three CoDEx datasets (Table 2):

- **CoDEx-S** (k = 15), which has 36k triples. Because of its smaller size, we recommend that CoDEx-S be used for model testing and debugging, as well as evaluation of methods that are less computationally efficient (e.g., symbolic search-based approaches).
- **CoDEx-M** (k = 10), which has 206k triples. CoDEx-M is all-purpose, being comparable in size to FB15K-237 (§ 2.1), one of the most popular benchmarks for KGC evaluation.
- **CoDEx-L** (k = 5), which has 612k triples. CoDEx-L is comparable in size to FB15K (§ 2.1), and can be used for both general evaluation and "few-shot" evaluation.

We also release the raw dump that we collected via snowball sampling, but focus on CoDEx-S through L for the remainder of this paper.

To minimize train/test leakage, we removed inverse relations from each dataset (Toutanova and Chen, 2015). We computed (*head*, *tail*) and (*tail*, *head*) overlap between all pairs of relations, and removed each relation whose entity pair set overlapped with that of another relation more than 50% of the time. Finally, we split each dataset into 90/5/5 train/validation/test triples such that the validation and test sets contained only entities and relations seen in the respective training sets.

3.3 Auxiliary information

An advantage of Wikidata is that it links entities and relations to various sources of rich auxiliary information. To enable tasks that involve joint learning over knowledge graph structure and such additional information, we collected:

- **Entity types** for each entity as given by Wikidata's *instance of* and *subclass of* relations;
- **Wikidata labels and descriptions** for entities, relations, and entity types; and
- **Wikipedia page extracts** (introduction sections) for entities and entity types.

For the latter two, we collected text where available in Arabic, German, English, Spanish, Russian, and Chinese. We chose these languages because they are all relatively well-represented on Wikidata (Kaffee et al., 2017). Table 2 provides the coverage by language for each CoDEx dataset.

---

[2] A similar approach was used to extract the FB15K dataset from Freebase (Bordes et al., 2013).

Table 3: Selected examples of hard negatives in CoDEx with explanations.

Negative	Explanation
(*Frédéric Chopin*, *occupation*, *conductor*)	Chopin was a pianist and a composer, not a conductor.
(*Lesotho*, *official language*, *American English*)	English, not American English, is an official language of Lesotho.
(*Senegal*, *part of*, *Middle East*)	Senegal is part of West Africa.
(*Simone de Beauvoir*, *field of work*, *astronomy*)	Simone de Beauvoir's field of work was primarily philosophy.
(*Vatican City*, *member of*, *UNESCO*)	Vatican City is a UNESCO World Heritage Site but not a member state.

3.4 Hard negatives for evaluation

Knowledge graphs are unique in that they only contain positive statements, meaning that triples *not* observed in a given knowledge graph are not necessarily false, but merely unseen; this is called the Open World Assumption (Galárraga et al., 2013). However, most machine learning tasks on knowledge graphs require negatives in some capacity. While different negative sampling strategies exist (Cai and Wang, 2018), the most common approach is to randomly perturb observed triples to generate negatives, following Bordes et al. (2013).

While random negative sampling is beneficial and even necessary in the case where a large number of negatives is needed (i.e., training), it is not necessarily useful for evaluation. For example, in the task of triple classification, the goal is to discriminate between positive (true) and negative (false) triples. As we show in § 5.5, triple classification over randomly generated negatives is trivially easy for state-of-the-art models because random negatives are generally not meaningful or plausible. Therefore, we generate and manually evaluate *hard negatives* for KGC evaluation.

Generation To generate hard negatives, we used each pre-trained embedding model from § 5.2 to predict tail entities of triples in CoDEx. For each model, we took as candidate negatives the triples $(h, r, \hat{t})$ for which (i) the type of the predicted tail entity $\hat{t}$ matched the type of the true tail entity t; (ii) $\hat{t}$ was ranked in the top-10 predictions by that model; and (iii) $(h, r, \hat{t})$ was not observed in G.

Annotation We manually labeled all candidate negative triples generated for CoDEx-S and CoDEx-M as *true* or *false* using the guidelines provided in Appendix C.[3] We randomly selected among the triples labeled as *false* to create **validation and test negatives for CoDEx-S and CoDEx-M**, examples of which are given in Table 3. To assess the quality of our annotations, we gathered judgments from two independent native English speakers on a random selection of 100 candidate negatives. The annotators were provided the instructions from Appendix C. On average, our labels agreed with those of the annotators 89.5% of the time. Among the disagreements, 81% of the time we assigned the label *true* whereas the annotator assigned the label *false*, meaning that we were comparatively conservative in labeling negatives.

4 Analysis of relation patterns

To give an idea of the types of reasoning necessary for models to perform well on CoDEx, we analyze the presence of learnable binary relation patterns within CoDEx. The three main types of such patterns in knowledge graphs are **symmetry**, **inversion**, and **compositionality** (Trouillon et al., 2019; Sun et al., 2019). We address symmetry and compositionality here, and omit inversion because we specifically removed inverse relations to avoid train/test leakage (§ 3.2).

4.1 Symmetry

Symmetric relations are relations r for which $(h, r, t) \in G$ implies $(t, r, h) \in G$. For each relation, we compute the number of its (*head*, *tail*) pairs that overlap with its (*tail*, *head*) pairs, divided by the total number of pairs, and take those with 50% overlap or higher as symmetric. CoDEx datasets have five such relations: *diplomatic relation*, *shares border with*, *sibling*, *spouse*, and *unmarried partner*. Table 4 gives the proportion of triples containing symmetric relations per dataset. Symmetric patterns are more prevalent in CoDEx-S, whereas the larger datasets are mostly **antisymmetric**, i.e., $(h, r, t) \in G$ implies $(t, r, h) \notin G$.

4.2 Composition

Compositionality captures **path rules** of the form $(h, r_1, x_1), \ldots, (x_n, r_n, t) \rightarrow (h, r, t)$. To learn these rules, models must be capable of "multi-hop" reasoning on knowledge graphs (Guu et al., 2015).

---

[3] We are currently investigating methods for obtaining high-quality crowdsourced annotations of negatives for CoDEx-L.

Table 4: Relation patterns in CoDEx. For symmetry, we give the proportion of triples containing a symmetric relation. For composition, we give the proportion of triples participating in a rule of length two or three.

	CoDEx-S	CoDEx-M	CoDEx-L
Symmetry	17.46%	4.01%	3.29%
Composition	10.09%	16.55%	31.84%

To identify compositional paths, we use the AMIE3 system (Lajus et al., 2020), which outputs rules with confidence scores that capture how many times those rules are seen versus violated, to identify paths of lengths two and three; we omit longer paths as they are relatively costly to compute. We identify 26, 44, and 93 rules in CoDEx-S, CoDEx-M, and CoDEx-L, respectively, with average confidence (out of 1) of 0.630, 0.556, and 0.459. Table 4 gives the percentage of triples per dataset participating in a discovered rule.

Evidently, composition is especially prevalent in CoDEx-L. An example rule in CoDEx-L is "if *X* was founded by *Y*, and *Y*'s country of citizenship is *Z*, then the country [i.e., of origin] of *X* is *Z*" (confidence 0.709). We release these rules as part of CoDEx for further development of KGC methodologies that incorporate or learn rules.

5 Benchmarking

Next, we benchmark performance on CoDEx for the tasks of link prediction and triple classification. To ensure that models are fairly and accurately compared, we follow Ruffinelli et al. (2020), who conducted what is (to the best of our knowledge) the largest-scale hyperparameter tuning study of knowledge graph embeddings to date.

Note that CoDEx can be used to evaluate any type of KGC method. However, we focus on embeddings in this section due to their widespread usage in modern NLP (Ji et al., 2020).

5.1 Tasks

Link prediction The link prediction task is conducted as follows: Given a test triple (h, r, t), we construct queries $(?, r, t)$ and $(h, r, ?)$. For each query, a model scores candidate head (tail) entities $\hat{h}$ $(\hat{t})$ according to its belief that $\hat{h}$ $(\hat{t})$ completes the triple (i.e., answers the query). The goal is of link prediction is to rank true triples $(\hat{h}, r, t)$ or $(h, r, \hat{t})$ higher than false and unseen triples.

Link prediction performance is evaluated with mean reciprocal rank (**MRR**) and **hits@**k. MRR is the average reciprocal of each ground-truth entity's rank over all $(?, r, t)$ and $(h, r, ?)$ test triples. Hits@k measures the proportion of test triples for which the ground-truth entity is ranked in the top-k predicted entities. In computing these metrics, we exclude the predicted entities for which $(\hat{h}, r, t) \in G$ or $(h, r, \hat{t}) \in G$ so that known positive triples do not artificially lower ranking scores. This is called "filtering" (Bordes et al., 2013).

Triple classification Given a triple (h, r, t), the goal of triple classification is to predict a corresponding label $y \in \{-1, 1\}$. Since knowledge graph embedding models output real-valued scores for triples, we convert these scores into labels by selecting a decision threshold per relation on the validation set such that validation accuracy is maximized for the model in question. A similar approach was used by Socher et al. (2013).

We compare results on three sets of evaluation negatives: (1) We generate one negative per positive by replacing the positive triple's tail entity by a tail entity t' sampled **uniformly at random**; (2) We generate negatives by sampling tail entities according to their **relative frequency in the tail slot** of all triples; and (3) We use the CoDEx **hard negatives**. We measure **accuracy** and **F1 score**.

5.2 Models

We compare the following embedding methods: **RESCAL** (Nickel et al., 2011), **TransE** (Bordes et al., 2013), **ComplEx** (Trouillon et al., 2016), **ConvE** (Dettmers et al., 2018), and **TuckER** (Balazevic et al., 2019b). These models represent several classes of architecture, from linear (RESCAL, TuckER, ComplEx) to translational (TransE) to nonlinear/learned (ConvE). Appendix D provides more specifics on each model.

5.3 Model selection

As recent studies have observed that training strategies are equally, if not more, important than architecture for link prediction (Kadlec et al., 2017; Lacroix et al., 2018; Ruffinelli et al., 2020), we search across a large range of hyperparameters to ensure a truly fair comparison. To this end we use the PyTorch-based LibKGE framework for training and selecting knowledge graph embeddings.[4] In the remainder of this section we outline the most important parameters of our model selection process.

---

[4] https://github.com/uma-pi1/kge

Table 5: Comparison of link prediction performance on CoDEx.

	CoDEx-S			CoDEx-M			CoDEx-L		
	MRR	Hits@1	Hits@10	MRR	Hits@1	Hits@10	MRR	Hits@1	Hits@10
RESCAL	0.404	0.293	0.623	0.317	0.244	0.456	0.304	0.242	0.419
TransE	0.354	0.219	0.634	0.303	0.223	0.454	0.187	0.116	0.317
ComplEx	**0.465**	**0.372**	**0.646**	**0.337**	**0.262**	**0.476**	0.294	0.237	0.400
ConvE	0.444	0.343	0.635	0.318	0.239	0.464	0.303	0.240	0.420
TuckER	0.444	0.339	0.638	0.328	0.259	0.458	**0.309**	**0.244**	**0.430**

Table 10 in Appendix F gives further details and all hyperparameter ranges and values. All experiments were run on a single NVIDIA Tesla V100 GPU with 16 GB of RAM.

Training negatives Given a set of positive training triples $\{(h, r, t)\}$, we compare three types of negative sampling strategy implemented by LibKGE: (a) **NegSamp**, or randomly corrupting head entities h or tail entities t to create negatives; (b) **1vsAll**, or treating *all* possible head/tail corruptions of (h, r, t) as negatives, including the corruptions that are actually positives; and (c) **KvsAll**, or treating batches of head/tail corruptions *not* seen in the knowledge graph as negatives.

Loss functions We consider the following loss functions: (i) **MR** or margin ranking, which aims to maximize a margin between positive and negative triples; (ii) **BCE** or binary cross-entropy, which is computed by applying the logistic sigmoid to triple scores; and (iii) **CE** or cross-entropy between the softmax over the entire distribution of triple scores and the label distribution over all triples, normalized to sum to one.

Search strategies We select models using the Ax platform, which supports hyperparameter search using both quasi-random sequences of generated configurations and Bayesian optimization (BO) with Gaussian processes.[5] At a high level, for each dataset and model, we generate both quasi-random and BO trials *per negative sampling and loss function combination*, ensuring that we search over a wide range of hyperparameters for different types of training strategy. Appendix F provides specific details on the search strategy for each dataset, which was determined according to resource constraints and observed performance patterns.

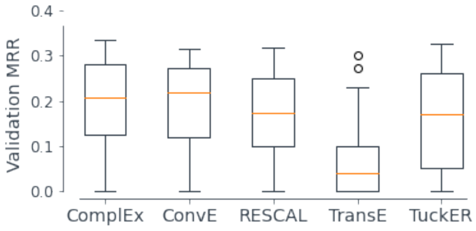

Figure 1: Distribution of validation MRR, CoDEx-M.

5.4 Link prediction results

Table 5 gives link prediction results. We find that ComplEx is the **best at modeling symmetry and antisymmetry**, and indeed it was designed specifically to improve upon bilinear models that do not capture symmetry, like DistMult (Trouillon et al., 2016). As such, it performs the best on CoDEx-S, which has the highest proportion of symmetric relations. For example, on the most frequent symmetric relation (*diplomatic relation*), ComplEx achieves 0.859 MRR, compared to 0.793 for ConvE, 0.490 for RESCAL, and 0.281 for TransE.

By contrast, TuckER is **strongest at modeling compositional relations**, so it performs best on CoDEx-L, which has a high degree of compositionality. For example, on the most frequent compositional relation in CoDEx-L (*languages spoken, written, or signed*), TuckER achieves 0.465 MRR, compared to 0.464 for RESCAL, 0.463 for ConvE, 0.456 for ComplEx, and 0.385 for TransE. By contrast, since CoDEx-M is mostly asymmetric and non-compositional, ComplEx performs best because of its ability to model asymmetry.

Effect of hyperparameters As shown by Figure 1, hyperparameters have a strong impact on link prediction performance: Validation MRR for all models varies by *over 30 percentage points* depending on the training strategy and input configuration. This finding is consistent with previous observations in the literature (Kadlec et al., 2017; Ruffinelli et al., 2020). Appendix F provides the best configurations for each model.

---

[5] https://ax.dev/

Table 6: Comparison of triple classification performance on CoDEx by negative generation strategy.

	CoDEx-S						CoDEx-M					
	Uniform		Relative freq.		Hard neg.		Uniform		Relative freq.		Hard neg.	
	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1
RESCAL	0.972	0.972	0.916	0.920	**0.843**	**0.852**	0.977	0.976	0.921	0.922	0.818	0.815
TransE	0.974	0.974	0.919	0.923	0.829	0.837	**0.986**	**0.986**	0.932	0.933	0.797	0.803
ComplEx	**0.975**	**0.975**	**0.927**	**0.930**	0.836	0.846	0.984	0.984	0.930	0.933	0.824	0.818
ConvE	0.972	0.972	0.921	0.924	0.841	0.846	0.979	0.979	**0.934**	**0.935**	**0.826**	**0.829**
TuckER	0.973	0.973	0.917	0.920	0.840	0.846	0.977	0.977	0.920	0.922	0.823	0.816

Overall, we find that the choice of loss function in particular significantly impacts model performance. Each model consistently **achieved its respective peak performance with cross-entropy (CE) loss**, a finding which is corroborated by several other KGC comparison papers (Kadlec et al., 2017; Ruffinelli et al., 2020; Jain et al., 2020). As far as negative sampling techniques, we do not find that a single strategy is dominant, suggesting that the choice of loss function is more important.

5.5 Triple classification results

Table 6 gives triple classification results. Evidently, triple classification on ***randomly*** **generated negatives is a nearly-solved task**. On negatives generated uniformly at random, performance scores are nearly identical at almost 100% accuracy. Even with a negative sampling strategy "smarter" than uniform random, all models perform well.

Hard negatives Classification performance degenerates considerably on our hard negatives, around 8 to 11 percentage points from relative frequency-based sampling and 13 to 19 percentage points from uniformly random sampling. Relative performance also varies: In contrast to our link prediction task in which ComplEx and TuckER were by far the strongest models, RESCAL is slightly stronger on the CoDEx-S hard negatives, whereas ConvE performs best on the CoDEx-M hard negatives. These results indicate that **triple classification is indeed a distinct task** that requires different architectures and, in many cases, different training strategies (Appendix F).

We believe that few recent works use triple classification as an evaluation task because of the lack of true hard negatives in existing benchmarks. Early works reported high triple classification accuracy on sampled negatives (Socher et al., 2013; Wang et al., 2014), perhaps leading the community to believe that the task was nearly solved. However, our results demonstrate that the task is far from solved when the negatives are plausible but truly false.

6 Comparative case study

Finally, we conduct a comparative analysis between CoDEx-M and FB15K-237 (§ 2.1) to demonstrate the unique value of CoDEx. We choose FB15K-237 because it is the most popular encyclopedic KGC benchmark after FB15K, which was already shown to be an easy dataset by Toutanova and Chen (2015). We choose CoDEx-M because it is the closest in size to FB15K-237.

6.1 Content

We first compare the content in CoDEx-M, which is extracted from Wikidata, with that of FB15K-237, which is extracted from Freebase. For brevity, Figure 2 compares the top-15 relations by mention count in the two datasets. Appendix E provides more content comparisons.

Diversity The most common relation in CoDEx-M is *occupation*, which is because most people on Wikidata have multiple occupations listed. By contrast, the frequent relations in FB15K-237 are mostly related to awards and film. In fact, over 25% of all triples in FB15K-237 belong to the */award* relation domain, suggesting that CoDEx covers a more diverse selection of content.

Interpretability The Freebase-style relations are also arguably less interpretable than those in Wikidata. Whereas Wikidata relations have concise natural language labels, the Freebase relation labels are hierarchical, often at five or six levels of hierarchy (Figure 2). Moreover, all relations in Wikidata are binary, whereas some Freebase relations are n-nary (Tanon et al., 2016), meaning that they connect more than two entities. The relations containing a dot (".") are such n-nary relations, and are difficult to reason about without understanding the structure of Freebase, which has been deprecated.

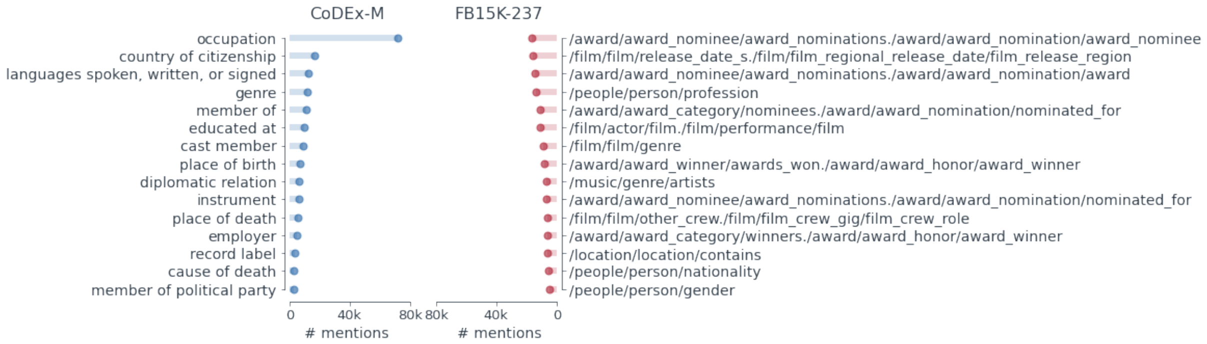

Figure 2: Top-15 most frequent relations in CoDEx-M and FB15K-237.

We further discuss the impact of such n-nary relations for link prediction in the following section.

6.2 Difficulty

Next, we compare the datasets in a link prediction task to show that CoDEx-M is more difficult.

Baseline We devise a "non-learning" link prediction baseline. Let $(h, r, ?)$ be a test query. Our baseline scores candidate tail entities by their relative frequency in the tail slot of all training triples mentioning r, filtering out tail entities t for which (h, r, t) is already observed in the training set. If all tail entities t are filtered out, we score entities by frequency before filtering. The logic of our approach works in reverse for $(?, r, t)$ queries. In evaluating our baseline, we follow LibKGE's protocol for breaking ties in ranking (i.e., for entities that appear with equal frequency) by taking the mean rank of all entities with the same score.

Setup We compare our baseline to the best pretrained embedding model per dataset: RESCAL for FB15K-237, which was released by Ruffinelli et al. (2020), and ComplEx for CoDEx-M. We evaluate performance with MRR and Hits@10. Beyond overall performance, we also compute *per-relation improvement* of the respective embedding over our baseline in terms of percentage points MRR. This measures the amount of learning beyond frequency statistics necessary for each relation.

Results and discussion Table 7 compares the overall performance of our baseline versus the best embedding per dataset, and Figure 3 shows the improvement of the respective embedding over our baseline per relation type on each dataset. The improvement of the embedding is much smaller on FB15K-237 than CoDEx-M, and in fact our baseline performs on par with or even *outperforms* the embedding on FB15K-237 for some relation types.

Table 7: Overall performance (MRR) of our frequency baseline versus the best embedding nodel per benchmark. "Improvement" refers to the improvement of the embedding over the baseline.

	Baseline	Embedding	Improvement
FB15K-237	0.236	0.356	+0.120
CoDEx-M	0.135	0.337	+0.202

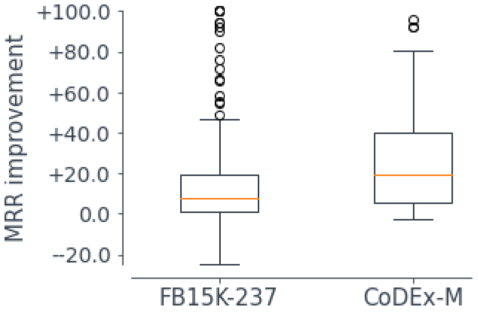

Figure 3: Improvement in MRR of the embedding over our frequency baseline per relation type. Negative means that our baseline outperforms the embedding. The medians are 8.27 and 20.04 percentage points on FB15K-237 and CoDEx-M, respectively.

To further explore these cases, Figure 4 gives the empirical cumulative distribution function of improvement, which shows the percentage of test triples for which the level of improvement is less than or equal to a given value on each dataset. Surprisingly, the improvement for both MRR and Hits@10 is less than five percentage points for nearly 40% of FB15K-237's test set, and is *zero or negative* 15% of the time. By contrast, our baseline is significantly weaker than the strongest embedding method on CoDEx-M.

The disparity in improvement is due to two relation patterns prevalent in FB15K-237:

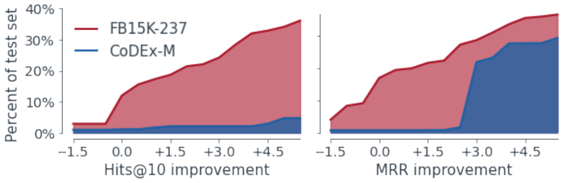

Figure 4: Empirical CDF of improvement of the best embedding over our frequency baseline.

- **Skewed relations** FB15K-237 contains many relations that are skewed toward a single head or tail entity. For example, our baseline achieves perfect performance over all $(h, r, ?)$ queries for the */common/topic/webpage./common/webpage/category* relation because this relation has only *one* unique tail entity. Another example of a highly skewed relation in FB15K-237 is */people/person/gender*, for which 78.41% of tails are the entity *male*. In fact, 11 relations in FB15K-237 have only one unique tail entity, accounting for 3.22% of all tail queries in FB15K-237. Overall, 15.98% of test triples in FB15K-237 contain relations that are skewed 50% or more toward a single head or tail entity, whereas only 1.26% of test triples in CODEX-M contain such skewed relations.

- **Fixed-set relations** Around 12.7% of test queries in FB15K-237 contain relation types that connect entities to *fixed sets of values*. As an example, each head entity that participates in the FB15K-237 relation */travel/travel_destination/climate./travel/travel_destination_monthly_climate/month* is connected to the *same* 12 tails (months of the year) throughout train, validation, and test. This makes prediction trivial with our baseline: By filtering out the tail entities already seen in train, only a few (or even one) candidate tail(s) are left in test, and the answer is guaranteed to be within these candidates. These relations only occur in FB15K-237 because of the way the dataset was constructed from Freebase. Specifically, Freebase used a special type of entity called Compound Value Type (CVT) as an intermediary node connecting *n-ary* relations. Binary relations were created by traversing through CVTs, yielding some relations that connect entities to fixed sets of values.

We conclude that while FB15K-237 is a valuable dataset, CODEX is more appropriately difficult for link prediction. Additionally, we note that in FB15K-237, all validation and test triples containing entity pairs directly linked in the training set were deleted (Toutanova and Chen, 2015), meaning that symmetry cannot be tested for in FB15K-237. Given that CODEX datasets contain both symmetry and compositionality, CODEX is more suitable for assessing how well models can learn relation patterns that go beyond frequency.

7 Conclusion and outlook

We present **CODEX**, a set of knowledge graph **CO**mpletion **D**atasets **EX**tracted from Wikidata and Wikipedia, and show that CODEX is suitable for multiple KGC tasks. We release data, code, and pretrained models for use by the community at https://bit.ly/2EPbrJs. Some promising future directions on CODEX include:

- **Better model understanding** CODEX can be used to analyze the impact of hyperparameters, training strategies, and model architectures in KGC tasks.

- **Revival of triple classification** We encourage the use of triple classification on CODEX in addition to link prediction because it directly tests discriminative power.

- **Fusing text and structure** Including text in both the link prediction and triple classification tasks should substantially improve performance (Toutanova et al., 2015). Furthermore, text can be used for few-shot link prediction, an emerging research direction (Xiong et al., 2017; Shi and Weninger, 2017).

Overall, we hope that CODEX will provide a boost to research in KGC, which will in turn impact many other fields of artificial intelligence.

A Literature review

Table 8 provides an overview of knowledge graph embedding papers with respect to datasets and evaluation tasks. In our review, we only consider papers published between 2014 and 2020 in the main proceedings of conferences where KGC embedding papers are most likely to appear: Artificial intelligence (AAAI, IJCAI), machine learning (ICML, ICLR, NeurIPS), and natural language processing (ACL, EMNLP, NAACL).

The main evaluation benchmarks are **FB15K** (Bordes et al., 2013), **WN18** (Bordes et al., 2013), **FB15K-237** (Toutanova and Chen, 2015), **WN18RR** (Dettmers et al., 2018), **FB13** (Socher et al., 2013), **WN11** (Socher et al., 2013), **NELL-995** (Xiong et al., 2017), **YAGO3-10** (Dettmers et al., 2018), **Countries** (Bouchard et al., 2015). **UMLS** (McCray, 2003), **Kinship** (Kemp et al., 2006), **Families** (Hinton, 1986), and other versions of **NELL** (Mitchell et al., 2018).

B Seeds for data collection

Table 9 provides all seed entity and relation types used to collect CoDEx. Each type is given first by its natural language label and then by its Wikidata unique ID: Entity IDs begin with Q, whereas relation (property) IDs begin with P. For the entity types that apply to *people* (e.g., actor, musician, journalist), we retrieved seed entities by querying Wikidata using the *occupation* relation. For the entity types that apply to *things* (e.g., airline, disease, tourist attraction), we retrieved seed entities by querying Wikidata using the *instance of* and *subclass of* relations.

C Negative annotation guidelines

We provide the annotation guidelines we used to label candidate negative triples (§ 3.4).

Task You must label each triple as either *true* or *false*. To help you find the answer, we have provided you with Wikipedia and Wikidata links for the entities and relations in each triple. You may also search on Google for the answer, although most claims should be resolvable using Wikipedia and Wikidata alone. If you are not able to find any reliable, specific, clear information supporting the claim, choose *false*. You may explain your reasoning if need be or provide sources to back up your answer in the optional explanation column.

Examples False triples may have problems with grammar, factual content, or both. Examples of *grammatically incorrect* triples are those whose entity or relation types do not make sense, for example:

- (*United States of America*, *continent*, *science fiction writer*)
- (*Mohandas Karamchand Gandhi*, *medical condition*, *British Raj*)
- (*Canada*, *foundational text*, *Vietnamese cuisine*)

Examples of grammatically correct but *factually false* triples include:

- (*United States of America*, *continent*, *Europe*)
- (*Mohandas Karamchand Gandhi*, *country of citizenship*, *Argentina*)
- (*Canada*, *foundational text*, *Harry Potter and the Goblet of Fire*)
- (*Alexander Pushkin*, *influenced by*, *Leo Tolstoy*) — Pushkin died only a few years after Tolstoy was born, so this sentence is unlikely.

Notice that in the latter examples, the entity types match up, but the statements are still false.

Tips For triples about people's *occupation* and *genre*, try to be as specific as possible. For example, if the triple says (<person>, *occupation*, *guitarist*) but that person is mainly known for their singing, choose *false*, even if that person plays the guitar. Likewise, if a triple says (<person>, *genre*, *classical*) but they are mostly known for jazz music, choose *false* even if, for example, that person had classical training in their childhood.

D Embedding models

We briefly overview the five models compared in our link prediction and triple classification tasks.

RESCAL (Nickel et al., 2011) was one of the first knowledge graph embedding models. Although it is not often used as a baseline, Ruffinelli et al. (2020) showed that it is competitive when appropriately tuned. RESCAL treats relational learning as tensor decomposition, scoring entity embeddings $\mathbf{h}, \mathbf{r} \in \mathbb{R}^{d_e}$ and relation embeddings $\mathbf{R} \in \mathbb{R}^{d_e \times d_e}$ with the bilinear form $\mathbf{h}^\top \mathbf{R} \mathbf{t}$.

Table 8: An overview of knowledge graph embedding papers published between 2014 and 2020 with respect to datasets and evaluation tasks. Original citations for datasets are given in Appendix A. Link pred. refers to link prediction, and triple class. refers to triple classification, both of which are covered in § 5.

Relations	airline alliance (P114), airline hub (P113), architect (P84), architectural style (P149), author (P50), capital (P36), cast member (P161), cause of death (P509), chairperson (P488), chief executive officer (P169), child (P40), continent (P30), country (P17), country of citizenship (P27), country of origin (P495), creator (P170), diplomatic relation (P530), director (P57), drug used for treatment (P2176), educated at (P69), employer (P108), ethnic group (P172), field of work (P101), foundational text (P457), founded by (P112), genre (P136), head of government (P6), head of state (P35), headquarters location (P159), health specialty (P1995), indigenous to (P2341), industry (P452), influenced by (P737), instance of (P31), instrument (P1303), language of work or name (P407), languages spoken, written, or signed (P1412), legal form (P1454), legislative body (P194), located in the administrative terroritorial entity (P131), location of formation (P740), medical condition (P1050), medical examinations (P923), member of (P463), member of political party (P102), member of sports team (P54), mountain range (P4552), movement (P135), named after (P138), narrative location (P840), notable works (P800), occupant (P466), occupation (P106), official language (P37), parent organization (P749), part of (P361), place of birth (P19), place of burial (P119), place of death (P20), practiced by (P3095), product or material produced (P1056), publisher (P123), record label (P264), regulated by (P3719), religion (P140), residence (P551), shares border with (P47), sibling (P3373), sport (P641), spouse (P26), studies (P2578), subclass of (P279), symptoms (P780), time period (P2348), tributary (P974), unmarried partner (P451), use (P366), uses (P2283)

TransE (Bordes et al., 2013) treats relations as translations between entities, i.e., $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ for $\mathbf{h}, \mathbf{r}, \mathbf{t} \in \mathbb{R}^{d_e}$, and scores embeddings with negative Euclidean distance $-\|\mathbf{h} + \mathbf{r} - \mathbf{t}\|$. TransE is likely the most popular baseline for KGC tasks and the most influential of all KGC embedding papers.

ComplEx (Trouillon et al., 2016) uses a bilinear function to score triples with a diagonal relation embedding matrix and complex-valued embeddings. Its scoring function is $\mathrm{re}\left(\mathbf{h}^\top \mathrm{diag}(\mathbf{r})\overline{\mathbf{t}}\right)$, where $\overline{\mathbf{t}}$ is the complex conjugate of $\mathbf{t}$ and re denotes the real part of a complex number.

ConvE (Dettmers et al., 2018) is one of the first and most popular *nonlinear* models for KGC. It concatenates head and relation embeddings $\mathbf{h}$ and $\mathbf{r}$ into a two-dimensional "image", applies a pointwise linearity over convolutional and fully-connected layers, and multiplies the result with the tail embedding $\mathbf{t}$ to obtain a score. Formally, its scoring function is given as $f(\mathrm{vec}(f([\overline{\mathbf{h}}; \overline{\mathbf{r}}] * \omega))\mathbf{W})\mathbf{t}$, where f is a nonlinearity (originally, ReLU), $[\overline{\mathbf{h}}; \overline{\mathbf{r}}]$ denotes a concatenation and two-dimensional reshaping of the head and relation embeddings, ω denotes the filters of the convolutional layer, and vec denotes the flattening of a two-dimensional matrix.

TuckER (Balazevic et al., 2019b) is a linear model based on the Tucker tensor decomposition, which factorizes a tensor into three lower-rank matrices and a core tensor. The TuckER scoring function for a single triple (h, r, t) is given as $\mathcal{W} \times_1 \mathbf{h} \times_2 \mathbf{r} \times_3 \mathbf{t}$, where $\mathcal{W}$ is the mode-three core tensor that is shared among all entity and relation embeddings, and $\times_n$ denotes the tensor product along the n-th mode of the tensor. TuckER can be seen as a generalized form of other linear KGC embedding models like RESCAL and ComplEx.

E Content comparison

We provide additional comparison of the contents in CoDEx-M and FB15K-237.

Figure 5, which plots the **top-30 entities by frequency** in the two benchmarks, demonstrates that both dataset are biased toward developed Western countries and cultures. However, CoDEx-M is more diverse in domain. It covers academia, entertainment, journalism, politics, science, and writing, whereas FB15K-237 covers mostly entertaiment and sports. FB15K-237 is also much more biased toward the United States in particular, as five of its top-30 entities are specific to the US: *United States of America*, *United States dollar*, *New York City*,

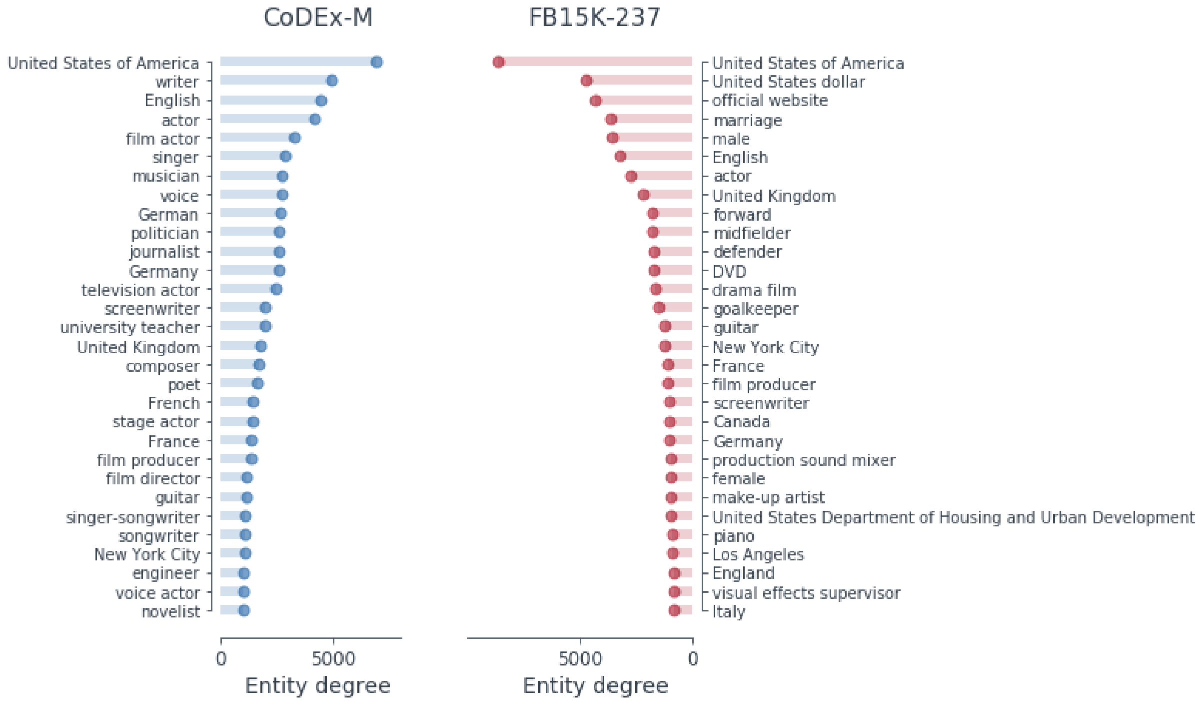

Figure 5: Top-30 **most frequent entities** in CODEX-M and FB15K-237.

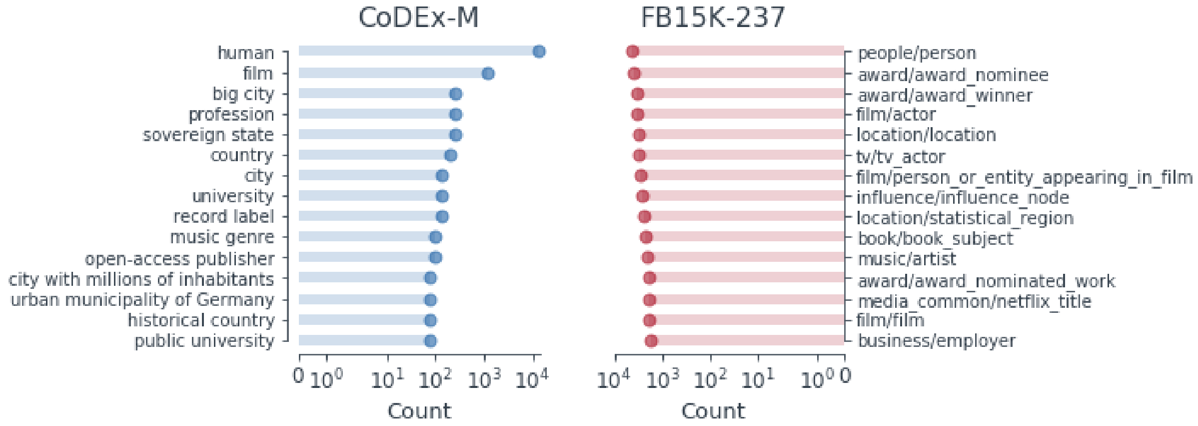

Figure 6: Top-15 **most frequent entity types** in CODEX-M and FB15K-237.

Los Angeles, and the *United States Department of Housing and Urban Development*.

Figure 6 compares the **top-15 entity types** in CODEX-M and FB15K-237. Again, CODEX-M is diverse, covering people, places, organizations, movies, and abstract concepts, whereas FB15K-237 has many overlapping entity types mostly about entertainment.

F Hyperparameter search

Table 10 gives our hyperparameter search space. Tables 11, 12, and 13 report the best hyperparameter configurations for link prediction on CODEX-S, CODEX-M, and CODEX-L, respectively. Tables 14 and 15 report the best hyperparameter configurations for triple classification on the hard negatives in CODEX-S and CODEX-M, respectively.

Terminology For embedding initialization, **Xv** refers to Xavier initialization (Glorot and Bengio, 2010). The **reciprocal relations** model refers to learning separate relation embeddings for queries in the direction of $(h, r, ?)$ versus $(?, r, t)$ (Kazemi and Poole, 2018). The **frequency weighting** regularization technique refers to regularizing embeddings by the relative frequency of the corresponding entity or relation in the training data.

Search strategies Recall that we select models using Ax, which supports hyperparameter search using both quasi-random sequences of generated configurations and Bayesian optimization (BO). The search strategy for each CODEX dataset is as follows:

- **CODEX-S**: Per negative sampling type/loss combination, we generate 30 quasi-random trials followed by 10 BO trials. We select the best-performing model by validation MRR over all such combinations. In each trial, the model is trained for a maximum of 400 epochs with an early stopping patience of 5. We also terminate a trial after 50 epochs if the model does not reach ≥ 0.05 MRR.
- **CODEX-M**: Per negative sampling type/loss combination, we generate 20 quasi-random trials. The maximum number of epochs and early stopping criteria are the same as for CODEX-S.
- **CODEX-L**: Per negative sampling type/loss combination, we generate 10 quasi-random trials of 20 training epochs instead of 400. We reduce the number of epochs to limit resource usage. In most cases, MRR plateaus after 20-30 epochs, an observation which is consistent with (Ruffinelli et al., 2020). Then, we take the best-performing model by validation MRR over all such combinations, and retrain that model for a maximum of 400 epochs.

Note that we search using MRR as our metric, but the triple classification task measures 0/1 accuracy, not ranking performance. For triple classification, we choose the model with the highest validation accuracy among the pre-trained models across all negative sampling type/loss function combinations.

We release all pretrained LibKGE models and accompanying configuration files in the centralized CODEX repository.

Table 10: Our hyperparameter search space. We follow the naming conventions and ranges given by Ruffinelli et al. (2020), and explain the meanings of selected hyperparameter settings in Appendix F. As most KGC embedding models have a wide range of configuration options, we encourage future work to follow this tabular scheme for transparent reporting of implementation details.

Hyperparameter	Range

META: Metadata-Empowered Weak Supervision for Text Classification

Dheeraj Mekala[1] **Xinyang Zhang**[2] **Jingbo Shang**[1,3]

Abstract

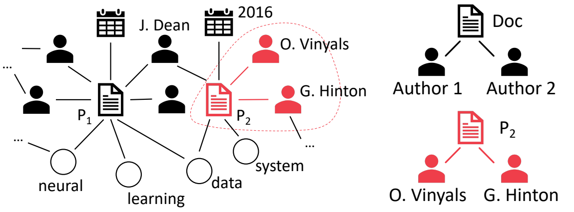
Recent advances in weakly supervised learning enable training high-quality text classifiers by only providing a few user-provided seed words. Existing methods mainly use text data alone to generate pseudo-labels despite the fact that metadata information (e.g., author and timestamp) is widely available across various domains. Strong label indicators exist in the metadata and it has been long overlooked mainly due to the following challenges: (1) metadata is multi-typed, requiring systematic modeling of different types and their combinations, (2) metadata is noisy, some metadata entities (e.g., authors, venues) are more compelling label indicators than others. In this paper, we propose a novel framework, META, which goes beyond the existing paradigm and leverages metadata as an additional source of weak supervision. Specifically, we organize the text data and metadata together into a text-rich network and adopt network motifs to capture appropriate combinations of metadata. Based on seed words, we rank and filter motif instances to distill highly label-indicative ones as "seed motifs", which provide additional weak supervision. Following a bootstrapping manner, we train the classifier and expand the seed words and seed motifs iteratively. Extensive experiments and case studies on real-world datasets demonstrate superior performance and significant advantages of leveraging metadata as weak supervision.

1 Introduction

Weakly supervised text classification has recently gained much attention from the researchers because it reduces the burden of annotating the data. So far, the major source of weak supervision lies in text data itself (Agichtein and Gravano, 2000; Kuipers et al., 2006; Riloff et al., 2003; Tao et al., 2015; Meng et al., 2018; Mekala and Shang, 2020). These methods typically require a few user-provided seed words for each class as weak supervision. They expand seed words with generated pseudo labels and improve their text classifier in an iterative fashion.

Paper	Authors	Year	Category
P_1	G. Hinton, S. Osindero, YW. Teh	2006	ML
P_2	G. Hinton, O. Vinyals, J. Dean	2015	ML
P_3	J. Dean, S.Ghemawat	2008	Sys

(a) Examples of research papers with metadata.



(b) A text-rich network view of the papers.

(c) A motif pattern and a motif instance.

Figure 1: Text corpus, text-rich network, and motif.

Metadata information (e.g., author, published year) in addition to textual information, is widely available across various domains (e.g., news articles, social media posts, and scientific papers) and it could serve as a strong, complementary weak supervision source. Take a look at the research papers in Figure 1(a) as an example. It shall be learned in a data-driven manner that *G. Hinton* is a highly-reputed machine learning researcher, thus his presence is a strong indicator of a paper belonging to the *Machine Learning* category.

Distilling effective metadata for weak supervision faces several major challenges. Metadata is often multi-typed, each type and the type combinations could have very different semantics and may not be equally important. Moreover, even entities within a single metadata type could be noisy. Continuing our example in Figure 1(a), we shall notice that *year* is less helpful than an *author* to do classification. Among the authors, *J. Dean* might be an important figure but has research interests

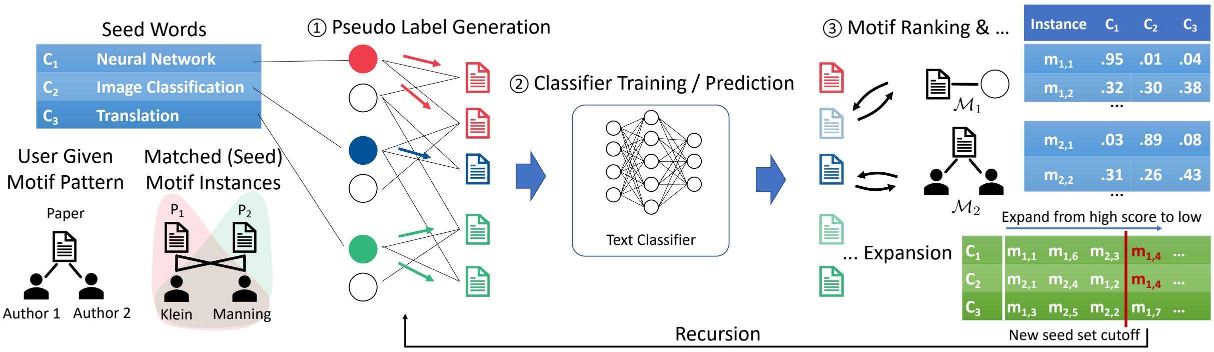

Figure 2: Our META framework. In each iteration, we generate pseudo labels for documents, train the text classifier, and rank all words and motif instances in a unified ranking framework. We then expand seed sets until an automatic cutoff is reached. The quality of the classifier and the seed sets are improved through iterations.

spanning across different domains. However, if we join the *author* with *year*, it carries more accurate semantics, and we may discover *J. Dean* has more interest in machine learning in recent years, thus becoming highly label-indicative.

Bearing the challenges in mind, we propose META, a principled framework for metadata-empowered weakly-supervised text classification. As illustrated in Figure 1 and Figure 2, we first organize the text data and metadata together into a text-rich network. The network structure gives us a holistic view of the corpus and enables us to rank and select useful metadata entities. We leverage motif patterns (Benson et al., 2016; Milo et al., 2002; Shang et al., 2020) to model typed metadata as well as their combinations. A motif pattern is a subgraph pattern at the meta-level that captures higher-order connections and the semantics represented by these connections. It serves as a useful tool to model typed edges, typed paths (a.k.a. meta-paths) (Sun et al., 2011), and higher-order structures in the network. With little effort, users can specify a few possibly useful motif patterns as input to our model. We develop a unified, principled ranking mechanism to select label-indicative motif instances and words, forming expanded weak supervision. Note that, such instance-level selection process also implicitly refines the motif patterns, ensuring the robust performance of META even when irrelevant motif patterns exist in input. It is worth a mention that META is compatible with any text classifiers.

Our contributions are summarized as follows:

- We explore to incorporate metadata information as an additional source of weak supervision for text classification along with seed words.
- We propose a novel framework META, which introduces motif patterns to capture the high-order combinations among different types of metadata and conducts a unified ranking and selection of label-indicative motif instances and words.
- We conduct experiments on two real-world datasets. The results and case studies demonstrate the superiority of incorporating metadata as parts of weak supervision and verify the effectiveness of META.

Reproducibility. Our code is made publicly available at GitHub[1].

2 Preliminaries

2.1 Documents as Text-rich Network

Given a collection of n text documents $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2, \dots, \mathcal{D}_n\}$, and their corresponding metadata, we propose to organize them into a *text-rich network*, as illustrated in Figure 1(b). A text-rich network is a heterogeneous network with documents, words, different types of metadata as nodes, and their associations as edges. For example, our text-rich network for research papers has papers, words, authors, and publication years as nodes. Each paper is connected to its associated words and metadata nodes. Such a network provides a holistic and structured representation of the input.

2.2 Seed Words and Motif Patterns

Users are asked to provide a few seed words $\mathcal{S} = \{\mathcal{S}_1^w, \mathcal{S}_2^w, \dots, \mathcal{S}_l^w\}$ for each of l classes (i.e., $\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_l$) in our classification problem, as well as k motif patterns $\{\mathcal{M}_1, \mathcal{M}_2, \dots, \mathcal{M}_k\}$. Motif patterns are sub-graph patterns at the meta-level (i.e., every node is abstracted by its type). They are able to capture semantics and higher-order interconnections among nodes. A motif instance is a

---

[1] `https://github.com/dheeraj7596/META`

sub-graph instance in the graph that follows a motif pattern. Figure 1 presents an example of a motif pattern that captures co-authorship and a motif instance following this motif pattern. In this paper, we discover seed motif instances for each class label, denoted as $\{\mathcal{S}_1^m, \mathcal{S}_2^m, \ldots, \mathcal{S}_l^m\}$.

2.3 Problem Formulation

Given the text-rich network and user-provided seed words and motif patterns as input, we aim to build a high-quality document classifier, assigning one class label $\mathcal{C}_j$ to each document $\mathcal{D}_i$.

3 Our META Framework

As shown in Figure 2, META is an iterative framework, generating pseudo labels and training the text classifier alternatively, similar to many other weakly supervised text classification methods (Kuipers et al., 2006; Tao et al., 2015; Meng et al., 2018). One iteration in META consists of the following steps:

- Generate pseudo labels based on the seeds;
- Train a text classifier based on pseudo labels;
- Rank and select words and motif instances to expand the seeds.

We repeat these steps iteratively. We denote the number of iterations as T, which is the only hyperparameter in our framework.

The novelty of META mainly lies in integrating two sources of weak supervisions, seed motif instances, and seed words. Given each motif instance m or each word w, for each label l, we estimate a *ranking score* $\mathcal{R}_{m,l}$ or $\mathcal{R}_{w,l}$ ranging between 0 and 1, measuring how label-indicative it is to the particular label l. Such ranking scores are utilized to select new seed motif instances and seed words. Note that, while this selection is conducted at the instance level, it also selects motif patterns implicitly and therefore ensures robust performance when users provide some irrelevant motif patterns.

3.1 Pseudo Labels and Text Classifier

Based on seed words, seed motif instances, and their respective ranking scores for each class, we generate pseudo labels for unlabeled text documents and train a classifier based on these pseudo labels. In the first iteration, we have no seed motif instances and the ranking score is 1 for all seed words.

Pseudo-Label Generation. Suppose we have seed word sets $\mathcal{S}_{1..l}^w$ and seed motif instance sets $\mathcal{S}_{1..l}^m$ for all l labels, we generate pseudo labels using a simple yet effective count-based technique. Specifically, given a document $\mathcal{D}_i$, the probability that it belongs to the class l is proportional to the aggregated ranking scores of its respective seed words and seed motif instances.

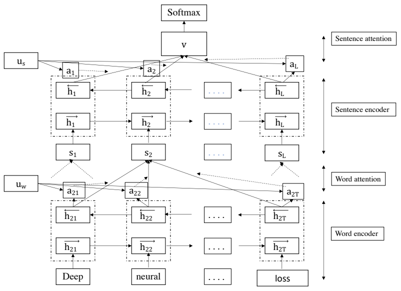

Figure 3: HAN Classifier used in our META.

$$P(l|\mathcal{D}_i) \propto \sum_{w \in \mathcal{D}_i \cap \mathcal{S}_l^w} f_{\mathcal{D}_i,w} \cdot \mathcal{R}_{w,l} + \sum_{m \in \mathcal{D}_i \cap \mathcal{S}_l^m} \mathcal{R}_{m,l}$$

where $f_{\mathcal{D}_i,w}$ is the term frequency of the word w in document $\mathcal{D}_i$. The pseudo label of document $\mathcal{D}_i$ is then assigned as follows:

$$l(\mathcal{D}_i) = \arg\max_l P(l|\mathcal{D}_i)$$

Document Classifier. Our framework is compatible with any text classification model as a classifier. We use Hierarchical Attention Networks (HAN) (Yang et al., 2016) as the classifier. HAN is designed to capture the hierarchical document structure i.e. words – sentences – documents. As illustrated in Figure 3, HAN performs attention first on the sentences in the document to find the important sentence in a document and on the words in the sentence to identify important words in a sentence. We train a HAN model on unlabeled documents with the generated pseudo-labels. For the document $\mathcal{D}_i$, it estimates the probability $\hat{Y}_{i,l}$ for each class l. Such predicted distributions are used in the expansion of seed words and motifs.

3.2 Unified Seed Ranking and Expansion

Once the text classifier is trained, we rank words and motif instances together for each class. Then, we expand the seed sets by adding top-ranked words and motif instances. This improves the quality of the weak supervision over iterations, thereby improving the text classifier. We present our design of the unified ranking and expansion as follows.

Ranking Score Design. An ideal seed word or motif instance for a particular class should be highly relevant and highly exclusive to this class. So an

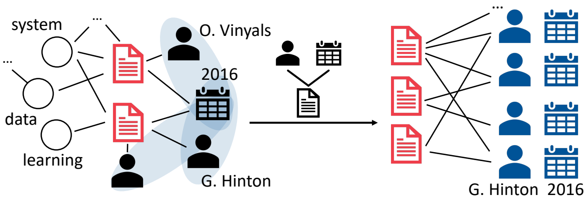

Figure 4: Using motif patterns, we construct bipartite graphs from the text-rich network linking documents to their respective motif instances.

effective ranking score must quantify relevance and exclusiveness. Such a ranking score for words alone has been explored by previous studies (Tao et al., 2015; Mekala and Shang, 2020), typically based on similarity and frequency-based metrics. In this paper, we have motif instances in addition to words, therefore, we build upon the text-rich network to unify the ranking process.

Given k user-provided motif patterns $\mathcal{M}_1, \ldots, \mathcal{M}_k$ and the text-rich network $\mathcal{G}$, we construct k bipartite graphs $\mathcal{G}_1^B, \ldots, \mathcal{G}_k^B$, one for each motif pattern (see Figure 4). In the i-th bipartite graph $\mathcal{G}_i^B$, the node set contains two parts: (1) all documents and (2) all motif instances following the motif pattern $\mathcal{M}_i$ in the text-rich network $\mathcal{G}$; The edges in the graph $\mathcal{G}_i^B$ connect the documents to the motif instances which are subsets of the metadata associated with the documents.

For the sake of simplicity, we introduce one more motif pattern, document–word. It makes words a special case of motif instances, and one can easily construct a similar bipartite graph for words. Therefore, in the rest of this section, we use motif instances to explain our ranking score design.

For each motif pattern $\mathcal{M}$, we conduct one personalized random walk on its corresponding bipartite graph $\mathcal{G}^B$ for each label l. Specifically, we normalize each column of the adjacency matrix of the bipartite graph $\mathcal{G}^B$ by the degree of its respective node, resulting in the transition matrix $\mathbf{W}$. Suppose $\mathbf{p}_{l,u}$ represents the personalized PageRank (PPR) score of each node u for each label l, we initialize the PPR score of each document node to $\hat{Y}_{i,l}$ and PPR score of each motif instance node to 0. This initialization ensures that a random walk starts from a document node and since $\mathcal{G}^B$ is bipartite, it ends at a motif instance node. We iteratively update the PPR scores as follows:

$$\mathbf{p}_l^{(t+1)} \leftarrow \mathbf{W}\mathbf{p}_l^{(t)}$$

Since each document node is initialized with probabilities corresponding to l and the random walk starts from a document node and ends at a motif instance node, this can be viewed as a label propagation problem. Based on the previous work in label propagation (Hensley et al., 2015), similar nodes are more likely to form edges and the PPR score is used to measure the similarity. Therefore, we believe that $\mathbf{p}_{l,m}$ reflects the *relevance* of a motif instance m to the particular class label l.

Though the absolute values of PPR scores are quite small, their relative magnitude conveys their affinity towards a label. Therefore, we normalize these PPR scores into a distribution, resulting in the ranking scores. Mathematically, for a label l, the ranking score of a motif instance m is:

$$\mathcal{R}_{m,l} = \frac{\mathbf{p}_{l,m}}{\sum_{l' \in \mathcal{C}} \mathbf{p}_{l',m}}$$

If a motif instance has similar relevance to multiple labels, the ranking score distribution becomes flat irrespective of the magnitude of its respective PPR scores. From this, we realize that our ranking score also quantifies *exclusiveness*, which is an essential characteristic of a highly label-indicative term.

Based on this ranking score, we rank words and motif instances in a unified manner and expand the seed word set and seed motifs set.

Expansion. Given the ranking scores of all words and motif instances for every label, we expand the seed words and seed motifs simultaneously for all labels. Intuitively, a highly label-indicative motif instance would not belong to the seed sets of multiple labels. Therefore, when any motif instance is expanded to seed sets of multiple classes, we stop the expansion of motif instances of the corresponding motif pattern. Also, we set a hard threshold of $\frac{1}{|\mathcal{C}|}$, where $|\mathcal{C}|$ is the number of classes, on ranking scores for those added motif instances. In this way, the number of new seed words and seed motif instances is decided by the method automatically. It is worth mentioning that our expansion here is adaptive and every label may have a different number of seeds. Note that, in the first iteration, pseudo labels are generated using only seed words but ranking scores are obtained for all words and motif instances. The highly ranked motif instances and words are used as seeds in further iterations.

After expanding the seed sets for every label, we generate pseudo labels and train the classifier. This process is repeated iteratively for T iterations.

Table 1: Dataset statistics.

Dataset	# Docs	# Classes	Avg Doc Len
DBLP	38,128	9	893
Book Graph	33,594	8	620

4 Experiments

In this section, we evaluate META and compare it with existing techniques on two real-world datasets in a weakly supervised classification setting.

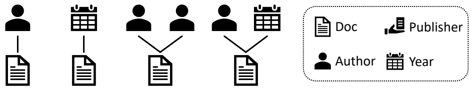
4.1 Experimental Settings

Datasets. We conduct experiments on the DBLP dataset (Tang et al., 2008) and the Book Graph dataset (Wan and McAuley, 2018; Wan et al., 2019). The dataset statistics are shown in Table 1. The details of the datasets are mentioned below.

- **DBLP dataset:** The DBLP dataset contains a comprehensive set of research papers in computer science. We select 38,128 papers published in flagship venues. In addition to text data, it has information about authors, published year, and venue for each paper. There are 9,300 distinct authors and 42 distinct years. For each paper, we annotate its research area largely based on its venue as the classification objective[2]. Therefore, in our experiments, we drop the venue information to ensure a fair comparison.
- **Book Graph dataset:** The Book Graph dataset is a collection of the description of books, user-book interactions, and users' book reviews collected from a popular online book review website named Goodreads[3]. We select books belonging to eight popular genres[4]. The genre of a book is viewed as the label to be predicted. The total number of books selected is 33,594. We use the title and description of a book as text data and author, publisher, and year as metadata. In total, there are 22,145 distinct authors, 5,186 distinct publishers, and 136 distinct years.

Motif Patterns. The motif patterns we used as metadata information for DBLP and Book Graph datasets are shown in Figure 5.

Seed Words. The seed words are obtained as follows: we asked 5 human experts to recommend 5 seed words for each class and selected the final seed words based on majority voting i.e. ($>$ 3 recommendations).



(a) Motif patterns: DBLP

(b) Motif patterns: Book Graph

Figure 5: Motif Patterns used in Experiments.

Evaluation Metrics. Both datasets are imbalanced with respect to the label distribution. Being aware of this fact, we adopt micro- and macro-F$_1$ scores as evaluation metrics.

Implementation Details. To make the model robust to multi-word phrases as supervision, we extract phrases using Autophrase (Liu et al., 2015; Shang et al., 2018). We set the word vector dimension to be 100 for all the methods that use word embeddings. We set the number of iterations parameter for META to 9.

4.2 Compared Methods

We compare our proposed method with a wide range of methods described below:

- **IR-TF-IDF** treats seed words as a query. It computes the relevance of a document to a class by aggregating the TF-IDF values of its seed words. Each document is assigned the label which is the most relevant to this document.
- **Word2Vec** learns word vector representations (Mikolov et al., 2013) for all words in the corpus. It computes label representations by aggregating the word vectors of all its seed words. Each document is assigned the label whose cosine similarity with this document is maximum.
- **Doc2Cube** (Tao et al., 2015) considers label surface names as seed set and performs multi-dimensional document classification by learning dimension-aware embedding.
- **WeSTClass** (Meng et al., 2018) leverages seed words to generate bag-of-words pseudo documents for neural model pre-training and then bootstraps the model on unlabeled data. Specifically, we compare with WeSTClass-CNN which is the best configuration under our setting. We use the public implementations of WeSTClass[5]

HAN-Sup	0.75	0.72	0.77	0.76
HAN-Sup++	0.79	0.77	0.81	0.81

with the hyperparameters mentioned in the paper.

- **Metapath2Vec** (Dong et al., 2017) learns node representations in the text-rich network using meta-path-guided random walks by capturing the structural and semantic correlations of differently typed nodes. We use the first two motif patterns in Figure 5(a) and the first three motif patterns in Figure 5(b) as meta-paths because the rest cannot be represented as meta-paths. We generate pseudo-labels using the seed words and train a logistic regression classifier with document nodes representations as input to predict the labels.

We denote our framework with HAN classifier as **META**, with CNN classifier as **META-CNN**, and with BERT(bert-base-uncased) classifier as **META-BERT**. We also compare with their respective ablated versions **META-NoMeta**, **META-CNN-NoMeta**, **META-BERT-NoMeta** where metadata information is not expanded and not considered while generating pseudo labels.

For a fair comparison, we also present results of all the baselines on the **metadata-augmented** datasets, where a token for every relevant motif instance is appended to the text data of a document. This is denoted by **++** in Table 2, e.g., WeSTClass++ represents the performance of WeSTClass on metadata-augmented datasets.

We also present the performance of HAN in a supervised setting which is denoted as **HAN-Sup**. The results of HAN-Sup reported are on the test set which follows an 80-10-10 train-dev-test split.

4.3 Performance Comparison

The evaluation results of all methods are summarized in Table 2. We can observe that our proposed framework outperforms all the compared weakly supervised methods. We discuss the effectiveness of our proposed META as follows:

- META achieves the best performance among all the compared weakly supervised methods with significant margins. By extracting the highly label-indicative motif instances along with words and using them together in pseudo label generation, META successfully leverages metadata information and achieves superior performance.
- We observe that the performance of META is better than all the compared weakly supervised models on metadata-augmented datasets. By comparing those **++** methods with their text-only counterparts, one can easily observe that adding metadata in text classification is indeed helpful. However, META does not restrict to single metadata types and goes beyond by employing motif patterns to capture the metadata information. It is successful in identifying the appropriate label-indicative metadata combinations and therefore achieves even better performance.
- The comparison between META and Metapath2Vec demonstrates the advantages of motif patterns over the meta-paths. For example, on the Book Graph dataset, the last three motif patterns in Figure 5(b) cannot be represented through meta-paths and this significantly affects the performance. It's also worth mentioning that Metapath2Vec cannot handle new documents directly without re-training the embedding whereas our framework can directly predict without any additional effort.
- The comparison between META and the ablation method META-NoMeta demonstrates the effectiveness of our motif instance expansion. For example, on the Book Graph dataset, the motif instance expansion improves the micro-F1 score from 0.58 to 0.62 and macro-F1 score from 0.58 to 0.63, which are quite significant.
- The comparison between META-CNN, META-BERT, and their respective ablated versions META-CNN-NoMeta, META-BERT-NoMeta demonstrate that our proposed approach provides significant additive gains to different classifiers and thereby showing the effectiveness of leveraging metadata information as an additional source of weak supervision.

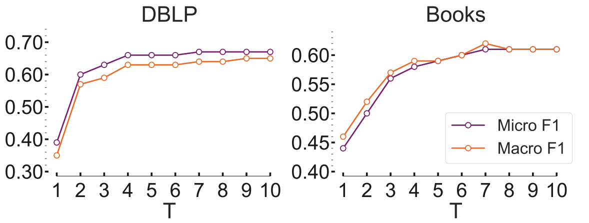

Figure 6: Micro- and Macro-F_1 scores w.r.t. the number of iterations.

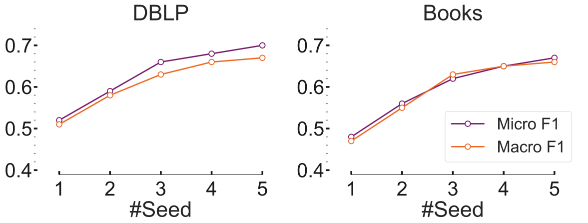

Figure 7: Micro- and Macro-F_1 scores w.r.t. the number of seed words.

- The comparison between META and HAN-Sup demonstrates that META is effective in decreasing the gap between the performance of the weakly supervised and supervised settings.

4.4 Parameter Study

The only hyper-parameter in our framework META is T, the number of iterations. We experiment on both datasets to study the effect of the number of iterations on the performance. The plots of micro-F1 score and macro-F1 score with respect to the number of iterations are shown in Figure 6. We observe that the performance increases initially and gets gradually converged by 6 or 7 iterations. We also observe that the expanded seed words and seed motifs have become almost unchanged. While there is some fluctuation, a reasonably large T, such as $T = 9$ or $T = 10$, is recommended.

4.5 Number of Seed Words

We vary the number of seed words per class and plot the performance in Figure 7. We observe that the performance increases as the number of seed words increase, which is generally intuitive. For reasonable performance, we observe that three seed words are sufficient.

4.6 Case Study

We present case studies to showcase the effectiveness of our framework in addressing the challenges of leveraging metadata.

Leveraging Metadata Combinations. Table 3 shows a few samples of expanded motif instances.

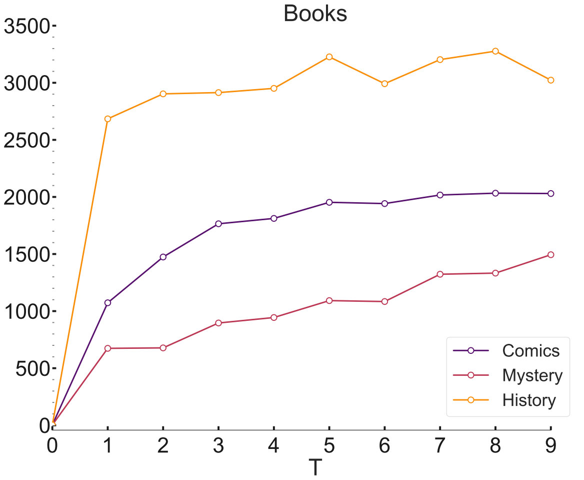

Figure 8: Number of seed words w.r.t. the number of iterations

First, let's take a look at motif instances related to authors and publishers. We can observe that strong label-indicative authors and publishers are mined accurately. For example, *Marvel*, a widely known comics publisher, is present in the expanded publishers for *comics* genre; A classic American poet *E. Dickinson* is successfully identified as label-indicative for *poetry* genre.

Note that, the author *N. Gaiman* (in blue) who has written books in multiple genres including comic books, graphic novels, etc., is not a label-indicative author for any of these categories, because he is not exclusive to any one category, which is accurately captured by our framework. However, his works in various genres together with their respective publisher information form a unique label-indicative pattern which is reflected by the "Author-Publisher" motif pattern.

Now, adding *year* metadata into the loop, although "Year-Document" is a user-provided motif pattern, META identifies that *year* information alone is not much helpful in classification. This demonstrates the robustness of our framework when users provide some irrelevant motif patterns. However, if we combine author information with year, it then carries more accurate semantics, and we may discover that *N.Gaiman* had authored more children's books in early 2000, thus becoming highly label-indicative.

Eliminating Noise in Metadata. Table 4 presents the percentage of motif instances expanded out of the total motif instances following a motif pattern, for every label. One can observe that META actually prunes out many motif instances, as the final selection ratio is far less than 100%.

Table 3: Case Study: Expanded motif instances.

Expanded motif instances of Book Graph dataset					
Class	**Author**	**Publisher**	**Author-Publisher**	**Year**	**Author-Year**
children	Z. Fraillon, K. Argent	Brighter Child, HarperCollins Children's Books	(**N. Gaiman**, Bloomsbury UK) (M. Fox, Penguin Australia)	N/A	(**N. Gaiman**, 2004) (S. Blackall, 2010)
comics	F. Teran, B. Kane	Marvel, Titan Books Ltd	(**N. Gaiman**, Marvel) (T. McFarlane, Marvel Comics)	N/A	(T. Hairsine, 2013) (A. Sinclair, 2009)
fantasy	J. Barne, S. Dubbin	DAW Books, Inc., Edge Publishing	(W. King, Titan Books Ltd) (G.J. Grant, Prime Books)	N/A	(G.J. Grant, 2012) (M. Lingen, 2012)
poetry	B. Guest, E. Dickinson	Shearsman Books, Souvenir Press	(**N. Gaiman**, MagicPress) (R. Browning, Wordsworth Editions)	1692, 1914	(E. Dickinson, 1959) (J. McCrae, 1929)

Table 4: Case Study: Percentage of motif instances expanded for Book Graph dataset. **A** stands for author, **P** for publisher and **Y** for year.

Percentage of motif instances expanded						
Label	**A**	**P**	**Y**	**A-P**	**P-Y**	**A-Y**
children	5.12	9.42	0	9.21	12.73	9.68
comics	4.91	1.33	0	9.52	1.48	14.11
fantasy	6.2	2.8	0	13.1	2.95	10.97
history	4.31	10.5	6.12	8.1	11.8	7.94
mystery	4.11	8.6	3.67	9.8	11.04	9.59
poetry	6.8	9.2	15.4	10	8.17	9.11
romance	5.6	13.5	1.47	9.6	12.28	9.19
y. adult	3.52	13.7	2.2	9.1	15.04	9.32

Table 5: Expanded seed words of *comics*, *history*, and *mystery* classes in Books dataset.

Expanded seed words	
Label	**Seed words**
comics	batman, superman, marvel, mary-jane, general zod
history	history, world war, world war ii, political science
mystery	serial killer, sherlock holmes, inspector lestrade

For the "**Y**ear-Document" motif pattern, we observe that its motif instances are only expanded for a few genres, which is generally intuitive. For example, one can see that a significant percentage of "Year-Document" motif instances expanded for *history* and *poetry*. After a closer inspection, we find that the expanded years were concentrated between the late 1800 and early 1900, thus developing an affinity for this time period.

One can also observe that the percentage of motif instances following the "**P**ublisher-Document" motif pattern expanded varies for different labels, ranging from 1 to 13.5. This illustrates that our expansion is adaptive.

Seed words Expansion. Figure 7 shows the number of seed words expanded after each iteration for *comics*, *hystory*, and *mystery* classes in Books dataset. We observe that the number varies for each label because of our data-driven, adaptive thresholds, which is different for each label.

One can also observe that the the number increases over iterations and gets almost stagnated at the end, indicating that the seed sets are getting refined and converged. A few examples of expanded seed words are shown in Table 5.

5 Related Work

We review the literature about (1) weakly supervised text classification methods, (2) text classification with metadata, and (3) document classifiers.

5.1 Weakly Supervised Text Classification

Due to the training data bottleneck in supervised classification, weakly supervised classification has recently attracted much attention from researchers. The majority of weakly supervised classification techniques require seeds in various forms, including label surface names (Li et al., 2018; Song and Roth, 2014; Tao et al., 2015), label-indicative words (Chang et al., 2008; Meng et al., 2018; Tao et al., 2015; Mekala and Shang, 2020), and labeled-documents (Tang et al., 2015b; Xu et al., 2017; Miyato et al., 2016; Meng et al., 2018).

Dataless (Song and Roth, 2014) considers label surface names as seeds and classifies documents by embedding both labels and documents in a semantic space and computing semantic similarity between a document and a potential label; Along similar lines, Doc2Cube (Tao et al., 2015) expands label-indicative words using label surface names and performs multi-dimensional document classification by learning dimension-aware embedding; WeSTClass (Meng et al., 2018) considers both word-level and document level supervision sources. It first generates bag-of-words pseudo documents for neural model pre-training, then bootstraps the model on unlabeled data. This method is later extended to a hierarchical setting with a pre-defined hierarchy (Meng et al., 2019); ConWea (Mekala and Shang, 2020) leverages contextualized representation techniques to provide contextualized weak supervision for text classification.

However, all these techniques consider only the text data and don't leverage metadata information for classification. In this paper, we focus on user-provided seed words and mine label-indicative words and metadata in an iterative manner.

5.2 Text Classification with Metadata

Previous studies try to incorporate metadata information to improve the performance of the classifier. Tang et al. (2015a) and Chen et al. (2016) consider the user and product information as metadata for document-level sentiment classification; Rosen-Zvi et al. (2012) use author information for paper classification; Zhang et al. (2017) employ user biography data for tweet localization. However, all these frameworks are in a supervised setting and use fixed metadata types for each task whereas our method is generalized for different metadata types and multiple metadata combinations.

Another way to leverage metadata for text understanding is to organize the corpus into a heterogeneous information network. A straightforward approach is to obtain document representations using their respective meta-path guided node embeddings (Dong et al., 2017; Shang et al., 2016) and train a classifier. However, higher-order connectivity cannot be captured by meta-paths and this approach can't handle new documents directly without re-training the embeddings. Recently, Zhang et al. (2020) proposed a minimally supervised framework to categorize text with metadata. However, they require labeled documents as supervision and they only consider typed edges in the model. Network motifs (Milo et al., 2002) can capture higher-order connectivity and have been proved fundamental in complex real-word networks across various domains (Benson et al., 2016). Shang et al. (2020) leveraged motifs for topic taxonomy construction in an unsupervised setting. Our proposed method mines highly label-indicative metadata information with a unified motif and word ranking framework, and effectively expands weak supervision to improve document classification.

5.3 Document classifier

Document classification has been a long-studied problem in Natural Language Processing. CNN-based classifiers (Kim, 2014; Johnson and Zhang, 2014; Lai et al., 2015), RNN-based classifiers (Socher et al., 2013) achieve competitive performance. Yang et al. (2016) proposed Hierarchical Attention Network (HAN) for document classification that performs attention first on the sentences in the document, and on the words in the sentence to find the most important sentences and words in a document. Though our framework uses HAN as the document classifier, it is also compatible with all the above-mentioned text classifiers. We choose HAN for the demonstration purpose.

6 Conclusion and Future Work

In this paper, we propose META, a novel framework that leverages metadata information as an additional source of weak supervision and incorporates it into the classification framework. Our method organizes the text data and metadata together into a text-rich network and employs motif patterns to capture appropriate metadata combinations. Using the initial user-provided seed words and motif patterns, our method generates pseudo labels, trains classifier, and ranks and filters highly label-indicative words, motifs in a unified manner and adds them to their respective seed set. Experimental results and case studies demonstrate that our model outperforms previous methods significantly, thereby signifying the advantages of leveraging metadata as weak supervision.

In the future, we are interested in effectively integrating different forms of supervision including annotated documents. Also, we only consider positively label-indicative metadata combinations currently. There should be negatively label-indicative combinations as well which can eliminate some classes from potential labels. This is another potential direction for the extension of our method.

Abstract

The uncertainty measurement of classified results is especially important in areas requiring limited human resources for higher accuracy. For instance, data-driven algorithms diagnosing diseases need accurate uncertainty score to decide whether additional but limited quantity of experts are needed for rectification. However, few uncertainty models focus on improving the performance of text classification where human resources are involved. To achieve this, we aim at generating accurate uncertainty score by improving the confidence of winning scores. Thus, a model called MSD, which includes three independent components as “mix-up”, “self-ensembling”, “distinctiveness score”, is proposed to improve the accuracy of uncertainty score by reducing the effect of overconfidence of winning score and considering the impact of different categories of uncertainty simultaneously. MSD can be applied with different Deep Neural Networks. Extensive experiments with ablation setting are conducted on four real-world datasets, on which, competitive results are obtained.

1 Introduction

Text classification is a popular topic with broad applications. A successful and common model for text classification is Deep Neural Network (DNN). However, some real-world applications expect results with higher accuracy than the ones achieved by state-of-the-art algorithms. Hence, the most uncertain predictions need domain experts for further decisions (Zhang et al., 2019). To efficiently leverage the limited human resources, it is essential to calculate *uncertainty score* of the model prediction, which quantifies how unconfident the model prediction is. This paper aims at generating more accurate uncertainty score through DNNs in the text classification with human involvement in the testing process. This is different from active learning, which involves experts in the training process.

Though various metrics of the uncertainty score have been studied (Dong et al., 2018; Wang et al., 2019; Shen et al., 2019; Xiao and Wang, 2019; Kumar et al., 2019), the existing metrics directly or indirectly depend on *winning score*, which is the maximum probability in a semantic vector (softmax vector from the last layer of a DNN model) (Thulasidasan et al., 2019). Therefore, improving *Confidence of Winning Score* (CWS), which describes how confident the winning score matches the sample uncertainty and represents the accuracy of the winning score, is helpful to improve the accuracy of uncertainty score. To show the effect of improving CWS, this paper considers a basic way to measure uncertainty score, which is the reciprocal of winning score (Snoek et al., 2019). However, we face two challenges in improving CWS: (1) how to reduce effect of *overconfidence of winning score*[1] to boost negative correlation between the winning score and sample uncertainty, (2) how to generate winning scores by considering comprehensive categories of uncertainty in one model rather than only one or two categories of uncertainty at a time.

The overconfidence of winning scores has been neglected by vast previous works in Natural Language Processing. We identify the presence of *overconfidence* for the training samples: because the winning scores of training samples are all set as 1 by one-hot labels, each sample will have the same uncertainty score. Consequently, the training sample uncertainty will be the same. Together, the winning scores and sample uncertainty are the same for various training samples. Hence, the negative correlation between the winning scores and sample uncertainty cannot be guaranteed, which is a negative effect of the overconfidence. The effect will affect calculating the uncertainty scores. Concretely, in the testing process, we apply different

November 16–20, 2020.

predicted winning scores to match different sample uncertainty based on a latent assumption that the predicted winning score is negatively correlated to the sample uncertainty. However, the assumption is biased because of the negative effect of the overconfidence. To mitigate the impact of overconfidence, we generate new training sample representations with different winning scores, which are also negatively correlated to the sample uncertainty.

Additionally, the process generating the winning score should consider the impact of different categories of uncertainty simultaneously, while vast of the previous works (Shen et al., 2019; Wang et al., 2019; Xiao and Wang, 2019; Zhang et al., 2019) only consider one or two categories of uncertainty at a time[2]. We assume the partial consideration will decrease the CWS, and so will the accuracy of uncertainty score. We verify this assumption by our ablation experiments. The uncertainty of a model prediction is derived from two parts: *data uncertainty* and *model uncertainty*. The data uncertainty (Rohekar et al., 2019) is further divided into two categories: *epistemic uncertainty* comes from lack of knowledge, such as only few training data or out-of-distribution testing data; *aleatoric uncertainty* is caused by noisy data in the generation of both training data and testing data. The model uncertainty (Liu et al., 2019) also has two categories: *parametric uncertainty* comes from different possibilities of parameter values in estimating model parameters under the current model structure and training data; *structural uncertainty* is uncertainty about whether the current model design (e.g., layers, loss functions) is reasonable or sufficient for the current task and training data. Since the solution of structural uncertainty requires extremely high computations, such as Neural Architecture Search (NAS) (Zoph and Le, 2016; Xie et al., 2019), we only reduce or scale the other three categories of uncertainty simultaneously to improve the CWS.

To address the above two challenges, we propose a model called MSD, which is named as the initials of its components ("Mix-up", "Self-ensembling", and "Distinctiveness score") aiming at handling overconfidence and various uncertainty with flexibility. The flexibility means that MSD is effective on different DNN models (Convolutional Neural Network (CNN), Recurrent Neural Network (RNN) and Transformer (Vaswani et al., 2017)), and each component in MSD is independent, which can be arbitrarily assembled. The main contributions of our work can be summarized as follows,

Reducing impact of overconfidence. To reduce the impact of overconfidence in calculating uncertainty scores, we apply mix-up to generate new sample representations boosting the negative correlation between the winning scores and sample uncertainty.

Considering various uncertainty comprehensively. We propose MSD with three components to handle the epistemic uncertainty, aleatoric uncertainty, and parametric uncertainty simultaneously, so that the uncertainty score is more accurate.

Designing flexibility of MSD. MSD can be applied with different DNNs (CNN, RNN, and Transformer). Each component in MSD can be assembled with other components arbitrarily due to their independence.

Implementing extensive experiments. We evaluated MSD by the improvement of text classification accuracy in simulating human involvement. The experiments of MSD with ablation setting on four datasets achieved competitive results, which demonstrated that MSD generates more accurate uncertainty scores.

2 Related work

Methods mitigating uncertainty: One main solution to mitigate uncertainty is Bayesian Neural Network (BNN) (Klein et al., 2017), which is a neural network with a prior distribution on its weights. Based on BNN, variational Bayesian inference is proposed, which finds an approximated distribution of parameters for the true distribution of parameters by Kullback-Leibler (KL) divergence (Xiao and Wang, 2019; Wen et al., 2018; Louizos and Welling, 2017; Malinin and Gales, 2019). Further, as an approximation of variational Bayesian inference, Monte Carlo dropout is proposed (Gal and Ghahramani, 2016; Kendall and Gal, 2017). This is implemented by training a model with dropout before every layer, and also performing the dropout in the testing process to derive results from different sampled parameter sets. Plus, an approximation of Monte Carlo dropout is tried by only adding dropout before the last layer (Riquelme et al., 2018; Snoek et al., 2019). Besides BNN, noise injection is the other main technique to mitigate uncertainty. It has two categories: parameter noise injection adds noise perturbation in network weights (Plappert et al., 2017); data noise injection

---

[2] Please refer to our appendix for detailed comparisons

directly inputs noise perturbation into data (Dong et al., 2018).

Metrics scaling uncertainty: Many metrics about uncertainty score are proposed based on the softmax vectors. As an important element in the sofmax vectors, winning score is proposed in (Hendrycks and Gimpel, 2016). Furthermore, temperature scaling (Guo et al., 2017) is proposed to get the calibrated probability by adding a scalar parameter to each class in calculating softmax vector. Applying winning score as prediction confidence is proposed in (Niculescu-Mizil and Caruana, 2005; Guo et al., 2017). This confidence is further applied in Expected Calibration Error (Naeini et al., 2015), which is the absolute value of the difference between the accuracy and confidence of results. Besides, Overconfidence Error is proposed by applying winning score as confidence and penalizing samples with confidence values greater than accuracy values (Thulasidasan et al., 2019). In addition, four metrics for result confidence are proposed in (Wang et al., 2019) by combining expectation and variance of predictions from different sampled parameter sets. In addition, cross-entropy is applied to calculate uncertainty score by dropout sampling and bin counting in (Zhang et al., 2019), which also considers text classification with human involvement. Different from previous works, we improve the accuracy of uncertainty score by reducing the effect of overconfidence and considering three categories of uncertainty simultaneously.

3 Model

3.1 Basic Text Classification Model

In the traditional text classification model (Zhang et al., 2019; Shen et al., 2018), given an original text, we apply preprocessing (tokenization, lemmatization, etc.) to get its tokens in discrete numbers. Then, a pre-trained token embedding, such as word2vec (Mikolov et al., 2013) or Glove (Pennington et al., 2014) is applied as a projector. After that, a sequence of dense vectors for i-th text $\mathbf{Z}_i = [\mathbf{z}_{i1}, \mathbf{z}_{i2}, ..., \mathbf{z}_{in}]$ is derived by the embedding, where $\mathbf{z}_{ij}$ is the embedding of j-th word. The $\mathbf{Z}_i$ is fed to a sequence model f, such as CNN or RNN. Finally, we get i-th text representation $\mathbf{x}_i$ from the penultimate layer of f with dropout, and predicted semantic vector $\mathbf{y}_i = [y_{i1}, y_{i2}, ..., y_{ic}]$ from the last layer of f, where c is the number of classes and y_{ij} is the probability that i-th text belongs to j-th class. Finally, the f is trained by cross-entropy loss between the predicted semantic vector $\mathbf{y}_i$ and one-hot label $\widehat{\mathbf{y}}_i = [\widehat{y}_{i1}, \widehat{y}_{i2}, ..., \widehat{y}_{ic}]$ as follows,

$$L_{CE} = \sum_{j=1}^{c} \widehat{y}_{ij} log(y_{ij}). \tag{1}$$

In the testing process, uncertainty score U is formulated as follows,

$$U = \frac{1}{\max(\mathbf{y}_i^*)} \tag{2}$$

where $\mathbf{y}_i^*$ is semantic vector of i-th testing sample and $\max(\mathbf{y}_i^*)$ is the winning score of $\mathbf{y}_i^*$. Then, U conveys the uncertainty of model result.

3.2 Overview Of MSD

Fig. 1 illustrates the training process of our model. In the first row, after prepossessing training text, we calculate the text representations, which is output of the penultimate layer with dropout. Then, we mix these representations in the batch-level. These mix-up-generated representations are fed into a fully connected (FC) layer for final semantic vectors. In the second row, we apply another model, which implements self-ensembling, with independent optimized parameters but the same structure as the one in the first row.

In the testing process, besides computing the reciprocals of winning scores with dropout mechanism, distinctiveness scores is also calculated by the Mahalanobis distance between the testing samples and distributions of training samples. Finally, the uncertainty score is calculated by adding the reciprocal of winning score and distinctiveness score.

3.3 MSD Training: Mix-up

Since the overconfidence is caused by the training samples with same winning scores due to the one-hot labels, and adding noise perturbation in the training process is a way to mitigate aleatoric uncertainty, we apply mix-up (Zhang et al., 2017; Thulasidasan et al., 2019) to jointly address the two issues. Mix-up generates new sample representations with various winning scores.

Concretely, we have i-th sample representation $\mathbf{x}_i$ from the penultimate layer of f with dropout. In a batch, we randomly mix i-th and j-th samples' representations ($\mathbf{x}_i$ and $\mathbf{x}_j$) and one-hot labels ($\widehat{\mathbf{y}}_i$ and $\widehat{\mathbf{y}}_j$) to get a mix-up sample representation $\widetilde{\mathbf{x}}$ and ground truth label $\widetilde{\mathbf{y}}$. We formulate mix-up as,

$$\widetilde{\mathbf{x}} = \alpha \mathbf{x}_i + (1 - \alpha)\mathbf{x}_j \tag{3}$$

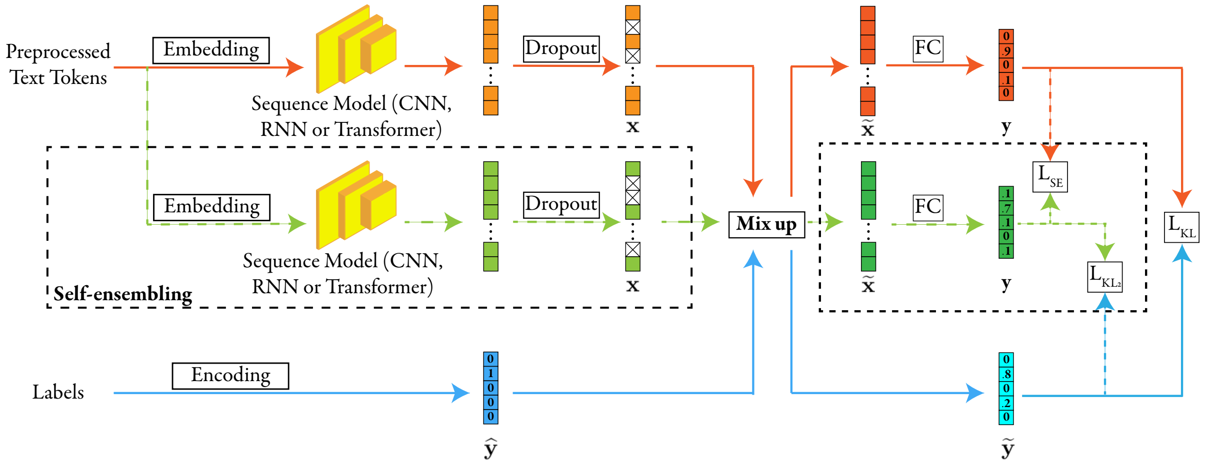

Figure 1: Diagram of training process of MSD. Orange arrows, green arrows, and blue arrows represent data flow of the first (default) model, second model, and labels respectively. Since self-ensembling is optional, it is illustrated as dotted lines. The distinctiveness score is not shown in the diagram since it is applied in the testing process. The numbers shown in $\mathbf{y}$, $\widehat{\mathbf{y}}$ and $\widetilde{\mathbf{y}}$ are probabilities of the semantic vectors.

$$\widetilde{\mathbf{y}} = \alpha\widehat{\mathbf{y}}_i + (1-\alpha)\widehat{\mathbf{y}}_j \tag{4}$$

where α is a random number ranging from Ω to 1.00. The Ω is set above 0.5, so the i-th sample's semantics will be the main semantics of $\widetilde{\mathbf{x}}$, which is regarded as class of $\widetilde{\mathbf{x}}$ in MSD. Since the *difference* among winning scores and *negative correlation* between the winning scores and sample uncertainty are essential to reduce the impact of overconfidence, we analyze the two factors below.

Difference: Since $1 \geq \alpha \geq \Omega > 0.5$, $\widetilde{\mathbf{y}}$ has a winning score as α if $\mathbf{x}_i$ and $\mathbf{x}_j$ have different classes, or as 1 if two samples have the same class. Then, firstly, α or 1 is randomly chosen; secondly, the specific value of α is randomly sampled. Thus, different values of winning scores of training samples are achieved by the mix-up.

Negative correlation: Since $\widetilde{\mathbf{x}}$ includes i-th sample's representation $\mathbf{x}_i$ with ratio $\alpha > 0.5$, $\mathbf{x}_j$ can be regarded as noise of $\widetilde{\mathbf{x}}$. In one scenario, when $\mathbf{x}_i$ and $\mathbf{x}_j$ have different classes, $\mathbf{x}_j$ has obvious effect from noise on $\mathbf{x}_i$ due to different distributions in various semantics. In this case, when α is greater, $\widetilde{\mathbf{x}}$ has less noise from different semantic distributions. Then, $\widetilde{\mathbf{x}}$ is less adulterated and has higher confidence belonging to the class of $\mathbf{x}_i$. Since now winning score equals to α and the transitivity in math: the higher winning score is, the less adulterated $\widetilde{\mathbf{x}}$ is, which means $\widetilde{\mathbf{x}}$ has less uncertainty. In another scenario, where $\mathbf{x}_i$ and $\mathbf{x}_j$ belong to same class, we assume that $\mathbf{x}_j$ has no effect from noise on $\mathbf{x}_i$, because $\mathbf{x}_j$ belongs to same distributions as $\mathbf{x}_i$ due to same semantics. Thus, the $\widetilde{\mathbf{x}}$ is the least uncertain in its class, and its winning score is the highest as 1. Hence, the negative correlation is boosted by mix-up.

After the mix-up, we feed $\widetilde{\mathbf{x}}$ rather than $\mathbf{x}$ to FC layer for its predicted semantic vector $\mathbf{y}$. However, we do not use cross-entropy loss (Eq. 1) in MSD, because it will learn the winning scores close to 1 due to no limit on the upper bound, which cannot ensure the negative correlation. Instead, we use KL divergence loss as one of our loss functions,

$$L_{KL} = \sum_{j=1}^{c} \widetilde{y}_{ij} log(\frac{\widetilde{y}_{ij}}{y_{ij}}) \tag{5}$$

because $\widetilde{\mathbf{y}}_i$ approximates to provide both upper and lower bound limitations by its non-zero element(s). The $\widetilde{y}_{ij}$ is a random value in each batch and each epoch. The overconfidence is reduced by mix-up due to *difference* and *negative correlation*. Besides, $\mathbf{x}_j$ can be regarded as random noise perturbation. Therefore, the aleatoric uncertainty is mitigated.

3.4 MSD Training: Self-ensembling

The parametric uncertainty comes from different sets of weights achieving similar training losses. Although the dropout can mitigate parametric uncertainty, previous works ignore the effect of self-ensembling (Laine and Aila, 2016; Park et al., 2018), which can boost the model combination and further decrease parametric uncertainty. We assume the dropout reduces the parametric uncertainty by loss generated within a model, while the self-ensembling reduces it from loss generated between models. The loss generated between models can help stabilize the model weights, because it can provide extra limitations besides the loss generated in a model, which reduce feasible weight sets. Plus, the designed component should aim at mitigating parametric uncertainty while have little impact on the model performance. Consider that the self-ensembling calculates the loss between the same models, which has more effect on model robustness and less impact on model performance, we apply the self-ensembling in addition to dropout to further mitigate the parametric uncertainty.

We construct another model with the same framework (e.g. layers, loss functions, dropout rate), and apply a self-ensemble loss L_{SE} to minimize the difference between two outputs from two models (the first model and the second model[3]) with the same framework and inputs,

$$L_{SE} = D[f_{\theta_1}(\tilde{\mathbf{x}}, \phi_1), f_{\theta_2}(\tilde{\mathbf{x}}, \phi_2)] \tag{6}$$

where θ_a is parameter set of a-th model, ϕ_a represents randomly sampled dropout neurons in neural network f, and $D[\mathbf{y_1}, \mathbf{y_2}]$ is a metric between two semantic vectors. D is Mean Square Error (MSE).

Although we already have the loss L_{SE}, we add KL divergence loss L_{KL_2} in the second model for the same setting. The L_{KL_2} is same as Eq. 5, while y_{ij} comes from the second model. We formulate MSD loss function L_{MSD} as follows,

$$L_{MSD} = L_{KL} + \lambda_1 L_{KL_2} + \lambda_2 L_{SE} \tag{7}$$

where λ_1 and λ_2 equal to 1 and a positive value respectively, when we apply self-ensembling, otherwise they both equal to 0. Together, the parametric uncertainty is further reduced.

3.5 MS$\underline{\text{D}}$ Testing: Distinctiveness Score

We also consider the epistemic uncertainty. Though out-of-distribution testing samples are known as the sources of epistemic uncertainty, they show that the epistemic uncertainty is the distinctiveness between the testing and training texts. However, it is not easy to consider the distinctiveness in the training process, because the training process is not aware of distributions of the testing samples. Therefore, we assume each class-level distribution of the training data can be modeled as a multivariable Gaussian distribution. We consider distance between a testing sample and each class-level Gaussian distribution as one part of the distinctiveness score. Motivated by (Lee et al., 2018), we apply Mahalanobis distance as follows,

$$m_{is} = (\mathbf{x}_i^* - \mu_s)^T \mathbf{\Sigma}^{-1} (\mathbf{x}_i^* - \mu_s) \tag{8}$$

where $\mathbf{x}_i^*$ is the representation of i-th testing sample in the first model without mix-up, and μ_s is the mean of representations of all training samples that belong to s-th class. $\mathbf{\Sigma}^{-1}$ is inverse of the covariance of all training samples. We do not apply the covariance in class-level to avoid singular matrices. After we obtain the Mahalanobis distance $\mathbf{m}_i = [m_{i1}, m_{i2}, ..., m_{ic}]$ of i-th testing sample to each class-conditional Gaussian distribution, we can also have a predicted class from this view, which is the class with the smallest distance in $\mathbf{m}_i$. In this way, we design penalty p as the other part in the distinctiveness score, which is not considered in (Lee et al., 2018), as below,

$$p_i = \begin{cases} 0 & r_m = r_y \\ \xi & r_m \neq r_y \end{cases} \tag{9}$$

where r_m is a classified result by $\mathbf{m}_i$ and r_y is the class with maximum probabilities in predicted semantic vector $\mathbf{y}_i^*$. ξ is a constant and set as 10 in our work. Our distinctiveness score d_i is,

$$d_i = log(\beta_1 \times p_i + \beta_2 \times min(\mathbf{m}_i)) \tag{10}$$

where log is a logarithm to the base 10; β_1 and β_2 are constants, both set as 1. Thus, the epistemic uncertainty is scaled in the uncertainty score to improve its accuracy. And the component improves CWS indirectly, because it remedies CWS for missing the epistemic uncertainty in the training process.

3.6 $\underline{\text{MSD}}$ Testing: Uncertainty Score

After we have trained our model by applying mix-up and self-ensembling, the winning scores will have higher confidence and accuracy due to reducing the overconfidence, aleatoric uncertainty, and parametric uncertainty. Regardless of whether we use self-ensembling or not, we only apply the first model to calculate the mean of predicted semantic vectors $\bar{\mathbf{y}}_i^*$ with dropout mechanism. Concretely, given a testing sample $\mathbf{x}_i^*$, we obtain k different predicted semantic vectors $\mathbf{y}_{i1}^*, \mathbf{y}_{i2}^*, ..., \mathbf{y}_{ik}^*$ by k times tryouts with the same dropout rate, from which, $\bar{\mathbf{y}}_i^*$ is the mean of k different $\mathbf{y}_i^*$. The maximum probability in $\bar{\mathbf{y}}_i^*$ is our winning score. Besides training for more confident winning scores, we also scale

---

[3] The first model is our default model, and the second model is only required when we apply self-ensembling. They are shown in the first row and second row respectively in Fig. 1.

distinctiveness score d_i to measure the impact of epistemic uncertainty. We calculate our final uncertainty score U as,

$$U = \gamma_1 \times \frac{1}{\max(\bar{\mathbf{y}}_i^*)} + \gamma_2 \times d_i \qquad (11)$$

where γ_1 and γ_2 are constants.

4 Experiments

Focusing on the text classification with human involvement, we evaluate the performance of MSD on four real-world datasets. Sec. 4.1 shows an overview of our experiment settings. Sec. 4.2 compares the performance between MSD and the state-of-the-art methods, and analyzes results of ablation experiments and parameter sensitivity analysis.

4.1 Experimental Setup

We apply Glove embedding (Pennington et al., 2014), which is pretrained with dimension of 200, as our word embedding by default. For CNN model, we train MSD by setting a sequence model as a 3-layer CNN by default, with batch size of 32, momentum of 0.9, initial learning rate as 0.001 by Adam (Kingma and Ba, 2014), kernel size of each layer as 3, 4, 5, respectively, as well as dropout rate of 0.3. For RNN model, Bidirectional Gated Recurrent Units (BiGRU) (Jabreel et al., 2018) is applied as an example of RNN model with two hidden layers. For Transformer, we apply XLnet (Yang et al., 2019) as an example[4].

4.1.1 Datasets

The four real-world-based datasets used in our experiments are as follow: (1) **20 Newsgroups** (20News) (Lang, 1995) includes 20 different news categories with 20,000 documents in it. (2). **Amazon Reviews** (Amazon) (McAuley and Leskovec, 2013) is a collection of reviews from Amazon from May 1996 to July 2013. For better comparison, we apply data from Sports and outdoors category, which is same as (Zhang et al., 2019). This dataset has 272,630 text samples with sentimental rating labels from 1 to 5. (3) **IMDb Reviews** (IMDb) has binary sentimental rating with 50,000 popular movie reviews. (4). **Yelp Reviews** (Yelp) (Zhang et al., 2015) is a collection with sentimental rating labels from 1 to 5. It has two parts: the first part has 130,000 samples for each rating; the second part has 10,000 samples for each rating.

For the first three datasets, we apply the same split setting as (Zhang et al., 2019), where for each dataset, 70% of samples form the training set, 10% of samples form the validation set, and the rest 20% form the testing set. For the Yelp dataset, we choose 9,000 samples randomly from the second part for each label as training set and the rest 1,000 samples for each label as the validation set, while all samples in the first part form the testing set.

4.1.2 Metrics

To evaluate the performance improvement of text classification with human involvement, which shows accuracy of uncertainty scores, we scale classification accuracy in different eliminated ratios. Concretely, for a testing set S with q samples and eliminated ratio r, we remove the most uncertain samples S_r from S based on uncertainty score ranking, where S_r has $r \times q$ samples. The more accurate uncertainty score we obtain, the more misclassified samples will be removed with the same r. Thus, if a model generates more accurate uncertainty scores, then the F1 scores for the rest testing samples will be higher with the same r. Because uncertainty score is more crucial for semantics with less training samples (e.g. “patient data samples” versus “the data for the healthy” in disease detection), we apply macro F1 score for the rest testing samples in the different eliminated ratios.

4.1.3 Baselines and Ablation Setting

We compare MSD with a state-of-the-art method, which achieves superior improvement of F1 scores in text classification with human involvement (Zhang et al., 2019). It proposes two methods: Dropout-Entropy (**DE**) is a dropout-entropy based model, and **DE+Metric** is a **DE** model along with metric learning. As for MSD, we divide MSD into three sub-models for ablation study: **MSD1** is a sub-model with only mix-up component; **MSD2-a** (abbreviate as **MSD2**) is one with two components, we apply mix-up and self-ensembling components by default; to show the flexibility of MSD, we design **MSD2-b**, which has two components as mix-up and distinctiveness score; and **MSD3** is one with all three components.

4.2 Experimental Results

4.2.1 Results of CNN model

Table 1, 2, 3, 4 report the F1 score improvement in the text classification with various eliminated ratios (10%, 20%, 30%, 40%) for CNN model. The

---

[4] More details and the experimental results on RNN and Transformer are shown in the appendix.

improved ratios of F1 scores compared with no uncertainty elimination (0% column), are illustrated after the F1 scores. The parameter setting of Ω, λ_2, γ_1, γ_2 are given after each MSD in order. Three datasets (20 Newsgroups, Amazon, Yelp) are compared in macro F1 scores, except IMDb, which applies weighted F1 score for better comparison with (Zhang et al., 2019). From the tables, we conclude as below.

1) **Better values of F1 scores:** MSDs (MSD1, MSD2, MSD3) improve F1 scores in values when certain portions of the most uncertain samples are eliminated. Especially for the Amazon dataset, the DE and DE+Metric both have negative growth when more uncertain samples are removed with eliminated ratios increased. This shows the accuracy of uncertainty score scaled in the testing is low for Amazon by DE and DE+Metric, while MSDs achieve significant increase on F1 when the most uncertain samples are eliminated, such as 26.64% increase in 40% elimination. In the 20News, MSDs achieve slightly lower F1 scores compared with DE+Metric, although slightly higher in F1 scores compared with DE. This is caused by obvious difference between texts with various semantics, so the uncertainty influence weakens and MSD is not very effective in the 20News.

2) **Better improved ratios of F1 scores:** If the uncertainty scores are more accurate, higher improvement in the ratios of F1 scores would also be achieved. In comparison to DE and DE+Metric, MSDs always achieve better improved ratios of F1. Thus, MSDs generate more accurate uncertainty score. Especially, though MSD2 has lower F1 score compared with DE+Metric in 0% elimination, it still gets higher F1 score in 40% elimination in IMDb. Plus, though the F1 scores of MSDs are not higher compared with DE+Metric in 20News, higher improved ratios of F1 scores are achieved by MSDs. Thus, MSD is also competitive in comparison with baselines in 20News.

3) **Effectiveness for each component by ablation setting:** Our proposed three components can be applied independently and further improve accuracy of uncertainty scores by combining them in the most situations, which shows effect of comprehensive consideration of uncertainty. In the 20News and Yelp datasets, when one or two components are added, we find consistent increase on F1 scores from MSD1 to MSD2, and from MSD2 to MSD3. Though the MSD3 does not achieve consistently higher improvement in various ratio eliminations in the IMDb and Amazon datasets, the performance of MSD2 is consistently higher than MSD1. It shows the effectiveness of self-ensembling in reducing the influence of uncertainty. Besides, the MSD3 achieves higher improvement of F1 scores in some eliminated ratios compared with MSD2 in the IMDb and Amazon datasets. We explain this as: the out-of-distribution testing texts do not distribute evenly in various eliminated ratios.

4.2.2 Results of Transformer and RNN model

Table 5 and Table 6 report the F1 score improvement in text classification with various eliminated ratios (10%, 20%, 30%, 40%) for BiGRU and XLnet respectively. Then, we conclude as below.

1) **Higher performance in macro F1 by MSD3:** From Tables 5 and 6, MSD3 achieves higher improved ratios of F1 scores in different eliminated ratios. Though the MSD2-b has higher F1 scores with eliminated ratios 10% and 20%, the other F1 scores of MSD3 in the two tables are still the highest in each eliminated ratio. The superior improvement of both F1 scores and ratios of F1 scores shows the joint effect of three components. Furthermore, the results of MSD2-b and MSD3 show the effect of distinctiveness scores for macro F1 in Amazon, which has imbalanced data distributions. Besides, though MSD2-a performs poorly by mix-up and self-ensembling, this performance is reasonable. Because XLnet is a pretrained model, we have parameters of only two FC layers to train, which has much less feasible solutions of possible parameters compared with the CNN and RNN models. Thus, further decrease of feasible solutions of possible parameters brings negative effect in this case.

2) **Flexibility of MSD:** From the Table 5 and Table 6 for RNN and Transformer respectively, as well as Tables 1, 2, 3, and 4 for CNN model, we can observe the competitive performance of MSD in text classification F1 scores compared with two baselines. This verifies that MSD is effective to assemble with other DNNs (CNN, RNN and Transformer). Besides, the ablation setting of MSD1, MSD2-a, MSD2-b and MSD3 shows that the three components in MSD can be assembled arbitrarily based on the characteristics of datasets.

4.2.3 Parameter Sensitivity Analysis

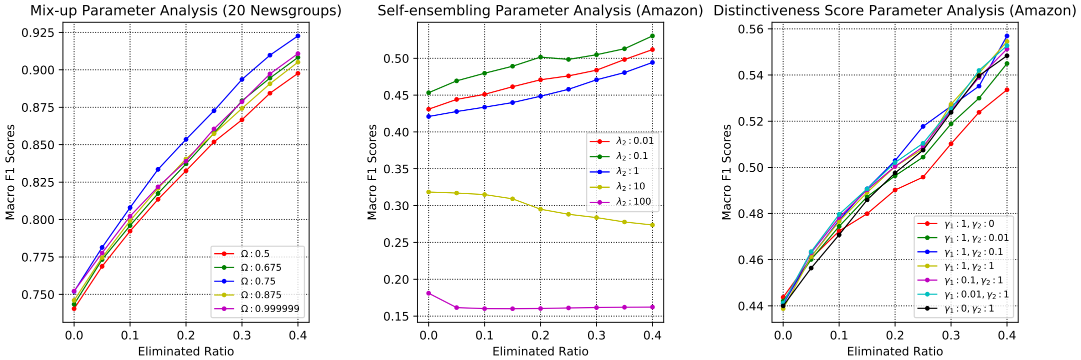

Figure 2: Diagrams for parameter sensitive analysis. The left panel shows how mix-up parameter Ω affects F1 scores. Middle panel shows how the self-ensembling parameter λ_2 affects F1 scores. Right panel shows how changes in γ_1 and γ_2 for distinctiveness score affect F1 scores.

tinctiveness score is discussed as below.

1) **Parameters for mix-up:** The left panel in Fig. 2 shows the effectiveness of different Ω. We apply $\Omega = 0.999999$ to approximate no mix-up. From the subfigure, we find: (1) the F1 scores are slightly sensitive to different Ω, while the improved ratios of F1 scores are not sensitive to the change of Ω. (2) For the 20News, when $\Omega = 0.75$, the macro F1 scores are the highest in different ratios, which are higher than the F1 scores of $\Omega = 0.999999$. This shows the effectiveness of mix-up in improving the accuracy of uncertainty score.

2) **Parameters for self-ensembling:** The impact of self-ensembling parameter λ_2 is shown in the middle panel in Fig. 2. This panel shows: (1) the F1 scores and their improved ratios in various eliminated ratios are significantly sensitive to λ_2, especially when λ_2 is greater than 1. (2) For Amazon dataset, macro F1 scores are the highest when $\lambda_2 = 0.1$ rather than $\lambda_2 = 0.01$. This again verifies the effectiveness of self-ensembling in improving the accuracy of uncertainty score.

3) **Parameters for distinctiveness score:** The right panel in Fig. 2 shows the impact of various γ_1 and γ_2 for distinctiveness score. We can see that: (1) the F1 scores are slightly sensitive to different γ_1 and γ_2. (2) The F1 scores of $\gamma_1 = 1, \gamma_2 = 0.1$ is around 2% higher compared with those of $\gamma_1 = 1, \gamma_2 = 0$, and nearly 1% higher compared with those of $\gamma_1 = 0, \gamma_2 = 1$. This presents the effect of distinctiveness score in generating more accurate uncertainty score.

5 Conclusion

We aims at generating more accurate uncertainty score to improve the performance of text classification with human involvement. We propose MSD with three independent components to improve the CWS by mitigating the effect of overconfidence and handling the impact of three categories of uncertainty. MSD can be applied to various DNNs (CNN, RNN and Transformer) and each component in MSD can be arbitrarily assembled. Extensive experiments on four real-world datasets demonstrate that MSD obtains more accurate uncertainty scores, and superiorly improved classification performance when partial uncertain predictions are simulatively assigned to the experts.

{cpethe,allekim,skiena}@cs.stonybrook.edu

Abstract

Books are typically segmented into chapters and sections, representing coherent subnarratives and topics. We investigate the task of predicting chapter boundaries, as a proxy for the general task of segmenting long texts. We build a Project Gutenberg chapter segmentation data set of 9,126 English novels, using a hybrid approach combining neural inference and rule matching to recognize chapter title headers in books, achieving an F1-score of 0.77 on this task. Using this annotated data as ground truth after removing structural cues, we present cut-based and neural methods for chapter segmentation, achieving an F1-score of 0.453 on the challenging task of *exact* break prediction over book-length documents. Finally, we reveal interesting historical trends in the chapter structure of novels.

1 Introduction

Text segmentation (Hearst, 1994; Beeferman et al., 1999) is a fundamental task in natural language processing, which seeks to partition texts into sequences of coherent segments or episodes. Segmentation tasks differ widely in scale, from partitioning sentences into clauses to dividing large texts into coherent parts, where each segment is ideally an independent event occurring in the narrative.

Text segmentation plays an important role in many NLP applications including summarization, information retrieval, and question answering. In the context of literary works, event detection is a central concern in discourse analysis (Joty et al., 2019). In order to obtain representations of events, it is essential to identify narrative boundaries in the text, where one event ends and another begins.

In novels and related literary works, authors often define such coherent segments by means of sections and chapters. Chapter boundaries are typically denoted by formatting conventions such as page breaks, white-space, chapter numbers, and titles. This physical segmentation improves the readability of long texts for human readers, providing transition cues for breaks in the story.

In this paper, we investigate the task of identifying chapter boundaries in literary works, as a proxy for that of large-scale text segmentation. The text of thousands of scanned books are available in repositories such as Project Gutenberg (Gutenberg, n.d.), making the chapter boundaries of these texts an attractive source of annotations to study text segmentation. Unfortunately, the physical manifestations of the printed book have been lost in the Gutenberg texts, limiting their usefulness for such studies. Chapter titles and numbers are retained in the texts but not systematically annotated: indeed they sit as hidden obstacles for most NLP analysis of these texts.

We develop methods for extracting ground truth chapter segmentation from Gutenberg texts, and use this as training/evaluation data to build text segmentation systems to predict the natural boundaries of long narratives. Our primary contributions [1] include:

- **Project Gutenberg Chapter Segmentation Resource:** To create a ground-truth data set for chapter segmentation, we developed a hybrid approach to recognizing chapter formatting which is of independent interest. It combines a neural model with a regular expression based rule matching system. Evaluation on a (noisy) silver-standard chapter partitioning yields a mean value F1 score of 0.77 of a test set of 640 books, but manual investigation shows this evaluation receives an artificially low recall score due to incorrect header tags in the silver-standard.

  Our data set consists of 9,126 English fiction books in the Project Gutenberg corpus. To

November 16–20, 2020.

encourage further work on text segmentation for narratives, we make the annotated chapter boundaries data publicly available for future research.

- **Local Methods for Chapter Segmentation:** By concatenating chapter text following the removal of all explicit signals of chapter boundaries (white space and header notations), we create a natural test bed to develop and evaluate algorithms for large-document text segmentation. We develop two distinct approaches for predicting the location of chapter breaks: an unsupervised weighted-cut approach minimizing cross-boundary cross-references, and a supervised neural network building on the BERT language model (Devlin et al., 2019). Both prove effective at identifying likely boundary sites, with F1 scores of 0.164 and 0.447 respectively on the test set.

- **Global Break Prediction using Optimization:** Social conventions encourage authors to maintain chapters of modest yet roughly equal length. By incorporating length criteria into the desired optimization criteria and using dynamic programming to find the best global solution enables us to control how important it is to keep the segments equal. We find that a balance between equal segments and model-influenced segments gives us the best segmentation, with minimal error. Indeed, augmenting the BERT-based local classifier with dynamic programming yielded an F1 score of 0.453 on the challenging task of *exact* break prediction over book-length documents, while simultaneously beating challenging baselines on two other error metrics.

  Incorporating chapter length criteria require an independent estimate of the number of chapters in a given text. We demonstrate that there are approximately five times as many likely break candidates as there are chapter breaks in the weighted cut approach, reflecting the number of sub-events within an average book chapter.

- **Historical Analysis of Segmentation Conventions** – We exploit our data analysis of segmented books in two directions. We demonstrate that novels grew in length to an average of roughly 30 chapters/book by 1800, and retained this length until 1875 before beginning a steady decline. Second, an analysis of regular expression patterns reveal the wide variety of chapter header conventions and which forms dominate.

2 Previous Work

Many approaches have been developed in recent years to address variants of the task of identifying structural elements in books.

McConnaughey et al. (2017) attempt this task at the page-level, by assigning a label (e.g. Preface, Index, Table of Contents, etc.) to each page of the book. Wu et al. (2013) address the task of recognizing and extracting tables of contents from book documents, with a focus on identifying its style. Participants of the Book Structure Extraction competition at ICDAR 2013 (Doucet et al., 2013) attempted to use various approaches for the task. These include making use of the table of contents, OCR information, whitespace, and indentation. Déjean and Meunier (2005) present approaches to identify a table of contents in a book, and Déjean and Meunier (2009) attempt to structure a document according to its table of contents.

However, our approach relies only on text, and does not require positional information or OCR coordinates to extract front matter and headings from book texts.

For text segmentation, many approaches have been developed over the past years, suitable for different types of data, such as news articles, scientific article, Wikipedia pages, and conversation transcripts.

The TextTiling algorithm (Hearst, 1994) makes use of lexical frequency distributions across blocks of a fixed number of words. Dotplotting (Reynar, 1994) is a graphical technique to locate discourse boundaries using lexical cohesion across the entire document.

Yamron et al. (1998) and Beeferman et al. (1999) propose methods to identify story boundaries in news transcripts.

The C99 algorithm (Choi, 2000) uses a global lexical similarity matrix and a ranking scheme for divisive clustering. Choi et al. (2001) further proposed the use of Latent Semantic Analysis (LSA) to compute inter-sentence similarity.

Utiyama and Isahara (2001) proposed a statistical model to find the maximum probability segmentation. The Minimum Cut model (Barzilay and Malioutov, 2006) addresses segmentation as a graph partitioning task.

This problem has also been addressed in a Bayesian setting (Eisenstein and Barzilay, 2008; Eisenstein, 2009). TopicTiling (Riedl and Biemann, 2012) is a modification of the TextTiling algorithm, and makes use of LDA for topic modeling.

Segmentation using sentence similarity has been extensively explored using affinity propagation (Kazantseva and Szpakowicz, 2011; Sakahara et al., 2014). More recent approaches (Alemi and Ginsparg, 2015; Glavaš et al., 2016) involve the use of semantic representations of words to compute sentence similarities. Koshorek et al. (2018) and Badjatiya et al. (2018) propose neural models to identify break points within the text.

Sims et al. (2019) address the slightly different, but relevant task of event prediction using a neural model, on a human-annotated dataset of short events.

3 Header Annotation

In order to create a ground-truth dataset for chapter segmentation, we first build a system to recognize chapter headings, using a hybrid approach combining a neural model with a regular expression (regex)-based rule matching system.

3.1 Data

In the absence of human-annotated gold standard data with annotated front matter and chapter headings, we derive silver-standard ground truth from Project Gutenberg. We identify 8,400 English fiction books available in HTML format, and extract (noisy) HTML header elements from these books. We use a train-test split of 90-10%.

3.2 Methodology

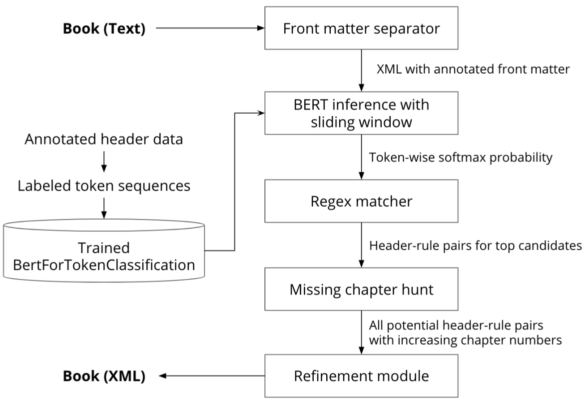

Figure 1: Header Annotation Pipeline

The annotation pipeline has five components, as shown in Figure 1. First, we make use of whitespace cues and string matching for keywords such as 'Preface', 'Table of contents' etc. to identify front matter. We tag all such content up to the first chapter heading as the front matter, and identify the remaining content as body.

3.2.1 BERT Inference

We fine-tune a pretrained BERT model (Devlin et al., 2019) with a token classification head, to identify the lines which are likely to be headers.

Training: For each header extracted from the Project Gutenberg HTML files, we append content from before and after the header, to generate training sequences of fixed length. We empirically select a sequence length of 120. We use a custom BERT Cased Tokenizer with a special token for the newline character, to tokenize the input sequences. The training samples are of the format:

Sequence: $[p_1, ..., p_x, h_1, ..., h_k, q_1, ..., q_y]$
Labels: $[0, ..., 0, 1, ..., 1, 0, ..., 0]$

where $p_1, ..., p_x$ are x tokens before the header, $h_1, ..., h_k$ are k tokens from the header, and $q_1, ..., q_y$ are y tokens after the header. x and y are randomly generated numbers, such that $x+k+y = 120$. This is done in order to prevent header tokens from appearing only in the center of the input sequence.

We fine-tune a pre-trained model for token classification using headers from 6,515 books in our training set for 4 epochs using the BertAdam optimizer. A compute server with a 2.30 GHz CPU and TeslaV100 GPU was used for all experiments.

Inference: For inference on a test set example, we tokenize the text using the custom BERT Cased Tokenizer, and use the model to generate a confidence score for each token. We do this using a sliding window approach, wherein we run inference on a text window of 120 tokens, and slide the window forward by 60 tokens in each iteration. We then perform token-wise max pooling to obtain a single confidence score per token. Further, we detokenize the output by concatenating sub-word tokens and mean-pooling their confidence scores.

We choose the top 10% tokens with the highest confidence scores, and use the lines containing these tokens as potential header candidates for regex matching.

3.2.2 Regex Rule Matching

We compile a list of regular expressions for constituent elements in chapter headings:

- Keywords like 'Chapter', 'Section', 'Volume'

- Punctuation marks and whitespace
- Title (uppercase and mixed case)
- Roman numerals (uppercase and lowercase)
- Cardinal, ordinal, and digital numbers.

Using the rules for these constituent elements, we further generate a list of 1,015 regex rules for valid permutations of these elements.

For every potential header candidate generated using the BERT model, we pick the best matching regex rule as the longest rule that captures constituent elements in order of priority, and discard the candidate if there is no matching rule.

3.2.3 Missing Chapter Hunt

Once we have the list of candidates and their corresponding matching rules, we search for chapter headings the BERT model may have missed. For each matched rule that contains a number in some format, we search for chapter headings in the same format with the missing number. In order to account for chapter numbering restarts in different sections of the book, we search for missing headers within all increasing subsequences in the list of chapter numbers found.

3.2.4 Refinement

We get rid of false positive matches, by removing headers between consecutive chapter numbers, which do not match the same rule.

3.3 Evaluation

Table 1 shows the stage-wise performance of the annotation pipeline. Stage 1 contains all candidates generated using the BERT model, Stage 2 contains headers predicted after applying regex rules and searching for missing chapters, Stage 3 contains headers after removing false positives.

Stage	Precision	Recall	F1
1	0.02	0.67	0.05
2	0.75	0.79	0.76
3	0.78	0.78	0.77

Table 1: Stage-wise performance for header annotation

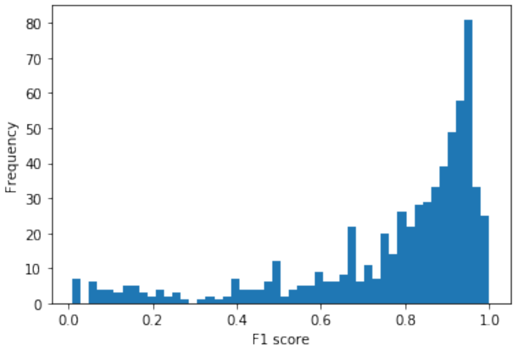

Figure 2: F1 score distribution for 640 test set books

Figure 2 shows the distribution of evaluation metrics on the test set of 640 books, evaluated on the ground truth extracted from HTML files. The mean value of the F1 score is 0.77. Manual investigation of a sub-sample of the test set shows that several books get a low recall score due to false negatives, caused due to incorrect header tags in the silver-standard ground truth. Thus we have even greater confidence in our testbed than the F1-score suggests.

3.4 Popularly used rule formats

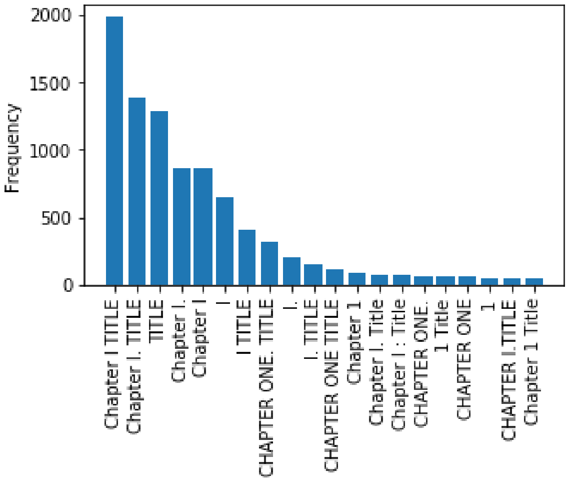

Figure 3: Number of books in which the most frequent header formats occur the most frequently

For each book, we count the number of occurrences of each header format. Figure 3 shows the number of books in which the respective header format occurs most frequently, namely “Chapter # TITLE”.

3.5 Historical Trends

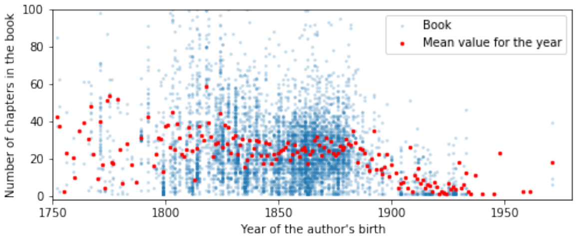

Figure 4: Trend in the number of chapters in a book

Figure 4 presents the number of chapters in each book as obtained by our annotation pipeline, against the author's year of birth. For authors born before 1875, novels were roughly 30 chapters long, after which there has been a steady decline in the number of chapters per book.

4 Local Methods for Segmentation

After removing all explicit signals of chapter boundaries from the texts, we now evaluate algorithms for segmenting text into chapters.

We formulate our task as follows:

Given: Sentences $S_0, S_1, ..., S_{N-1}$ in the book, and P, the number of breaks to insert

Compute: P break points $B_0, B_1, ..., B_{P-1} \in \{0, 1, ..., N-1\}$ corresponding to chapter breaks.

4.1 Weighted Overlap Cut (WOC)

The motivation behind this technique is based on the intuition that chapters are relatively self-contained in the words that they use. For example, consider a chapter that refers to a "cabin in the woods". We would expect references to this cabin to be higher within the same chapter as compared to other chapters. Hence, our hypothesis is that there will be fewer words in common across a break point separating two chapters, as compared to words within the same chapter.

Considering sentences as nodes, and common words as edges, we can compute the density of a potential break point as the sum of the number of edges going across it, weighted by their distance from the break point. As per our hypothesis, we expect the break point between two chapters to appear as local minima in density as a function of sentence number.

We restrict potential break points to the points between paragraphs, and compute the local minima in density. For each local minimum, we compute its prominence as the vertical distance between the minimum and its highest contour line. We then pick the top P most prominent local minima as the break points.

Note that the same hypothesis can also be made at the paragraph level. However, a major limitation of this approach is that paragraph sizes vary widely, ranging from a single word to a considerably huge block of text. Hence, we have taken the approach of computing sentence-level density and then restricting the potential break points to points between paragraphs.

Preprocessing: We use the Stanford CoreNLP pipeline (Manning et al., 2014) for sentence tokenization and lemmatization. We consider paragraphs as text separated by two or more newline characters.

Computation: For every potential break point i between sentences S_i and S_{i+1}, we compute the density of the break point, which is essentially a weighted sum of the number of overlapping word lemmas within a certain window before and after the break point (weighted by the distance of the word occurrence from the break point). We compute the density d_i of break point candidate i as:

$$d_i = \sum_{x=i-w}^{i} \left(\sum_{y=\max(x+1,i)}^{x+w} \frac{\text{overlap}_{xy}}{|i-x||i-y|} \right)$$

where w is the window size and overlap_{xy} is the number of common lemmas in sentences S_x and S_y, excluding stopwords and punctuation. (Note that we use only valid sentence indices during summation, considering the first and last sentences of the book as cutoffs.)

Experiments: We perform experiments on 2,546 books in the test set, using window sizes of 50, 100, 150, and 200 sentences.

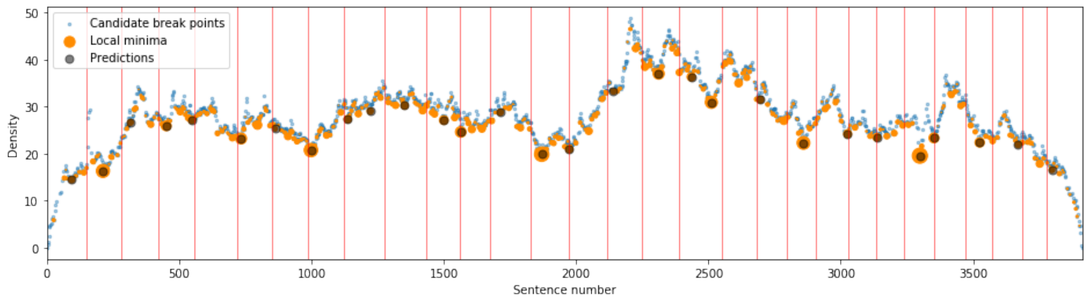
Figure 5a shows the computed densities and local minima for window size 200, for a sample book (*"The Rover Boys Out West"*, by Edward Stratemeyer). The figure shows that chapter breaks roughly correspond to prominent local minima in density.

4.2 BERT for Break Prediction (BBP)

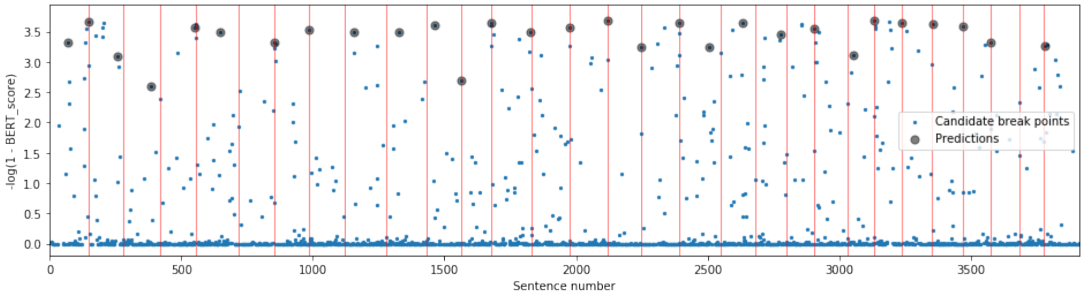
We fine-tune a pre-trained BERT model for the Next Sentence Prediction task, to classify pairs of sequences in which the second sequence is a coherent continuation of the first. Intuitively, for text sequences which are separated by a chapter break, we expect the second sequence to not be a continuation of the first, i.e. the output label should be 0. Whereas for consecutive text sequences within the same chapter, the output label should be 1, denoting that it is a logical continuation.

Training: We generate training sequences from 7,582 books in the training set. We generate training examples in the following format:
`[CLS]<Seq A>[SEP]<Seq B>[SEP]`

To generate negative training samples (i.e. class 0, meaning chapter break), we consider all the chapter boundaries, and construct the input using the



(a) WOC density (Local minima point sizes are proportional to their prominences)



(b) Processed BERT confidence scores

Figure 5: Breakpoint probability scores as a function of sentence number, for a sample book (*"The Rover Boys Out West"*, by Edward Stratemeyer). Vertical red lines denote chapter breaks in ground truth. Predictions are computed using the dynamic programming approach (described in Section 5) with $\alpha = 0.8$.

text just before the chapter break as `Seq A`, and text just after the break as `Seq B`. To generate positive training samples (i.e. class 1, meaning no break) we consider the break points between paragraphs within the same chapter, and construct the input sequence similarly. We use these sequence pairs to fine-tune a pre-trained model for next sentence prediction. Note that class 0 is of interest to us in this task, as lack of continuity between the sequences denotes the possibility of a chapter break.

Inference: During inference on a book, we consider all break points between paragraphs, and generate input sequences as described above. We run each pair of input sequences through the classifier, and generate confidence scores per class. We then use the confidence score for class 0 as the probability of a break. We select the top P break points with the highest confidence scores.

Experiments: We perform experiments using the following variants of training sequences to fine-tune the BERT model:

- *Single paragraph:* We use only one paragraph from before, and one paragraph from after the break point.
- *Full window:* We use 254 tokens each, from before and after the break point. (If the paragraph length exceeds 254 tokens, we cut off the text before/after that point, depending on which side the paragraph lies.)

Figure 5b shows the modified BERT scores for the full window configuration, for a sample book in the test set. The figure shows that BERT is able to capture points close to chapter breaks in most cases, indicating a good recall as well as precision.

4.3 Evaluation

We evaluate our algorithms using three metrics:

$\mathbf{P_k}$ (Beeferman et al., 1999): To compute this metric, k is set to half of the average true segment size. Using a moving window of length k, a penalty is computed based on whether the two ends of the window are in the same or different segments, and whether the ground truth segmentation is in agreement.

WindowDiff (WD) (Pevzner and Hearst, 2002): This metric also uses a moving window, and compares the number of ground truth segmentation boundaries that fall in the window, with the number of boundaries assigned by the algorithm. A penalty is added if the counts are not equal.

F1 score : We use the F1 score to evaluate *exact* break prediction, and consider a match only if the break matches with the ground truth exactly, i.e. predictions near the true break points are not counted.

Lower values of P_k and WindowDiff, and a high value for F1 score are indicative of better performance.

Table 2 shows the evaluation metrics P_k, WD (WindowDiff), and the F1 score for the WOC and BBP configurations described above.

Algorithm	$\mathbf{P_k}$	**WD**	**F1**
Equidistant breaks	0.482	0.492	0.052
TextTile (Hearst, 1994)	0.587	0.714	0.085
C99 (Choi, 2000)	0.493	0.517	0.049
P(Badjatiya et al., 2018)	0.485	0.555	0.111
L(Badjatiya et al., 2018)	0.493	0.569	0.087
WOC (window=50)	0.442	0.465	0.144
WOC (window=100)	0.425	0.450	0.158
WOC (window=150)	0.418	0.447	0.162
WOC (window=200)	0.416	0.446	0.164
BBP (single para.)	0.454	0.509	0.126
BBP (full window)	**0.303**	**0.384**	**0.447**

Table 2: Evaluation metrics for chapter break insertion approaches (For P_k, WD: lower is better. For F1: higher is better.)

We compare our approaches against the following baselines:

- **Equidistant:** We divide the book into $P + 1$ segments, such that each segment has the same number of sentences.
- **TextTiling:** We run the TextTiling algorithm (Hearst, 1994), using mean words per sentence as pseudosentence size, and number of paragraphs as block size for each book. The average number of breaks per book inserted by this algorithm is 574, which clearly does not reflect the actual number of chapters, resulting in poor performance.
- **C99:** We run the C99 algorithm (Choi, 2000) on our dataset, and choose the first P breaks obtained while performing divisive clustering.
- **Perceptron (P):** We train a 3-layer baseline perceptron model with 300 neurons in each layer, for 10 epochs, as described by Badjatiya et al. (2018). We use mean-pooled 300-dimensional word2vec embeddings (Mikolov et al., 2013) trained on the Google News dataset, as input to the perceptron.
- **LSTM (L):** We train a neural model as described by Badjatiya et al. (2018), using the same pre-trained word2vec embedding matrix. The network consists of an Embedding layer, followed by an LSTM layer, a dropout layer, a dense layer and finally, a sigmoid activation layer.

Our models outperform the baselines on all metrics, with the BERT (full window) model for break prediction model giving the best results. The approaches by Reynar (1994) and Utiyama and Isahara (2001), and the neural models proposed by Badjatiya et al. (2018) and Koshorek et al. (2018) are global models, and are prohibitively expensive on long documents.

5 Global Break Prediction

In the approaches described above, we simply select the highest scoring P points. However, this selection does not conform to spatial constraints. For example, the model may place two breaks close to one another, when realistically, chapter breaks are spaced fairly apart in practice.

To validate this, we compute the coefficient of variance (CV) for each book, in terms of the number of sentences per chapter. Figure 6 shows the distribution of the CV over all books in our dataset. Most books in our dataset have a low CV (distributions with CV less than 1 are considered to be low-variance), reflecting the fact that chapters breaks are spaced fairly equally apart.

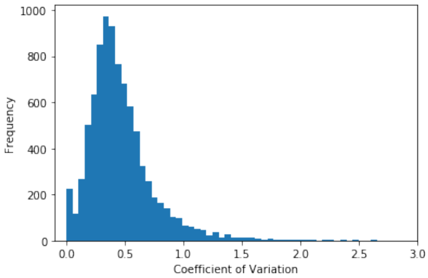


Figure 6: Frequency of distribution for the coefficient of variance of number of sentences per segment

Hence, we propose a dynamic programming approach, in order to incorporate a weight for keeping the chapter breaks equidistant.

We formulate the task in the same way as described previously, with an additional parameter α, which determines the importance of the confidence scores as compared to equidistant breaks. α ranges from 0 to 1, where 1 indicates that full weight is given to confidence scores, and 0 indicates that full weight is given to keeping the breaks equidistant. We define the cost of inserting a break at point n and inserting k breaks in points 0 to $n-1$ recursively as:

$$\text{cost}(n,k) = \min_{i\in[0,n-1]} \left(\text{cost}(i,k-1) + (1-\alpha)\tfrac{|n-i|}{L}\right) - \alpha \cdot s_n$$

where s_n is the confidence score for n being a break point, and L is the ideal chapter length, i.e. number of sentences in each chapter if the book is split into $P+1$ equal parts. At each step, we use the break point which results in cost minimization as the next break point, and repeat the recursive call.

5.1 Experiments

We apply dynamic programming for global break prediction, to both the approaches described above. We conduct experiments for α from 0 to 1, with a step increase of 0.2.

5.1.1 WOC

We use the prominences of local minima obtained using WOC, with window sizes 50, 100, 150, and 200 respectively. We apply min-max normalization on the prominences.

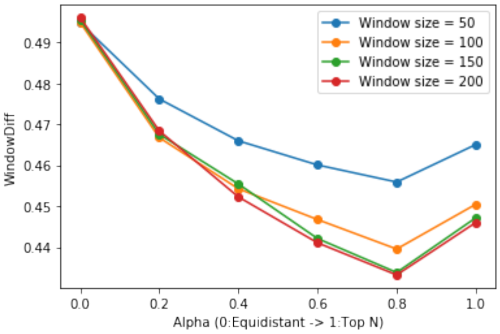

Figure 7: WindowDiff error metric for WOC

Figure 7 shows the WindowDiff error metric for the WOC approach, with differing window sizes, for different values of α. (Note that the window sizes here are in terms of the number of neighboring sentences used to compute density, and not used while calculating the WindowDiff metric.) The figure shows that an increase in window size results in lower error, and for all window sizes, $\alpha = 0.8$ shows the best performance.

5.2 BBP

We use the confidence scores for class 0 obtained using the BERT model. We observe that confidence scores are clustered close to 0 and 1. Higher confidence scores are of more interest to us, as they are indicative of potential chapter boundaries. Hence, in order to distribute the values closer to 1 further apart, we apply the log function and compute the modified confidence score as $-\ln(1-\text{score})/c$, where c is a normalizing constant. In practice, we use $c = 10$ to limit a majority of the values between 0 and 1. We optimize for the best value of alpha independently of this constant.

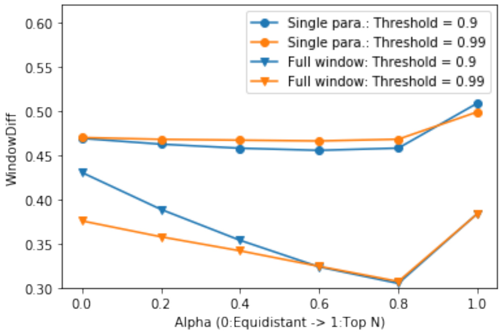

Figure 8: WindowDiff error metric for BBP

Figure 8 shows the WindowDiff error metric for the BERT-based approach for the single paragraph and full window models respectively. We use thresholds of 0.9 and 0.99 for each of the models, meaning that we consider only those break points with confidence scores above the threshold as potential break point candidates.

The full window model shows the least error at $\alpha = 0.8$. Note that a higher threshold of 0.99 shows a performance almost equal to that of 0.9, since a higher threshold means fewer potential break point candidates, and hence a lower runtime. Figures 5a and 5b depict predictions from the WOC and BBP approaches respectively, with $\alpha = 0.8$.

Algorithm	**P_k**	**WD**	**F1**
Best BBP (local)	0.303	0.384	0.447
WOC (window=50)	0.443	0.456	0.144
WOC (window=100)	0.426	0.440	0.158
WOC (window=150)	0.421	0.434	0.162
WOC (window=200)	0.420	0.433	0.164
BBP (single para.)	0.441	0.455	0.128
BBP (full window)	**0.284**	**0.305**	**0.453**

Table 3: Metrics for global chapter break insertion

Table 3 shows the evaluation metrics for global chapter break insertion. The dynamic programming approach consistently improves the WindowDiff and F1 metrics. The BERT model (full window) gives the best performance in terms of all

Algorithm	MSE	MAE	R2	Pk	WD	F1
Baseline (# sent)	205.97	8.928	0.44	-	-	-
WOC (win=50)	203.26	8.797	0.45	0.46	0.50	0.13
WOC (win=100)	203.23	8.804	0.45	0.45	0.49	0.14
WOC (win=150)	203.19	8.805	0.45	0.44	0.49	0.14
WOC (win=200)	203.17	8.804	0.45	0.44	0.49	0.14
BBP (thr=0.9)	192.22	8.366	0.48	0.33	0.38	0.41
BBP (thr=0.99)	**188.08**	**8.155**	**0.49**	**0.32**	**0.38**	**0.41**

Table 4: Evaluation metrics for regression to predict number of chapter breaks in a book (Window size [WOC] and threshold [BBP] denoted in parentheses)

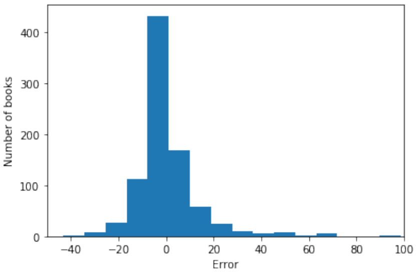

Figure 9: Error distribution over test set using predictions for number of chapters from BBP (threshold=0.99)

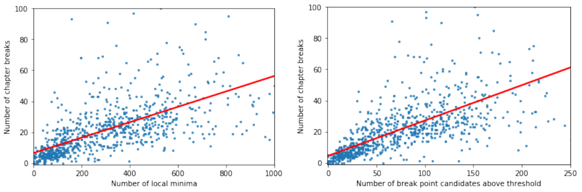
three metrics.

5.3 Estimating the Number of Breaks

The models described above require the number of chapter boundaries to be specified. We now address the independent question of estimating how many chapter breaks to insert.



(a) WOC local minima (window size 200) (Slope = 0.045)

(b) BBP (full-window) candidates (threshold = 0.99) (Slope = 0.213)

Figure 10: Number of chapter breaks as a function of the number of candidate break points

Figure 10 shows the number of chapters against the number of break point candidates for both the approaches. The number of local minima in WOC are approximately 20 times the number of chapter breaks, reflecting potential event boundaries within chapters. The number of break point candidates obtained using BERT are approximately 5 times the number of chapter breaks. This can also be seen in Figures 5a and 5b. Although the BBP model performs better at exact break prediction, the WOC model provides more information in terms of events within chapters.

We now use a regression model to predict the number of breaks, with the number of candidate break points and the total number of sentences in the book, as features. For the number of candidate breaks, we use:

- **WOC:** The total number of local minima
- **BBP:** The number of candidate break points above a certain threshold.

We perform experiments on 2,626 books in the test set, so as to keep the results comparable for both the approaches. We perform a train-test split of 67-33%. We predict the number of chapter breaks using this regression, and further evaluate global break prediction with $\alpha = 0.8$.

Table 4 shows the evaluation metrics on the test set, for regression using the models described above. The full-window BERT model shows the best performance in predicting the number of chapter breaks as well as break locations. Figure 9 shows the error distribution over the test set for the best performing model.

6 Conclusion and Future Work

We build a chapter segmentation dataset resource consisting of 9,126 English fiction novels, using a hybrid approach combining neural inference and regular expression-based rule matching. We achieve and F1 score of 0.77 on this task. Further, we use this dataset, remove structural cues, and address the task of predicting chapter boundaries. We present two methods for chapter segmentation. Our supervised approach achieves the best performance in exact break prediction, while our unsupervised approach provides information about potential subchapter break points.

Our work opens up avenues for further research in text segmentation, with potential applications in summarization and discourse analysis. Potential future work includes combining the neural and cut-based approaches into a stronger method. Finally, it would be interesting to do a deeper dive into variations of author strategies in chapterization, focusing more intently on books with large numbers of short chapters as being more reflective of episode boundaries.

Abstract

In recent years, the task of generating realistic short and long texts have made tremendous advancements. In particular, several recently proposed neural network-based language models have demonstrated their astonishing capabilities to generate texts that are challenging to distinguish from human-written texts with the naked eye. Despite many benefits and utilities of such neural methods, in some applications, being able to tell the "author" of a text in question becomes critically important. In this work, in the context of this *Turing Test*, we investigate the so-called *authorship attribution* problem in three versions: (1) given two texts T_1 and T_2, are both generated by the same method or not? (2) is the given text T written by a human or machine? (3) given a text T and k candidate neural methods, can we single out the method (among k alternatives) that generated T? Against one human-written and eight machine-generated texts (i.e., CTRL, GPT, GPT2, GROVER, XLM, XLNET, PPLM, FAIR), we empirically experiment with the performance of various models in three problems. By and large, we find that most generators still generate texts significantly different from human-written ones, thereby making three problems easier to solve. However, the qualities of texts generated by GPT2, GROVER, and FAIR are better, often confusing machine classifiers in solving three problems. All codes and datasets of our experiments are available at: `https://bit.ly/302zWdz`

1 Introduction

Recent rapid advancements in deep learning technologies have enabled the generation of realistic artifacts (e.g., Deepfakes) that are difficult to distinguish from genuine human-generated artifacts. In the *text* domain, which is the main focus of this work, similarly, the advancement of *Natural Language Generation* (NLG), especially those based on neural language models, has led to the inundation of realistic text generation.

As novel NLG techniques become more sophisticated and prevalent, corresponding pitfalls and risks of such technologies also increase. Adversaries may use such technologies to generate realistic artifacts to trick naive users in fraudulent activities (e.g., machine-generated chatbot conversation in a phishing scam or deepfake-based disinformation campaign). Therefore, the need to distinguish machine-generated texts from human-written ones, so-called the *Turing Test*, naturally arises. Furthermore, in some security applications, merely being able to identify machine-generated text may not be sufficient. Instead, a more critical solution would be to tell *which* NLG method among many candidates has generated a given text in question–so-called the *Authorship Attribution (AA)* problem. To improve our understanding of this newly-emerging problem, we empirically investigate three versions of the AA problem in this paper. For all three versions, we assume that there are k different NLG methods[1].

Problem 1 (Same Method or Not) *Given two texts T_1 and T_2, determine if both T_1 and T_2 are generated by the same NLG method (or human) or not.*

Problem 2 (Human vs. Machine) *Given a text T_1, determine if T_1 is written by human or generated by any k NLG methods.*

Problem 3 (Authorship Attribution) *Given a text T_1, single out one NLG method (among k alternatives) that generated T_1.*

We model P1 and P2 as the binary classification problem, while P3 as the multi-class classification

[1] In the future, we envision that k can be huge, say 1000, but for this experiment, we set $k = 8$.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8384–8395,
November 16–20, 2020.

problem. All three problems are related, with several motivations as follows.

First, solutions to P1 may be useful when one needs to determine the plagiarism or identity theft issue of an NLG method. For instance, suppose GPT2 becomes very powerful in the near future so that other NLG methods may even try to mimic the characteristic features in the GPT2-generated texts. Then, a solution to P1 can determine if two texts in question are both generated by GPT2 or not. Second, as NLG methods become ubiquitous, the threat of generating misinformation at scale increases naturally. Thus, using solutions to P2, being able to accurately distinguish between machine- and human-generated texts is required to mitigate such security risks that NLG methods could pose. Finally, as to P3, as the number of state-of-the-art NLG methods increases, it will be beneficial not only just to separate them into two camps but also find out which generators are used. Furthermore, knowing each generator's writing signature or style moves us closer to quenching the security threats that they may introduce.

2 Related Work

2.1 Features for Authorship Attribution

Predicting an author based on their writing signature is called Authorship Attribution (AA). This AA problem has been previously and even recently solved with n-grams (Sharma et al., 2018; Sari et al., 2017; Shrestha et al., 2017; Proisl et al., 2018; Kestemont, 2014; Zečević, 2011; Li et al., 2014). Next, as complex datasets emerge, other techniques such as POS-tags (Ferracane et al., 2017; Sundararajan and Woodard, 2018; Hitschler et al., 2017), topic modeling (i.e. LDA, AT and DADT) (Seroussi et al., 2014, 2012, 2011), POS-Noise (Halvani et al., 2020) and LIWC (Uchendu et al., 2019; Li et al., 2014) are explored and used to solve the AA problem. However, Ferracane et al. claim that n-grams and POS-tags are not sufficient for solving the AA problem, and sometimes negatively impact classifiers' performance. Therefore, they recommend using discourse embedding features.

Furthermore, Zheng et al. attempt to solve the AA problem with online messages by investigating four types of writing-style features (i.e., lexical, syntactic, structural, and content-specific features). Structural and content-specific features were the best to assign authorship (Zheng et al., 2006).

Next, Kestemont examines the use of content and function words as relevant features for AA. Van Cranenburgh focuses on content words and so parse phrase-structures. Consequently, Hoenen and Schenk claim that word pairs could make strong features and extract function words, content words, similarity and relatedness. They find function words to be the most robust feature (Hoenen and Schenk, 2018). To establish distinct writing styles further, Solorio et al. extract lexical, syntactic, and stylistic features using bag-of-words (freq. of unigrams), POS-tags, Dependency relations, and Chunks (unigram freq.), respectively for the AA problem. With the new wave of nuanced techniques to solve the AA problem, Tschuggnall and Specht use syntax tree for each sentence to analyze grammar. Finally, Shao et al. use readability scores to distinguish human-written texts from machine texts, another form of AA. The results suggest that readability is a vital feature for distinguishing authors.

2.2 Classifiers for Authorship Attribution

Several well-established classical machine learning classifiers have been applied to the AA problem, including Naive Bayes (Howedi and Mohd, 2014; Baron, 2014), SVM (Solorio et al., 2011; Hou and Huang, 2017; Shao et al., 2019), Conditional Tree (Sharma et al., 2018), Random Forest (Hou and Huang, 2017; Alshaher and Xu, 2020; Sharma et al., 2018), and KNN (Alshaher and Xu, 2020). However, due to improvements in neural networks, recently, CNN (Convolution Neural Network) is said to be even more suited for the AA problem (Ferracane et al., 2017; Hitschler et al., 2017; Boumber et al., 2018). CNN architecture is better suited to represent the characteristics of each author. Consequently, Ferracane et al. improve the CNN's use with discourse features (i.e., n-grams and POS-tags). Ren and Ji further improve upon CNNs with the use of word embeddings to represent texts. Lastly, RNNs have also been shown to be well-suited for representing the authors' distinct writing styles (Alsulami et al., 2017).

2.3 Applications of Authorship Attribution

The applications of AA are vast and include: assigning authorship to literature/text, and ascertaining the demography of an author (e.g., age, gender, native language) (López-Monroy et al., 2020). AA can also be applied to predicting author(s) of source code (Simko et al., 2018), chatbot detection (Uchendu et al., 2019), and even detecting authors intentionally trying to mask their writing style (Juola, 2012; Sánchez-Junquera et al., 2020). Finally, our work bears similarity to (Manjavacas et al., 2017), which investigates the stylistic properties of different neural text generation techniques (i.e., Ngram-based and RNN-based).

3 Generation of Texts

We have nine text generators–i.e., one human writer and eight neural machine generators. All eight neural generators require a short prompt to begin their generation and the number of words to generate. These eight generators were chosen because we found that they had the best pre-trained models for our task. We used the titles of news articles (written by human journalists) as the prompt and set 500 as the number of words.

1. **Human**. We collected recently-published news titles and contents in mostly Politics–819 from CNN, 132 from Washington Post, and 113 from the New York Times. As professional reporters write these news articles, they represent human-written texts. Then, we used the news titles as the prompts for other neural methods.
2. **CTRL**. Also known as "Conditional Transformer Language Model For Controllable Generation," CTRL[2] is a huge language model with 1.63 billion parameters (Keskar et al., 2019). The model was trained on control codes to guide the styles and contents of generated texts. Among the 50 control codes available, we used the *News* control code to generate long articles.
3. **GPT**. The OpenAI GPT is built with Transformers. It was trained and modeled after a simple concept - to predict the next token, given the previous token (Radford et al., 2018). We used the medium GPT model with 345 million parameters since it was computationally less expensive while still being able to generate comparable results. We used the Transformer text generation setup by huggingface[3].
4. **GPT2**. We also used the GPT2 model with 774 million parameters. We used the gpt2 wrapper[4] to generate texts.
5. **GROVER**. Grover is another large language model, explicitly trained to generate political news (Zellers et al., 2019). It uses the same template as news outlets such as CNN and the New York Times. Grover uses the same architecture as GPT2 and the same concept of predicting the next token, given previous tokens. We used code from repo[5] to generate texts.
6. **XLM**. The Cross-lingual Language Model (XLM) is another generative language model (Lample and Conneau, 2019). Unlike other language models, XLM is trained for the task of cross-lingual classification. We generated texts from the English language model, using the same setup in huggingface as GPT.
7. **XLNET**. XLNET (Yang et al., 2019) improves language modeling by introducing bidirectional contexts. This technique involves a generalized auto-regressive pre-training method and adopts the Transformer-XL framework into pre-training. XLNET achieved state-of-the-art results, outperforming BERT on 20 tasks. We also used the huggingface Github repo to generate texts.
8. **PPLM**. The "Plug and Play Language Models (PPLM)" is another language model that improves upon GPT2 by fusing the medium model with bag of words models (Dathathri et al., 2019). We used the *Politics* bag of words model to generate texts', using the code[6], and used the perturbed version.
9. **FAIR**. Facebook's FAIR has three language models of English, Russian, and German (Ng et al., 2019). For our task, we used the English language model built with FAIRSEQ sequence modeling toolkit[7].

Table 1 shows the snippets of nine texts for the identical prompt message–i.e., one written by news reporters and eight by different neural language models. Table 2 shows the summary statistics of nine generated texts. Note that CTRL tends to generate the longest texts (in terms of the number of

Table 1: Snippets of nine texts using the titles of human-written articles as the prompt to neural methods.

words), while GPT2 tends to generate the shortest texts. Both XML and XLNET generated the texts with very long sentences.

4 Linguistic Analysis

We first conduct a psycholinguistics study to analyze different linguistic features of generated texts. The result is summarized in Table 3.

First, we use *Flesch Reading Ease* and *Flesh-Kincaid Grade* to gauge generated texts' readability. *Flesch Reading Ease* generates a score between 0 and 100, such that post-college level yields a score between 0-30, college-level yields 31-50, high-school level yields 51-70, middle school yields 71-90, and 5-th grade level of reading and below yields 91-100. These seven reading levels also go from a scale of very-difficult-to-understand due to the level of sophistication to very-easy because it is the grade level of readability. Therefore, obtaining a post-college level (i.e., low score) is uncommon and impressive if a machine generates such texts. On the other hand, the *Flesh-Kincaid Grade* generates a score representing the U.S. grade level of education (the higher, the more sophisticating). For instance, text given a 10.8 score suggests that its author can be in the 11-th grade and about 16-17 years old.

Next, we use *Linguistic Inquiry and Word Count (LIWC)* (Pennebaker et al., 2001) to capture the psycholinguistics features. LIWC has 93 features, of which 69 are categorized into: Standard Linguistic Dimensions (e.g., pronouns, past tense), Psychological Processes (e.g., social processes), Personal concerns (e.g., money, achievement), and Spoken Categories (e.g., assent, nonfluencies) (Uchendu et al., 2019). Table 3 includes top-3 distinguished LIWC features among all generation methods. A high *LIWC-Authentic* score means that the author of the text is honest or less evasive. We can observe that GPT and XLNET generates more personal content than GPT2 and FAIR. *LIWC-Analytic* reflects the formality, and logical nature of the text. GPT2,

Table 3: Linguistic features of nine generated texts.

GROVER, and FAIR scores are as high Human, suggesting that they all generate sophisticated texts. *LIWC-Article* shows the usage of *a, an, the*, which are crucial in any formal writing. Similar to *LIWC-Analytic*, GPT2, GROVER, and FAIR score similar to Human. Overall, the patterns among these LIWC features follow our observations that GPT2, GROVER and FAIR generally have higher news generation quality than other machine algorithms. Finally, we also measure the entropy scores of generated texts (Schürmann and Grassberger, 1996). Figure 1 shows the 2-dimensional distribution of generated texts using Principal Component Analysis (PCA) on all psycholinguistic features, with about 70% explained variation. As we can observe a large overlapped portion among generated texts. We expect a non-linear machine learning model (e.g., Random Forest) would perform better than a linear method such as Naive Bayes in classifying the texts according to their generators using these features.

5 Model Architecture

In solving three problems, we compare various relatively-simple neural models' performances, employing different architectures to encode generated texts into representation vectors, which then feed into a fully connected network followed by a *softmax* layer for prediction. Note that our goal is *not* to develop sophisticated neural models to solve three problems. Rather, we want to empirically evaluate how these simple neural models (as baselines) perform in solving three problems.

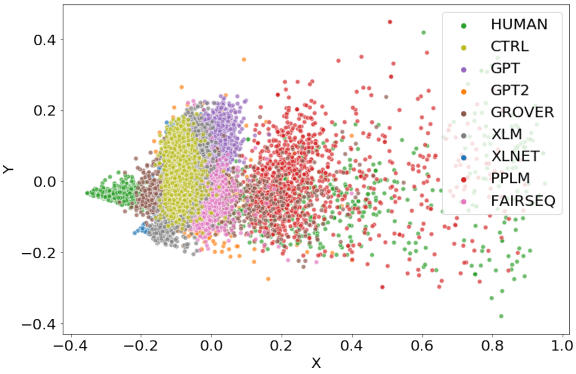

Figure 1: Distribution of generated texts on 2-dimensions using PCA.

1. **Embedding:** This model maps each word in the generated texts to a vector of 300 dimensions, then sums up all resulting vectors as the final representation.

2. **RNN:** This model uses a variant of recurrent neural network (RNN) with a GRU (Cho et al., 2014) layer to model the sequential dependency among words within each of the generated texts.

3. **Stacked_CNN:** This model is inspired by (Zhang et al., 2015), where each of generated texts is encoded by a sequence of six 1D convolutional layers of different kernel sizes. We reduced learning rates from 0.001 to 0.01/0.1.

4. **Parallel_CNN:** Similar to *Stacked_CNN*, but instead of using a stack of convolutional layers, we adopt (Kim, 2014) and use four parallel 1D convolutional layers of different kernel sizes, followed by a max pooling and concatenation operation.

5. **CNN-RNN:** This is a combination of *Stacked_CNN* and *RNN* where each word of a text is first encoded by a stack of two 1D convolutional layers before being input into each step of a GRU layer to model the sequential dependency of the whole text.

Experimenting with these neural models, we split the dataset into the training, validation, and testing parts in 7:1:2 ratio.

6 P1: Same Method or Not

The first version of the problem is to determine whether two given texts are generated by the same method (including human writers) or not. Even if one cannot pinpoint whom the author is for a given text, one may still notice similarities between texts. Therefore, P1 tests the varying capabilities of models to detect such *similarities* between the two texts.

We prepare two datasets of a similar size. In the balanced set, half of text pairs are generated by the same method (e.g., Human-Human or CTRL-CTRL), and the other half are random pairs of the two different methods (e.g., Human-CTRL or GROVER-FAIR). In the imbalanced set, 11% of text pairs are generated by the same method, while the remaining 89% are by different methods (1:8 ratio). Model-wise, we utilize the *Siamese neural network* (Koch et al., 2015) with one of the text encoders in Section 5 to predict whether the two input texts are generated by the same method. Table 4 summarizes the performances. Both RNN and CNN-RNN methods perform the best in the balanced and imbalanced settings, respectively. Recall that the imbalanced setting is more challenging than the balanced as # of positive samples is much smaller. Overall, neural models can identify two texts generated by the same method very well for the balanced setting (F1=0.9813) and reasonably well for the imbalanced setting (F1=0.7869).

7 P2: Human vs. Machine

The second version of the problem determines whether a given text is generated by human or machine (i.e., one of the neural methods). P2 is a type of the *Turing Test*. Despite the recent advancements in neural NLG methods, we hypothesize that there may still be latent differentiating characteristics between human-written and machine-generated texts. Therefore, P2 tests the varying capabilities of different models to detect such *differences* between human and machine writings.

For P2, in addition to five neural models introduced in Section 5, we also tested three known Turing Test models including RoBERTa (Liu et al., 2019) using a similar implementation of *GPT2 Output Detector*[8], GROVER-DETECT (Zellers et al., 2019)[9], and RoBERTa-tuned, which is the RoBERTa that we fine-tuned using 20% of our data. RoBERTa is fine-tuned by adding a classification layer on top of it. Next, the weight of the classification layer is randomly initialized and then trained on the GPT2 output and human written text [10]. Further, we utilize the 20% of the target data we collected to fine-tune the RoBERTa classification model. Note that GROVER-DETECT used in our experiment was trained using only 5K training samples, while its improved version trained with 100K samples is not publicly available. Additionally, *GLTR* is another state-of-the-art Turing tester used to distinguish machine-generated texts from human-generated texts (Gehrmann et al., 2019), although not used in these experiments.

Furthermore, in this setting, we tested both individual case (i.e., one neural method at a time) and collective case (i.e., eight neural methods combined). First, we prepare eight test sets for the individual case, each of which is the balanced test set between human (50%) vs. one neural generator (50%). Table 5 summarizes the performances in those eight individual test sets. For the collective case, on the other hand, we prepare two test sets. In the balanced set, the half of tests are written by human and the other eight neural methods generates the other half. In the imbalanced set, 11% of test texts are written by human, while the remaining 89% are generated by any of the eight neural methods (1:8 ratio). Table 6 summarizes the performances in both balanced and imbalanced settings.

In Table 5, we find that GPT2 generates texts that are almost indistinguishable from human-written

Table 5: P2: Binary classification performance in F1 score of "Human vs. Machine" on eight individual test sets. Each column name X indicates an individual balanced test set of HUMAN (50%) and X (50%).

texts (having the lowest average F1=0.6574 across eight models). FAIR is the second (F1=0.7547). Interestingly, we find that RoBERTa-tuned can still differentiate human-written texts from GPT2-generated ones with a high F1 score (0.9792) and has the highest average F1 (0.9702) across all eight datasets. This is likely so because RoBERTa-tuned is fine-tuned on two doses of GPT2 texts (i.e., RoBERTa was already fine-tuned on GPT2 dataset to begin with).

For the performance of collective cases shown in Table 6, RoBERTa-tuned is again the overall winner. It can differentiate human-written vs. machine-generated texts with F1=0.9152 for the balanced setting and F1=0.8489 for the imbalanced setting. Two existing Turing Test models (i.e. GROVER-DETECT and RoBERTa) significantly underperform, although RoBERTa aces in Recall.

8 P3: Authorship Attribution

The third version of the problem is to single out the real author of a given text, among many alternatives (e.g., one human and k neural methods). Therefore, P3 tests different models' varying capabilities to exploit both *similarities* within and *differences* across human and machine writings.

For P3, in addition to five neural models introduced in Section 5, we also tested four classical machine learning models (i.e., Naive Bayes, Decision Tree, SVM, and Random Forest) using psycholinguistic features discussed in Section 4 and four state-of-the-art AA solutions, including POS+CNN-LSTM and POS+LSTM-LSTM (Jafariakinabad et al., 2019), 3-grams + SVM (Sari et al., 2018) and Character n-gram + SVM (Stamatatos, 2017). Neural methods such as Embedding, RNN, and CNN-RNN used GloVe word embedding (Pennington et al., 2014), but Stacked_CNN and Parallel_CNN did not use GloVe due to its negative impact on performance.

Table 7 summarizes the performance results. Surprisingly, the overall winner is Random Forest, outperforming all five neural models and four existing AA methods. As to per-class F1 scores, Random Forest, a robust non-linear model, accurately solved the AA problem across all nine test sets (one human and eight neural generators). Most generated texts were relatively easy to identify their authorship, giving up high F1 scores (especially the generators such as CTRL, GPT, XLM, XLNET, and PPLM).

The most challenging test set turns out to be both Human and GROVER that yields relatively low average F1 scores across all of classical, neural, and existing AA models (0.5423 and 0.5542, respectively). Also, interestingly, neural classifiers are able to classify FAIR very accurately unlike classical or existing AA models, while classical

models, especially Random Forest and SVM, perform better for tough test sets such as GROVER and Human.

9 Discussion

9.1 P1: Same Method or Not

As expected, we find that the balanced setting yields significantly higher F1 scores across five neural models than the imbalanced setting. However, P1 is still nontrivial to solve, especially in the imbalanced setting, as can be seen in Figure 1, where many machine-generated texts are shown to be linearly inseparable. Furthermore, from Table 3 and Section 4, we can see that while some generators generate similar texts, all generated texts still possess distinct qualities that are leveraged in P1, achieving F1=0.9813 in the balanced setting. It is harder to grasp these distinct characteristics when looking at a single piece of text. As such, the comparison of two texts in the setting of P1 offers an advantage to the task.

9.2 P2: Human vs. Machine

We find that RoBERTa-tuned often outperforms neural classifiers in the individual human vs. machine setting, except for the case of GROVER (Table 5). RoBERTa-tuned outperforms all competing models in distinguishing machine texts from human texts, incredibly well on GPT2 texts (achieving F1=0.9792), probably due to sufficient training on GPT2 data. Next, we find that GROVER-DETECT underperforms in classifying the other machine-generated texts in Table 5, but performs well on Human vs. GROVER achieving the F1 score of 0.8135. This is because it was trained to detect GROVER-generated texts. For the collective settings, however, both RoBERTa and Parallel_CNN have similar F1 scores, while outperforming the rest by significant margins.

9.3 P3: Authorship Attribution

For this setting, in Table 7, we compare different settings, including (1) the use of GloVe word embedding with Embedding, RNN, and CNN-RNN; (2) no word embedding with Parallel_CNN and Stacked_CNN; (3) the use of linguistic features with classical learning algorithms; and (4) n-grams and POS-tags with state-of-the-art AA methods. In this task, we learn that the more accessible generators to classify are CTRL, XLM, and XLNET, while the harder ones are Human, GROVER, FAIR, and GPT2. This can be seen in Tables 5 and 3, where the more demanding generators underperform, and score highly in *LIWC-Analytic* and *LIWC-Article*, respectively. This is vice versa for the more accessible generator. We also find that the linguistic features effectively solve P3, slightly better than state-of-the-art AA solutions, and (simple) neural classifiers. The top stylistic features are *word count, article, period, word-per-sentence count, auxiliary verb, preposition, comma*. We expect this result will change in the future when: (1) the quality of machine-generated texts improve, losing revealing linguistic cues, and (2) neural models are trained better with an enormous amount of data and more powerful architectures.

One may wonder if some results with high F1 scores to solve P3 in Table 7 are simply due to the fact that different generators tend to generate texts on different topics (with non-overlapping word usage, thereby affecting embedding to neural models). In addition, while we only attempt to collect our articles from the domain of "politics," some other domains may have been added unintentionally. However, when we solve P3 using the combination of bigram and trigram models with top-20 LDA-extracted topics, we achieve only 0.38 as the overall average F1 score. Therefore, we believe that simple topical analysis of generated texts cannot solve P3 well.

10 Conclusion

We have conducted comprehensive experiments on three versions of the Authorship Attribution (AA) problem: (1) the same method or not, (2) human vs. machine (Turing Test), and (3) who is the author. Notable findings from our empirical evaluation include: (1) not all neural text generation methods generate high-quality human-mimicking texts–in particular, GPT2, GROVER, and FAIR generated better-quality texts and (2) using specific linguistic features and simple neural architectures, we can solve three problems reasonably well, except GPT2 and FAIR in P2 and GROVER in P3.

P2	6,825	881	1,888

Table 8: Details on Train, Validation and Test Set Splits

A Reproducibility

A.1 Implementation, Infrastructure, Software, and Data

We run all experiments using either P100 or Titan Xp GPU card on a standard server machine with 16GB of RAM. We utilize deep learning platform *Ludwig* (v.0.2.1) with *Tensorflow* (v.1.15.0) backend to develop and evaluate all text classification models in the paper. For classical ML, we utilize *scikit-learn* (v.0.22.1) library. All implementations are done using *python* language (v.3.0). For generating text, we adopt various models implementation provided by *huggingface*[11], *PPLM*[12], *grover*[13], and *Fairseq*[14] Github repo. To extract LIWC features, we utilize the LIWC2015 software (v.1.6.0)[15].

A.2 Data and Preprocessing

We generate all the text following the description in Section 3. Since the generated text of some machine algorithms includes artificial tokens such as <eos> and <sos>, we remove these tokens from the results. We also ensure that the prompts (i.e., article titles) are appended to every generated article. For P3, we use all the generated text by 9 methods (human and eight machine algorithms), resulted in a dataset with balanced label distribution. For P1, creating datasets generators' pairs is a combinatorial problem, which will create a very large dataset. Instead, we sample from each possible pairs of generators K samples while maintaining the relative distribution among them, resulting in the imbalanced dataset. Then, we adjust K and under-sample negative samples with 1:8 ratio to create the balanced dataset for P1. For P2, we curated the imbalanced dataset from P3, with 1 human and 8 machine generators. Then, we under-sample negative sample with 1:8 ratio to create a balanced dataset for P2. For each task P1, P2 and P3, we then split to train, validation and test set with 7:1:2 ratio. Table 8 summarizes statistics of datasets used for each task in balanced and imbalanced scenario, respectively. Also, using language_check, a python package for detecting and correcting grammatical errors, we found that most generators had less than a 3% grammatical error rate, except for XLM that had a 14% error rate.

A.3 Running Time

All experiments take an average running time of around 2 minutes for each training epoch. Depending on the text encoders being utilized, and one training epoch can take as low as 10 seconds (Embedding model) to as long as 8 minutes (CNN-RNN model).

A.4 Training and Model's Parameters

For each of neural network models tested in the paper, we use various text encoders to learn vector representations of input texts (Section 5), results of which are then input into a fully connected network (FCN) with Dropout followed by a softmax layer to make prediction. Table 9 describes the training hyper-parameters and various models' architectures. We train all neural network models using Adam optimizer (Kingma and Ba, 2014) with default parameters.

Parameter	**Value**
Max Words	500
Vocabulary Size	20,000
Early Stop	2
Batch Size	256
Learning Rate	0.01
Adam Optimizer	β_1: 0.9, β_2: 0.999, ϵ: 1e-08
Embedding Size	300
Stacked CNN Kernel Sizes	7, 7, 3, 3, 3 and 3
Stacked CNN Pool Sizes	3, 3, 3, 3, 3, and 3
Parallel CNN Kernel Sizes	2, 3, 4 and 5
RNN Hidden Size	256
FCN Layers (before Softmax)	256 - 256
Dropout	0.5

Table 9: Model's Parameters and Training's Hyper-Parameters

A.5 Evaluation Metrics

We use standard *Precision (P)*, *Recall (R)*, and *F1* score as the main evaluation metrics throughout the paper. We first construct a confusion matrix and calculate those scores as follows.

$$P = \frac{TP}{TP + FP}, \quad R = \frac{TP}{TP + FN}, \quad F1 = 2\frac{P * R}{P + R}$$

where TP is True Positive, FP is False Positive, FP is False Positive and FN is False Negative predictions.

Abstract

Millions of people irrespective of socio-economic and demographic backgrounds, depend on Wikipedia articles everyday for keeping themselves informed regarding popular as well as obscure topics. Articles have been categorized by editors into several quality classes, which indicate their reliability as encyclopedic content. This manual designation is an onerous task because it necessitates profound knowledge about encyclopedic language, as well navigating circuitous set of *wiki* guidelines. In this paper we propose **N**eural **w**ikipedia **Q**uality **M**onitor (NwQM), a novel deep learning model which accumulates signals from several key information sources such as *article text*, *meta data* and *images* to obtain improved Wikipedia article representation. We present comparison of our approach against a plethora of available solutions and show 8% improvement over state-of-the-art approaches with detailed ablation studies.

1 Introduction

Wikipedia is one of the most prominent sources of free information in the world today. Since reliable and advertisement free material is mostly behind pay-walled sources, a huge volume of global population is directed toward this extraordinary crowd sourced platform for information ranging from history, politics, pop-culture to even scientific topics (Horta Ribeiro et al., 2020).

Although Wikipedia has grown significantly in terms of volume and veracity over the last decade, the quality of articles is not uniform (Warncke-Wang et al., 2015). The quality of Wikipedia articles is monitored through a rating system where each article is assigned one of several class indicators. Some of the *major* article categories are **FA**, **GA**, **B**, **C**, **Start** and **Stub**. Most complete and dependable content is annotated by an FA (*aka featured article*) tag while lowest quality content is annotated with a Stub tag. The intention behind this elaborate scheme is to notify editors regarding current state of the article and extent of effort needed for escalating to encyclopedic standards[1].

There exist several guidelines which direct editors in annotating articles into respective classes. Some of the traits of a FA article are engaging and comprehensive prose with neutral point of view and verifiable claims. It must also rigorously follow the style manual, i.e. the page structure. Further the content should be stable, i.e. devoid of edit warring. Understanding compliance with these guidelines often require detailed knowledge about language usage as well as domain knowledge about Wikipedia page layout and style principles. Often it is nontrivial to discern qualifying differences between articles which merits their ratings without inculcating personal biases.

Consider the wikipage of two prominent US presidents *Abraham Lincoln* (GA) and *John F. Kennedy* (B). Both pages are indistinguishable in-terms of coverage and engagement, however on closer assessment it is apparent that President Kennedy's page contains unattributed opinion such as the statement *This crisis brought the world closer to nuclear war than at any point before or after ...* in the *Cuban Missile Crisis* section. It also has vague quantifiers such as *some questioned, some crtics, somewhat successful etc.* Similarly, if we look at wikipages of historical figures *Akhenaten* (B) and *Cleopatra* (FA) it is difficult to discern their quality just from the content. A deep dive into the individual *talk pages* reveal that the former page has unresolved content issues and disputes which justifies the given rating. Hence it is a difficult task to manually judge language specific nuances

November 16–20, 2020.

present in the main page text, topic level disputes manifesting in the talk pages as well as section layout and image positioning before deciding a correct rating. This is also apparent from the quality statistics[2] which shows that only 0.09%, 0.5% of the $\sim 6M$ English Wikipedia articles have a FA and a GA tag respectively.

Current approaches for automatic quality assessment by *Wikimedia foundation*[3] use handcrafted features from main article text for classifying quality class (Halfaker and Geiger, 2019). Analogous approaches exist (Dang and Ignat, 2016) which attempt to automatically generate features from main text using deep learning models such as *doc2vec* (Le and Mikolov, 2014). Other approaches use deep sequence models such as BILSTM (Shen et al., 2017) as well as combining representations obtained with additional modalities like image (Shen et al., 2019b). The principal focus of existing works have been concentrated on main article text. However one of the key sources of metadata about an article, i.e., the corresponding *talk page* has been ignored. Talk pages contain crucial information concerning stability of a page. They also hold evidence whether discussion threads encompassing topics are decisive. Besides, representation of main page text using sequence models cannot capture high level semantic signals such as whether the introduction section is a summary, whether the coverage of topics is polarized or the information is redundant or the wording is convoluted.

In this paper we propose **N**eural **w**ikipedia **Q**uality **M**onitor (**NwQM**) which integrates information from multiple sources, i.e., main page text, metadata and html rendering resulting in improved quality assessment. We use bidirectional contextual representation (Devlin et al., 2018) for encoding article text. However, contrary to document representation using BERT (Adhikari et al., 2019), which is not adequate for large text documents, we first segment articles organically based on sections. We fine tune on each section text individually followed by a summarization layer which preserves the sequential nature of sections. Similar representation of atomic units and summarisation is applied on talk pages. We also obtain images from the raw markup using Imagekit[4]. These images are further embedded in a vector space using Inception V3 (Szegedy et al., 2016). Inception V3 is pre-trained on Imagenet [5] and we fine tune on our dataset to cater to our task. Our experiments show that combining information sources from these sources leads to improved result eclipsing current state of the art (Shen et al., 2019b) by 8%.

Our main contributions are enumerated below.

1. We propose a multimodal framework from quality assessment of Wikipedia articles which leverages contextual representation obtained from bidirectional transformers and supports conditional summarization.
2. To the best of our knowledge this is the first work which utilizes meta pages, i.e., talk pages as an additional signal for this task. All code, sample data and image embeddings related to the paper are made available[6,7] to promote reproducible research.

2 Related work

Automatic article assessment is one of the key research agendas of the Wikimedia foundation[8]. One of the preliminary approaches (Halfaker and Taraborelli, 2015) seeking to solve this problem extracted structural features such as presence of infobox, references, level 2 headings etc. as indicators of the article quality. Other approaches explored distributional representation as well as sequence models (Dang and Ignat, 2016; Shen et al., 2017, 2019b). (Zhang et al., 2018) attempted to solve this problem by formulating features capturing dynamic nature of the articles. A complementary direction of exploration has been put forward by (Li et al., 2015; de La Robertie et al., 2015) where correlation between article quality and structural properties of co-editor network and editor-article network has been exploited.

This task can also be solved by exploring the rich literature of document classification. One of the characteristics of Wikipedia articles are that these are long documents hence sequence models can suffer from (Atkinson, 2018) catastrophic forgetting. (Yang et al., 2016) proposed to solve this by leveraging a hierarchical organization of documents. Further improvements have been demonstrated by employing bidirectional transformers (Adhikari et al., 2019; Ostendorff et al.,

Total	33089

Table 1: Wikipedia dataset of articles with respective *talk* pages.

2019). However to the best of our knowledge no previous work have used metadata about article pages as source of additional signals. Also we investigate information fusion from multimodal sources for generating improved article representation.

3 Dataset

Wikimedia foundation stores all data for its multilingual wikiprojects in the form of Wikidumps[9]. We downloaded first 100 English Wikipedia dumps which are 7z archived *xml* files. The combined uncompressed size of these files is $\sim 8TB$ and it contains a sample of $\sim 6M$ English Wikipedia text from the first version to last update as of June 2019. Because of limitation of space we did not go though the entire English Wikipedia archive. Each uncompressed file is approximately of $80GB$ size and have random samples of approximately $\sim 5k$ Wikipedia pages. We parsed each file using mediawiki xml parser[10] and in one linear scan we tried to locate if the main page text and talk page text is in the same dump xml file. More specifically if we encounter the main Wikipedia article *Cleopatra*, we remember it in a dictionary and seek to locate *Talk:Cleopatra* in future scans or vice versa. However it is entirely possible that *Talk:Cleopatra* is not present at all in the currently encountered xml file and may be present somewhere else; in such case we ignore that article. If we can locate both main and talk pages of the same article we save it for reference. We include in our corpus maximum number of articles for **GA**, **B**, **C**, **Start** and **Stub** while maintaining equality. For **FA** articles, we included entire extracted corpus, because such articles are scarce.

Although this process is naïve, yet we manage to extract moderately balanced number of datapoints for each class. We would further like to note that few other public datasets exits for this task. The first version is made available by the Wikimedia foundation[11] which has $30K$ datapoints with approximately $5k$ pages in each of the 6 classes. (Shen et al., 2017) has pointed out that this dataset contains many noisy datapoints, e.g., empty pages labeled as FA class. Other datasets are made available by (Shen et al., 2019a,c; Warncke-Wang et al., 2015). Our investigation shows that none of the former datasets contain meta pages which prompts us to extract this novel data ourselves. Also some of the datasets have uniform article length across classes, which is often not the case in reality. For example *Dodo* and *Grey-necked wood rail* are both FA articles with very different article length. Considering uniform article length may lead to overfitting. We used stratified random sample of 80% data for training and 10% each for validation and testing. The overall distribution of the articles with respective classes in our dataset is enumerated in Table 1.

4 Proposed solution

In this section we present a detailed description of our multimodal approach. We start this section by explaining the various notations that we use in the subsequent sections of the paper. We then proceed to first describe representation mechanisms of explicit signals about article quality, obtained from main text, i.e., presence of bias, claim verifiability, coherent wording, citations etc. We further elaborate on the mechanisms employed, to capture implicit quality indicators such as article stability, collaborative nature of editors obtained from article talk text as well as visual renderings of documents to capture how well the article follows the style manual. Further, we describe the different ways in which we combine the information to predict the quality of the page. We present the overall architecture of our model in Figure 1.

4.1 Preprocessing

We first pre-process the Wikipedia articles and talk pages to convert the text from Wiki Markup Language[12] to plain English text format using a python text crawler[13]. We then replace the meta content in

the page such as infobox, level 1 section headings, level 2 section heading, internal wikilink, external link, inline reference, footnote template, image template, quotation template and categories into special tokens which act as additional features using mediawiki parser[14]. We use this pre-processed text in the subsequent models.

4.2 NwQM overview

Our approach is inspired by the hierarchical document representation approach proposed in (Yang et al., 2016), designed to capture signals from multiple levels of document organization. Wikipedia pages have an organic structure, i.e., words form sentences, sentences form paragraphs, paragraphs form sections and sections form a page. We build page representation by first generating section embeddings, followed by a suitable summarization. We use BERT (Devlin et al., 2018) for section representation and bidirectional GRU with self attention for summarization. Explicitly our encoder has two levels in the hierarchy, however implicitly by employing bidirectional transformers (Vaswani et al., 2017) with special tokens, we can aggregate contextual features across multiple levels.

4.3 Fine tuning BERT

We fine tune the BERT (Devlin et al., 2018) model on the extracted Wikipedia pages for classifying them into the 6 quality categories. We pass the preprocessed textual content of the Wikipedia page to the BERT model and pass the [CLS] token's representation to a dense followed by softmax layers to classify the page. We follow the fine-tuning strategy proposed by (Sun et al., 2019) for long input sequences to overcome the limitations of BERT in handling inputs more than 512 tokens. We concatenate the first 128 and the last 384 tokens of the page. For the statistical observations on advantage of this approach please refer to (Sun et al., 2019). We use the BERT's tokenizer with additional meta content tokens explained in Section 4.1. We fine tune the model end-to-end (110M parameters). Once the model is finetuned we freeze the weights, thus in subsequent steps of the training the parameters are not updated.

4.4 BERT section encoder

We use previously obtained fine tuned BERT for generating section representations. It has been shown that fine tuned BERT performs extremely well in subject verb agreement task (Goldberg, 2019; Clark et al., 2019), hence it is able to capture long range semantic dependency. Besides, since it is pre-trained with next sentence prediction objective, it remembers context across multiple sentences. Also since 95% of the sections have less than 512 words, we use the pre-trained BERT model with maximum number of input tokens, to directly encode the sections, hence *collapsing* the hierarchy starting from words upto sections in the encoding process. We collapsed the hierarchy up to sections but do not extend further due to several drawbacks in the BERT model discovered through probing (Liu et al., 2019; Si et al., 2019) which state that very long sequences spanning multiple sentences leads to incorrect comprehension. We take the final hidden state h of the first token [CLS] as the aggregate representation of the section i.e. $\mathbf{Sc}_x$. (See Figure 1).

4.5 Conditional summarizer

We next generate the page representation ($\mathbf{D}_{p_i}$, see Figure 1) from the sequence of sections using attention based bidirectional GRU encoder as discussed in the previous section. The inputs i_x in equations (1) to (6) correspond to the section representations obtained from the BERT models. The α_x correspond to the attention weights, the final output o_n is the page representation $\mathbf{D}_{p_i}$ (see Figure 1). To aggregate the sequences at section level $Sc_x, x \in [1, n]$, we use the bidirectional GRU (Chung et al., 2014) which provides representations of the document text by summarizing information from both directions. We concatenate the forward and backward hidden states h_x and feed the hidden states to the self attention module (Lin et al., 2017; Bahdanau et al., 2014).

$$\overrightarrow{h}_x = \overrightarrow{GRU}(i_x), x \in [1, L] \tag{1}$$

$$\overleftarrow{h}_x = \overleftarrow{GRU}(i_x), x \in [L, 1] \tag{2}$$

$$h_x = [\overrightarrow{h}_x, \overleftarrow{h}_x] \tag{3}$$

$$u_x = \sigma(W_i h_x + b_i) \tag{4}$$

$$\alpha_x = \frac{exp(u_x^T u_i)}{\sum_{x=1}^{L} exp(u_x^T u_i)} \tag{5}$$

$$o_n = \sum_x \alpha_x u_x \tag{6}$$

4.6 Talk page encoder

We split the talk page content into sentences and pass each sentence through the Google Universe

---

[14] `mwparserfromhell.readthedocs.io`

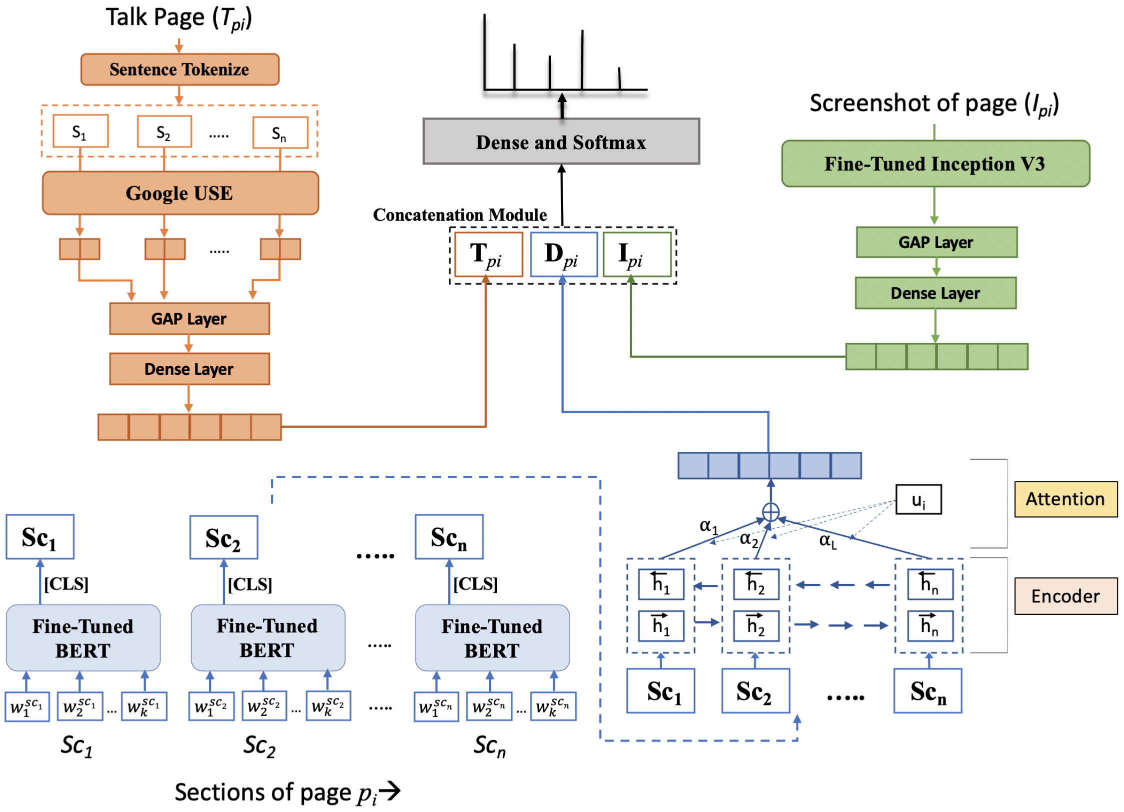

Figure 1: The overall pipeline of **NwQM**. We have taken cutoff for the number of tokens in sequence i.e $k = 512$ and no. of sequence $n = 16$. Parameters of fine-tuned BERT, Inception V3 are fixed.

Sentence Encoder model (Cer et al., 2018) to obtain a 512 dimensional representation of the sentence. These sentence embeddings are then passed through a global average pooling layer (Lin et al., 2013) followed by a dense layer to get a 200 dimensional final representation of the talk page ($\mathbf{T}_{p_i}$, see Figure 1). The motivation behind this approach is to obtain an aggregate representation of the discourse in talk pages.

4.7 Fine tuned Inception V3

Shen et al. (2019b) shows the effectiveness of using the visual rendering (screenshot image) of a page to predict the quality of a document in a multimodal setup. To embed the visual rendering we use the Inception V3 (Szegedy et al., 2016) model. Similar to the BERT model, to learn better representations, we fine tune the Inception V3 model. We follow the setting proposed in (Shen et al., 2019b) to fine-tune the Inception V3 model. We resize the images from varied high dimensions to a standard low dimension. We then fine tune the Inception v3 model to classify the screenshots of the pages into the 6 quality classes. We do an end-to-end training for fine tuning the Inception V3 model. We flatten the final representation from the last convolution layer, stack the dropout and global average 2D pooling layers, and classify using softmax layer. The hidden flat layer output (2048 dimension) of the fine tuned Inception V3 model is the final representation of the visual rendering of the page. The input to the fine tuned Inception model is the screenshot of the wikipage, and the output is a visual embedding of the page ($\mathbf{I}_{p_i}$, see Figure 1). We integrate this information with the text and talk content of the page and report the improved performance of the final model.

4.8 Concatenation module

In this subsection we illustrate the concatenation of the information from various modules representing the features from text and image modalities to assess the quality of a page. We experiment with different modes of concatenation presented in (Reimers and Gurevych, 2019) (u, v), $(u, v, |u - v|)$, $(u, v, |u - v|, u * v)$, $(u, v, u * v)$, $(|u - v|, u * v)$, $(|u - v|)$,$(u * v)$, and choose the best performing strategy $(u, v, |u - v|)$ to concatenate the vectors u and v. We experiment with various combinations of modules, i.e., conditional document summarizer (fine tuned BERT encoder with GRU summarizer), talk page encoder and visual rendering of the page (fine tuned Inception V3) and tabulate the best results in Table 2.

4.9 Model configurations

We set the hidden states $(\overrightarrow{h_x}, \overleftarrow{h_x})$ of the GRU units of the section encoder to 100. Therefore the final page representation ($\mathbf{D}_{p_i}$) is a 200 dimensional vector. Since 90% of the data has number of sections in a page less than 16 respectively, we limit their maximum size of a page to 16 sections. For sequences less than the specified length, we left-pad using $\overrightarrow{0}$. We load the pre-trained weights of BERT-base model from TensorflowHub[15].

We use the implementation of Google Universal Sentence Encoder available at TensorFlow Hub[16]. We use the nltk library[17] to tokenize the pre-processed talk page content into sentences. We train the hierarchical content encoder for 10 epochs with a learning rate of 0.001 and batches of 16 using Adam optimizer (Kingma and Ba, 2014). For fine tuning the BERT models, we use the Adam optimizer with a learning rate of 2e-5. We empirically set the number of training epochs to 4. To fine tune the Inception V3 model, we again use Adam optimizer with a learning rate 1e-4 and train for 20 epochs. We employ the categorical cross-entropy as loss function for all the models and train using batches of size 16. For all the joint models, we set the learning rate to 0.001, batch size to 32, number of epochs for training to 40. For classification, we use dense layers followed by softmax layer. We further utilize dropout probability of 0.5 in the dense layers. Prior fine-tuning of individual units reduces explosive training time, common in end-to-end models

5 Experiment

In this section we evaluate **NwQM** against several existing approaches.

Baselines. We provide a brief outline of the competing methods in the following.

- **ORES** (Halfaker and Geiger, 2019) is a machine learning service made available by Wikimedia foundation through a RESTful HTTP interface serving prediction about target articles. It uses handcrafted features along with gradient boosted machine as classifier.
- **DOC2VEC** (Dang and Ignat, 2016) proposed the first application of deep neural networks into quality assessment task where they employed distributional representation of documents (Le and Mikolov, 2014) without using manual features.
- **BILSTM+** (Shen et al., 2017) is a hybrid model, where textual content of the Wikipedia articles are encoded using a BILSTM model. The hidden representation captured by the sequence model is further augmented with handcrafted features and the concatenated feature vector is used for final classification
- **H-LSTM** (Zhang et al., 2018) is an edit history based approach where every version of an article is represented by 17 dimensional handcrafted features. Hence an acticle with k versions will be represented by $k \times 17$ matrix. This k length sequence is passed through a stacked LSTM for final representation used in classification.
- **M-BILSTM** (Shen et al., 2019b) proposed a multimodal information fusion approach where embeddings obtained from both article text as well as html rendering of the article webpage is used for final classification.
- **DocBert** (Adhikari et al., 2019) proposed this method to generate document representations using bidirectional transformers (Devlin et al., 2018). The primary idea is filtering the representation obtained from the CLS token using a fully connected layer which translates 768 dimensional encoding to class distribution using a softmax layer. This architecture is further fine tuned end-to-end for the respective document classification task.
- **HAN** (Yang et al., 2016) proposed a hierarchical approach which iteratively constructs a document vector by coalescing important words into sentence vectors and subsequently combining important sentences vectors to obtain the document vectors. A convenient consequence of this approach is that it is suitable for large documents like Wikipedia articles.

Result We evaluate **NwQM** against existing solutions for automatic quality assessment and tabulate the obtained results in Table 2. Since our classes are roughly balanced, we opt to report accuracy as the metric for evaluation. Some of the

---

[15] `https://tfhub.dev/google/bert_uncased_L-12_H-768_A-12/1`

[16] `https://tfhub.dev/google/universal-sentence-encoder/`

[17] `https://www.nltk.org/api/nltk.tokenize.html`

approaches that we compare our model with are ORES, DOC2VEC, BILSTM+, M-LSTM, H-LSTM. We achieve an improvement of 8% compared to the best performing baseline. This we believe is a considerable leap for a 6 class classification task.

We also compare our model against novel document classification approaches, i.e., DOCBERT and HAN because inherently Wikipedia quality assessment problem is closely related to document categorization. To this purpose, we compare the document classification approaches with textual content of the Wikipedia main article as well as concatenated version of the main article and talk pages denoted as DOCBERT-wT, HAN-wT respectively. We obtain at most 5% improvement against the existing approaches. Note that apart from our model, including the talk page meta data in the document classification models also considerably enhances their respective performances.

NwQM is constituted of concatenated representation from article text, talk and image and therefore it is important to look at how individual components perform independently. We evaluate **NwQM** without signals from image (**NwQM**-w/oI), without talk (**NwQM**-w/oT) and with solely the main article text, i.e., without any secondary and tertiary signals from image and metadata (**NwQM**-w/oTI). Our experiment show that the combined approach (**NwQM**) obtains the best result. Without talk and image we land in a drop of accuracy of 1.3% and 5% respectively validating our hypothesis that extracting signals from external sources can serve fruitful in this task. We also compare against representation from talk pages and fine tuned image embeddings individually for the sake of completeness and our results show significant drop in accuracy compared to the combined approach.

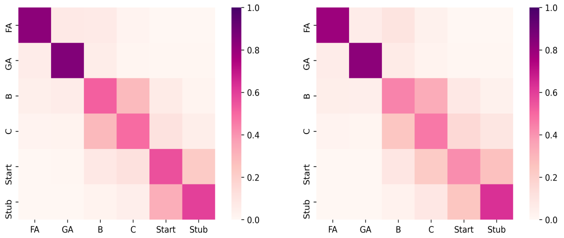

Figure 2: Left panel shows confusion matrix obtained by **NwQM**; Right panel shows confusion matrix obtained by M-BILSTM (Best viewed in color) .

Model	Accuracy
ORES (Halfaker and Geiger, 2019)	43.21

6 Discussion and qualitative analysis

In this section we perform a deep dive into the predictions obtained by our model and we contrast it with those from closest known competitor M-BILSTM (Shen et al., 2019b) for quality assessment. **Confusion matrix**: We first tabulate the confusion matrix obtained by **NwQM** on test data in Figure 2. Results show that most of the misclassifications made by **NwQM** are on average between very similar classes. This is due to the inherent ordinal nature of the classes in this dataset. More specifically, there is an increasing degree of quality in pages from Stub to FA, though the gradient may not be smooth. Thus FA, GA articles have overlapping guidelines which is very different from other pages. Likewise B, C and Start, Stub have mutually overlapping guidelines. **NwQM** can successfully recover this structure, hence misclassifications have occurred between closer classes. However, com-

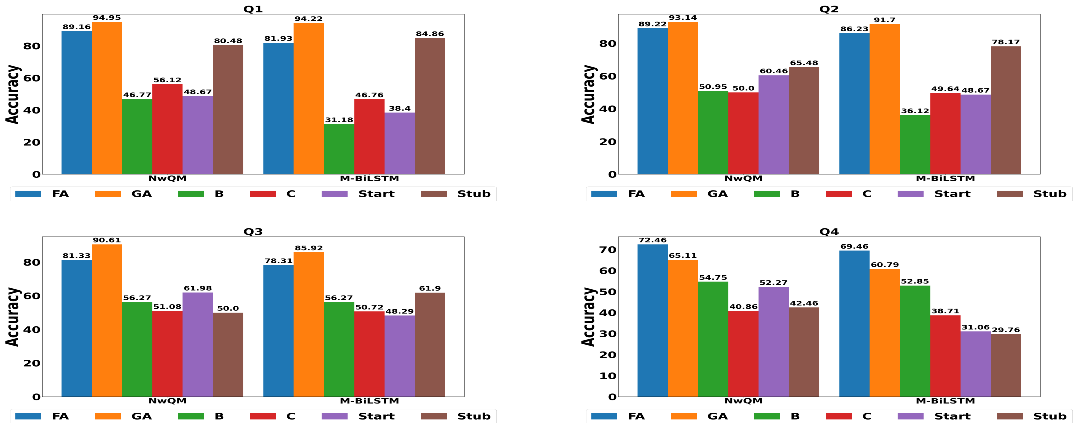

Figure 4: Accuracy per class for test data segregated into quartiles Q_1, Q_2, Q_3, Q_4 with respect to main article text length with Q_1 smallest and Q_4 largest. (Best viewed in color)

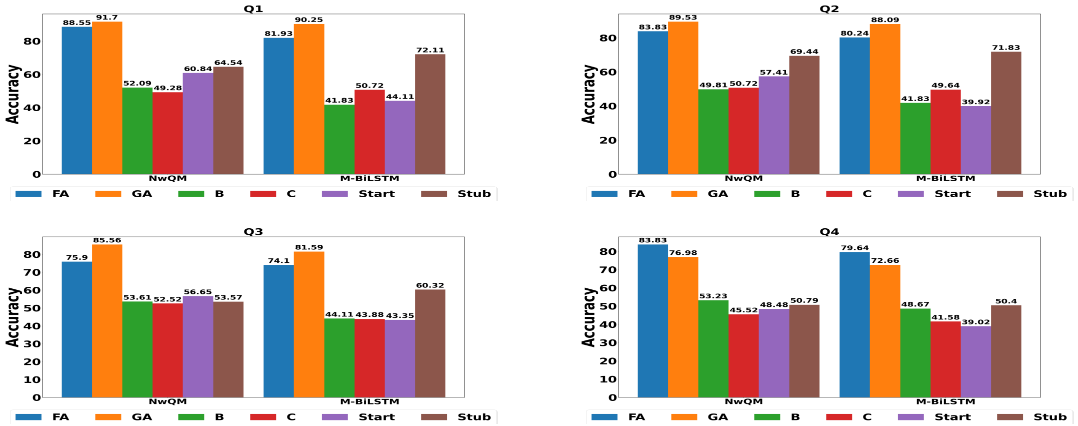

Figure 5: Accuracy per class for test data segregated into quartiles Q_1, Q_2, Q_3, Q_4 with respect to article talk length with Q_1 smallest and Q_4 largest. (Best viewed in color)

pared to M-BiLSTM (see Figure 2) **NwQM** can capture class specific features significantly better thus showing lower mistakes for certain datapoints especially in case of Start, B and C classes.

Distance of wrong predictions from ground truth: In cases of wrong predictions, we calculate how far individual models are from ground truth labels. We transform each class into integers with Stub transformed to 0 and FA transformed to 5. We then find the mean absolute distance of the incorrect predictions from the true labels for each individual class. The results are tabulated in Figure 3 where we observe that for **NwQM** the absolute distance is consistently lower. The results are statistically significant with a p-value of 1e-5 using Stuart-Maxwell test for multiclass classification (Sun and Yang, 2008).

Effect of article length: We further ascertain how the main text and talk page length of an plays a role in prediction, for respective models. Articles with detailed coverage of topics and multiple discussion threads may not be nominated among high quality articles. This is because even if the coverage is diverse, the language of the article may be biased, convoluted, there could be unverified claims or discord among editors. Deep learning models such as BERT have often been shown to rely on surface forms (Ettinger, 2020) as shotcuts for classification instead of semantic understanding. We investigate whether **NwQM** is relying spurious signals like article length in final classification. For example, article *Kauri Gum* (GA) and *Guar Gum* (Start) have very similar coverage, but are distant in terms of the quality criteria. Similarly, article *Frog cake* (GA) and *Sugar* (GA) have very different coverage but the same quality tag. For further investigation we rank predictions with respect to article and talk page length and divide our predictions into 4 quantiles. We investigate the accuracy of **NwQM** in the individual quantiles starting from the smallest quantile, i.e., Q_1 to the largest, i.e., Q_4. Accuracy scores for test set ordered by main article text are illustrated in Figure 4 and those ordered based on talk pages are shown in Figure 5. Results indicate that **NwQM** is not biased toward length and irrespective of the quantiles we obtain improved prediction accuracy almost always compared to the closest baseline.

t-SNE plots: Finally, we visualize the representations obtained by **NwQM** and M-BILSTM using t-SNE (Maaten and Hinton, 2008) scatter plots (see Figure 6). The degree of separation obtained by **NwQM** is much better which translates to the improved accuracy.

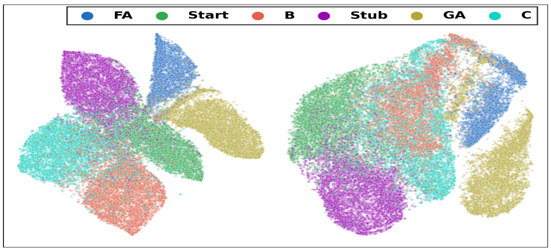

Figure 6: Left panel shows t-SNE visualization for **NwQM**; right panel shows visualization for M-BISTM. (Best viewed in color)

Interpreting the effect of the different modalities: One of the critical issues in deep learning models is interpretability. In order to ascertain whether different sources of signals are indeed contributing toward the final prediction task, we leverage the model agnostic evaluation tool LIME (Ribeiro et al., 2016). We generate representations for text, talk and images, i.e., $D_{p_i}, T_{p_i}, I_{p_i}$ respectively (see Figure 1) from our learned model. These embeddings are passed through classification layers comprising dense layer and softmax layer for prediction. This network takes concatenated input of $D_{p_i}, T_{p_i}, I_{p_i}$ and outputs the classification probabilities for each test instance. We evaluate this black box neural network using LIME. For data points on the test set we identify top 500 features contributing to the outcome of the highest class probability. We further calculate the average contribution from each modality toward the respective classes. More specifically for every test page instance, we identify the top 500 contributing features as per LIME. Each feature can be contributed by any one of the three modalities. We compute the mean of features scores per modality in the top 500 for a page and then aggregate that over all pages. The results are tabulate in Figure 7. Our results show that signals from D_{p_i} play most important overall role in prediction of quality. I_{p_i} play almost equal role in prediction of all the classes. Interestingly, for high quality pages, T_{p_i}, i.e., the talk page information contributes in classification higher than text and image information. Talk also contributes for low quality pages such as *Start, Stub*. We speculate that since high quality pages have larger discussion archives and low quality pages have very low discussion threads T_{p_i} plays significant role in distinguishing these classes. We stress that these interpretability results are the prime insights that these paper neatly establishes.

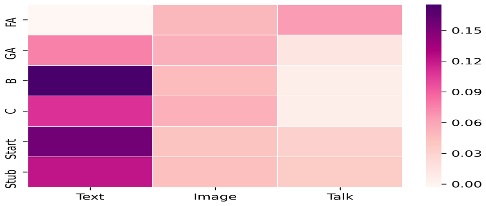

Figure 7: (Best viewed in color)

7 Conclusion

In this paper we proposed a novel multimodal deep learning based model **NwQM** for quality assessment of English Wikipedia articles. Our model combines signals from article text, meta pages and image rendering to construct an improved document representation. We evaluate it against several existing approaches and obtain at most 8% improvement compared to the state-of-the-art method. For a 6 class classification this leap in accuracy is notable. We also perform extensive investigation of the different components of our model to understand their individual utility. We perform in-depth qualitative analysis of the obtained predictions and contrast them with the closest baseline.

To the best of our knowledge this is the first work which combines several aspects of information available for Wikipedia articles and, in particular, the talk page dynamics toward quality assessment. We also showcase the utility of fine tuned bidirectional transformers toward document classification especially when combined with niche platform specific signals. We believe our work opens up the necessity of further investigation pertaining to careful information fusion techniques for downstream tasks.

Towards Modeling Revision Requirements in wikiHow Instructions

Irshad Ahmad Bhat **Talita Rani Anthonio** **Michael Roth**
University of Stuttgart
Institute for Natural Language Processing
{bhatid,anthonta,rothml}@ims.uni-stuttgart.de

Abstract

wikiHow is a resource of how-to guides that describe the steps necessary to accomplish a goal. Guides in this resource are regularly edited by a community of users, who try to improve instructions in terms of style, clarity and correctness. In this work, we test whether the need for such edits can be predicted automatically. For this task, we extend an existing resource of textual edits with a complementary set of approx. 4 million sentences that remain unedited over time and report on the outcome of two revision modeling experiments.

1 Introduction

Instructional texts have become an integral part of our daily lives, be it in the form of assembly instructions, product leaflets, troubleshooting guides, or board game manuals. A key property across all types of such texts is that they must be clear enough so that readers can actually achieve the goal described by the instructions.

Previous studies in computational linguistics have dealt with the clarity of specific types of instructions, such as route directions (Byron et al., 2009; Striegnitz et al., 2011) and software requirements (Willis et al., 2008; Yang et al., 2010). As an indicator for clarity, they relied either on successful execution in a virtual environment or on manual annotations of predefined ambiguity types. A large and more general dataset of instructional texts, wikiHowToImprove, has recently been introduced by Anthonio et al. (2020). wikiHowToImprove consists of edits for about 2.5 million sentences derived automatically from revision histories of wikiHow, a collaboratively edited platform of how-to guides. In a set of human and computational experiments, Anthonio et al. (2020) show that such edits are often made to clarify or correct a sentence and that the difference between an "older" and "newer" version of a sentence can be predicted computationally. We address two notable questions, using the work of Anthonio et al. (2020) as a starting point:

(1) Are results for the task of distinguishing two versions of a sentence (henceforth *version distinction*) specific to instructional texts, such as their guides from wikiHow, or can underlying linguistic characteristics be modelled to a similar extent in a different text genre? We reproduce version distinction results for different computational models on a variant of wikiHowToImprove and provide comparison results on an earlier dataset of revision edits (WikiAtomicEdits) derived from Wikipedia (Faruqui et al., 2018). In our experiments, we find that models for version distinction work best on instructional texts and that they are capable of detecting a variety of potential reasons for revision, including grammatical errors, semantic implausibilities and vague expressions.

(2) Given the results on instructional texts, is it possible to model whether a sentence requires revision in the first place? wikiHowToImprove only contains edited sentences. We extend the dataset with sentences from the revision history that remain identical over time. Based on this extension, we introduce the task of *predicting revision requirements* and assess its feasibility by testing whether models can distinguish sentences that get edited from ones that remain unedited. Our results show that it is possible to identify sentences that are subject to revision with a F_1-score close to 70%, indicating potential utility for downstream applications such as grammar correction (Yuan and Briscoe, 2016), ambiguity detection (Gleich et al., 2010), and machine translation refinement (Novak et al., 2016).

In summary, we make the following contributions:[1] First, we extend work on version distinction by providing experimental comparisons on wikiHow and Wikipedia. Second, we motivate a new

task of predicting revision requirements, for which we provide a new dataset as well as initial results.

2 Data and Models

Our experiments make use of WikiAtomicEdits, wikiHowToImprove and an extension of the latter that adds unrevised sentences (§2.1). For computational modeling, we re-use the publicly available baselines[2] from Anthonio et al. (2020) and further test models based on BERT (§2.2).

2.1 Data

WikiAtomicEdits. Faruqui et al. (2018) released a corpus of 43 million atomic edits across 8 languages, mined from Wikipedia edit history. The dataset consists of 26M atomic insertions and 17M atomic deletions. For our experiments, we focus on the 23M atomic edits (13.7M insertions and 9.3M deletions) from the English subcorpus, which we randomly split into training, development and test sets, setting the size of development and test set roughly equal to that of wikiHowToImprove.

wikiHowToImprove. Anthonio et al. (2020) introduced a dataset of over 2.7 million sentences and their revision histories, extracted from wikiHow. As a set of *revised sentences*, they collected *revision groups*, such that each group contains the base version of a sentence and all updated versions in chronological order. For our experiments, we use the same article-level training/development/testing splits. For a direct comparison with WikiAtomicEdits, we removed sentences longer than 50 tokens and edits that were made only because of typos (see Appendix A for more details). Statistics of both datasets are shown in Table 1.

Extensions. We extend the latter dataset by extracting around 4.25 million *unrevised sentences* from the same articles that are part of wikiHowToImprove. For each article, we collect this set by identifying sentences that have remained unchanged from the article version they were first introduced until the last version of the article. Since sentences that are introduced in the last few versions are still likely to receive revisions, we use an additional filtering criterion that measure the ratio of the number of unchanged versions of a sentence and the total number of article versions.

In preliminary experiments (see Appendix B for more details), we tested ratios between 0.0 to 0.9 on the development set to find the most suitable value. The main difference we observed in these experiments was that data imbalance and noise would make it difficult for models to distinguish between sentences requiring revision and sentences not requiring revision. For our final experiments, we use a ratio of 0.75 because we found it to reduce noise to an acceptable level and led to an almost balanced set (see Table 2). Statistics of the train/dev/test split are given in the Appendix C.

2.2 Computational Models

For both tasks, we evaluate the following methods:

Baselines. We apply as baselines for our experiments the open-source implementations of the methods from Anthonio et al. (2020): a multinomial Naive Bayes classifier with simple n-gram ($n = 1, 2$) features and a bidirectional long short-term memory (LSTM) network with an additional attention layer (Zhou et al., 2016). We use the same hyperparameters as previous work.

BERT. For additional comparisons, we train new models based on BERT (Devlin et al., 2019), a multi-layer bidirectional transformer encoder which uses bidirectional self-attention to learn deep bidirectional representations. These representations can be fine-tuned using labelled data, which led to state-of-the-art results for a range

---

[2] `github.com/irshadbhat/wikiHowToImprove`

Model	Training	Accuracy (%)	
		wikiHow	Wikipedia
Naive Bayes	Classification	58.03	51.80
BiLSTM	Classification	64.91	62.54
BiLSTM	Pairwise Ranking	72.10	60.21
BERT	Pairwise Ranking	**73.82**	65.90

Table 3: Classification results for version distinction in wikiHowToImprove and WikiAtomicEdits.

of NLP tasks (Devlin et al., 2019; Wang et al., 2018). The pre-trained BERT models are trained on large BookCorpus (800M words) and English Wikipedia (2,500M words). For both of our experiments, we use BERT-Base, cased model (12 transformer blocks, 768 hidden size, 12 attention heads and 110M parameters) fine-tuned with an additional output layer on top of BERT's final representation. In Experiment 1, we adopt the same pairwise ranking layer as used for the BiLSTM model in previous work (Anthonio et al., 2020).[3] Experiment 2 only requires binary classification, thus the output layer simply applies a linear transformation followed by a softmax.

3 Experiment 1: Version Distinction in wikiHow and Wikipedia

The aim of the first experiment is to compare models on the task of distinguishing older and newer versions of a sentence between wikiHow and Wikipedia. We make use of the same general setup as previous work (see Anthonio et al., 2020). Our hypothesis for this experiment is that distinguishing sentence versions will be easier in wikiHow than in Wikipedia, because edits in the latter provide new information more often than refinements (Faruqui et al., 2018), whereas the content of wikiHow is largely independent of world knowledge that may change over time.

Results. Table 3 shows the accuracy of our models on wikiHowToImprove and WikiAtomicEdits. In comparison to the results reported in Anthonio et al. (2020), we observe that the baseline models are approx. 2.5% less accurate. A possible explanation for this drop is that we removed (presumably easy to predict) typo-based edits from wikiHowToImprove for direct comparison with WikiAtomcEdits. The BiLSTM pairwise ranking model outperforms the BiLSTM binary classification model by 7.18% absolute accuracy in wikiHow but is 2.33% less accurate in Wikipedia. This is the case because the ranking mechanism can implicitly model information related to transitivity when there exist more than two versions of a sentence in wikiHow. In contrast, WikiAtomicEdits only contains two versions of each sentence and pairwise ranking only brings an additional overhead due to padding (see Appendix D for more details).

He was Palmerston Park until 1931. He was **at** Palmerston Park until 1931.

Table 4: Example version pairs where BiLSTM and BERT models assign labels correctly.

The best results are achieved by BERT, which outperforms the BiLSTM ranking model by additional 1.72 percentage points on wikiHow and the BiLSTM classification model by 3.36% on Wikipedia. Finally, we see that all the models perform better on wikiHow than Wikipedia and the best performing model on wikiHow is 7.91% more accurate than on Wikipedia. This confirms our hypothesis that different versions of a sentence are harder to distinguish in the WikiAtomicEdits data.

Discussion. One reason for the higher improvement of BERT on WikiAtomicEdits could be that wikiHow and Wikipedia contain texts of different genre and only Wikipedia is used for pretraining the BERT model (see Section 2.2). In a qualitative

---

[3] Specifically, the output layer scores BERT's final representation $\phi(s)$ of a sentence s by calculating the dot product between the individual components and a parameter vector v, which is trained using a margin-based loss function: $max(0, v^\top\phi(s_o) - v^\top\phi(s_n) + 1)$, where s_o and s_n are the older and newer version of a sentence, respectively.

Table 5: Example version pairs where the BiLSTM model fails, but BERT assigns labels correctly.

analysis of the results, we found that the BiLSTM and BERT models are able to detect typos as well as grammatically incorrect and ill-formed sentences in both data sets (see Table 4). The BERT-based model is further able to cover more subtle syntactic corrections and semantic clarifications. As exemplified in Table 5, these cases include improvements in terms of fluency and specificity, either through changes in word order or word choice (wikiHowToImprove) or through insertions of more detailed information (WikiAtomicEdits).

4 Experiment 2: Predicting Revision Requirements in wikiHow

The aim of this second experiment is to provide benchmark models for predicting whether or not a sentence requires revision. The previous experiment has shown that it is difficult to distinguish different versions of a sentence in WikiAtomicEdits (§3). Therefore, we perform this experiment only on wikiHow. We make the simplifying assumption that *all* changes in wikiHow's revision history are made for the better and therefore represent needed revisions to the original version of an article. Thus, we treat all sentences that went through revision in wikiHowToImprove as requiring revision and all unrevised sentences from our extension (see 2.1) as requiring no revision. We evaluate to what extent a model correctly identifies sentences that require revision using precision, recall and F_1-score.

Model	Precision	Recall	F_1-score
Naive Bayes	56.44	**73.99**	64.03
BiLSTM	**73.32**	51.86	60.75
BERT	70.90	66.10	**68.42**

Table 6: Classification results for predicting revision requirements; all results are given in percentages and are shown for 'requiring revision' as the "positive" class.

Some look silly than others . . . (revised: Some look sillier than others . . .)
Buying a used car is a mine field. (revised: Buying a used car is like . . .)
You can even organize a elocution for that. (revised: . . . an elocution for that purpose.)
It is very healthy way of fast frying minimal oil. (revised: It is a very . . . frying with minimal oil.)

Table 7: Examples that require revision and that are identified correctly by BERT but not by the BiLSTM.

Results. Table 6 shows the results of our models. As shown in the table, the BiLSTM model outperforms the Naive Bayes model by 16.88 percentage points in precision, but only achieves a recall of 51.86%. This result indicates that contextual information within the sentence is needed for precisely predicting revision requirements, but it is not sufficient to achieve good coverage. The BERT model achieves the highest F_1-score, outperforming the Naive Bayes and BiLSTM models by 4.39 and 7.67 percentage points, respectively.

Discussion. In a qualitative analysis of results, we find that all models are capable (to various degrees) of identifying grammar errors and sentences that are semantically implausible. A selected list of correctly classified example sentences are given in Table 7. As shown in the table, the BERT-based model seems to capture more subtle issues on the semantic level than the BiSTM model, including adjective degrees ("silly" vs. "sillier") and metaphorical comparisons ("X is a Y" vs. "X is like a Y"). Quite likely, the BERT-based model can handle

	#Samples	LSTM	BERT
Grammar Error	1233	783	942
Lexical Vag.	164	27	93

Table 8: Comparison of BiLSTM and BERT model predictions for grammatical errors and lexical vagueness.

such cases better than the BiLSTM because BERT is pre-trained on large amounts of fluent and well-written text.

We further checked the performance of the BiLSTM and BERT-based models quantitatively on two specific types of cases from the 'subject to revision' category: grammatical errors and lexically vague modifiers. We automatically identify typical grammar errors[4] as well as cases where an adjective or adverb is replaced with a full phrase (e.g. "frequently" vs. "about once a week") by lexically and syntactically comparing the original sentence in the data to its revised version. Table 8 shows the counts of instances and correct predictions, indicating that both models have a reasonable recall regarding grammatical errors. BERT identifies more than three times as many cases of lexical vagueness as the BiLSTM model, but still only achieves a recall of 56.7% (93/164).

5 Related Work

Wikipedia Revisions. Revisions in Wikipedia have been leveraged for various NLP tasks, such as spelling error correction (Ehsan and Faili, 2013; Grundkiewicz and Junczys-Dowmunt, 2014; Zesch, 2012), preposition error correction (Cahill et al., 2013), paraphrasing (Max and Wisniewski, 2010), sentence simplification and compression (Nelken and Yamangil, 2008; Yamangil and Nelken, 2008), textual entailment recognition (Zanzotto and Pennacchiotti, 2010) and lexical simplification (Yatskar et al., 2010). Within this framework, a number of studies have analyzed the type of edits that authors made (Daxenberger and Gurevych, 2013, 2012; Faruqui et al., 2018; Pfeil et al., 2006; Bronner and Monz, 2012; Liu and Ram, 2011) and their intentions (Yang et al., 2017; Zhang and Litman, 2016). These studies built further upon Faigley and Witte (1981) and Jones (2008). Daxenberger and Gurevych (2013) and Yang et al. (2017) performed multi-class classification to automatically detect edit types and edit intentions respectively. Other text classification studies focused on a smaller set of revision intentions in Wikipedia, such as Recasens et al. (2013) who worked on bias/non-bias detection. Attention has also been given to distinguish between vandalism and non-vandalism (Adler et al., 2011; Harpalani et al., 2011; Potthast et al., 2008) and between factual and fluency edits (Fong and Biuk-Aghai, 2010)

wikiHow Revisions. Compared to Wikipedia revisions, wikiHow has received less attention in NLP. Apart from (Anthonio et al., 2020), there is no other work that leveraged the revision history of wikiHow articles. However, wikiHow has been used for summarization (Koupaee and Wang, 2018) and knowledge acquisition (Chu et al., 2017; Zhou et al., 2019). Others have also employed it to model procedure-specific relationships in sentences (Park and Motahari Nezhad, 2018) and underlying reasons for these relationships (Mishra et al., 2019).

Related Tasks. Afrin and Litman (2018), in a related task, worked with revisions in argumentative essays from ArgRewrite (Zhang et al., 2017). The authors trained a RandomForest classifier to predict, given an original sentence and a revised one, if the revised sentence is better than the original. Tan and Lee (2014) conducted a related study, which analyzed potential strength differences in original–revised sentence pairs in academic writing using a qualitative approach.

6 Conclusions

We demonstrated in an experimental comparison that it is easier to distinguish sentence versions computationally in wikiHowToImprove than in WikiAtomicEdits. We further introduced a new task of predicting whether a sentence requires revision and showed promising first results on specific types of revisions. As next steps, we plan to address further types of revisions and extend our experiments to document-level settings.

A Filtering Typos

For each revision pair (base, revised), we find the sentence edits and edit types using Levenshtein distance algorithm. If all the edits are of substitution type and every substitution fixes a typo, we remove the base sentence.

B Selection of Filtering Ratio.

In order to select an appropriate filtering ratio, we ran Experiment 2 (*Predicting Revision Requirements*) with 10 different ratios from 0.0 to 0.9. Based on the results on our validation set (see Figure 1) and the data imbalance at each ratio, we selected a ratio of 0.75, which lead to an almost balanced set. A ratio of 0.75 means that sentences have to remain “identical” for the last 3 out of 4 article-level revisions in order to be considered as “not requiring revision”.

C Training/Development/Testing Split for Experiment 2

D Padding in Pairwise Ranking Models

We train all our BiLSTM models with a batch size of 512. For the BiLSTM classification model, we simply batch the sentences based on sentence length, so no padding is required. But for the pairwise ranking models, we have to batch version pairs (base, revised) together. We can only batch these pairs if the number of tokens in both versions of a sentence are equal. So we first append pads to the shorter sentence in the version pair to make its length equal to the longer sentence and then batch these pairs based on length.

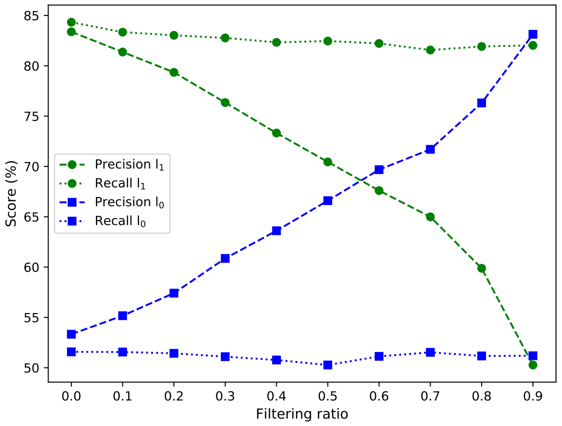

Figure 1: Scores for predicting revision requirements at different filtering ratios. l_0=‘requiring revision’, l_1=‘requiring no revision’.

Split	subject to revision	no revision
Train	3 249 521	3 467 462
Dev	378 996	393 770

Abstract

In the financial domain, risk modeling and profit generation heavily rely on the sophisticated and intricate stock movement prediction task. Stock forecasting is complex, given the stochastic dynamics and non-stationary behavior of the market. Stock movements are influenced by varied factors beyond the conventionally studied historical prices, such as social media and correlations among stocks. The rising ubiquity of online content and knowledge mandates an exploration of models that factor in such multimodal signals for accurate stock forecasting. We introduce an architecture that achieves a potent blend of chaotic temporal signals from financial data, social media, and inter-stock relationships via a graph neural network in a hierarchical temporal fashion. Through experiments on real-world S&P 500 index data and English tweets, we show the practical applicability of our model as a tool for investment decision making and trading.

1 Introduction

Stock prices have an intrinsically volatile and non-stationary nature, making their rise and fall hard to forecast (Adam et al., 2016). Investment in stock markets involves a high risk regarding profit-making. Prices are driven by diverse factors that include but are not limited to company performance (Anthony and Ramesh, 1992), historical trends (Kohara et al., 1997), investor sentiment (Neal and Wheatley, 1998). Uninformed trading decisions can leave traders and investors prone to financial risk and experience monetary losses. On the contrary, careful investment choices can maximize profits (de Souza et al., 2018). Conventional research focused on time series and technical analysis of a stock, i.e., using patterns from historical price signals to forecast stock movements (B et al., 2013). However, price signals alone fail to capture market surprises and impacts of sudden unexpected events. Social media texts like tweets can have huge impacts on the stock market. For instance, US President Donald Trump shared tweets expressing negative sentiments against Lockheed Martin, which led to a loss of around $5.8 Billion to the company's market capitalization.[1]

The Efficient Market Hypothesis (EMH) (Malkiel, 1989) states that financial markets are *informationally efficient*, such that stock prices reflect all known information. Existing works **(Sec. 2)** mainly focus on subsets of stock relevant data. Although useful, they do not jointly optimize learning over modalities like social media text and inter stock relations limiting their potential to capture a broader scope of stock movement affecting data, as we show in **Sec. 6**. Multimodal stock prediction involves multiple challenges (Hu et al., 2018). Both price signals and tweets exhibit *sequential context dependencies*, where singular samples may not be informative enough but can be considered a sequence for a unified context. Tweets often have *diverse influence* on stock prices, based on their intrinsic content, such as breaking news as opposed to noise like vague comments. Fusing multiple modalities of vast stock related data generated with varying characteristics *(frequency, noise, source)* is complex and mandates the careful design of joint optimization over modality-specific components.

Building on the EMH and prior work **(Sec. 2)**, we propose MAN-SF: Multipronged Attention Network for Stock Forecasting that jointly learns from historical prices, social media, and inter stock relations. MAN-SF through hierarchical attention captures *relevant* signals across diverse data to train a Graph Attention Network (GAT) for stock prediction **(Sec. 3)**. MAN-SF **(Sec. 4)** jointly learns from

November 16–20, 2020.

price and tweets over graph-based models for stock prediction. Through varied experiments **(Sec. 5)**, we show the predictive power of MAN-SF along with profitability analysis **(Sec. 6)** and qualitatively analyze MAN-SF in high risk scenarios **(Sec. 7)**.

2 Related Work

Predicting stock movements spans multiple domains (Jiang, 2020); 1) theoretical: quantitative models like *Modern Portfolio Theory* (Elton et al., 2009), *Black-Scholes model* (Black and Scholes, 1973), etc. and, 2) practical: investment strategies (Blitz and Van Vliet, 2007), portfolio management (Hocquard et al., 2013), and beyond the world of finance (Erb et al., 1994; Rich and Tracy, 2004). Financial models conventionally focused on technical analysis (TA) relying only on numerical features like past prices (Ding and Qin, 2019; Nguyen et al., 2019) and macroeconomic indicators like GDP (Hoseinzade et al., 2019). Such TA methods include discrete: GARCH (Bollerslev, 1986), continuous (Andersen, 2007), and neural approaches (Nguyen and Yoon, 2019; Nikou et al., 2019).

Newer models based on the EMH that are categorized under fundamental analysis (FA) (Dichev and Tang, 2006), account for stock affecting factors beyond numerical ones such as investor sentiment through news, etc. Work in natural language processing (NLP) from sources such as news (Hu et al., 2018), social media data (Xu and Cohen, 2018), earnings calls (Qin and Yang, 2019; Sawhney et al., 2020b) shows the merit of FA in capturing market sentiment, surprises, mergers, acquisitions that traditional TA based methods fail to account. A limitation of existing NLP methods for stock prediction is that they assume stock movements to be independent of each other, contrary to true market function (Diebold and Yilmaz, 2014). This assumption hinders NLP centric FA's ability to learn latent patterns for the study of interrelated stocks.

Another line of FA revolves around employing graph-based methods to improve TA (e.g., price-based models) by augmenting them with inter stock relations (Feng et al., 2019b; Sawhney et al., 2020a). Matsunaga et al. (2019) combine historical prices with stock graphs through Graph Convolution Networks (GCNs), outperforming price-only models. Similarly, Kim et al. (2019) further improve graph neural network methods by weighing stock relations through attention mechanisms, as not all stock movements are equally correlated.

Despite the popularity of NLP and graph-based stock prediction, multimodal methods that capture inter stock relations and market sentiment through linguistic cues are seldom explored. Jue Liu (2019) combines feature extraction from news *sentiment scores*, financial information *(price-earnings ratio, etc.)* along with knowledge graph embeddings through TransR. However, such existing approaches (Deng et al., 2019) are unable to represent textual signals from social media and prices temporally, as they only utilize sentiment scores and do not account for stock correlations. To cover this gap in prior research, MAN-SF captures a broader set of features as opposed to both conventional TA and FA that singularly focus on either text or graph modalities, but not both together.

3 Problem Formulation

MAN-SF's main objective is to learn *temporally relevant information* jointly from tweets and historical price signals and make use of corporate relations among stocks to predict movements. Following Xu and Cohen (2018), we formalize movement based on the difference between the adjusted closing prices of the stock $s \in S$ on trading days d and $d-1$. We formulate stock movement prediction as a binary classification problem.

Problem Statement: Given stock $s \in S$, and historical price data and tweets for stock s over a lookback window of T days over the day range $[t-T, t-1]$, we define the price movement of stock s from day $t-1$ to t as:

$$Y_t = \begin{cases} 0, & p_d^c < p_{d-1}^c \\ 1, & p_d^c \geq p_{d-1}^c \end{cases} \tag{1}$$

where p_d^c represents the widely used (Yang et al., 2020; Qin and Yang, 2019) adjusted closing price[2] of a given stock on day t. Here, 0 represents a price downfall, and 1 represents a rise in the price.

4 MAN-SF: Components and Learning

In this section, we first give an overview of MAN-SF, followed by a detailed explanation of each component. As shown in Figure 1, MAN-SF first encodes market data for each stock over a fixed period. Formally, we encode stock features $x_t \in \mathbb{R}^w$ for each trading day t as, $x_t = \mathcal{B}(c_t, q_t)$; where, $c_t \in \mathbb{R}^u$ represents a social media feature that we

---

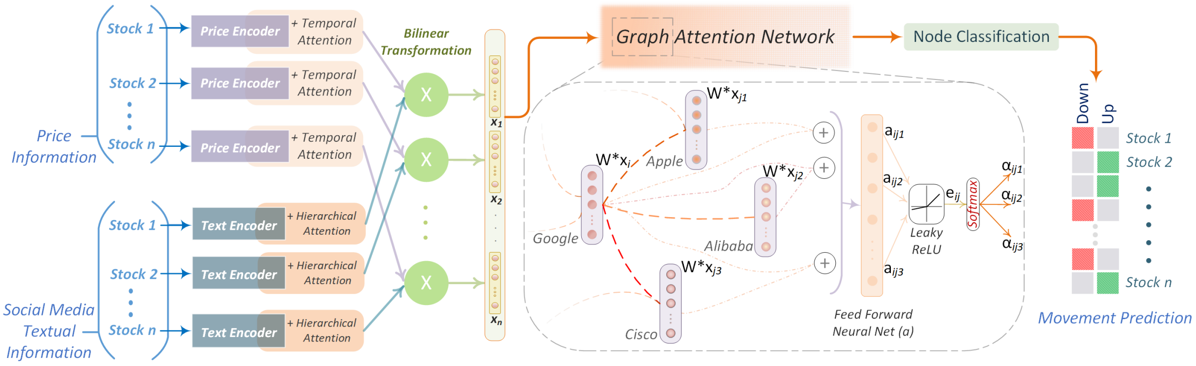

Figure 1: An overview of MAN-SF: Encoding Mechanisms, GAT Mechanism, Joint Optimization.

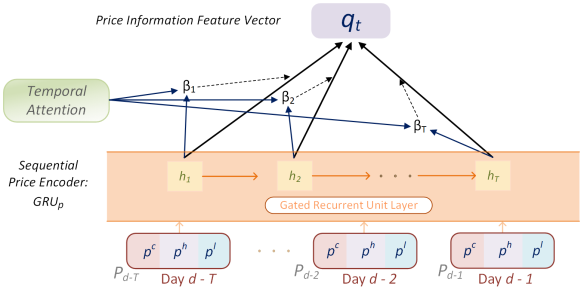

Figure 2: An overview of the Price Encoder.

obtain by encoding tweets over the lag window for each stock $s \in S = \{s_1, s_2, \dots s_S\}$. Similarly, $q_t \in \mathbb{R}^v$ are the features obtained from historical prices for a stock in the lag window. We detail these encoders first, and then explain the fusion $\mathcal{B}(\cdot)$ over c_t and q_t to obtain $x_t \in \mathbb{R}^w$. We then describe the graph to represent the inter stock relations. Lastly, we explain the GAT to which the fused feature vector x_t is passed to propagate features based on inter-stock relations along with the joint optimization of MAN-SF.

4.1 Price Encoder

Technical Analysis shows that historical price information is a strong indicator of future trends (Jeanblanc et al., 2009). Therefore, price data from each day is a crucial input to MAN-SF. The Price Encoder shown in Figure 2 encodes historical stock price movements to produce price feature, q_t. It takes in a per-day price feature from the lookback of T days and encodes the temporal trend in prices. To capture such sequential dependencies across trading days, we use a Gated Recurrent Unit (GRU) (Cho et al., 2014; Giles et al., 2001). The output of the GRU on day i is denoted by:

$$h_i = GRU_p(p_i, h_{i-1}) \quad t - T \le i \le t \tag{2}$$

where, $p_i \in \mathbb{R}^{d_p}$ is the price vector on day i for each stock s in the lookback. The raw price vector, $p_i = [p_i^c, p_i^h, p_i^l]$ comprises of a stock's adjusted closing price, highest price and lowest price for a trading day i. Since it is the price change that determines the stock movement rather than the absolute price value, we normalize it with its last adjusted closing price, $p_i = p_i / p_{i-1}^c$.

It has been shown that the stock trend of each day has a different impact on stock trend prediction (Feng et al., 2019a). Towards this end, we employ temporal attention $\zeta(\cdot)$ (Li et al., 2018) that learns to weigh critical days and forms an aggregated feature representation across all hidden states of the GRU (Qin et al., 2017). The temporal attention mechanism yields $q_t = \zeta(\overline{h}_p)$; where, $\overline{h}_p \in \mathbb{R}^{d_p \times T}$ is the concatenated hidden states of GRU_p for each stock s. This temporal attention mechanism $\zeta(\cdot)$ rewards days with more impactful information and aggregates it from all days in the lag window to produce price features $q_t \in \mathbb{R}^v$.

Temporal Attention We use a temporal attention mechanism that is a form of additive attention (Bahdanau et al., 2014). The mechanism $\zeta(\cdot)$ aggregates all the hidden representations of the GRU across different time-steps into an overall representation with learned adaptive weights (Feng et al., 2019a). We formulate this mechanism $\zeta(\cdot)$ as:

$$\beta_i = \frac{\exp\left(h_i^T W \overline{h}_z\right)}{\sum_{i=1}^{T} \exp\left(h_i^T W \overline{h}_z\right)} \tag{3}$$

$$\zeta(\overline{h}_z) = \sum_i \beta_i h_i \tag{4}$$

where, $\overline{h}_z \in \mathbb{R}^{T \times d_m}$ denotes the concatenated hidden states of the GRU. β_i represents the learned attention weights for trading day i, and W is a learnable parameter matrix.

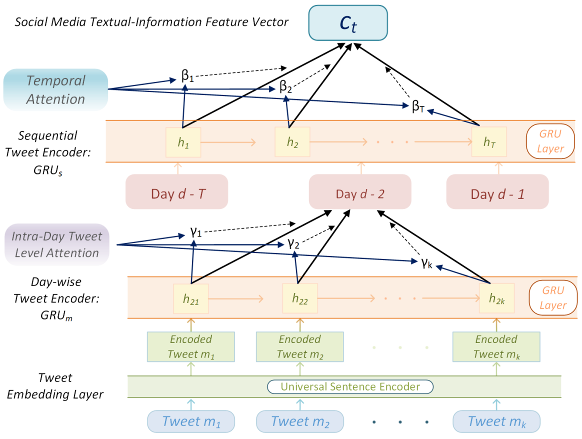

Figure 3: Social Media Information Encoder.

4.2 Social Media Information Encoder (SMI)

Xu and Cohen (2018) suggest that tweets not only convey factual data, but also portray user sentiment towards stocks that influence financial prediction (Bollen et al., 2011). A variety of market factors beyond historical prices drive stock trends (Abu-Mostafa and Atiya, 1996). With the rising ubiquity of the Internet, social media platforms, such as Twitter, influence investors to follow market trends (Tetlock, 2007; Hu et al., 2018). Tweets not only convey factual information but also portray user sentiment towards stocks (Xu and Cohen, 2018; Fung et al., 2002). To this end, MAN-SF uses the SMI encoder to extract a feature vector c_t using tweets. The encoder shown in Figure 3 extracts social media features, c_t, by first encoding tweets for a day and then over multiple days using a hierarchical attention mechanism (Yang et al., 2016).

Tweet Embedding For any given tweet t_w, we generate an embedding vector $m \in \mathbb{R}^d$. We explored word and sentence level embedding methods to learn tweet representations: Global Vectors for Word Representation (GloVe) (Pennington et al., 2014), Fasttext (Joulin et al., 2017), and Universal Sentence Encoders (USE) (Cer et al., 2018). Empirically, sentence-level embeddings generated using a deep averaging network encoder variant of the USE[3] gave us the most promising results. Thus, we encode each tweet t_w using USE.

Learning Representations for one day On any day i, a variable number tweets $[t_{w1}, t_{w2}, \dots t_{wK}]$ for each stock s are posted, and these capture and influence the stock trends (Fung et al., 2002). For each tweet, we obtain a representation using the Tweet Embedding layer (USE) as $[m_1, m_2, \dots m_K]$ where $m_j \in \mathbb{R}^d$ and K is the number of tweets per stock on day i. To model the sequence of tweets within a day, we use a GRU. For stock s on each day i:

$$h_j = GRU_m(m_j, h_{j-1}); j \in [1, K] \tag{5}$$

The influence of online tweets on the market can vary greatly (Hu et al., 2018). To identify tweets that are likely to have a more substantial influence on the market, we use an intraday tweet level attention. For each stock s on each day i the mechanism can be summarized as:

$$\gamma_j = \frac{\exp\left(h_j^T W \bar{h}_m\right)}{\sum_{j=1}^{K} \exp\left(h_j^T W \bar{h}_m\right)} \tag{6}$$

$$r_i = \sum_j \gamma_j h_j \tag{7}$$

where, $\bar{h}_m \in \mathbb{R}^{K \times d_m}$ denotes a concatenation of all hidden states from GRU_m and d_m is the dimension of each hidden state. γ_j represents the attention weights and r_i represents the features obtained from several published tweets on day i for each stock s. W is a learned linear transformation.

Learning Representations across days Analyzing a temporal sequence of tweets and combining them can provide a more reliable assessment of market trends (Zhao et al., 2017). We learn a social media representation from the sequence of day level tweet representations r_i. This feature vector encodes all the information in a lookback window. We then feed temporal day level tweet vectors to a GRU for sequential modeling given by:

$$h_i = GRU_s(r_i, h_{i-1}) \quad t - T \leq i \leq t \tag{8}$$

where, h_i summarizes the tweets on day i for stock s as well as tweets from preceding days while focusing on day i. Like historical prices, tweets from each day have a different impact on stock movements. Hence, the previously described temporal attention mechanism used for historical prices is also used for social media. This mechanism learns a procedure to aggregate impactful information to form SMI features c_t over a lookback of T days for each stock s. The temporal attention mechanism yields $c_t = \zeta(\bar{h}_s)$; $\bar{h}_s \in \mathbb{R}^{T \times d_s}$ represents the concatenated hidden states of GRU_s and d_s is the size of output space of the GRU. This temporal

---

[3] Implementation used: `https://tfhub.dev/google/universal-sentence-encoder/2`

attention $\zeta(\cdot)$, along with the intraday tweet-level attention, forms a hierarchical attention mechanism. This mechanism captures the fact that tweets are differently informative and have varied impacts during different market phases. The obtained SMI and price features for each stock are then blended to obtain a joint representation.

4.3 Blending Multimodal Information

Signals from different modalities often carry complementary information about different events in the market (Robert P. Schumaker, 2019). Direct concatenation treats information from Price and SMI encoders equally (Li et al., 2016). Furthermore, the interdependencies between price and tweets are not appropriately captured, damping the framework's capacity to learn their correlations to market trends (Li et al., 2014). We use a bilinear transformation that learns the pairwise feature interactions from historical price features and tweets. Formally, $q_t \in \mathbb{R}^v$ and $c_t \in \mathbb{R}^u$ are obtained from the Price Encoder and SMI Encoder, respectively. The output $x_t \in \mathbb{R}^w$ is given by:

$$x_t = \mathcal{B}(c_t, q_t,) = ReLU(q_t^T W c_t + b) \qquad (9)$$

where, $W \in \mathbb{R}^{w \times v \times u}$ is the weight matrix, and $b \in \mathbb{R}^w$ is the bias. Methods like direct mean and attention-based aggregation (Bahdanau et al., 2014) do not account for pair-wise interactions as shown in the results **(Sec. 6)**. Other methods like factorized bilinear pooling (Yu et al., 2017), reduce computational complexity; however, we empirically find that the generalized bilinear layer outperforms these techniques. This layer learns an optimum blend of features from prices and tweets in a translationally invariant manner.

4.4 Graph Attention Network (GAT)

Stocks are often interlinked with one another, and thus, we model stocks and their relations as a graph.

Graph Creation Following Feng et al. (2019b), we make use of Wiki company-based relations. Using Wikidata[4], we extract first and second-order relations between the company stocks in the S&P 500 index. A first-order relation is defined as $X \xrightarrow{\text{R1}} Y$ where X and Y denote entities in Wikidata that correspond to the two stocks. A second-order relation is defined by $X \xrightarrow{\text{R2}} Z \xleftarrow{\text{R3}} Y$ where Z denotes another entity connecting the two entities X and Y. R1, R2, and R3, defined in Wikidata, are different types of entity-relations. For instance, Wells Fargo and Bank of America are related to Berkshire Hathaway via a first-order company relation "owned by." Another example is Microsoft and Berkshire Hathaway that are related through Bill Gates (second-order relation: "owned by" - "is a board member of") since Bill Gates possesses ownership over Microsoft and is a Board member of Berkshire Hathaway. We define the stock relation network as a graph $G(S, E)$ where S denotes the set of nodes, and E is the set of edges. Each node $s \in S$ represents a stock, and two stocks $s_1, s_2 \in S$ are joined by an edge $e \in E$ if s_1, s_2 are linked by a first or second-order relation.

Graph Attention Graph-based representation learning through graph neural networks can be considered as information exchange between related nodes (Gilmer et al., 2017). As each stock has a different degree of influence on another stock, it is essential that the graph encoding suitably weighs more relevant relations between stocks. To this end, we use graph attention networks (GATs), which are graph neural networks with node-level attention (Veličković et al., 2017).

We first describe a single GAT layer that is used throughout the GAT component. The input to the GAT is a set of stock (node) features, $h = [x_1, x_2, \ldots x_{|S|}]$, where x_i is the encoded multi-modal market information (Sec. 4.3). The GAT layer produces an updated set of of node features $h' = [z_1, z_2, \ldots z_{|S|}]$; $z_i \in \mathbb{R}^{w'}$ based on the GAT mechanism (shown in Figure 1). We first apply a shared linear transform parameterized by $W \in \mathbb{R}^{w' \times w}$ to all the nodes. Then, we apply a shared self-attention mechanism to each node i in its immediate neighborhood $\mathcal{N}_i$. For each node $j \in \mathcal{N}_i$, we compute normalized attention coefficients α_{ij} representing the importance of relations among stocks i and j. Formally, α_{ij} is given as:

$$\alpha_{ij} = \frac{\exp\left(LeakyReLU(a_w^T[Wx_i \oplus Wx_j])\right)}{\sum\limits_{k \in N_i} \exp\left(LeakyReLU(a_w^T[Wx_i \oplus Wx_k])\right)} \qquad (10)$$

where, $.^T$ and $\oplus$ represent transpose and concatenation respectively. $a_w \in \mathbb{R}^{2w'}$ is a learnable weight matrix of a single layer feed forward neural network. The learned attention coefficients α_{ij} are used to weigh and aggregate feature vectors from neighboring with a non-linearity σ. The updated

---

[4] `https://www.wikidata.org/wiki/Wikidata:List_of_properties/all`

node feature vector z_i is given as:

$$z_i = \sigma\left(\sum_{j \in N_i} \alpha_{ij} W x_j\right) \tag{11}$$

We use multi-head attention to stabilise training (Vaswani et al., 2017). Formally, U independent executors apply the above attention mechanism. Their output features are concatenated to yield:

$$z_i = \bigoplus_{k=1}^{U} \sigma\left(\sum_{j \in \mathcal{N}_i} \alpha_{ij}^k W^k x_j\right) \tag{12}$$

where, α_{ij}^k and W^k denote normalised attention coefficients and linear transformation parameter matrix computed by the k^{th} attention mechanism.

We use a two-layer GAT, the first layer is followed by Exponential Linear Unit (Clevert et al., 2015), and the second layer outputs a vector y_i for each stock i, which is then used to classify the stock's future price movements. MAN-SF is trained using the Adam optimiser by optimizing the cross-entropy loss, given as:

$$L_{cse} = -\sum_{i=1}^{|\mathcal{S}|} Y_i \ln(y_i) + (1 - Y_i)\ln(1 - y_i) \tag{13}$$

where, Y_i is the true price movement of stock i.

5 Experiments

5.1 Dataset and Training Setup

We adopt the StockNet dataset (Xu and Cohen, 2018) for the training and evaluation of MAN-SF. The dataset contains data of high-trade-volume stocks in the S&P 500 index in the NYSE and NASDAQ markets. Stock specific tweets are extracted using regex queries made out of NASDAQ ticker symbols, for instance, \$AMZN for Amazon. The price data has been obtained from Yahoo Finance[5]. We shift a 5-day lag window along the trading days to generate samples. We label the samples according to the movement percentage of the closing price such that those $\geq 0.55\%$ and $\leq -0.5\%$ are labeled positive and negative samples, respectively. This leaves us with $26,614$ samples divided as 49.78% and 50.22% in the two classes. We temporally split the dataset in a ratio of Train:Validation:Test in 70:10:20, leaving us with date ranges from 01/01/2014 to 31/07/2015 for training, 01/08/2015 to 30/09/2015 for validation, and 01/10/2015 to 01/01/2016 for testing. Following Xu and Cohen (2018), we align trading days by dropping samples that lack either prices or tweets, and further align the data across trading windows for related stocks to ensure data is available for all trading days in the window for all stocks. The hidden size of all GRUs is 64, and the USE embedding dimension is 512. We use $U = 8$ attention heads for both GAT layers. We use the Adam optimizer with a learning rate set to $5e{-}4$ and train MAN-SF for $10,000$ epochs. It takes 3hrs to train and test MAN-SF on Tesla K80 GPU. We use early stopping based on Matthew's Correlation Coefficient (MCC) taken over the validation set.

5.2 Evaluation

Following prior research for stock prediction (Ding et al., 2014; Xu and Cohen, 2018), we use accuracy, F1 score, MCC (implementations from *sklearn*[6]) for classification performance. We use MCC because, unlike the F1 score, MCC avoids bias due to data skew as it does not depend on the choice of the positive class and accounts for the True Negatives. For a given confusion matrix $\begin{pmatrix} tp & fn \\ fp & tn \end{pmatrix}$:

$$\text{MCC} = \frac{tp \times tn - fp \times fn}{\sqrt{(tp + fp)(tp + fn)(tn + fp)(tn + fn)}} \tag{14}$$

Like prior work (Kim et al., 2019; Feng et al., 2019b), to evaluate MAN-SF's applicability to real-world trading, we assess its profitability on the test data of the S&P 500 index using two metrics: Cumulative Profit and Sharpe Ratio (Sharpe, 1994). We follow a trading strategy where, if MAN-SF predicts a rise in a stock's value the next day, then one share of that stock is bought (long position) at the closing price of the current trading session and sold on the next day's closing price. Otherwise, if the strategy speculates a fall in price, a short sell[7] is performed. We compute the cumulative profit (Krauss, 2018) earned as:

$$\text{Profit}_t = \sum_{i \in S} \frac{p_i^t - p_i^{t-1}}{p_i^{t-1}} (-1)^{Action_i^{t-1}} \tag{15}$$

where, S denotes the set of stocks, p_i^t denotes the price of stock i at day t. $Action_i^{t-1}$ is a binary value $[0, 1]$. The $Action_i^{t-1}$ is 0 if the long position is taken at time t for stock i; otherwise it is 1.

Table 1: Results compared with baselines. **Bold** shows the best results. Green is indicative of higher performance. TA and FA represent Technical Analysis and Fundamental Analysis models, respectively.

The Sharpe Ratio is a measure of the return of a portfolio compared to its risk. We calculate the Sharpe ratio by computing the ratio of the expected return R_a of a portfolio to its standard deviation as:

$$\text{Sharpe Ratio}_a = \frac{E[R_a]}{std[R_a]} \tag{16}$$

5.3 Baselines

We compare MAN-SF with the below baselines spanning both technical and fundamental analysis.

Technical Analysis: These methods uses only historical price information.

- **RAND:** Random guess as price rise or fall.
- **ARIMA:** Autoregressive Integrated Moving Average models historical prices as a non-stationary time series (Brown, 2004).
- **Selvin et al. (2017)**: Three deep neural architectures (RNN, CNN and LSTM) using prices. We compare with the best performing LSTM.

Fundamental Analysis: These methods use other modalities such as text information and company relationships along with historical prices.

- **RandForest:** Random Forests classifier trained over word2vec (Mikolov et al., 2013) embeddings for tweets.
- **TSLDA:** Topic Sentiment Latent Dirichlet Allocation model is a generative model that uses sentiments and topic modeling on social media (Nguyen and Shirai, 2015).
- **HAN:** A hierarchical attention mechanism to encode textual information during a day and across multiple days (Hu et al., 2018).
- **StockNet:** A variational Autoencoder (VAE) that uses price and text information. Text is encoded using hierarchical attention during and across days. Price features are modeled sequentially (Xu and Cohen, 2018). We compare with all five variants of StockNet.
- **HATS:** A hierarchical graph attention method that uses a multi-graph to weigh different relationships between stocks. It uses only historical price data (Kim et al., 2019).
- **Chen et al. (2018)**: GCNs to model inter stock relations with only historical price data.

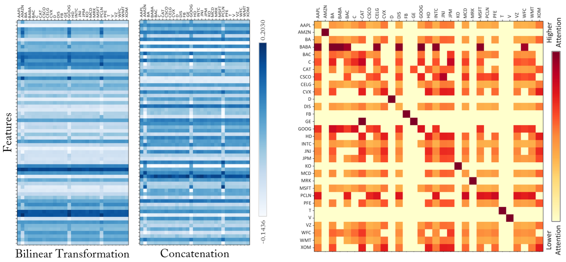
6 Results and Analysis

We now discuss the experimental results and some findings with their financial implications.

Performance Comparison Table 1 shows the performance of the compared methods on StockNet's test data split from 01/10/2015 to 31/12/2015 on the S&P 500 index averaged over ten different runs. Using a learned blend of historical price and tweets using corporate relationships, MAN-SF achieves the best performance, outperforming the strongest baselines, StockNet, and Adversarial LSTM. We also note that Fundamental Analysis (FA) techniques outperform numerical only Technical Analysis (TA) methods, reiterating the effectiveness of factoring in social media signals and

Model Component	F1 ↑	MCC ↑
LSTM + Historical Price	0.521	0.002
GRU + Social Media Text (BERT)	0.539	0.077
GCN + Historical Price	0.532	0.093
GRU + Social Media Text (USE)	0.546	0.101
GCN + Social Media Text (USE)	0.555	0.102
GAT + Historical Price	0.562	0.117
MAN-SF (Concatenation)	0.588	0.156
MAN-SF (Attention Fusion)	0.594	0.173
MAN-SF (Bilinear Transformation)	**0.605**	**0.195**

Table 2: Ablation study over MAN-SF's components.



(a) Feature fusion maps (b) Graph attention map

Figure 4: Feature weight heatmaps for MAN-SF

inter stock relations. These results empirically validate the effectiveness of multimodal signals due to a broader capture of stock price influencing information, including tweets and other related stocks.

Ablation Study In Table 2, we observe the ability of price and text models to predict the market trend to an extent using unimodal features. Improvements over individual modalities are noted with the inclusion of a graph-based learning model, i.e., GCN and GAT validating the premise of using inter stock relations for enhanced forecasting. When the text and price signals are fused, and more relevant information is extracted using the attention mechanisms, a performance gain is seen. The ablation study ties up with the EMH, as we add additional modalities, we note an increment in MAN-SF's ability for stock prediction. Two critical observations from Table 2 are the substantial MCC gains when using GAT over GCN and the contrast between fusing text and prices via concatenation and bilinear transformations. We discuss these next.

Impact of Bilinear Transformations Bilinear blending outperforms concatenation, and attention fusion variants, as seen in Table 2. We postulate that the bilinear transformation can better learn the interplay between the signals compared to other variants. On examining Figure 4a, we observe that the bilinear layer blends highly non-linear relationships between the two signals leading to a joint representation that captures more specific features noticed by areas of concentrated attention as compared to simple concatenation based fusion.

Table 3: Annualized sharpe Ratio comparison with baselines. **Bold** and *italics* denotes best and second best results, respectively.

Model	Sharpe Ratio↑
Stocknet	*0.83*
HATS	0.78
MAN-SF	**1.05**

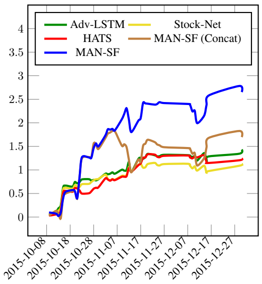


Figure 6: Cumulative profit trend

Analyzing Graph Attention We notice that equally weighing all correlations using GCN-based models leads to smaller performance gains, as shown in Table 2, as compared to GAT (GAT, and MAN-SF variants). To analyze this difference, we first calculate each neighbor's attention scores in the stock relations graph, as shown in Figure 4b. By analyzing the different stock associations with the highest and lowest attention scores, we observe that some relations between stocks, such as being a part of the same industry or having the same founder, are more critical than other relations like stocks having the same country of origin. For instance, C (CitiCorp) and JPM (JP Morgan) have a relatively high attention score and are a part of the same investment and banking industry, whereas the attention score for JPM and CSCO (Cisco) is relatively low. We also observe that some stocks share hidden correlations captured by the GAT due to the market's temporal nature. We explain one such example in Section 7.

Profitability We examine MAN-SF's practical applicability through a profitability analysis on real-world stock data. From Table 3 and Figure 6, we note that MAN-SF achieves higher risk-adjusted returns and an overall profit. MAN-SF outperforms different baselines over the common testing period of three months using the stocks data in the S&P 500 index. These observations show the profitability of MAN-SF over models that do not capture stock correlations (StockNet) and models that do not use the impact of textual data (HATS). We potentially attribute these improvements to MAN-SF's ability to learn a more concentrated blend of text and price features as opposed to competitive

models. We extend this analysis in the next section.

7 Qualitative Analysis

We conduct an extended analysis across two high-risk scenarios, as shown in Figure 5, to study the applicability of MAN-SF to investors in the stock market. The study is based on Apple's (AAPL) trend during 12th Nov - 18th Nov. Figure 5 shows some of the tweets posted and AAPL's relations with relevant stocks such as Alibaba (BABA), Google (GOOG), and among others during that period.

12th Nov to 16th Nov: Failure of StockNet and models that do not capture inter stock relations: From Figure 5, we see from the price movement that 12th to 16th November 2015 shows a decline in Apple's stock price. Here, we observe that StockNet predicts a further drop in Apple's price, and similar models that use only price and text are unable to predict the price rise for Apple on 17th November correctly. However, we discover that Apple shares a strong relationship with Alibaba and Google during that time, as indicated by the attention weights. MAN-SF incorporates inter-stock relations through graph attention to learn latent correlations between AAPL, BABA, and GOOG, as shown by the graph snippet in Figure 5. MAN-SF correctly predicts a rise in Apple's price and makes a profit, unlike StockNet. We attribute this prediction to MAN-SF likely having a broader context by blending multimodal signals.

14th Nov to 18th Nov: Failure of HATS and models that do not leverage social media data: Despite Apple's sharp fall on 18^{th} November, we see tweets with positive sentiment having higher attention weights during the lookback window, indicating a possible increase in Apple's price. MAN-SF uses hierarchical attention mechanisms over tweets and inter-stock correlations correctly. Thereby likely predicting a rise in Apple's stock price, similar to models such as StockNet. As opposed to these, models such as HATS forecast a continual decrease in Apple's price, potentially due to not factoring in social media data.

8 Conclusion and Future Work

We study stock movement prediction by using natural language, graph-based and numeric features. We propose MAN-SF, a neural model that jointly learns *temporally relevant* signals from *chaotic* multimodal data spanning historical prices, tweets, and inter stock correlations in a hierarchical fashion. Extensive quantitative and qualitative experiments on real market data demonstrate MAN-SF's applicability for neural stock forecasting. We plan to further use news articles, earnings calls, and other data sources to capture market dynamics better. Another interesting direction of future research is to explore the cold start problem, where MAN-SF could be leveraged to predict stock movements for new stocks. Lastly, we would also like to extend MAN-SF's architecture to not be limited to model all stocks together (because of its GAT component) to increase scalability to cross-market scenarios.

Abstract

In recent years, there has been an increasing interest in the application of Artificial Intelligence – and especially Machine Learning – to the field of Sustainable Development (SD). However, until now, NLP has not been systematically applied in this context. In this paper, we show the high potential of NLP to enhance project sustainability. In particular, we focus on the case of community profiling in developing countries, where, in contrast to the developed world, a notable data gap exists. Here, NLP could help to address the cost and time barrier of structuring qualitative data that prohibits its widespread use and associated benefits. We propose the new extreme multi-class multi-label *Automatic User-Perceived Value classification* task. We release *Stories2Insights* (S2I), an expert-annotated dataset of interviews carried out in Uganda, we provide a detailed corpus analysis, and we implement a number of strong neural baselines to address the task. Experimental results show that the problem is challenging, and leaves considerable room for future research at the intersection of NLP and SD.

1 Introduction

Sustainable Development (SD) is an interdisciplinary field which studies the integration and balancing of economic, environmental and social concerns to tackle the broad goal of achieving inclusive and sustainable growth (Brundtland, 1987; Keeble, 1988; Sachs, 2015). As a collective, trans-national effort toward sustainability, in 2015 the United Nations approved the *2030 Agenda* (United Nations, 2015), which identifies 17 Sustainable Development Goals (SDGs) to be reached by 2030 (Lee et al., 2016). In recent years, there has been increasing recognition of the fundamental role played by data in achieving the objectives set out in the SDGs (Griggs et al., 2013; Nilsson et al., 2016; Vinuesa et al., 2020).

In this paper, we focus on data-driven planning and delivery of projects[1] which address one or more of the SDGs in a developing country context. When dealing with developing countries, a deep understanding of project beneficiaries' needs and values (hereafter referred to as *User-Perceived Values* or UPVs, Hirmer and Guthrie (2016)) is of particular importance. This is because beneficiaries with limited financial means are especially good at assessing needs and values (Hirji, 2015). When a project fails to create value to a benefiting community, the community is less likely to care about its continued operation (Watkins et al., 2012; Chandler et al., 2013; Hirmer, 2018) and as a consequence, the chances of the project's long-term success is jeopardised (Bishop et al., 2010). Therefore, comprehensive community profiling[2] plays a key role in understanding what is important for a community and act upon it, thus ensuring a project's sustainability (van der Waldt, 2019).

Obtaining data with such characteristics requires knowledge extraction from qualitative interviews which come in the form of unstructured free text (Saggion et al., 2010; Parmar et al., 2018). This step is usually done manually by domain experts (Lundegård and Wickman, 2007), which further raises the costs. Thus, structured qualitative data is often unaffordable for project developers. As a consequence, project planning heavily relies upon sub-optimal aggregated statistical data, like household surveys (WHO, 2016) or remotely-sensed satellite imagery (Bello and Aina, 2014; Jean et al., 2016), which unfortu-

---

[1] Examples of projects for SD include *physical infrastructures* (as the installation of a solar mini-grid to provide light (Bhattacharyya, 2012)) or of *programmes* to change a population's behaviour (as the awareness raising campaigns against HIV transmission implemented by Avert (2019)).

[2] *Community profiling* is the detailed and holistic description of a community's needs and resources (Blackshaw, 2010).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8427–8444,
November 16–20, 2020.

nately is of considerable lower resolution in developing countries. Whilst these quantitative data sets are important and necessary, they are insufficient to ensure successful project design, lacking insights on UPVs that are crucial to success. In this context, the application of NLP techniques can help to make qualitative data more accessible to project developers by dramatically reducing time and costs to structure data. However, despite having been successfully applied to many other domains – ranging from biomedicine (Simpson and Demner-Fushman, 2012), to law (Kanapala et al., 2019) and finance (Loughran and McDonald, 2016) – to our knowledge, NLP has not yet been applied to the field of SD in a systematic and academically rigorous format[3].

In this paper, we make the following contributions: (1) we articulate the potential of NLP to enhance SD—at the time of writing this is the first time NLP is systematically applied to this field; (2) as a case-study at the intersection between NLP and SD, we focus on enhancing project planning in the context of a developing country, namely Uganda; (3) we propose the new task of *UPV Classification*, which consists in labeling qualitative interviews using an annotation schema developed in the field of SD; (4) we annotate and release *Stories2Insights*, a corpus of UPV-annotated interviews in English; (5) we provide a set of strong neural baselines for future reference; and (6) we show – through a detailed error analysis – that the task is challenging and important, and we hope it will raise interest from the NLP community.

2 Background

2.1 Artificial Intelligence for Sustainable Development

While NLP has not yet been applied to the field of SD, in recent years there have been notable applications of Artificial Intelligence (AI) in this area. This is testified by the rise of young research fields that seek to help meet the SDGs, as *Computational Sustainability* (Gomes et al., 2019) and *AI for Social Good* (Hager et al., 2017; Shi et al., 2020).

In this context, Machine Learning, in particular in the field of Computer Vision (De-Arteaga et al., 2018), has been applied to contexts ranging from conservation biology (Kwok, 2019), to poverty (Blumenstock et al., 2015) and slavery mapping (Foody et al., 2019), to deforestation and water quality monitoring (Holloway and Mengersen, 2018).

2.2 Ethics of AI for Social Good

Despite its positive impact, it is important to recognise that some AI techniques can act both as an enhancer and inhibitor of sustainability. As recently shown by Vinuesa et al. (2020), AI might inhibit meeting a considerable number of targets across the SDGs and may result in inequalities within and across countries due to application biases. Understanding the implications of AI and its related fields on SD, or Social Good more generally, is particularly important for countries where action on SDGs is being focused and where issues are most acute (UNESCO, 2019a,b).

2.3 Project biases

Various works highlight the importance of understanding the local context and engaging with local stakeholders, including beneficiaries, to achieve project sustainability. Where such information is not available, projects are designed and delivered based on the judgment of other actors (e.g. project funders, developers or domain experts, (Risal, 2014; Axinn, 1988; Harman and Williams, 2014)). Their judgment, in turn, is subject to biases (Kahneman, 2011) that are shaped by past experiences, beliefs, preferences and worldviews: such biases can include, for example, preferences towards a specific sector (e.g. energy or water), technology (e.g. solar, hydro) or gender-group (e.g. solutions which benefit a gender disproportionately), which are pushed without considering the local needs.

NLP has the potential to increase the availability of community-specific data to key decision makers and ensure project design is properly informed and appropriately targeted. However, careful attention needs to be paid to the potential for bias in data collection resulting from the interviewers (Bryman, 2016), as well as the potential to introduce new bias through NLP.

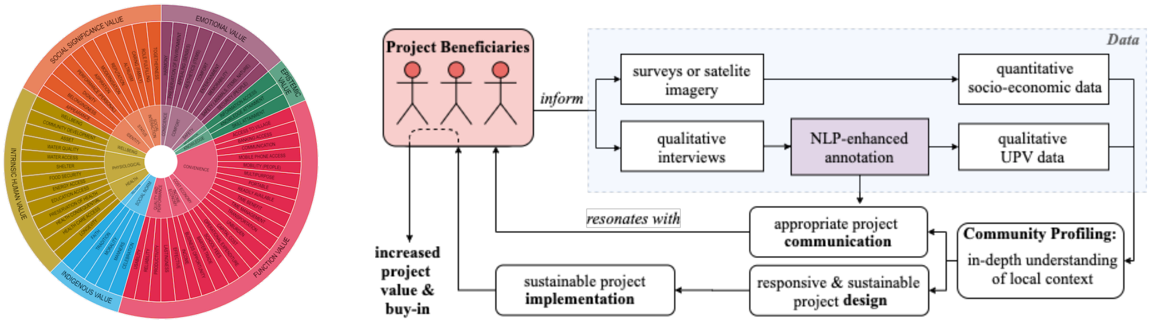
3 User-Perceived Values (UPVs) for Data-driven Sustainable Projects

3.1 The User-Perceived Values (UPV) Framework.

As a means to obtain qualitative data with the characteristics mentioned above, we adapt the

---

[3] We have found sporadic examples of the application of NLP, e.g. for analysing data from a gaming app used in a developing country (Pulse Lab Jakarta, 2016).



(a) User-Perceived Value wheel.

(b) Flowchart of the intersection between NLP (purple square) and the delivery of SD projects.

Figure 1: Using UPVs (1a) to build sustainable projects: note the role of NLP (purple square in 1b).

User-Perceived Values (UPV) framework (Hirmer, 2018). The UPV framework builds on value theory, which is widely used in marketing and product design in the developed world (Sheth et al., 1991; Woo, 1992; Solomon, 2002; Boztepe, 2007). Value theory assumes that a deep connection exists between what consumers perceive as important and their inclinations to adopt a new product or service (Nurkka et al., 2009).

In the context of developing countries, our UPV framework identifies a set of 58 UPVs which can be used to frame the wide range of perspectives on what is of greatest concern to project beneficiaries (Hirmer and Guthrie, 2016). UPVs (or *tier 3* (T3) values) can be clustered into 17 *tier 2* (T2) value groups, each one embracing a set of similar T3 values; in turn, T2 values can be categorized into 6 *tier 1* (T1) high-level value pillars, as follows: (Hirmer and Guthrie, 2014):

1. *Emotional*: contains the T2 values *Conscience*, *Contentment*, *Human Welfare* (tot. 9 T3 values)
2. *Epistemic*: contains the T2 values *Information* and *Knowledge* (tot. 2 T3 values)
3. *Functional*: contains the T2 values *Convenience*, *Cost Economy*, *Income Economy* and *Quality and Performance* (tot. 21 T3 values)
4. *Indigenous*: containing the T2 values *Social Norm* and *Religion* (tot. 5 T3 values)
5. *Intrinsic Human*: *Health*, *Physiological* and *Quality of Life* (tot. 11 T3 values)
6. *Social significance*: contains the T2 *Identity*, *Status* and *Social Interaction* (tot. 11 T3 values)

The interplay between T1, T2 and T3 values is graphically depicted in the *UPV Wheel* (Figure 1a). See Appendix A for the full set of UPV definitions.

3.2 Integrating UPVs into Sustainable Project Planning.

The UPV approach offers a theoretical framework to place communities at the centre of project design (Figure 1b). Notably, it allows to (a) facilitate more responsible and beneficial project planning (Gallarza and Saura, 2006); and (b) enable effective communication with rural dwellers. The latter allows the use of messaging of project benefits in a way that resonates with the beneficiaries' own understanding of benefits, as discussed by Hirji (2015). This results in a higher end-user acceptance, because the initiative is perceived to have personal value to the beneficiaries: as a consequence, community commitment will be increased, eventually enhancing the project success rate and leading to more sustainable results (Hirmer, 2018).

3.3 The role of NLP to enhance Sustainable Project Planning.

Data conveying the beneficiaries' perspective is seldom considered in practical application, mainly due to the fact that it comes in the form of unstructured qualitative interviews. As introduced above, data needs to be *structured* in order to be useful (OECD, 2017; UN Agenda for Sustainable Development, 2018). This makes the entire process very long and costly, thus making it almost prohibitive to afford in practice for most small-scale projects. In this context, the role of AI, and more specifically NLP, can have a yet unexplored opportunity. Implementing successful NLP systems to automatically perform the annotation process on interviews (Figure 1b, purple square), which constitutes the major bottleneck in the project planning pipeline (Section 4.1), would dramatically speed up the entire project life-cycle and drastically reduce its costs.

(a) (b) (c)

Figure 2: Playing the UPV game in Uganda. From left to right: 2a) Cards for the items *generator*, *cow*, *flush toilet* and *newspapers* (adapted to the Ugandan context with the support of international experts and academics from the U. of Cambridge; 2b) Women playing the UPV game in village (1)[4]; 2c) Map of case-study villages.

In this context, we introduce the task of *Automatic UPV classification*, which consists of annotating each sentence of a given input interview with the appropriate UPV labels which are (implicitly) conveyed by the interviewee.

4 The *Stories2Insights* Corpus: a Corpus Annotated for User-Perceived Values

To enable research in UPV classification, we release S2I, a corpus of labelled reports from 7 rural villages in Uganda (Figure 2c). In this Section, we report on the corpus collection and annotation procedures and outline the challenges this poses for NLP.

4.1 Building a Corpus with the UPV game

The UPV game. As widely recognised in marketing practice (Van Kleef et al., 2005), consumers are usually unable to articulate their own values and needs (Ulwick, 2002). This requires the use of methods that elicit what is important, such as laddering (Reynolds and Gutman, 2001) or Zaltman Metaphor Elicitation Technique (ZMET) (Coulter et al., 2001). To avoid direct inquiry (Pinegar, 2006), Hirmer and Guthrie (2016) developed an approach to identify perceived values in low-income settings by means of a game (hereafter referred to as *UPV game*). Expanding on the items proposed by Peace Child International (2005), the UPV game makes reference to 46 everyday-use items in rural areas[5], which are graphically depicted (Figure 2a). The decision to represent items graphically stems from the high level of illiteracy across developing countries (UNESCO, 2013).

Building on the techniques proposed by Coulter *et al.* (2001) and Reynolds *et al.* (2001), the UPV game is framed in the form of semi-structured interviews:
(1) participants are asked to select 20 items, based on what is most important to them (*Select stimuli*), (2) to rank them in order of importance; and finally, (3) they have to give reasons as to why an item was important to them. *Why-probing* was used to encourage discussion (*Storytelling*).

Case-Study Villages. 7 rural villages were studied: 3 in the West Nile Region (Northern Uganda); 1 in Mount Elgon (Eastern Uganda); 2 in the Ruwenzori Mountains (Western Uganda); and 1 in South Western Uganda. All villages are located in remote areas far from the main roads (Figure 2c). A total of 7 languages are spoken across the villages[6].

Data Collection Setting and Guidelines for Interviewers. For each village, 3 native speaker interviewers guided the UPV game. To ensure consistency and data quality, a two-day training workshop was held at Makerere University (Kampala, Uganda), and a local research assistant oversaw the entire data collection process in the field.

Data Collection. 12 people per village were interviewed, consisting of an equal split between men and women with varying backgrounds and ages. In order to gather complete insight into the underlying decision-making process – which might be influenced by the context (Barry et al., 2008) – interviews were conducted both individually and in groups of 6 people following standard focus group

---

[5] Such items included livestock (*cow, chicken*), basic electronic gadgets (*mobile phone, radio*), household goods (*dishes, blanket*), and horticultural items (*plough, hoe*) (Hirmer, 2018).

[5] While permission of photographing was granted from the participants, photos were pixelised to protect their identity.

[6] Rukonjo, Rukiga, Lugwere and Swahili (Bantu family); Sebei/Sabaot, Kupsabiny, Lugbara (Nilo-Saharan family).

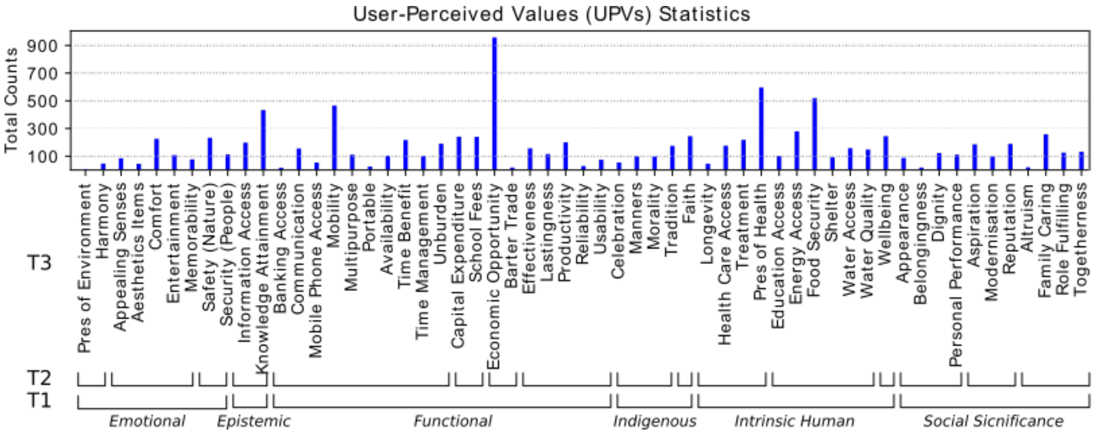


Figure 3: UPV frequencies from the S2I corpus (see Appendix A for UPV definitions).

methods (Silverman, 2013; Bryman, 2016). Each interview lasted around 90 minutes. The data collection process took place over a period of 3 months and resulted in a total of 119 interviews.

Ethical Considerations. Participants received compensation in the amount of 1 day of labour. An informed consent form was read out loud by the interviewer prior to the UPV game, to cater for the high-level of illiteracy amongst participants. To ensure integrity, a risk assessment following the University of Cambridge's *Policy on the Ethics of Research Involving Human Participants and Personal Data* was completed. To protect the participants' identity, locations and proper names were anonymized.

Data Annotation. The interviews were translated[7] into English, analysed and annotated by domain experts[8] using the computer-assisted qualitative data analysis software *HyperResearch* (Hesse-Biber et al., 1991). To ensure consistency across interviews, they were annotated following Bryman (2012), using cross-sectional indexing (Mason, 2002). Due to the considerable size of collected data, the annotation process took around 6 months.

4.2 Corpus Statistics and NLP Challenges

We obtain a final corpus of 5102 annotated utterances from the interviews. Samples present an average length of 20 tokens. The average number of samples per T3 label is 169.1, with an extremely skewed distribution: the most frequent T3, *Economic Opportunity*, occurs 957 times, while the least common, *Preservation of the Environment*, only 7 (Figure 3).

58.8% of the samples are associated with more than 1 UPV, and 22.3% with more than 2 UPVs (refer to Appendix B for further details on UPV correlation). Such characteristics make UPV classification highly challenging to model: the task is an extreme multi-class multi-label problem, with high class imbalancy. Imbalanced label distributions pose a challenge for many NLP applications – as sentiment analysis (Li et al., 2011), sarcasm detection (Liu et al., 2014), and NER (Tomanek and Hahn, 2009) – but are not uncommon in user-generated data (Imran et al., 2016). The following interview excerpt illustrates the multi-class multi-label characteristics of the problem:

1. *If I have a flush toilet in my house I can be a king of all kings because I can't go out on those squatting latrines* [Reputation][Aspiration]
2. *And recently I was almost rapped* (sic.) *when I escorted my son to the latrine* [Security]
3. *That [...] we have so many cases in our village of kids that fall into pit latrine* [Safety][Caring]

Further challenges for NLP are introduced by the frequent use of non-standard grammar and poor sentence structuring, which often occur in oral production (Cole et al., 1995). Moreover, manual transcription of interviews may lead to spelling errors, thus increasing OOVs. This is illustrated in the below excerpts (spelling errors are underlined):

- *Also men like phone there are so jealous for their women for example like in the morning my husband called me and asked that are you in church; so that's why they picked a phone.*

---

[7] Note that translating into English (or other languages commonly spoken in international workplaces, `https://www.un.org/en/sections/about-un/official-languages/`) is often a crucial step when applying knowledge to practical application in SD, in this case project decision-making (Bergström et al., 2012).

[8] A team of researchers from the Department of Engineering for Sustainable Development, supported by researchers in Development Studies and Linguistics, all at the University of Cambridge.

5 User-Perceived Values Classification

As outlined above, given an input interview, the task consists in annotating each sentence with the appropriate UPV(s). The extreme multi-class multi-label quality of the task (Section 4.2) makes it impractical to tackle as a standard *multi-class classification* problem—where, given an input sample x, a system is trained to predict its label from a tagset $T = \{l_1, l_2, l_3\}$ as $x \rightarrow l_2$ (i.e. [0,1,0]). Instead, we model the task as a *binary classification* problem: given x, the system learns to predict its *relatedness* with each one of the possible labels, i.e. $(x, l_1) \rightarrow 0$, $(x, l_2) \rightarrow 1$ and $(x, l_3) \rightarrow 0$ [9].

We consider the samples from the S2I corpus as *positive instances*. Then, we generate three kinds of *negative instances* by pairing the sample text with random labels. To illustrate, consider the three T2 classes *Convenience*, *Identity* and *Status*, which contain the following T3 values:

- $\textit{Contentment}_{T2} = \{\textit{Aesthetic}_{T3}, \textit{Comfort}_{T3}, ...\}$
- $\textit{Identity}_{T2} = \{\textit{Appearance}_{T3}, \textit{Dignity}_{T3} ...\}$
- $\textit{Status}_{T2} = \{\textit{Aspiration}_{T3}, \textit{Reputation}_{T3}, ...\}$

Moreover, $\textit{Contentment}_{T2} \in \textit{Emotional}_{T1}$ and $\{\textit{Identity}_{T2}, \textit{Status}_{T2}\} \in \textit{SocialSignificance}_{T1}$. Given a sample x and its gold label $\textit{Aspiration}_{T3}$, we can generate the following training samples:

- $(x, \textit{Aspiration}_{T3})$ is a *positive sample*;
- $(x, \textit{Reputation}_{T3})$ is a *mildly negative sample*, as x is linked with a wrong T3 with the same T2;
- $(x, \textit{Dignity}_{T3})$ is *negative sample*, as x is a associated with a wrong T3 from a different T2 class, but both T2 classes belong to the same T1; and
- $(x, \textit{Aesthetic}_{T3})$ is a *strictly negative sample*, as x is associated with a wrong label from the another T2 class in a different T1.

In this way, during training the system is exposed to positive (real) samples and negative (randomly generated) samples.

A UPV classification system should satisfy the following desiderata: (1) it should be relatively light, given that it will be used in the context of developing countries, which may suffer from access bias[10] and (2) the goal of such a system isn't to completely replace the work of human SD experts, but rather to reduce the time needed for interview annotation. In this context, false positives are quick to notice and delete, while false negatives are more difficult to spot and correct. Moreover, when assessing a community's needs and values, missing a relevant UPV is worse than including one which wasn't originally present. For these reasons, recall is particularly important for a UPV classifier.

In the next Section, we provide a set of strong baselines for future reference.

5.1 Neural Models for UPV Classification

5.1.1 Baseline Architecture

Embedding Layer. The system receives an input sample $(x, T3)$, where x is the sample text $(e_1, ..., e_n)$, $T3$ is the T3 label as the sequence of its tokens $(e_1, ..., e_m)$, and e_i is the word embed-

---

[9] Note that this is different to the classic *binary relevance* method, where a *separated* binary classifier is learned for each considered label (Read et al., 2011).

[10] With *access bias* we refer to contexts with limited computational capacity and cloud services accessibility.

ding representation of a token at position i. We obtain a T3 embedding e_{T3} for each T3 label using a max pool operation over its word embeddings: given the short length of T3 codes, this proved to work well and it is similar to findings in relation extraction and targeted sentiment analysis (Tang et al., 2016). We replicate e_{T3} n times and concatenate it to the text's word embeddings x (Figure 4).

Encoding Layer. We obtain a hidden representation $\vec{h}_{text}$ with a forward LSTM (Gers et al., 1999) over the concatenated input. We then apply attention to capture the key parts of the input text w.r.t. the given T3. In detail, given the output matrix of the LSTM layer $H = [h_1, ..., h_n]$, we produce a hidden representation h_{text} as follows:

$$M = tanh(\begin{bmatrix} W_h H \\ W_v e_{upv} \otimes e_N \end{bmatrix})$$

$$\alpha_{text} = softmax(w^T M)$$

$$h_{text} = H\alpha^T$$

This is similar in principle to the attention-based LSTM by Wang et al. (2016), and proved to work better than classic attention over H on our data.

Decoding Layer. We predict $\hat{y} \in [0, 1]$ with a dense layer followed by a sigmoidal activation.

5.1.2 Including Description Information

Each T3 comes with a short description, which was written by domain experts and used during manual labelling (the complete list is in the Appendix A). We integrate information from such descriptions into our model as follows: given the ordered word embeddings from the UPV description $(e_1, ..., e_d)$, we obtain a description representation h_{descr} following the same steps as for the sample text.

In line with previous studies on siamese networks (Yan et al., 2018), we observe better results when sharing the weights between the two LSTMs. We keep two separated attention layers for sample texts and descriptions. We concatenate h_{text} and h_{descr} and feed the obtained vector to the output layer.

5.1.3 Multi-task Training

A clear hierarchy exists between T3, T2 and T1 values (Section 3). We integrate such information using multi-task learning (Caruana, 1997; Ruder, 2017). Given an input sample, we predict its relatedness not only w.r.t. a T3 label, but also with its corresponding T2 and T1 labels[11]. In practice, given the hidden representation $h = h_{text} \oplus h_{descr}$, we first feed it into a dense layer $dense_{T1}$ to obtain h_{T1}, and predict $\hat{y}_{T1}$ with a sigmoidal function. We then concatenate h_{T1} with the previously obtained h, and we predict $\hat{y}_{T2}$ with a T2-specific dense layer $\sigma(dense_{T2}(h \oplus h_{T1}))$. Finally, $\hat{y}_{T3}$ is predicted as $\sigma(dense_{T3}(h \oplus h_{T2}))$.

	text	+att	+descr	+att+descr
P	77.5	78.1	**80.4**	78.9
R	65.5	**71.0**	66.5	70.6
F_1	71.0	74.2	72.8	**74.4**

Table 1: Results of ablation study (single-task).

In this way, the prediction $\hat{y}_i$ is based on both the original h and the hidden representation computed in the previous stage of the hierarchy, h_{i-1} (Figure 4).

6 Experiments and Discussion

6.1 Experimental Setting

6.1.1 Data Preparation

For each positive sample, we generate 40 negative samples (we found empirically that this was the best performing ratio, see Appendix C).

Moreover, to expose the system to more diverse input, we slightly deform the sample's text when generating negative samples. Following Wei and Zou (2019), we implement 4 operations: random deletion, swap, insertion, and semantically-motivated substitution. We also implement character swapping to increase the system's robustness to spelling errors (Figure 5).

We consider only samples belonging to UPV labels with a support higher than 30 in the S2I corpus, thus rejecting 12 very rare UPVs. We select a random 80% proportion from the data as training set; out of the remaining 980 samples, we randomly select 450 as dev and use the rest as test set.

6.1.2 Training Setting

In order to allow for robust handling of OOVs, typos and spelling errors in the data, we use FastText subword-informed pretrained vectors (Bojanowski et al., 2017) to initialise the word embedding matrix. We train using binary cross-entropy loss, with early stopping monitoring the development set loss with a patience of 5. Sample weighting was used to account for the different error seriousness (1 for *negative* and *strictly neg* and 0.5 for *mildly neg*).

---

[11] The mapping between sample and correct labels [T3, T2, T1] is as follows: *positive*: [1, 1, 1]; *slightly negative*: [0, 1, 1]; *negative*: [0, 0, 1]; *strictly negative*: [0, 0, 0].

		Multi-task train setting		
Label		T3	T2+T3	T1+T2+T3
T3	P	78.9	**83.5**	79.5
	R	70.6	67.0	**72.0**
	F_1	74.4	74.4	**75.4**
T2	P	–	**92.0**	84.9
	R	–	40.5	**62.3**
	F_1	–	56.2	**71.9**
T1	P	–	–	89.8
	R	–	–	70.1
	F_1	–	–	78.7

Table 2: Results considering all granularities and all (multi-)task training settings (T3, T2+T3, T1+T2+T3).

Network hyperparameters are reported in Appendix C for replication.

6.2 Results and Discussion

6.2.1 Models Performance

During experiments, we monitor precision, recall and F_1 score. For evaluation, we consider a test set where negative samples appear *in the same proportion* as in the train set (1/40 positive/negative ratio). The results of our experiments are reported in Table 1. Notably, adding attention and integrating signal from descriptions to the base system lead to significant improvements in performance.

6.2.2 Multi-task Training

We consider the best performing model and run experiments with the three considered multi-task train settings (Section 5.1.3). We consider 3 layers of performance, corresponding to T3, T2 and T1 labels. This is useful because, in the application context, different levels of granularity can be monitored. As shown in Table 2, we observe relevant improvements in F1 scores when jointly learning more than one training objective. This holds true not only for T3 classification, but also for T2 classification when training with the T3+T2+T1 setting. This seems to indicate that the signal encoded in the additional training objectives indirectly conveys information about the label hierarchy which is indeed useful for classification.

6.2.3 Real-World Simulation and Error Analysis

To simulate a real scenario where we annotate a new interview with the corresponding UPVs, we perform further experiments on the test set by generating, for each sample, *all possible* negative samples. We annotate using the T1+T2+T3 model, finetuning the threshold for each UPV on the development set, and perform a detailed error analysis of the results on the test set.

Table 3: Single label results in the *Real-World Simulation* setting, with label support in S2I corpus.

As reported in Table 3, we observe a significant drop in precision, which confirms the extreme difficulty of the task in a real-world setting due to the extreme data imbalancy. Note, however, that recall remains relatively stable over changes in evaluation settings. This is particularly important for a system which is meant to enhance the annotators' speed, rather than to completely replace human experts: in this context, missing labels are more time consuming to recover than correcting false positives.

Not surprisingly, particularly good performance is often obtained on T3 labels which tend to correlate with specific terms (as *School Fees*, or *Faith*). In particular, we observe a correlation between a T3 label's support in the corpus and the system's precision in predicting that label: with very few exceptions, all labels where the system obtained a precision lower than 30 had a support similar or lower than 3%.

The analysis of the ROC curves shows that, overall, satisfactory results are obtained for all T1 labels considered (Appendix D), leaving, however, considerable room for future research.

7 Conclusions and Future Work

In this study, we provided a first stepping stone towards future research at the intersection of NLP and Sustainable Development (SD). As a case study, we investigated the opportunity of NLP to enhancing project sustainability through improved community profiling by providing a cost effective way towards structuring qualitative data.

This research is in line with a general call for AI towards social good, where the potential positive impact of NLP is notably missing. In this context, we proposed the new challenging task of *Automatic User-Perceived Values Classification*: we provided the task definition, an annotated dataset (the *Stories2Insights* corpus) and a set of light (in terms of overall number of parameters) neural baselines for future reference.

Future work will investigate ways to improve performance (and especially precision scores) on our data, in particular on low-support labels. Possible research direction could include more sophisticated thresholding selection techniques (Fan and Lin, 2007; Read et al., 2011) to replace the simple threshold finetuning which is currently used for simplicity. While deeper and computationally heavier models as Devlin et al. (2019) could possibly obtain notable gains in performance on our data, it is the responsibility of the NLP community – especially with regards to social good applications – to provide solutions which don't penalise countries suffering from access biases (as contexts with low access to computational power), as it is the case of many developing countries.

We hope our work will spark interest and open a constructive dialogue between the fields of NLP and SD, and result in new interesting applications.

Acknowledgments

We thank the anonymous reviewers for their effort in reviewing this paper, their constructive feedback and suggestions. We are grateful to Dr. Nigel Collier (University of Cambridge) for providing valuable feedback on early versions of this paper. We also thank Simon Anthony Patterson for helping to define the UPV hierarchy. Data collection was funded by QUALCOMM European Research Studentships in Technology (Grant No. 1068) and the Engineering and Physical Sciences Research Council (EPSRC) (Grant No. EP/K503009/1). Finally, we are particularly grateful to Rural Senses for helping to define this research and guide us along.

Appendix A – Definitions of User-Perceived Values

Emotional	**Conscience**	
	Preservation of Environment	Preservation of natural resources
	Harmony	Being at peace with one another
	Contentment	
	Appealing Senses	Being pleasing to the senses taste and smell
	Aesthetics Items	Physical appearance of item or person which is pleasing to look at
	Comfort	State of being content, having a positive feeling
	Entertainment	Something affording pleasure, diversion or amusement
	Memorability	Association to a past event with emotional significance
	Human Welfare	
	Safety (Animals Items Nature)	Being protected from or prevent injuries or accidents by animals or nature
	Security People	Being free from danger and threat posed by people
Epistemic	**Information**	
	Information Access	Ability to stay informed
	Knowledge	
	Knowledge attainment	The ability to learn or being taught new knowledge
Function	**Convenience**	
	Banking Access	Having continuous access to banking services
	Communication	Ability to interact with someone who is far
	Mobile Phone Access	Having continuous access to mobile telecommunication services
	Mobility	Being able to transport goods, or to carry people from one place to another
	Multipurpose	Able to be used for a multitude of purposes
	Portable	An item that can easily be carried, transported or conveyed by hand
	Availability	Possible to get, buy or find in the area
	Time Benefit	Accomplish something with the least waste of time or minimum expenditure of time
	Time Management	Being able to work or plan towards a schedule
	Unburden	Making a task easier by simplifying
	Cost Economy	
	Capital Expenditure	Cost savings achieved
	School Fees	Ability to pay for school fee
	Income Economy	
	Economic Opportunity	Obtaining cash, assets, income through one-off sales or ongoing business opportunities
	Barter Trade	Non-monetary trade of goods or services
	Quality and Performance	
	Effectiveness	Adequate to accomplish a purpose or producing the result
	Lastingness	Continuing or enduring a long time
	Productivity	Rate of output and means that lead to increased productivity
	Reliability	The ability to rely or depend on operation or function of an item or service
	Usability	Refers to physical interaction with item being easy to operate handle or look after
Indigenous	**Social Norm**	
	Celebration	Association chosen as they play important part during celebration
	Manners	Ways of behaving with reference to polite standards and social components
	Morality	Following rules and the conduct
	Tradition	Expected form of behaviour embedded into the specific culture of city or village
	Religion	
	Faith	Belief in god or in the doctrines or teachings of religion
Intrinsic Human	**Health**	
	Longevity	Means that lead to an extended life span
	Health Care Access	Being able to access medical services or medicine
	Treatment	To require a hospital or medical attention as a consequence of illness or injury
	Preserv. of Health	Practices performed for the preservation of health
	Physiological	
	Education Access	Being able to access educational services
	Energy Access	Being able to obtain energy services or resources
	Food Security	The ability to have a reliable and continuous supply of food
	Shelter	A place giving protection from bad weather or danger
	Water Access	Continuous access or availability of water
	Water Quality	To have clean water as sickness, colour and taste
	Quality of Life	
	Wellbeing	Obtaining good or satisfying living condition (for people or for the community)
Significance	**Identity**	
	Appearance	Act or fact of appearing as to the eye or mind of the public
	Belongingness	Association with a certain group, their values and interests
	Dignity	The State or quality of being worthy of honour or respect
	Personal Performance	The productivity to which someone executes or accomplishes work
	Status	

Social	Aspiration	Desire or aim to become someone better or more powerful or wise
	Modernisation	Transition to a modern society away from a traditional society
	Reputation	Commonly held opinion about ones character
	Social Interaction	
	Altruism	The principle and practice of unselfish concern
	Family Caring	Displaying kindness and concern for family members
	Role Fulfilling	Duty to fulfilling tasks or responsibilities associated with a certain role
	Togetherness	Warm fellowship, as among friends or members of a family

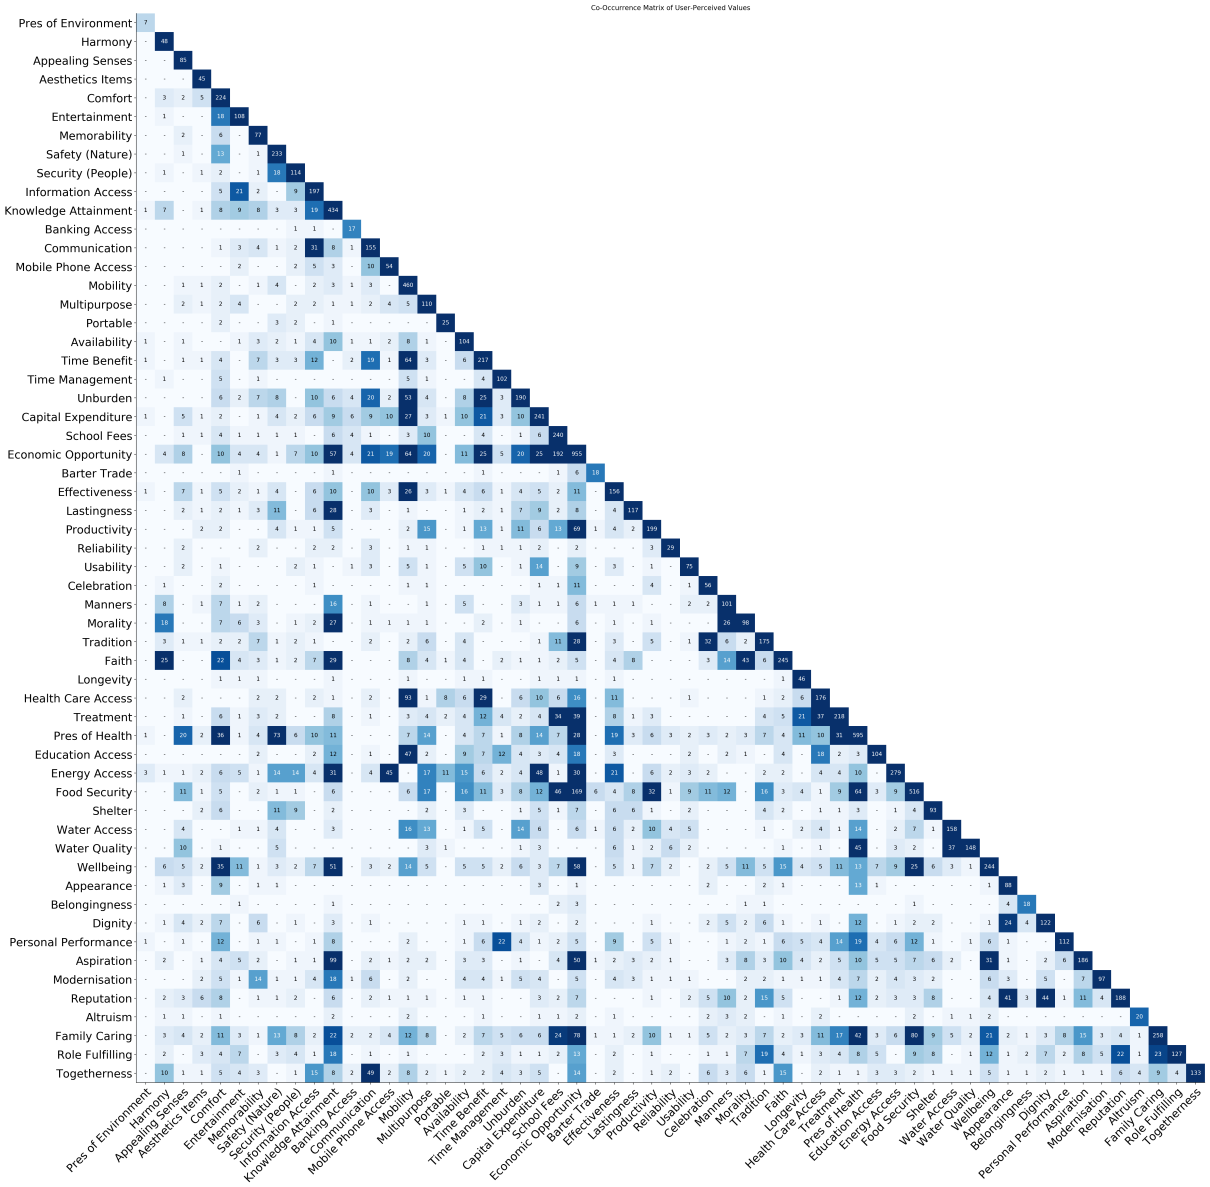

Figure 6: Co-occurrence matrix of T3 labels in the S2I corpus.

Appendix B – Co-occurrence matrix of User-Perceived Values in the S2I corpus.

The co-occurrence matrix in Figure 6 depicts the inter-relatedness between different T3 labels. The intensity of colour corresponds to the number of samples in the S2I corpus where the given T3 labels co-occur.

The analysis of labels co-occurrence can offer valuable insights on commonly associated User-Perceived Values (UPVs, (Hirmer and Guthrie, 2014)): this can be useful to highlight challenges and problems in the considered community, which might not be known to the dwellers themselves. While some correlations are typical and expected, others are related to the specific Ugandan context, and might be surprising to those external to the location.

For example, *Economic Opportunity*, *Food Security* and *Preservation of Health* appear to frequently co-occur with other T3 labels. Note that the lack of employment opportunity, the availability of food and the quality of healthcare services represent endemic problems in the rural context studied in this paper. As they constitute primary concerns for most interviewees, it is therefore unsurprising that they were mentioned frequently in relation to many of the items selected as part of the UPV game (Section 4). A further illustrative example of the cultural context - in this case rural Uganda - is the high concurrence of *Unburden* and *Mobility*. This can be explained by the fact that rural roads are often of poor quality and villages or areas are inaccessible by motorised vehicles. Henceforth, people are required to find alternatives moves of transport for moving themselves to hospital or crops to the nearest market for sell, for example. As a final example, the frequent mentioning of *Faith*, *Harmony* and *Morality*, which also tend to co-occur in similar contexts, testifies the fundamental role played by religion in the rural villages considered in this study.

The information on the (co-)occurrence of UPVs in a community is also particularly valuable for designing appropriate project communication (Figure 1b), which can increase project buy-in through focused messaging (Section 3).

Appendix C – Experimental Specifications.

In this Appendix, we report on the exact experimental setting used for experiments to aid experiment reproducibility.

C.1 Data Specifications

Data Selection and Splitting. We select all sentences from the 119 interviews which were at least 3 tokens long and which were annotated with at least one UPV. We then randomly select an 80% proportion of the data as training set, and take the rest as heldout data (with a dev/test split of respectively 450 and 530 samples). Figure 7 shows that the obtained label distribution is similar.

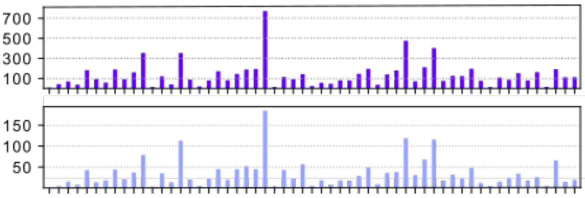

Figure 7: From top to bottom: distribution of UPVs in the training and heldout (dev+test) sets. Labels in the x axis follow the same order as in Figure 3 of the main document.

Data Anonymization. In order to prevent the identification of the interviewees (Sweeney, 2000), data was manually anonymized. We anonymized all occurrences of: proper names, names of villages, cities or other geographical elements, and other names that might be sensitive (as names of tribes, languages, ...).

Data Sample. We are providing a sample of the data in the supplementary material. Each data sample is associated with the following fields:

- *id*: a unique identifier of the sample;
- *text*: a sentence to be classified;
- *t3_labels*: a list of the gold T3 labels associated with the sample.

For privacy reasons, we are not releasing metadata information associated with the samples (as the interviewee's name, gender, age, or the exact village name).

Data Preprocessing. For sentence splitting and word tokenization, we used NLTK's `sent_tokenize` and `word_tokenize` tokenizers (Bird and Loper, 2004)[12]. We use a set of regex to find interviewer comments and questions. Given that *Why-Probing* (Section 4.1, Reynolds and Gutman (2001)) was used, interviewers' comments are very limited and standard.

Negative Samples Generation. To generate negative samples (Section 6.1), we slightly modify Wei and Zou (2019)'s implementation[13] EDA (Easy Data Augmentation techniques) by adding a new function for character swapping and by adapting the stopword list. For semantic-based replacement, we rely on NLTK's interface[14] to WordNet (Fellbaum, 2012). Random shuffling and choice are controlled by a seed.

C.2 Further Specifications

(Hyper)-Parameters Selection. All parameters used for experiments are reported in Table 4.

parameter	value	parameter	value
mildly neg s. ratio	5	embedding size	300
neg sample ratio	11	LSTM hid. size	128
strictly neg s. ratio	24	dropout (all l.)	0.2
max sample len	25	batch size	32
max descr len	15	no epochs	70
max UPV code len	4	optimizer	*Adam*

Table 4: Adopted (hyper-)parameters.

We use 300-dimensional FastText subword-informed pretrained vectors (Bojanowski et al.,

---

[12] https://www.nltk.org/api/nltk.tokenize.html

[13] https://github.com/jasonwei20/eda_nlp/blob/d75e8bd4631f4d93260cb291aa47852d8eacd51d/code/eda.py#L65

[14] https://www.nltk.org/_modules/nltk/corpus/reader/wordnet.html

2017)[15] to get the word embedding representations for each input sample.

Note that the goal of this paper is to present a new interesting NLP application, namely NLP for Sustainable Development: therefore, our goal here is to provide a set of robust baselines on our new S2I dataset, which can be referenced for future research. For this reason, we don't perform extensive hyper-parameter tuning on the selected models.

The only parameters we optimize are the number of generated negative samples of each type (*mildly negative, negative* and *strictly negative*). The best ratios were found empirically through experiments. The ratio used for optimization are reported in Table 5.

total	mildly negative	negative	strictly negative
0	0	0	0
5	1	2	2
10	2	2	6
15	3	4	8
20	4	7	9
25	5	8	12
30	5	11	14
35	5	11	19
40	**5**	**11**	**24**
45	5	10	30
50	5	12	33
55	5	13	37
60	5	14	41

Table 5: Details of the relative number of *mildly negative, negative* and *strictly negative* samples used for experiments. Best ratio (used in all reported experiments) is in bold.

The analysis of the performance progression over training (Figure 8) shows that, in line with Wei and Zou (2019), adding negative examples is useful to improve performance: in our case, the plateau is reached around 40 augmented samples. In particular, we observe gains in all considered output levels (T1, T2 and T3 labels).

Number of Parameters and Runtime Specifications. Table 6 reports on the total number of (trainable) parameters and the average runtime/step for each considered model. Embeddings are kept fixed over training to avoid overfitting.

Computing Infrastructure. We run experiments on an NVIDIA GeForce GTX 1080 GPU.

Evaluation Specifications. For computing the evaluation metrics, we use the sklearn's (Pedregosa et al., 2011) implementation of precision, recall and F_1 score[16].

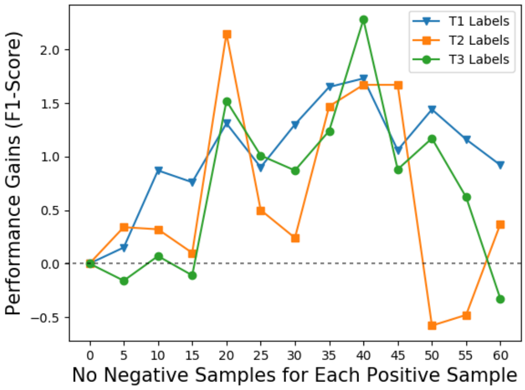

Figure 8: Progression of performance gains in F1-Score, considering the three labels T1, T2 and T3.

(Multi-)task Setting	Model	#pars	avg runtime/ step
T3	text	373,377	55s
	+att	590,013	56s
	+descr	373,505	74s
	+att+descr	806,777	75s
T2T3	+att+descr	844,154	78s
T1T2T3	+att+descr	865,019	85s

Table 6: Number of trainable parameters and average runtime/step for all considered models and (multitask) training settings.

---

[15] We chose the `wiki.en.zip` model pretrained on the English Wikipedia `https://fasttext.cc/docs/en/pretrained-vectors.html`

[16] `https://scikit-learn.org/stable/modules/classes.html#module-sklearn.metrics`

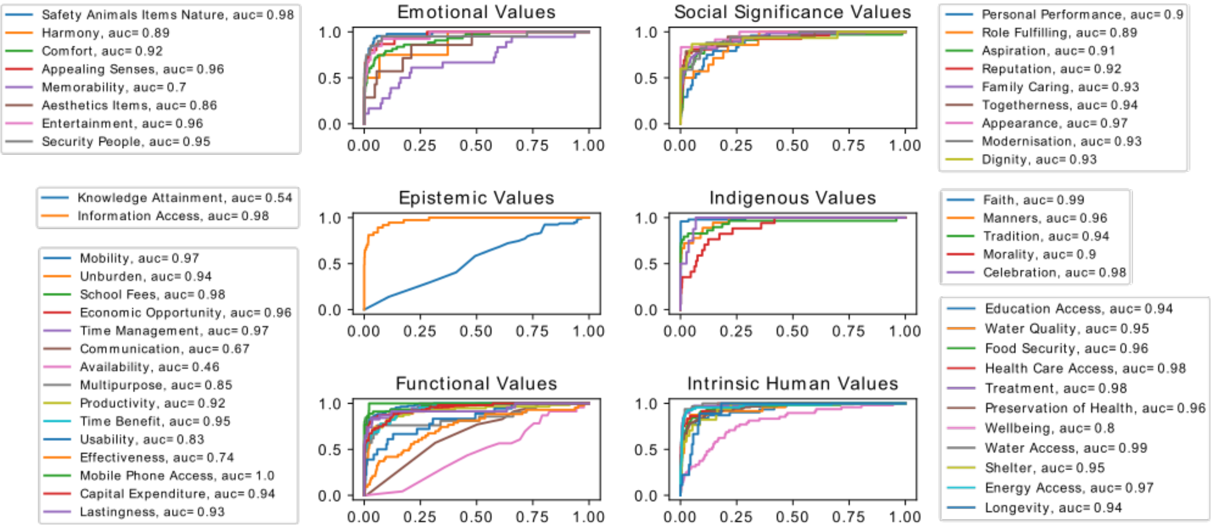

Figure 9: ROC curves for each T3 label, grouped by T1 categories.

Appendix D – Single-Label Performance.

In this Appendix, we report the ROC curves for each T3 label, grouped by T1 categories. Figure 9 reports results obtained with the best performing model (Base+Attention+Description) trained with the T1+T2+T3 multi-task framework.

We evaluate with the "real-world" evaluation setting (Section 6.1), that is, we generate *all* positive and negative instances for each training sample. In practice, for a test sample x associated with the T3 labels $T3_2$ and $T3_{45}$, we would generate 50 test instances $\{(x, T3_1) \rightarrow 0, (x, T3_1) \rightarrow 0, (x, T3_2) \rightarrow 1, ..., (x, T3_{50}) \rightarrow 0\}$, one for each of the T3 considered during training. All generated test samples would be negative, with the exception of $(x, T3_2)$ and $(x, T3_{45})$.

The single T3 labels' AUC show that satisfactory results are obtained overall for all T1 macro-labels: in particular, we obtain an AUC $>=$ 70 for 47 out of 50 labels. Despite these promising results, our best model still struggles with some T3 labels, notably *Knowledge Attainment*, *Availability* and *Communication*. While the paper leaves ample room for future research, preliminary results are encouraging.

Refer to Section 6.2 for further details.

To Schedule or not to Schedule: Extracting Task Specific Temporal Entities and Associated Negation Constraints

Barun Patra, Pamela Bhattacharya, Chala Fufa, Charles Lee
Microsoft
{bapatra, pamelabh, chfufa, charlle}@microsoft.com

Abstract

State of the art research for date-time[1] entity extraction from text is task agnostic. Consequently, while the methods proposed in literature perform well for generic date-time extraction from texts, they don't fare as well on task specific date-time entity extraction where only a subset of the date-time entities present in the text are pertinent to solving the task. Furthermore, some tasks require identifying negation constraints associated with the date-time entities to correctly reason over time. We showcase a novel model for extracting task-specific date-time entities along with their negation constraints. We show the efficacy of our method on the task of date-time understanding in the context of scheduling meetings for an email-based digital AI scheduling assistant. Our method achieves an absolute gain of 19% f-score points compared to baseline methods in detecting the date-time entities relevant to scheduling meetings and a 4% improvement over baseline methods for detecting negation constraints over date-time entities.

1 Introduction

Temporal entity extraction and normalization is an important aspect of Natural Language Processing (Alonso et al., 2011; Campos et al., 2014). There has been a substantial body of work on the task and there exist numerous well performing publicly available models for identifying and normalizing temporal entities (Strötgen and Gertz, 2010; Chang and Manning, 2012; Zhong and Cambria, 2018).

There exist however a growing number of NLP applications which require extraction of only a relevant subset of time entities that are useful for solving specific problems within a larger body of text. Examples of such tasks include understanding search queries ("Find me all emails sent by April between May 11^{th} and May 21^{st}"), Goal Oriented Dialogue Systems ("Deliver George Orwell's 1984 by next week.", "Send the "FY 2020 Budget" to Watson Monday morning.") etc. Using the temporal entity extraction models for these tasks is insufficient, since they fail to disambiguate between general date-time entities and entities necessary to solve the task.

In this paper, we address the task of recognizing date-time entities required by an AI scheduling assistant for correctly scheduling meetings. Cortana from Microsoft Scheduler, Clara from Clara Labs and Amy from X.ai are examples of such email based digital assistants for scheduling meetings. For such systems, a user organizing the meeting adds the digital assistant as a recipient in an email with other attendees and delegates the task of scheduling to the digital assistant in natural language. For the assistant to correctly schedule the meeting, it must correctly extract the date-time entities expressed by the user in the email to indicate the times they want the meeting scheduled, as well as the times that do not work for them. The verbose nature of emails often exacerbates the difficulty of identifying relevant date-time entities; since the number of distractor (i.e valid date-time entities not pertinent to the task) tend to increase (Eg: In Fig. 1 "today" serves as a distractor entity).

To this end, we present SHERLOCK: **S**c**H**eduling **E**ntity **R**ecovery by **LO**oking at **C**ontextual **K**nowledge, a novel model for detecting relevant date-time entities in the context of scheduling as well as identifying the entities associated with a negation constraint. SHERLOCK comprises of 3 modules for identifying the relevant entities as well as negation constraints associated with them:

---

[1] We use date-time entities, date entities, time entities and temporal entities interchangeably to denote entities associated with dates and/ or times.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8445–8455,
November 16–20, 2020.

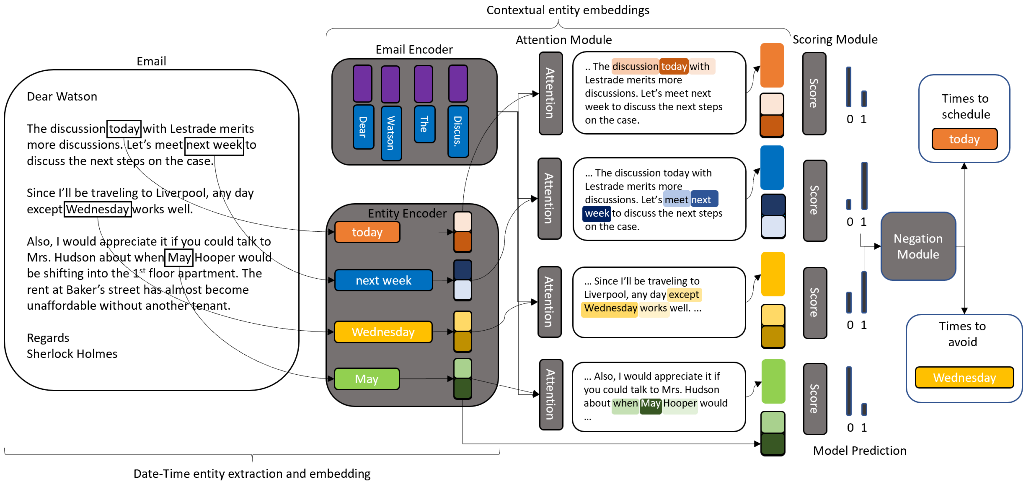

Figure 1: The 3 modules of SHERLOCK: First a high recall rule based extractor generates the potential entities. The neural module then takes the email and the entities and generates scores for each entity. Only the relevant entities are passed to the final negation module to detect times to schedule and times to avoid.

Date-Time Extractor: A high recall date-time entity extractor to identify all date-time entities in an email

Entity Relevance Scorer: A neural model to classify each of the extracted entities as being relevant to scheduling or not by considering the context presented in the email.

Negation Detector: A negation module to identify if there exists a negation constraint associated with each of the extracted relevant entities.

Fig. 1 illustrates each module: the entity extractor extracts “today”, “next week”, “Wednesday” and “May”. Each of these entities is scored by the neural module, and only “next week” and “Wednesday” are identified as being relevant to scheduling. Finally, the negation module identifies that “Wednesday” has a negation constraint. While SHERLOCK focuses on the task of scheduling, we believe that a similar approach can be used to tackle the problem of extracting relevant date-time entities from documents for other tasks.

The contributions of this paper are as follows:

Task specific date-time extractor: A novel method for combining conventional high recall rule-based model with a novel neural model for incorporating contextual information to identify relevant date-time entities for the task at hand.

Identifying negation constraints for temporal entities: A heuristic negation module that helps identify negation constraints associated with time entities in the context of scheduling meetings. To the best of our knowledge, prior to this work, negation constraints associated with time-entity extraction have not been studied before.

We first present our proposed method for extracting time entities relevant to the task of scheduling a meeting in (§2). Next, we describe our approach for identifying negation constraints associated with extracted entities in (§3). In (§4), we describe our experimental setup and baselines. We discuss the results in (§5) and show that SHERLOCK helps improve performance both on the task of identifying relevant entities as well as identifying negation constraints. We then present the related work in (§6), and finally conclude in (§7).

2 Contextual Date-Time Extraction

In order to correctly extract relevant temporal entities in the context of scheduling meetings from an email, we first extract potential entities using an off-the-shelf date-time entity extractor. Both the email and the extracted entities are then encoded using neural modules. For each extracted entity, we then generate a context embedding using the encoded email and the encoded entity. Both the contextual and encoded entity embedding are then used to predict if an entity is relevant or not. We describe each component in detail below:

2.1 Entity Extraction and Encoding

Given an email $\boldsymbol{X} = \{w_1 \cdots w_n\}$, we first use a rule-based tagger for extracting potential date-time entities from an email. Specifically, we use LUIS[2] (Williams et al., 2015) for extracting the entities. The model is recall heavy and identifies potential time utterances (Eg: in Figure 1, LUIS detects “today”, “next week”, “wednesday”, “may”). We denote the extracted entities as $\mathcal{E} = \{e_1 \cdots e_m\}$, where $e_i = \{e_{i,1} \cdots e_{i,l_i}\}$ represents the i^{th} entity and l_i denotes the length of e_i.

For each entity e_i, we generate an embedding $u_{e_i} \in \mathbb{R}^{d_e}$ (where d_e denotes the entity embedding dimension) as follows:

$$\begin{aligned} t_{i,j} &= \texttt{LookUp}(e_{i,j}) \\ r_{i,j} &= \texttt{CharEncoder}(e_{i,j}) \\ h_{i,j} &= [r_{i,j}; t_{i,j}] \\ u_{e_i} &= \texttt{Seq2SeqEncoder}(h_{i,1} \cdots h_{i,l_i}) \end{aligned} \tag{1}$$

In Equation (1), $t_{i,j}$ denotes the word level embedding of the j^{th} word if the i^{th} entity ($e_{i,j}$). As is standard practice, OOV words all share a common word embedding, while other entities encountered during training are represented by a learnt vector. We also augment this with an embedding from a character level encoder. $r_{i,j}$ denotes the word level embedding obtained by passing $e_{i,j}$[3] through a character level encoder, which allows the model to represent OOV entities. The two embeddings are concatenated, and then passed through another `Seq2SeqEncoder` model (any Sequence-to-Sequence encoder (Sutskever et al., 2014)) to get the final entity encoding u_{e_i}[4].

2.2 Contextual Entity Embeddings

From Figure 1, we can observe that it is clear from context that “May” is not a time entity, and “today” is not an entity relevant to scheduling. We want to capture this contextual information for each entity. To do so, we first encode the email as follows:

$$(v_{w_1} \cdots v_{w_n}) = \texttt{Seq2SeqEncoder}(w_1 \cdots w_n) \tag{2}$$

In Equation (2), v_{w_i} denotes the embedding for the i^{th} word of the email $\boldsymbol{X}$. d_w here denotes the embedding size for the email embedding.

Once we have the email embeddings, we then compute the contextual embedding for each entity using an attention mechanism (Bahdanau et al., 2014). For entity e_i, given the entity embedding u_{e_i}, and the email embeddings $(v_{w_1} \cdots w_{w_n}), v_{w_i} \in \mathbb{R}^{d_w}$, the contextual embedding $c_{e_i} \in \mathbb{R}^{d_w}$ is obtained as follows:

$$\begin{aligned} a_{w_j} &= Av_{w_j} + b \\ b_{w_j} &= \texttt{tanh}(a_{w_j} + u_{e_i}) \\ logit_{w_j} &= Bb_{w_j} + d \\ \alpha w_j &= \texttt{softmax}(logit_{w_j}) \\ c_{e_i} &= \sum_{w' \in \{w_1 \cdots w_n\}} \alpha_{w'} v_{w'} \end{aligned} \tag{3}$$

Where $A \in \mathbb{R}^{d_e \times d_w}, b \in \mathbb{R}^{d_e}, B \in \mathbb{R}^{d_e \times 1}, d \in \mathbb{R}$ are learned parameters. The final entity embedding (f_{e_i}) is the concatenation of the entity embedding and the contextual embedding. Finally, for each entity, we generate a probability score to indicate if an entity is relevant or not.

$$\begin{aligned} f_{e_i} &= [u_{e_i}; c_{e_i}] \\ s_{e_i} &= \sigma(Mf_{e_i} + g) \end{aligned} \tag{4}$$

Where $M \in \mathbb{R}^{(d_e+d_w)\times 1}, g \in \mathbb{R}$ are learned parameters, and σ indicates the sigmoid function.

2.3 Learning

Given the entities that are relevant to scheduling $\mathcal{Y} \subseteq \mathcal{E}$ (Eg: “next week” and “Wednesday” in Figure 1), we train the model with a scoring loss as follows:

$$\mathcal{L}_s = -(\sum_{e \in \mathcal{Y}} \log(s_e) + \sum_{e \in \mathcal{E} \setminus \mathcal{Y}} \log(1 - s_e)) \tag{5}$$

Similar to (Ruder, 2017; Gehrmann et al., 2018; Li et al., 2018), we find that augmenting the learning with a related auxiliary task helps improve performance. In this case, a simple related auxiliary function is the task of sequence tagging. Specifically, given the email $\boldsymbol{X}$, and the relevant entities $\mathcal{Y}$, we tag the location of each entity with I-Time tag, and every other token with an O tag. Let the generated tags be $\boldsymbol{z} = (z_1 \cdots z_n)$ and let C denote the set of possible tagging labels (in our case 2: {I-Time, O}) We then train a standard CRF for

---

[2] `https://www.luis.ai/home`

[3] Technically the embeddings associated with characters of $e_{i,j}$ are passed to the character level encoder

[4] For a unidirectional encoder, the final hidden state is used as the embedding. The concatenation of the forward and backward hidden states is used for a bidirectional encoder

tagging as follows:

$$
\begin{aligned}
g_i &= Pv_i + q \\
\texttt{score}(\boldsymbol{X}, \boldsymbol{z}) &= \sum_{i=2}^{n} T_{z_i, z_{i-1}} + \sum_{i=1}^{n} g_{i, z_i} \\
p(\boldsymbol{z}|\boldsymbol{X}) &= \frac{e^{\texttt{score}(\boldsymbol{X}, \boldsymbol{z})}}{\sum_{\boldsymbol{z}' \in \mathcal{Z}} e^{\texttt{score}(\boldsymbol{X}, \boldsymbol{z}')}} \\
\mathcal{L}_t &= -(\texttt{score}(\boldsymbol{X}, \boldsymbol{z}) - \\
&\quad \log(\sum_{\boldsymbol{z}' \in \mathcal{Z}} e^{\texttt{score}(\boldsymbol{X}, \boldsymbol{z}')}))
\end{aligned}
\tag{6}
$$

Where $P \in \mathbb{R}^{d_w \times |C|}, q \in \mathbb{R}^{|C|}$ are trainable parameters, $T \in \mathbb{R}^{|C| \times |C|}$ is the transition matrix and $\mathcal{Z}$ is the set of all possible sequence labels.

The final loss that we optimize for is

$$\mathcal{L}_{final} = \gamma \mathcal{L}_s + (1 - \gamma)\mathcal{L}_t \tag{7}$$

Where γ balances between the two loss functions.

2.4 Choosing the Prediction Threshold

In order to find the threshold for classifying the positive class (i.e t such that $e_i = 1$ if $s_{e_i} > t$), we compute the F1 score on the validation set using a grid of thresholds[5], and choose the threshold maximizing the F1 score.

3 Identifying Negation Constraints

For a Scheduling Assistant to be able to correctly schedule meetings, understanding negations is crucial; otherwise it can lead to an unsatisfactory user experience (E.g.: In Figure 1, the meeting being scheduled on Wednesday would be a frustrating experience for the organizer Sherlock). Only about 10% of scheduling requests in our dataset have negation constraints. Building a model directly for the task did not show promising results from our preliminary experiments. We hypothesize this was due to the small volume of the data as well as the lack of good quality supervised data. Consequently, to find negated time-entities, we adopt the approach of first finding the negation scope. If an entity occurs inside the negation scope, we mark it to be negated.

In order to find the negation scope, we build on the approach proposed in Rosenberg (2013). We first find the negation cue ("except" in Figure 1). To find the negation cue, we first tokenize the email into sentences. For each sentence, we try fo find if cue from a set of negating cues (Appendix A) occurs in the sentence.

After finding the negation cue, we identify the POS tag of the negating cue (Prep. for "except"). Given the POS tag and the negation cue, we trigger a set of heuristics to identify the negation scope. Most heuristics work by identifying the negation cue from the dependency parse of the sentence as well as the governor of the negating word. Generating the narrow scope of negation (i.e. not containing the subject) then involves identifying the constituent from the constituency parse that contains both the negation cue and the governor word ("any day except Wednesday", see Figure 2). This constituent is considered to be the candidate narrow scope, and usually, the part following the cue is considered to be the narrow scope.

For some cases, the narrow negation scope is not enough to identify the time entity being negated. Consider the second example from Figure 2:

Example: *Next week does not work Watson.*
Narrow: *Next week does not [work Watson].*
Wide: *[Next week] [does] not [work Watson].*

For this case, the narrow scope is not enough to identify the entity being negated ("next week"). To find the wide scope, the heuristics leveraging the dependency path starting from the governor word are used. The main idea is to find the subject associated with the governor node, and extract that as the wide scope ("Next week"). Following the guidelines set by Morante and Daelemans (2012), we also include the aux dependency node in the wide scope ("does").

We also expand the heuristic set presented in Rosenberg (2013), adding the following rules:

- If a Noun Phrase (NP) acting as an adverbial modifier acts as a subject to the governor, we include it in the wide scope (Figure 2)
- If a NP exists as a subject of a passive clause, we include it in the wide scope, as well as the passive auxiliary associated with it.
- A Prepositional Phrase (PP) acting as a subject to the governor is included in the wide scope.
- For the narrow scope, we prune out the subtree that exists as an object an adverbial clause relation (advcl) headed by the governor node.

Due to space constraints, we include examples for the above in Appendix B.

---

[5] We use the precision_recall_curve provided by sklearn (Buitinck et al., 2013)

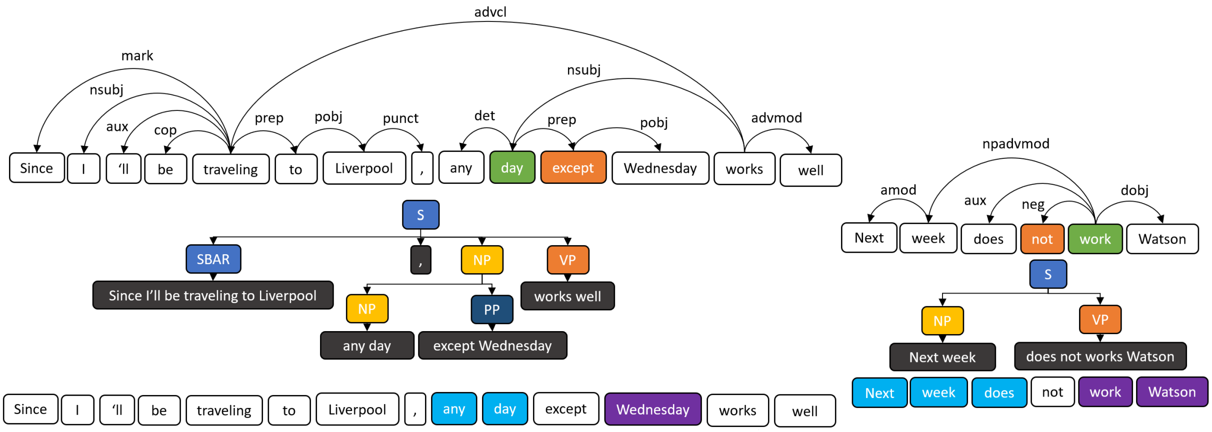

Figure 2: The negation extraction model. Orange indicates the negation cue, Green denotes the governing node. Purple denotes the narrow scope, and Light Blue denotes the wide scope.

After obtaining the narrow and wide scopes, we check if any entities are found in the narrow scope. If found, those entities are scored negated. If no entities are found in the narrow scope, we then check the wide scope to find negated entities.

Finally, for some cases, we also use domain specific cues that imply a non-availability (For example, in "Dr. John out of office on Monday.", "out of office" implies an unavailability to meet.) When such implied negation cues are encountered, we default to a custom heuristic which marks any entity occurring within the sentence containing the cue word as a negation.

4 Experimental Setup

We first show the effectiveness of our proposed entity scoring method of incorporating context for improving temporal entity extraction on the TempEval-3 dataset (UzZaman et al., 2013) (§4.1). We then show the efficacy of SHERLOCK for the task of extracting the correct temporal entities relevant for the context of scheduling, a task for which context becomes substantially more important (§4.2). Finally, we show that SHERLOCK's negation module outperforms baseline methods on the task of identifying the entities with negation constraints (§4.3). All our models have been implemented using the AllenNLP framework (Gardner et al., 2017). The hyperparameters for all the experiments can be found in Appendix C and D.

4.1 TempEval-2013

4.1.1 Dataset

We use the TimeBank dataset (Pustejovsky et al., 2003) which serves as the benchmark dataset for the TempEval series. The dataset consists of 256 documents, comprising of 95,391 tokens and 1,822 TimeEx entities for training and validation purposes, and 20 documents (6,375 tokens, 138 TimeEx) for serving as the test set.

4.1.2 Baseline Models

We show the performance of augmenting 3 rule-based models with our proposed model. Specifically, we consider SUTime (Chang and Manning, 2012), HeidelTime (Strötgen and Gertz, 2010) and Syntime (Zhong et al., 2017) as the rule-based extractors. We also compare against UWTime (Lee et al., 2014), a learning based model.

4.1.3 Evaluation

We use the official TempEval-3 scoring script and report the standard metrics. Specifically, we report the detection precision, recall and F1 with the relaxed and strict metrics. A gold mention is considered for the relaxed metric if any of the output candidates overlap with it and for the strict case, an exact string match is considered.

4.2 Date-Time extraction for Scheduling

This task aims at extracting the date-time entities necessary for the Scheduling Agent to correctly schedule the meeting. The task necessarily needs the model to incorporate context for making the correct prediction (E.g.: In Figure 1, "today" is a valid date-time entity, but not relevant for scheduling, while "May" refers to a person.)

4.2.1 Dataset

We use an internal scheduling dataset for training and evaluating the models. The dataset consists of emails and annotated times to schedule. The training and validation set consists of 44,214 emails (4,589,631 tokens, and 48083 entities), while the test set consists of 4914 emails (519,021 tokens, 5233 entities).

4.2.2 Baseline Models

We compare the performance of our model against SUTime, HidelTime and LUIS. We use LUIS as our base date-time extractor since it provides a much larger coverage for date-time entities [6].

4.2.3 Evaluation

We use the Strict F1 measure to compare the performance of the different models proposed.

4.3 Negation Detection

Finally, we compare the performance of our proposed model on the task of negation extraction.

4.3.1 Dataset

We use an internal dataset for comparing different models on the task of negation extraction. The dataset consists of 1253 emails for which time-entities that are relevant to scheduling are selected, and those that are a part of a negation constraint are marked as negated entities. There exist 3231 time-entities, of which 1589 are negated entities.

4.3.2 Baselines

We compare our proposed method against a naive heuristic method as well as a neural model trained on a publicly available negation scope detection dataset.

Heuristic: A naive heuristic model. If a negation cue is identified in a sentence, the model predicts that all entities in that sentence are negated.

NegNN: We use a NegNN model (Fancellu et al., 2016), modified to use BERT contextual embeddings and trained on the *SEM2012 Shared task (Morante and Blanco, 2012). The training, development and test sets are a collection of stories from Conan Doyle's *Sherlock Holmes*, with the cue and scope annotated. An entity is considered negated if it is a part of a negated scope, as predicted by the model. The performance of the modified NegNN model on the *SEM2012 Task can be found in Appendix E.

4.3.3 Evaluation

We measure the performance of different models by comparing the predicted set of negated entities and the gold labels for the entities. If the model makes a mistake (i.e. it predicts an entity to be negated, when it's not), that's considered a false positive. Likewise, any negated entities missed by the model contribute to the false negatives. We thus report the precision, recall and F1 score.

5 Results and Analysis

5.1 TempEval-2013

Model	Strict			Relaxed		
	Pre.	Rec.	F1	Pre.	Rec.	F1
SUTime	80.0	81.2	80.6	90.0	91.3	90.7
SUTime(+)	85.9	79.7	82.7	93.6	87.0	90.2
HeidelTime	83.9	79.7	81.7	93.1	88.4	90.7
HeidelTime(+)	84.6	79.7	82.1	93.1	87.7	90.3
Syntime	91.4	92.7	92.1	94.3	95.7	95.0
Syntime(+)	92.7	92.0	92.4	94.9	94.2	94.6
UWTime	84.6	83.4	84.0	92.8	91.5	92.1

Table 1: Performance on TempEval Dataset. Models with (+) indicate that the base extractor is augmented with the entity scoring module (Scale: 0-100)

Table 1 shows the performance of SHERLOCK's entity scoring module on the TempEval-2013 dataset. Note that SHERLOCK is limited by the recall of the base rule-based extractor[7]. We observe that augmenting the rule-based model with SHERLOCK improves the precision for all three cases without a substantial drop in recall. Furthermore, the precision obtained for all the augmented models compares favorably with UWTime.

5.2 Date-Time extraction for Scheduling

Model	Precision	Recall	F1
LUIS	0.38	0.98	0.54
SUTime	0.59	0.79	0.68
HidelTime	0.66	0.86	0.75
SHERLOCK - $\mathcal{L}_t$	0.91	0.96	0.93
SHERLOCK	0.91	0.98	0.94

Table 2: Performance on Date-Time Extraction for Scheduling. SHERLOCK - $\mathcal{L}_t$ denotes the SHERLOCK model without the tagging loss (Scale: 0 - 1)

Table 2 shows the performance of SHERLOCK for the Scheduling related date-time extraction task.

---

[6] For example, LUIS recognizes military time ("1530"), and has a much larger coverage for holidays

[7] The model only scores the predictions of the base extractor

As can be seen, being able to incorporate context yields a substantial improvement over the baseline methods.

We also observed that incorporating the tagging loss $\mathcal{L}_t$ helped improve performance (SHERLOCK vs SHERLOCK - $\mathcal{L}_t$). On investigating further, we observed that the attention weights associated with an entity for a model trained with $\mathcal{L}_t$ concentrated much better around the position of the entity in the email than for the model without it. To see why that is advantageous, consider the following example:

"Let's schedule for tomorrow. Next month, I plan on taking up Mr Baskerville's case"

Here, the model without $\mathcal{L}_t$ generates high attention weights for embeddings associated with "tomorrow", since the localization of the attention weights is much more spread out. Consequently, it also uses the embeddings associated with "tomorrow" for predicting the label of "next month", and hence, predicts it to be relevant to scheduling when it is not. Due to space constraints, we include our localization experiments in Appendix F.

5.3 Negation Detection

Model	Precision	Recall	F1
NegNN	0.73	0.13	0.22
Heuristic	0.78	0.63	0.70
SHERLOCK	0.91	0.62	0.74

Table 3: Negation Performance (Scale: 0 - 1)

Category	Model	Precision	Recall	F1
Explicit	NegNN	0.83	0.25	0.39
	Heuristic	0.76	0.86	0.81
	SHERLOCK	0.94	0.87	0.90
Implied	NegNN	0.23	0.01	0.03
	Heuristic	0.83	0.42	0.56
	SHERLOCK	0.87	0.40	0.54

Table 4: Explicit vs implied negations (Scale: 0 - 1)

Table 3 shows the performance of SHERLOCK compared to the baseline methods. We hypothesize the reason why SHERLOCK and the simple heuristic model outperform the neural baseline is two-fold: the neural negation model was trained on a dataset of Sherlock Holmes stories and consequently does not adapt well when used for negation extraction for emails; and that the neural model has no notion of implied negations.

To test this hypothesis, we split the negations into two categories: explicit negations (defined as a negation where the cue is one of the explicit negation cues), and the case wherein the negation is implied (any case that was not explicit was deemed implied). 50% of emails in the negation dataset contained explicit negations only, 48% contained implied negations only and 2% contained both.

Table 4 shows the performance of SHERLOCK and the baselines for both the explicit negation and the implied negation cases. Unsurprisingly, we see that both the baselines as well as SHERLOCK perform better on explicit negations than they do on implied negations. However, the gains observed by both the heuristic model and SHERLOCK substantially outperform NegNN, with SHERLOCK substantially outperforming the heuristic. Examples 1 and 2 in Table 5 give qualitative examples of where SHERLOCK outperforms the heuristic.

The primary source of errors for detecting implied negations is from failing to identify the correct cue. Since heuristics for implied negations are more heavily focused on precision, the absence of negation cues results in the model not detecting the implied negation, which in turn negatively impacts the recall. Examples 3, 4 and 5 in Table 5 show cases where the cue is not present in the heuristic set of implied cues.

For explicit negations, one source of errors is due to entity co-referencing. Consider Example 6: the negated time instance Tuesday is referenced as "then" and hence the negation scope "then" is insufficient to identify the correct negated entity. A few errors also stem from inherent ambiguity: in Example 7, the request can either be interpreted as being for anytime next week except Thursday 10am, or for 10 am on all days except Thursday. Finally, we also observe errors due to double negations (Example 8) and due to incorrect constituency and dependency parses.

6 Related Work

Existing approaches for time expression extraction can be categorized into rule-based methods and learning-based methods.

Rule-based Methods Rule-based methods like HeidelTime, and SUTime mainly handcraft deterministic rules to identify time expressions. TempEx and GUTime use both hand-crafted rules and machine-learnt rules to resolve time expressions (Mani and Wilson, 2000; Verhagen et al., 2005; Blamey et al., 2013). HeidelTime manually designs rules with time resources to recognize time

Idx	Example	Heuristic	SHERLOCK	Correct
1	Mycroft cannot do Monday but Tuesday should work fine.	[Monday, Tuesday]	[Monday]	[Monday]
2	If Watson is not busy, Wednesday also works.	[Wednesday]	[]	[]
3	I'm slammed on Thursday. - Lestrade	[]	[]	[Thursday]
4	I am out of town on Wednesday Irene but Thursday might work.	[]	[]	[Wednesday]
5	I am completely booked with appointments on Thursday Sherlock. – Watson	[]	[]	[Thursday]
6	Mr. Holmes, my trip's on Tuesday. I really can't meet then.	[]	[]	[Tuesday]
7	Let's just meet next week any day except Thursday at 10:00 am. - Holmes	[next week, Thursday at 10:00 am]	[Thursday]	[Thursday at 10:00 am]
8	Next week would not be possible, except on Friday.	[Next week, Friday]	[Next week, Friday]	[next week]

Table 5: Examples of SHERLOCK's Negation Model's predictions and errors

expressions (Strötgen and Gertz, 2010). SUTime designs deterministic rules at three levels (i.e., individual word level, chunk level, and time expression level) for time expression recognition (Chang and Manning, 2012). A recent type-based time tagger, SynTime, designs general heuristic rules with a token type system to recognize time expressions (Zhong et al., 2017). TOMN (Zhong and Cambria, 2018) uses the token regular expressions, similar to SUTime (Chang and Manning, 2012) and SynTime (Zhong et al., 2017), and further groups them into three token types, similar to SynTime. TOMN also leverages statistical information from entire corpus to improve the precisions and alleviate the deterministic role of deterministic and heuristic rules.

Learning-based Method Learning-based methods in TempEval series mainly extract features from text (e.g., character features, word features, syntactic features, and semantic features), and on the features apply statistical models (e.g., CRFs) to model time expressions (Bethard, 2013; Filannino et al., 2013; Llorens et al., 2010; UzZaman and Allen, 2010). Besides the standard methods, (Angeli et al., 2012; Angeli and Uszkoreit, 2013) exploit an EM-style approach with compositional grammar to learn latent time parsers. (Lee et al., 2014) leverage a learnt CCG (Steedman, 1996) parser and define a lexicon with linguistic context to model time expressions, using the loose structure information by grouping the constituent words of time expression under three token types.

Negation Scope Detection: Most negation detection research has focused in the Bio-Medical domain (Mehrabi et al., 2015; Agarwal and Yu, 2010). Non Bio-Medical text related negation detection tasks usually involve learning supervised classifiers over hand-crafted features leveraging syntactic structure (constituency and dependency parses) (Velldal et al., 2012; Lapponi et al., 2012; Chowdhury and Mahbub, 2012; White, 2012; Abu-Jbara and Radev, 2012). The current state of the art learned method uses a Neural BiLSTM-CRF model (Fancellu et al., 2016). However, the corpus available for negation detection is on Sherlock Holmes stories (*SEM2012 Shared task (Morante and Daelemans, 2012)), and consequently, as shown in this work, do not adapt well on language used in other document styles (like emails). In this work, we built over the work of (Rosenberg, 2013), who develop linguistic rules over constituency and dependency parses to identify negation scopes. The primary advantage of leveraging their work is that it is not strongly tied to the *SEM 2012 dataset, and we found this to generalize better.

Finally, there has been some work on directly training a model to extract entities and associated negation constraints (Bhatia et al., 2019). However, these works usually assume the availability of good quality annotated negated entities. Given enough annotated data, exploring this direction would be an interesting line of future work.

7 Conclusion

In this paper, we presented a novel model that leverages conventional high recall rule-based models and neural models for utilizing contextual information for identifying task relevant temporal entities. Our proposed model, when used in conjunction with 3 different rule-based models, achieves substantial precision gains for all of them without suffering from a huge recall drop. Further, the model substantially outperforms baseline methods for the task of identifying relevant date-time entities for the task of scheduling a meeting.

We also presented a novel approach for identifying the negation constraints of date-time entities. Identifying the negation constraints associated with date-time entities correctly is necessary for the task of scheduling. We showed that the existing neural approaches for detecting negation scopes do not transfer well, and that our proposed model based on heuristics defined over constituency and dependency parses achieves strong performance gains, especially for the case of explicit negations.

Abstract

This paper presents a comprehensive study on resume classification to reduce the time and labor needed to screen an overwhelming number of applications significantly, while improving the selection of suitable candidates. A total of 6,492 resumes are extracted from 24,933 job applications for 252 positions designated into four levels of experience for Clinical Research Coordinators (CRC). Each resume is manually annotated to its most appropriate CRC position by experts through several rounds of triple annotation to establish guidelines. As a result, a high Kappa score of 61% is achieved for inter-annotator agreement. Given this dataset, novel transformer-based classification models are developed for two tasks: the first task takes a resume and classifies it to a CRC level (`T1`), and the second task takes both a resume and a job description to apply and predicts if the application is suited to the job (`T2`). Our best models using section encoding and multi-head attention decoding give results of 73.3% to `T1` and 79.2% to `T2`. Our analysis shows that the prediction errors are mostly made among adjacent CRC levels, which are hard for even experts to distinguish, implying the practical value of our models in real HR platforms.

1 Introduction

An ongoing challenge for Human Resource (HR) is the process used to screen and match applicants to a target job description with a goal of minimizing recruiting time while maximizing proper matches. The use of generic job descriptions not clearly stratified by the level of competence or skill sets often leads many candidates to apply every possible job, resulting in misuse of recruiter and applicant's time. A more challenging aspect is the evaluation of unstructured data such as resumes and CVs, which represents about 80% of the data processed daily, a task that is typically not an employer's priority given the manual effort involved (Stewart, 2019).

The current practice for screening applications involves reviewing individual resumes via traditional approaches, that rely on string/regex matching. The scope of posted job positions varies by the hiring organization type, job level, focus area, and more. The latest advent in Natural Language Processing (NLP) enables the large-scale analysis of resumes (Deng et al., 2018; Myers, 2019). NLP models also allow for a comprehensive analyses on resumes and identification of latent concepts that may easily go unnoticed using a general manual process. This model's ability to infer core skills and qualifications from resumes can be used to normalize necessary content into standard concepts for matching with stated position requirements (Chifu et al., 2017; Valdez-Almada et al., 2018). However, the task of resume classification has been under-explored due to the lack of resources for individual research labs and the heterogeneous nature of job solicitations.

This paper presents new research that aims to help applicants identify the level of job(s) they are qualified for and to provide recruiters with a rapid way to filter and match the best applicants. For this study, resumes submitted to four levels of Clinical Research Coordinator (CRC) positions are used. To the best of our knowledge, this is the first time that resume classification is explored with levels of competence, not categories. The contributions of this work are summarized as follows:

- To create a high-quality dataset that comprises 3,425 resumes annotated with 5 levels of real CRC positions (Section 3).
- To present a novel transformer-based classification approach using section encoding and multi-head attention decoding (Section 4).
- To develop robust NLP models for the tasks of competence-level classification and resume-to-job_description matching (Section 5).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8456–8466,
November 16–20, 2020.

Type	Description
`CRC1`	Manage administrative activities associated with the conduct of clinical trials. Maintain data pertaining to research projects, complete source documents/case report forms, and perform data entry. Assist with participant scheduling.
`CRC2`	Manage research project databases and development study related documents, and complete source documents and case report forms. Interface with research participants and study sponsors, determine eligibility, and consent study participants according to protocol.
`CRC3`	Independently manage key aspects of a large clinical trial or all aspects of one or more small trials or research projects. Train and provide guidance to less experienced staffs, interface with research participants, and resolve issues related to study protocols. Interact with study sponsors, monitor/report SAEs, and resolve study queries. Provide leadership in determining, recommending, and implementing improvements to policies and procedures.
`CRC4`	Function as a team lead to recruit, orient, and supervise research staff. Independently manage the most complex research administration activities associated with the conduct of clinical trials. Determine effective strategies for promoting/recruiting research participants and retaining participants in long term clinical trials.

Table 1: Descriptions (and general responsibilities) of the four-levels of CRC positions.

2 Related Work

Limited studies have been conducted on the task of resume classification. Zaroor et al. (2017) proposed a job-post and resume classification system that integrated knowledge base to match 2K resumes with 10K job posts. Sayfullina et al. (2017) presented a convolutional neural network (CNN) model to classify 90K job descriptions, 523 resume summaries, and 98 children's dream job descriptions into 27 job categories. Nasser et al. (2018) hierarchically segmented resumes into sub-domains, especially for technical positions, and developed a CNN model to classify 500 job descriptions and 2K resumes.

Prior studies in this area have focused on classifying resumes or job descriptions into occupational categories (e.g., data scientist, healthcare provider). However, no work has yet been found to distinguish resumes by levels of competence. Furthermore, we believe that our work is the first to analyze resumes together with job descriptions to determine whether or not the applicants are suitable for particular jobs, which can significantly reduce the intensive labor performed daily by HR recruiters.

3 Dataset

3.1 Data Collection

Between April 2018 and May 2019, the department of Human Resources (HR) at Emory University received about 25K applications including resumes in free text for 225 Clinical Research Coordinator (CRC) positions. A CRC is a clinical research professional whose role is integral to initiating and managing clinical research studies. There are four levels of CRC positions, `CRC1-4`, with `CRC4` having the most expertise. Table 1 gives the descriptions about these four CRC levels.

Table 2 shows the statistics of the collected applications and the resumes. Out of the 24,933 applications, 89% are applied for the entry level positions, `CRC1-2`, that is expected since `CRC3-4` positions require more qualifications (`A`). At any time, there are various positions posted for the same level from different divisions, cardiology, renal, infectious disease, etc. Thus, it is common to see resumes from the same applicant applying to several job postings within the same CRC level.

After removing duplicated resumes within the same level, 9,286 resumes remain, discarding 63% of the original applications (`B`). It is common to see the same applicant applying to positions across multiple levels. After removing duplicated resumes across all levels and retaining only the resumes to the highest level (e.g., if a person applied for both `CRC1` and `CRC2`, retain the resume for only `CRC2`), 6,492 resumes are preserved, discarding additional 11% from the original applications (`C`).

	CRC1	CRC2	CRC3	CRC4	Total
A	13,794	8,415	2,238	486	24,933
B	4,779	3,005	1,106	396	9,286
C	2,961	2,250	885	396	6,492
B_r	2,730	1,702	696	234	5,362
C_r	1,477	1,172	542	234	3,425

Table 2: The counts of applications (`A`), unique resumes for each level (`B`), unique resumes across all levels (`C`), and resumes from `B` and `C` selected for our research while preserving level proportions (B_r and C_r).

For our research, we carefully select 3,425 resumes from `C` by discarding ones that are not clearly structured (e.g., no section titles) or contain too many characters that cannot be easily converted into text, while keeping similar ratios of the CRC levels (C_r). We also create a set similar to `B`, say B_r, that retains only resumes in C_r. C_r and B_r are used for our first task (§4.1) and second task (§4.2), respectively.

3.2 Preprocessing

The resumes collected by the HR come with several formats (e.g, `DOC`, `DOCX`, `PDF`, `RTF`). All resumes are first converted into the unstructured text format, `TXT`, using publicly available tools. They are then processed by our custom regular expressions designed to segment different sections in the resumes. As a results, every resume is segmented into the six sections, *Profile*, *Education*, *Work Experience*, *Activities*, *Skills*, and *Others*. Table 3 shows the ratio of resumes in each level including those sections.

	CRC1	**CRC2**	**CRC3**	**CRC4**	**Total**
`WoE`	98.0	98.3	97.2	97.4	98.0
`EDU`	96.0	95.6	96.3	96.6	96.0
`PRO`	94.4	94.3	94.1	94.0	94.3
`ACT`	40.4	43.4	47.4	40.2	42.5
`SKI`	37.7	36.4	33.6	41.5	36.9
`OTH`	32.2	32.8	30.8	37.2	32.5

Table 3: The existence ratio of each section in the CRC levels. `WoE`: Work Experience, `EDU`: Education, `PRO`: Profile, `ACT`: Activities, `SKI`: Skills, `OTH`: Others.

Most resumes consistently include the *Work Experience*, *Education*, and *Profile* sections, whereas the others are often missing. To ensure the matching quality of our regular expressions, 200 resumes are randomly checked, where 97% of them are found to have the sections segmented correctly. Finally, all resumes comprising segmented sections are saved in the `JSON` format for machine readability.

3.3 Annotation

2 experts with experience in recruiting applicants for CRC positions of all levels design the annotation guidelines in 5 rounds by labeling each resume with either one of the four CRC levels, `CRC1-4`, or *Not Qualified* (`NQ`), indicating that the applicant is not qualified for any CRC level. Thus, a total of 5 labels are used for this annotation. For each round, 50 randomly selected resumes from $\mathtt{C}_r$ in Table 2, by keeping similar ratios of the CRC levels as $\mathtt{C}_r$, are labeled by those two experts with improvement to subsequent guidelines based on their agreement.

Another batch of 50 resumes are then selected for the next round and annotated based on the revised guidelines. For batches 2-5, a third person (non-expert) is added and instructed to follow the guidelines developed from prior rounds; thus, annotation is completed by three people for these rounds. Table 4 shows the Fleiss Kappa scores to estimate the inter-annotator agreement (ITA) for each round with respect to the five competence levels.

	R1	**R2**	**R3**	**R4**	**R5**
`NQ`	13.2	53.8	38.5	52.0	66.8
`CRC1`	1.3	25.0	-7.3	57.3	65.3
`CRC2`	9.3	39.7	41.2	5.4	33.7
`CRC3`	29.1	63.5	66.7	69.8	69.6
`CRC4`	63.4	47.9	100.0	N/A	-0.7
Overall	16.1	45.3	40.7	55.5	**60.8**

Table 4: Fleiss Kappa scores measured for ITA during the five rounds of guideline development (`R1-5`). No annotation of `CRC4` is found in the batch used for `R4`. The negative kappa scores are achieved for (`CRC1`, `R3`) and (`CRC4`, `R5`) that have too few samples (≤ 2).

For `R1` with no guidelines designed, poor ITA is observed with the kappa score of 16.1%. The ITA gradually improves with more rounds, and reaches the kappa score of 60.8% among 3 annotators, indicating the high quality annotation in our dataset. The followings give brief summary of the guideline revisions after each round:

Round 1 (1) Clarify qualified and not-qualified applicants, (2) Define transferable skills (e.g, general research experience vs. experiences in healthcare), (3) Define clinical settings, clinical experience, and clinical research experience (4) Set requirements by levels of academic preparation.

Round 2 (1) Revise the length of clinical experience based on levels of academic preparation and whether the degree is in a scientific/health related field or non-scientific/non-health related field, (2) Refine `CRC2-4` degree requirements, years of clinical research, and clinical experience requirements, (3) Require clinical research certification for `CRC4`.

Round 3 (1) Update glossary examples of clinical settings, research experience, and clinical experiences with job titles, (2) Revise years of experience in clinical roles and research experience. (3) Add categorization of foreign trained doctors and bench/laboratory research personnel.

Round 4 (1) Remove clinical experience requirements from `CRC2-4` and require a minimum of 1-year clinical research for those with a scientific vs. non-scientific degree, (2) Revisit laboratory scientist requirements, (3) Remove academic experience as a research assistant unless it involved over 1000 hours. Rationale: participation by semester is typically data entry or participation in a component of the research but not full engagement in a project.

Round 5 Increase the number of years required for a bench/laboratory researcher.

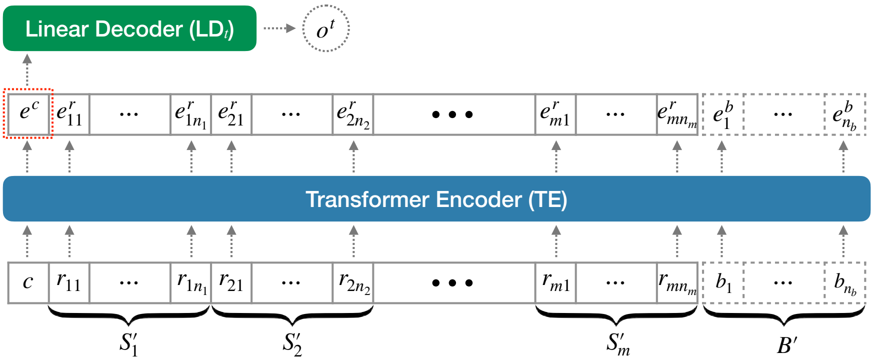

Figure 1: The whole context model using section trimming, used as baseline for `T1` (§4.1.1) and `T2` (§4.2.1).

During these five rounds, 250 resumes are triple annotated and adjudicated. Given the established annotation guidelines,[1] additional 3,175 resumes are single annotated and sample-checked. Thus, a total of 3,425 resumes are annotated for this study.

4 Approach

This section introduces transformer-based neural approaches to address the following two tasks:

`T1` Given a resume, decide which level of CRC positions that the corresponding applicant is suitable for (Section 4.1).

`T2` Given a resume and a CRC job description, decide whether or not the applicant is suitable for that particular job (Section 4.2).

`T1` is a multiclass classification task where the labels are the five CRC levels including `NQ` (Table 4). This task is useful for applicants who may not have clear ideas about what levels they are eligible for, and recruiters who want to match the applicants to the best suitable jobs available to them.

`T2` is a binary classification task such that even with the same resume, the label can be either positive (accept) or negative (reject), depending on the job description. This task is useful for applicants who have good ideas about what CRC levels they fit into but want to determine which particular jobs they should apply to, as well as recruiters who need to quickly screen the applicants for interviews.

4.1 Competence-Level Classification

For the competence-level classification task (`T1`), a baseline model that treats the whole resume as one document (§4.1.1) is compared to context-aware models using section pruning (§4.1.2), chunk segmenting (§4.1.3), and section encoding (§4.1.4).

4.1.1 Whole-Context: Section Trimming

Figure 1 shows an overview of the whole context model. Let $R = \{S_1, \ldots, S_m\}$ be a resume while $S_i = \{r_{i1}, \ldots, r_{i\ell_i}\}$ is the i'th section in R where r_{ij} is the j'th token in S_i. Let N be the maximum number of input tokens that a transformer encoder can accept. Then, n_i, the max-number of tokens in S_i allowed to be input, is measured as follows:

$$T = \textstyle\sum_{\forall j} |S_j|$$
$$n_i = \min(N, T) \cdot \frac{|S_i|}{T}$$

Let $S'_i = \{r_{i1}, \ldots, r_{in_i}\}$ be the trimmed section of S_i by discarding all tokens $r_{ij} \in S_i$ $(n_i < j \leq \ell_i)$. All trimmed sections are appended in order with the special token c, representing the entire resume, which creates the input list $I = \{c\} \oplus S'_1 \oplus \cdots \oplus S'_m$. I is fed into the transformer encoder (`TE`) that generates the list of embeddings $\{e^c\} \oplus E'_1 \oplus \ldots \oplus E'_m$, where $E'_i = \{e^r_{i1}, \ldots, e^r_{in_i}\}$ is the embedding list of S'_i, and e^c is the embeddings of c. Finally, e^c is fed into the linear decoder ($\texttt{LD}_t$) that generates the output vector $o^t \in \mathbb{R}^d$ to classify R into one of the competence levels (in our case, $d = 5$).

4.1.2 Context-Aware: Section Pruning

Section trimming in Section 4.1.1 allows the whole-context model to take part of every section as input. However, it is still limited because not all features necessary for the classification are guaranteed to be in the trimmed range. Moreover, this model makes no distinction between contents from different sections once $S'_{1..m}$ are concatenated. This section proposes a context-aware model to overcome those two issues by pruning tokens more intelligently and encoding each section separately so that the model learns weights for individual sections to make more informed predictions. Figure 2 shows an overview of the context-aware model using section pruning.

---

[1] The annotation guidelines are available at our project page.

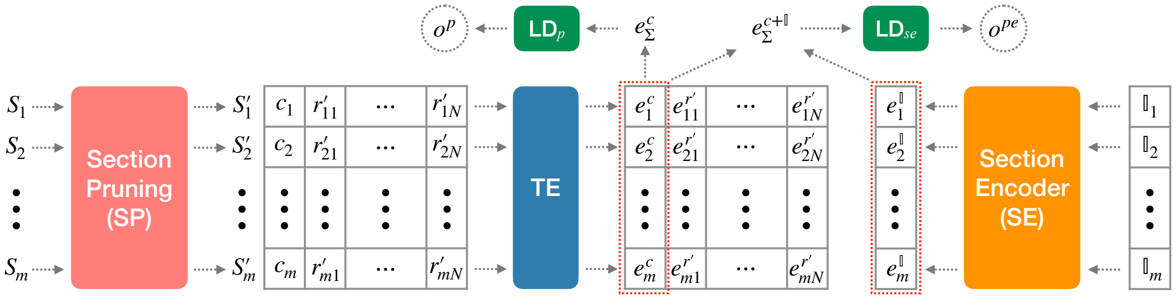

Figure 2: The context-aware model using section pruning (§4.1.2) and section encoding (§4.1.4).

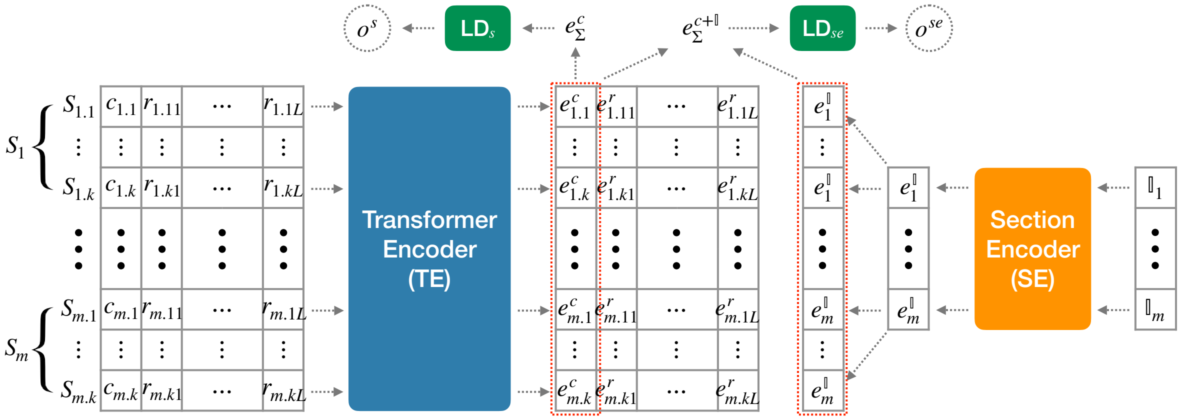

Figure 3: The context-aware model using chunk segmenting (§4.1.3) and section encoding (§4.1.4).

Given the maximum number of tokens, N, that the transformer encoder (`TE`) allows, any section $S_i \in R$ that contains more than N-number of tokens is pruned by applying the following procedure:

1. If $|S_i| > N$, remove all stop words in S_i.
2. If still $|S_i| > N$, remove all words whose document frequencies are among the top 5%.
3. If still $|S_i| > N$, remove all words whose document frequencies are among the top 30%.

Then, the pruned section S'_i is created for every S_i, where $S'_i \subseteq S_i$ and $|S'_i| \leq N$. Each S'_i is prepended by the special token c_i representing that section and fed into the transformer encoder (`TE`) that generates the list $\{e^c_i, e^{r'}_{i1}, \ldots, e^{r'}_{iN}\}$, where e^c is the embedding of c, called section embedding, and the rest are the embeddings of S'_i. Let $e^c_\Sigma = \sum_{i=1}^m e^c_i$, that is the sum of all section embeddings representing the whole resume. Finally, e^c_Σ is fed into the linear decoder (`LD`$_p$) that generates the output vector $o^p \in \mathbb{R}^d$ to classify R into a competence level.

4.1.3 Context-Aware: Chunk Segmenting

Section pruning in §4.1.2 preserves relevant information more than section trimming in §4.1.1; however, the model still cannot see the entire resume. Thus, this section proposes another method that uniformly segments the resume into multiple chunks and encodes each chunk separately. Figure 3 shows the context-aware model using chunk segmenting. Let $S_i = \{S_{i.1}, \ldots, S_{i.k}\}$ be the i'th section in R, where $S_{i.j}$ is the j'th chunk in S_i and $k = \lceil |S_i|/L \rceil$ given the maximum length L of any chunk so that $|S_{i.j}| = L$ for $\forall j < k$ and $|S_{i.k}| \leq L$.[2] Each chunk $S_{i.j}$ is prepended by the special token $c_{i.j}$ representing that chunk and fed into `TE` that generates the embedding list $E_{i.j} = \{e^c_{i.j}, e^r_{i.j1}, \ldots, e^r_{i.jL}\}$. Let $e^c_\Sigma = \sum_{\forall i \forall j} e^c_{i.j}$. Finally, e^c_Σ is fed into `LD`$_s$ that generates the output vector $o^s \in \mathbb{R}^d$ to classify R.

4.1.4 Context-Aware: Section Encoding

Chunk segmenting in §4.1.3 allows the model to see the entire resume; however, it loses information about which sections the chunks belong to. This section proposes a method to distinctively encode chunks from different sections, that can be applied to both models using section pruning (§4.1.2) and chunk segmenting. Figures 2 and 3 describe how section pruning can be applied to those two models.

Let $H = \{\mathbb{I}_1, \ldots, \mathbb{I}_m\}$ be the list of section IDs where $\mathbb{I}_i$ is the ID of the i'th section. H is then fed

---

[2] $S_{i.j} = \{r_{i.j1}, \ldots, r_{i.jL}\}$ and $r_{i.jp}$ is the p'th token in $S_{i.j}$, that is $r_{iq} \in S_i$ where $q = L \cdot (j-1) + p$.

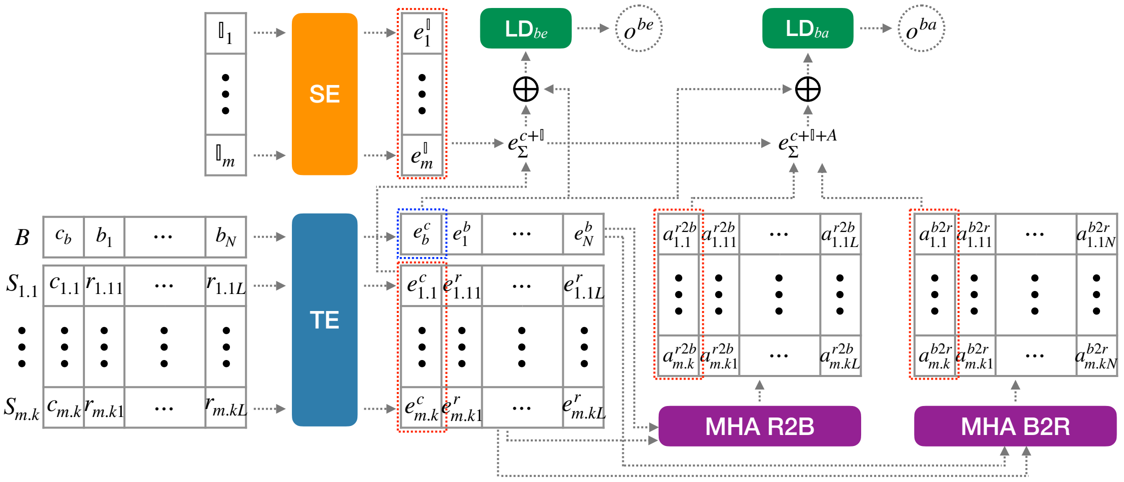

Figure 4: The context-aware models using chunk segmenting (4.1.3) + section encoding (§4.1.4) + job description embedding (§4.2.2), and multi-head attention between the resume and the job description (§4.2.3).

into the section encoder (`SE`), an embedding layer that learns the embedding list $E^{\mathbb{I}} = \{e^{\mathbb{I}}_1, \ldots, e^{\mathbb{I}}_m\}$ during training, where $e^{\mathbb{I}}_i$ is the embedding of $\mathbb{I}_i$. For the section pruning model in Figure 2, given $E^c = \{e^c_1, \ldots, e^c_m\}$, $F = E^c + E^{\mathbb{I}} = \{f_1, .., f_m\}$ and $e^{c+\mathbb{I}}_{\Sigma} = \sum_{i=1}^{m} f_i$. For the chunk segmenting model in Figure 3, given $E^c = \{e^c_{1.1}, \ldots, e^c_{m.k}\}$, $F = \{f_{1.1}, \ldots, f_{m.k}\}$ where $f_{i.j} = e^c_{i.j} + e^{\mathbb{I}}_i$. Let $e^{c+\mathbb{I}}_{\Sigma} = \sum_{\forall i \forall j} f_{i.j}$. Finally, $e^{c+\mathbb{I}}_{\Sigma}$ is fed into `LD`$_{se}$ that create $o^{pe} \in \mathbb{R}^d$, $o^{se} \in \mathbb{R}^d$ for the section pruning and chunk segmenting models, respectively.

4.2 Resume-to-Job_Description Matching

For the resume-to-job_description matching task (`T2`), the whole-context model is adapted to establish the baseline (§4.2.1), and compared to context-aware models using chunk segmenting + section encoding coupled with the job description embedding (§4.2.2), as well as multi-head attentions between the resume and the job description (§4.2.3).

4.2.1 Whole-Context: Sec./Desc. Trimming

The whole context model is similar to the one using section trimming in §4.1.1 with the additional input from the job description, illustrated as the dotted boxes in Figure 1. Let $B = \{b_1, \ldots, b_{\ell_b}\}$ be the job description where b_i is the i'th token in B. Given the max-number of tokens N that a transformer encoder can accept, the max-numbers of tokens in S_i and B, that are n_i and n_b respectively, allowed to be input are measured as followed:

$$T = \textstyle\sum_{\forall j} |S_j| + |B|$$
$$n_i = \min(N, T) \cdot {}^{|S_i|}/_{T}$$
$$n_b = \min(N, T) \cdot {}^{|B|}/_{T}$$

Let $B' = \{b_1, \ldots, b_{n_b}\}$ be the trimmed job description discarding all tokens $b_j \in B$ ($n_b < j \leq \ell_b$). Then, the input list $I = \{c\} \oplus S'_1 \oplus \cdots \oplus S'_m \oplus B'$ is created and fed into `TE` that generates the embedding list $\{e^c\} \oplus E_1 \oplus \ldots \oplus E_m \oplus E_b$, where E_b is the embeddings of B'. Finally, e^c is fed into `LD` that generates $o^t \in \mathbb{R}^2$ to make the binary decision of whether or not R is suitable for B.

4.2.2 Context-Aware: Chunk Segmenting + Section Encoding + Desc. Embedding

The most advanced competence-level classification model using chunk segmenting (§4.1.3) and section encoding (§4.1.4) is adapted for the context-aware model with the addition of $B = \{c_b, b_1, \ldots, b_N\}$, which is fed into `TE` to generate the embedding list $E^b = \{e^c_b, b^b_1, \ldots, b^b_N\}$. Then, the job description embedding e^c_b is concatenated with the section encoded resume embedding $e^{c+\mathbb{I}}_{\Sigma}$ (§4.1.4) and fed into `LD`$_{be}$ that generates $o^{be} \in \mathbb{R}^2$.

4.2.3 Context-Aware: Multi-Head Attention

Figure 4 depicts an overview of the context-aware model using the techniques in §4.2.2 empowered by multi-head attention (Vaswani et al., 2017) between the resume R and the job description B, which allows the model to learn correlations between individual tokens in R and B, r_* and b_*, as well as the chunk and job description representations, c_*.

Let $\mathcal{E}^r \in \mathbb{R}^{\gamma \times \lambda}$ be the matrix representing R, where γ is the total number of chunks across all sections in R, $\lambda = L + 1$, and L is the max-length of any chunk. Thus, each row in $\mathcal{E}^r$ is the embedding list $E_{i.j} \in \mathbb{R}^{1 \times \lambda}$ of the corresponding chunk $S_{i,j}$. Let $\mathcal{E}^b \in \mathbb{R}^{\gamma \times \nu}$ be the matrix representing B where

$\nu = N+1$ and N is the max-length of B. Each row in $\mathcal{E}^b$ is a copy of the embedding list $E^b \in \mathbb{R}^{1\times\nu}$ in §4.2.2. Thus, every row is identical to the other rows in $\mathcal{E}^b$. These two matrices, $\mathcal{E}^r$ and $\mathcal{E}^b$, are fed into two types of multi-head attention (MHA) layers, one finding correlations from R to B (R2B) and the other from B to R (B2R), which generate two attention matrices, $\mathcal{A}^{r2b} \in \mathbb{R}^{\gamma\times\lambda}$ and $\mathcal{A}^{b2r} \in \mathbb{R}^{\gamma\times\nu}$.

The embeddings of the chunks, $\{e^c_{1.1}, \dots, e^c_{m.k}\}$, and the section encodings, $\{e^{\mathbb{I}}_1, \dots, e^{\mathbb{I}}_m\}$, as well as the outputs of MHA−R2B, $\{a^{r2b}_{1.1}, \dots, a^{r2b}_{m.k}\}$, and MHA−B2R, $\{a^{b2r}_{1.1}, \dots, a^{b2r}_{m.k}\}$, together make $F^a = \{f^a_{1.1}, \dots, f^a_{m.k}\}$ s.t. $f_{i.j} = e^c_{i.j} + e^{\mathbb{I}}_i + a^{r2b}_{i.j} + a^{b2r}_{i.j}$. Finally, $e^{c+\mathbb{I}+A}_{\Sigma} = \sum_{\forall i \forall j} f^a_{i.j}$ is fed into $\mathtt{LD}_{ba}$ that generates $o^{ba} \in \mathbb{R}^2$ for the binary classification.

5 Experiments

5.1 Data Distributions

Table 5 shows the data split used to develop models for the competence-level classification task (T1). The annotated data in the row $\mathtt{C}_r$ of Table 2 are split into the training (TRN), development (DEV) and test (TST) sets with the ratios of 75:10:15 by keeping similar label distributions across all sets.

	TRN	**DEV**	**TST**	**Total**	**Dist.**
NQ	355	48	72	475	13.87%
CRC1	1,510	202	302	2,014	58.80%
CRC2	286	38	58	382	11.15%
CRC3	392	53	79	524	15.30%
CRC4	22	3	5	30	0.88%
Total	2,565	344	516	3,425	100.00%

Table 5: Data statistics for the competence-level classification task (T1) in Section 4.1.

70% of the data are annotated with the entry levels, CRC1 and CRC2, that is not surprising since 77.3% of the applications are submitted for those 2 levels. The ratio of CRC4 is notably lower than the application ratio submitted to that level, 6.8%, implying that applicants tend to apply to jobs for which they are not qualified. 13.9% of the applicants are NQ; thus, if our model detects even that portion robustly, it can remarkably reduce human labor.

Table 6 shows the data split used for the resume-to-job_description matching task (T2). The same ratios of 75:10:15 are applied to generate the TRN:DEV:TST sets, respectively. Note that an applicant can submit resumes to more than one CRC level. Algorithm 1 is designed to avoiding any overlapping applicants across datasets while keeping the similar label distributions (Appendix A.1).

		TRN	**DEV**	**TST**	**Total**	**Dist.**
CRC1	Y	1,279	171	257	1,707	31.84%
	N	772	100	151	1,023	19.08%
CRC2	Y	183	25	38	246	4.59%
	N	1,086	148	222	1,456	27.15%
CRC3	Y	153	21	32	206	3.84%
	N	373	46	71	490	9.14%
CRC4	Y	8	0	2	10	0.19%
	N	169	22	33	224	4.18%
Total		4,023	533	806	5,362	100.00%

Table 6: Data statistics for the resume-to-job_ description matching task (T2) in Section 4.2. Y/N: applicants whose applied CRC levels match/do not match our annotated label, respectively.

Out of the 5,362 applications, 40.5% of them match our annotation of the CRC levels, indicating that less than a half of applications are suitable for the positions they apply. The number of matches drops significantly for CRC2; only 14.5% are found to be suitable according to our labels. Too few instances are found for CRC4; only 4.3% of the applicants applying for this level match our annotation.

5.2 Models

For our experiments, the BERT base model is used as the transformer encoder (Devlin et al., 2019) although our approach is not restricted to any particular type of encoder. The following models are developed for T1 (Section 4.1):

- $\mathtt{W}_r$: Whole context model + section trimming (§4.1.1)
- P: Context-aware model + section pruning (§4.1.2)
- P⊕I: P + section encoding (§4.1.4)
- C: Context-aware model + chunk segmenting (§4.1.3)
- C⊕I: S + section encoding (§4.1.4)

The followings are developed for T2 (Section 4.2):

- $\mathtt{W}_{r+b}$: Whole context + sec./job_desc. trimming (§4.2.1)
- P⊕I⊕J: P⊕I + job_desc. embedding (≈§4.2.2)
- P⊕I⊕J⊕A: P⊕I⊕J + multi-head attention (≈§4.2.3)
- P⊕I⊕J⊕A⊖E: P⊕I⊕J - E^c (§4.1.4)
- C⊕I⊕J: C⊕I + job_desc. embedding (§4.2.2)
- C⊕I⊕J⊕A: C⊕I⊕J + multi-head attention (§4.2.3)
- C⊕I⊕J⊕A⊖E: C⊕I⊕J - E^c (§4.1.4)

The P⊕I⊕J model adapts section pruning to generate $e^{c+\mathbb{I}}_{\Sigma}$ instead of chunk segmenting in §4.2.2. For the P⊕I⊕J⊕A model, the attention matrices in §4.2.3 are reconfigured as $\mathcal{A}^{r2b}, \mathcal{A}^{b2r} \in \mathbb{R}^{m\times\nu}$ (m: the number of sections in R). These models are developed to make comparisons between those two approaches for T2. Also, the ⋆⊖E models exclude the embedding list E^c such that $f_{i.j}$ is redefined as $f_{i.j} = e^{\mathbb{I}}_i + a^{r2b}_{i.j} + a^{b2r}_{i.j}$ in §4.2.3 to estimate the pure impact of multi-head attention.

5.3 Results

Labeling accuracy is used as the evaluation metric for all our experiments. Each model is developed three times and their average score as well as the standard deviation are reported.[3] Table 7 shows the results for T1 achieved by the models in Sec. 5.2. All context-aware models without section encoding perform significantly better, 1.5% with section pruning (P) and 3.3% with chunk segmenting (C), than the baseline model ($\mathtt{W}_r$). C shows a greater improvement of 1.8% than P, implying that the additional context used in C is essential for this task. Section encoding (I) helps both P and C. As the result, C⊕I shows 4.2% improvement over $\mathtt{W}_r$ and also gives the least variance of 0.16.

	DEV	**TST**	δ
$\mathtt{W}_r$	69.38 (±0.14)	69.06 (±1.56)	-
P	68.99 (±0.49)	70.58 (±0.38)	1.52
P⊕I	69.19 (±0.63)	70.87 (±0.40)	1.81
C	70.36 (±0.34)	72.35 (±0.24)	3.29
C⊕I	**70.64** (±0.41)	**73.26** (±0.16)	**4.20**

Table 7: Accuracy (± standard deviation) on the development (DEV) and test (TST) sets for T1, achieved by the models in Section 5.2. δ: delta over $\mathtt{W}_r$ on TST.

Table 8 shows the results for T2 achieved by the models in Section 5.2. Neither the context-aware model using section pruning (P) or chunk segmenting (C) with section encoding (⊕I) performs better than the baseline model ($\mathtt{W}_{r+b}$) by simply concatenating the job description embedding (⊕J). Indeed, none of the P⊕⋆ models performs better than $\mathtt{W}_{r+b}$, that is surprising given the success they depict for T1 (Table 7). However, C with multi-head attention (C⊕I⊕J⊕A) show a significant improvement of 4.6% over its counterpart, that is very encouraging.

	DEV	**TST**	δ
$\mathtt{W}_{r+b}$	76.24 (±1.08)	77.70 (±0.59)	-
P⊕I⊕J	74.73 (±0.54)	75.60 (±1.07)	-2.1
P⊕I⊕J⊕A	75.36 (±0.57)	77.25 (±0.87)	-0.5
P⊕I⊕J⊕A⊖E	76.42 (±0.22)	77.58 (±0.95)	-0.1
C⊕I⊕J	73.85 (±0.87)	74.65 (±1.87)	-3.1
C⊕I⊕J⊕A	**76.99** (±1.10)	**79.20** (±0.26)	**1.5**
C⊕I⊕J⊕A⊖E	76.20 (±0.96)	78.49 (±0.74)	0.8

Table 8: Accuracy (± standard deviation) on the development (DEV) and test (TST) sets for T2, achieved by the models in Section 5.2. δ: delta over $\mathtt{W}_r$ on TST.

Multi-head attention (A) gives good improvement to P as well. Interestingly, the one excluding the embedding list (⊖E) performs slightly better than the one including it (P⊕I⊕J⊕A), implying that the embeddings from the pruned sections are not as useful once the attention is in place.

5.4 Analysis

Figure 5 shows the confusion matrix for T1's best model, C⊕I. The prediction of CRC1 shows robust performance, which has the most number of training instances (Table 5), whereas the other dimensions are mostly confused around their neighbors, often hard to distinguish even for human experts.

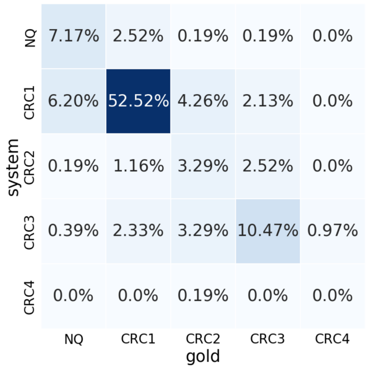

Figure 5: Confusion matrix for the best model of T1.

Figure 6 shows the confusion matrix for T2's best model, C⊕I⊕J⊕A. In general, this model shows robust performance across all dimensions.

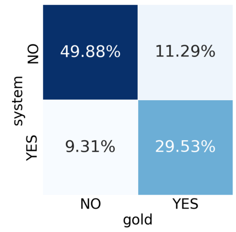

Figure 6: Confusion matrix for the best model of T2.

5.5 Error Analysis

This section provides a detailed analysis from our experts about prediction errors made by our best model in Section 5.3.

General The following observations are found as general error cases:

- Classifying foreign trained MDs and persons with PhDs with no clinical research experience to overrate them. (1) It picks up research project done in training as significant research. (2) It is unable to identify clinical research experience.

---

[3] Appdendix A.2 provides details of our experimental settings for the replicability of this work.

- Classifying laboratory personnel entering CRC area.
- Counting research experience: identifying dates of experience. (1) It needs to accumulate experience (e.g., `CRC1`: 6 months; `CRC2`: 2-3 years). (2) It needs implications for creating a structured entry form versus resume (3) Academic research experiences that are less than 1000 hours not counted; a semester experience not counted. (4) It needs to count paid research experience.
- Not picking up research related titles or terms such as (1) Research coordinator, research assistant, senior assistant; (2) IRB, informed consent, regulatory, specimen management, SOP, interviews, questionnaires; (3) Lab researcher: assays, immunohistochemistry.
- Not recognizing transferable skills such as clinical setting, clinical experience, and laboratory experience.
- Recognizing correct certifications. CRC positions require Clinical Research Certification but do not require CITI or CPR Certificates.
- Not distinguishing levels of preparation and associated clinical experience or research experience. Distinguishing scientific vs. nonscientific degrees for `CRC1` and `CRC2` is particularly important.

The following error cases are found between the adjacent pairs of CRC positions:

`NQ` vs. `CRC1` It needs to distinguish transferable skills, clinical setting, clinical experiences.

`CRC1` vs. `CRC2` It needs to count for (1) Levels of education; (2) Scientific vs. non-scientific degree; (3) Clinical experience that is a must for `CRC2` at lower educational levels;

`CRC2` vs. `CRC3` It needs to count for (1) Length of clinical research experience; (2) Foreign trained MD; (3) Laboratory personnel length of time

`CRC3` vs. `CRC4` (1) Foreign MD are often classified too high. (2) `CRC4` needs Certification in Clinical Research

6 Conclusion

This paper proposes two novel tasks, competence-level classification (`T1`) and resume-description matching (`T2`), and provides a high-quality dataset as well as robust models using several transformer-based approaches. The accuracies achieved by our best models, 73.3 for `T1` and 79.2 for `T2`, show a good promise for these models to be deployed in real HR systems. To the best of our knowledge, this is the first time that those two tasks are thoroughly studies, especially with the latest transformer architectures. We will continuously explore to improve these models by integrating expert's knowledge.

A Appendices

A.1 Spliting Algorithm for `T2`

Algorithm 1 is to split the `TRN`/`DEV`/`TST` sets for `T2` (Table 6) without overlapping applicants across them while keeping the label distributions. The key idea is to split the data by targeted label distributions but with a smaller training set ratio than the original one. If there are overlapping applicants, then it puts all of the overlaps into the training set so that the training set ratio will be large enough to be close to the targeted training set ratio while the label distributions are still kept in a great extent.

Algorithm 1: Splitting Algorithm for `T2`

```
Result: The splitted dataset for T2
Initialize a random training set ratio $T_i$ smaller than
  the targeted training and evaluation ratio $T_t$;
while True do
    Split the training and evaluation set by $T_i$ based
      on the ratio $R$ of positions applied and
      annotated matching results;
    if There are overlap resumes between training
      and evaluation set then
        Put all overlap resumes into the splitted
          training set;
        Compute the new training ratio $T_n$;
        if $T_n$ is not closed to $T_t$ then
            Adjust $T_i$ based on the relation between
              $T_n$ and $T_t$;
            Continue;
        else
            Split the evaluation set into the
              development and test set based on $R$;
            Return the splitted set;
        end
    else
        if $T_i$ is not closed to $T_t$ then
            Adjust $T_i$ based on the relation between
              $T_i$ and $T_t$;
            Continue;
        else
            Split the evaluation set into the
              development and test set based on $R$;
            Return the splitted set;
        end
    end
end
```

A.2 Experimental Settings

Table 9 shows the hyper-parameters used for each model (Section 5.2). For chunk segmenting in Section 4.1.3, let k_i be the number of chunks in the i'th section, then $K = \sum_{i=1}^{m} k_i$ is the total number of chunks in R. To utilize the GPU memory wisely, resumes with the same K are put to the same batch and different batches are trained with different batch sizes based on K and GPU memory to maximum the GPU usage. Different seeds are used when developing models for three times.

Model	**L**	**GAS**	**BS**	**LR**	**E**	**T**	**PS**
$\mathtt{W}_r$/$\mathtt{W}_{r+b}$	512	2	5	2e-05	20	1-3h	109M
`P`/`P`$\oplus$`I`	512	2	3	2e-05	20	4-6h	109M

`C`$\oplus$`I`$\oplus\star$	128	1	1,2,4	2e-05	20	6-8h	112M

Table 9: Hyperparameters. L: `TE` input length; GAS: gradient accumulation steps; BS: batch size; LR: learning rate; E: number of training epochs; T: approximate training time(h: hours); PS: approximate models training parameters size.

A.3 Analysis on Section Pruning

Section pruning is used to discard insignificant tokens in order to meet the limit of input size required by the transformer encoder (Section 4.1.2). Tables 10 and 11 show the section lengths before and after section pruning, respectively. These tables show that section pruning can noticeably reduce the maximum and average lengths of the sections.

Section	**Average (±stdev)**	**Max**	**Ratio**
`Profile`	100.65 (±215.75)	2139	94.93%
`Skills`	60.70 (±102.61)	1157	98.95%
`Work Experience`	314.61 (±316.61)	3605	80.26%
`Education`	174.30 (±289.37)	3662	89.50%
`Other`	77.41 (±145.40)	2184	98.34%
`Activities`	168.09 (±289.40)	3967	91.13%

Table 10: Section lengths before section pruning (Section 4.1.2). Average/Max: the average and max lengths of input sections. Ratio: the ratios of input sections that are under the max-input length restricted by the transformer encoder.

Section	**Average(±stdev)**	**Max**	**Ratio**
`Profile`	77.95(±127.70)	1514	99.60%
`Skills`	55.59 (±70.36)	546	99.93%
`Work Experience`	232.63 (±168.84)	2099	98.98%
`Education`	129.91 (±165.06)	1755	98.81%
`Other`	72.19 (±108.80)	1468	99.38%
`Activities`	125.71 (±57.74)	1514	99.13%

Abstract

Evaluation of grammatical error correction (GEC) systems has primarily focused on essays written by non-native learners of English, which however is only part of the full spectrum of GEC applications. We aim to broaden the target domain of GEC and release CWEB, a new benchmark for GEC consisting of website text generated by English speakers of varying levels of proficiency. Website data is a common and important domain that contains far fewer grammatical errors than learner essays, which we show presents a challenge to state-of-the-art GEC systems. We demonstrate that a factor behind this is the inability of systems to rely on a strong internal language model in low error density domains. We hope this work shall facilitate the development of open-domain GEC models that generalize to different topics and genres.

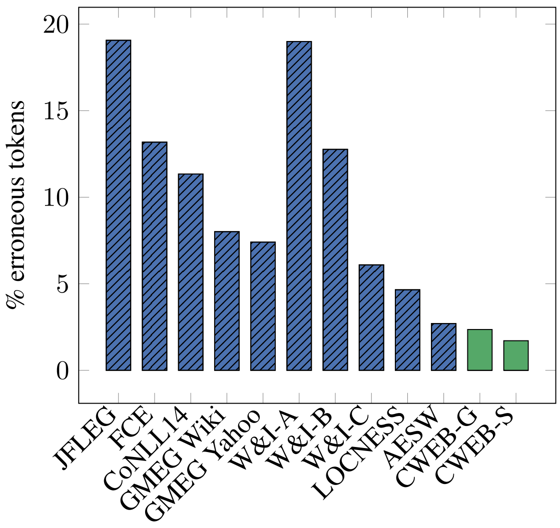

Figure 1: Percentage of erroneous tokens per domain. CWEB-G/S are our newly devised datasets.

1 Introduction

Grammatical error correction (GEC) is the task of automatically editing text to remove grammatical errors; for example: [*A link to registration can also be found* ~~*at*~~ ***on*** *the same page.*]. GEC systems so far have primarily focused on correcting essays produced by English-as-a-second-language (ESL) learners, providing fast and inexpensive feedback to facilitate language learning. However, this is only one target domain in the full spectrum of GEC applications. GEC models can also help to improve written communication outside of the formal education setting. Today the largest medium of written communication is the internet, with approximately 380 new websites created every minute.[1] Ensuring grammatical correctness of websites helps facilitate clear communication and a professional commercial presentation. Therefore, it is important that GEC models perform well in the open-domain setting and generalize, not only to writing produced in the educational context, but also to language production "in the wild". Website data specifically represent a broad and diverse range of writing and constitute a major part of what people read and write on an everyday basis.

This work highlights two major prevailing challenges of current approaches to GEC: *domain adaptation* and *low precision* in texts with low error density. Previous work has primarily targeted essay-style text with high error density (see Figure 1); however, this lack of diversity means that it is not clear how systems perform on other domains and under different error distributions (Sakaguchi et al., 2017).[2]

Current publicly available datasets are restricted to non-native English essays [e.g. FCE (Yannakoudakis et al., 2011); CoNLL14 (Ng et al.,

Table 1: Example sentences from the CWEB dataset. Erroneous text is struck through and corrections are in bold.

2014)], student essays [W&I+LOCNESS (Bryant et al., 2019; Granger, 1998)] or target a specific domain [scientific writing; AESW (Daudaravicius et al., 2016)]. Supervised systems trained on specific domains are less likely to be as effective at correcting distinctive errors from other domains, as is the case for systems trained on learner data with different native languages (Chollampatt et al., 2016; Nadejde and Tetreault, 2019). The recent BEA 2019 shared task (Bryant et al., 2019) encouraged research in the use of low-resource and unsupervised approaches; however, evaluation primarily targeted the restricted domain of student essays. We show that when applied to data outside of the language learning domain, current state-of-the-art systems exhibit low precision due to a tendency to over-predict errors. Recent work tackled the domain adaptation problem, and released GEC benchmarks from Wikipedia data and online comments [GMEG Wiki+Yahoo (Napoles et al., 2019)]. However, these datasets present a high density of errors and represent a limited subset of the full distribution of errors in online writing.

Contributions: We (i) release a new dataset, CWEB (**C**orrected **Web**sites), of website data that is corrected for grammatical errors;[3] (ii) systematically compare it to previously released GEC corpora; (iii) benchmark current state-of-the-art GEC approaches on this data and demonstrate that they are heavily biased towards existing datasets with high error density, even after fine-tuning on our target domain; (iv) perform an analysis showing that a factor behind the performance drop is the inability of systems to rely on a strong internal language model in low error density domains.

We hope that the new dataset will contribute towards the development of robust GEC models in the open-domain setting.

Table 2: Distribution of sentences and tokens in the CWEB dataset.

2 CWEB Dataset

We create a new dataset of English texts from randomly sampled websites, and annotate it for grammatical errors. The source texts are randomly selected from the first 18 dumps of the CommonCrawl[4] dataset and represent a wide range of data seen online such as blogs, magazines, corporate or educational websites. These include texts written by native or non-native English speakers and professional as well as amateur online writers.

Text Extraction To ensure English content, we exclude websites with country-code top-level domains; e.g., .fr, .de. We use the `jusText`[5] tool to retrieve the content from HTML pages (removing boilerplate elements and splitting the content into paragraphs). We heavily filter the data by removing paragraphs which contain non-English[6] and incomplete sentences. To ensure diversity of the data, we also remove duplicate sentences. Among the million sentences gathered, we select paragraphs randomly.

We split the data with respect to where they

Table 3: Statistics on GEC Corpora; type–token is the average ratio of vocabulary size by the total number of tokens (calculated as an average over a sliding window of $1,000$ tokens); ratio of edits per sentence is calculated on erroneous sentences; sent-$\mathcal{K}$ is sentence-level Cohen's Kappa score (†: calculated for datasets with > 1 annotator); NEs stands for Named Entities (extracted using Spacy).

come from: sponsored[7] (CWEB-S) or generic[8] (CWEB-G) websites. The sponsored data represent a more focused domain (professional writing) than the generic one which includes writing from various proficiency levels.

Annotation The data is corrected for errors by two expert annotators, trained for correcting grammatical errors in English text: not attempting to rewrite the text nor make fluency edits, but rather to make minimal edits – minimum number of edits to make the text grammatical. During error annotation, the annotators have access to the entire paragraph in which a sentence belongs, therefore using the context of a sentence to help them in the correction. Examples of erroneous sentences from our data are shown in Table 1. Annotator agreement is calculated at the sentence level using Cohen's Kappa, i.e. we calculate whether annotators agree on which sentences are erroneous. This approach is preferable to relying on exact matching of error corrections, as as there are often many different ways to correct a sentence (Bryant and Ng, 2015). Kappa is 0.39 and 0.44 for sponsored (CWEB-S) and generic website (CWEB-G) data respectively, and Table 3 presents how our agreement results compare to those of existing GEC datasets. The table also includes a number of other statistics, and the different datasets are further analyzed, compared and contrasted in Section 5.

The texts are tokenized using SpaCy[9] and automatically labeled for error types (and converted into the M2 format) using the ERRor ANnotation Toolkit (ERRANT) (Bryant et al., 2017).

Release For each dataset, we release a development and a test set: we propose a roughly equal division of the data into the two splits, which presents a fair amount of errors to evaluate on (see Table 2).

To avoid copyright restrictions, we split the collected paragraphs into sentences and shuffle all sentences in order to break the original and coherent structure that would be needed to reproduce the copyrighted material. This approach has successfully been used in previous work for devising web-based corpora (Schäfer, 2015; Biemann et al., 2007). The data is available at `https://github.com/SimonHFL/CWEB`.

3 GEC Corpora

We compare our data with existing GEC corpora which cover a range of domains and proficiency levels. Table 3 presents a number of different statistics and Table 4 their error-type frequencies.[10]

3.1 English as a second language (ESL)

JFLEG (Napoles et al., 2017) The JHU Fluency-Extended GUG corpus consists of sentences written by English language learners (with different proficiency levels and L1s) for the TOEFL® exam,

Table 4: Number of error occurrences for the most frequent error types (per $10,000$ token).

covering a range of topics. Texts have been corrected for grammatical errors and fluency.

FCE (Yannakoudakis et al., 2011) consists of $1,244$ error corrected texts produced by learners taking the First Certificate in English exam, which assesses English at an upper-intermediate level. We use the data split made available for the BEA GEC shared task 2019 (Bryant et al., 2019).

CoNLL14 (Ng et al., 2014) consists of (mostly argumentative) essays written by ESL learners from the National University of Singapore, which are annotated for grammatical errors by two native speakers of English.

Write&Improve (W&I) (Bryant et al., 2019) Cambridge English Write & Improve (Yannakoudakis et al., 2018) is an online web platform that automatically provides diagnostic feedback to non-native English-language learners, including an overall language proficiency score based on the Common European Framework of Reference for Languages (CEFR).[11] The W&I corpus contains $3,600$ texts across 3 different CEFR levels – A (beginner), B (intermediate), and C (advanced) – that have been annotated for errors.[12]

3.2 Other Corpora

LOCNESS (Bryant et al., 2019; Granger, 1998) The LOCNESS corpus consists of essays written by native English students. A sample of 100 essays has been annotated for errors with a 50:50 development/test split.[13]

GMEG Wiki (Napoles et al., 2019) is devised based on edits in the Wikipedia revision history, and the writing therefore represents formal articles. Note that collecting sentences based on edits in the Wikipedia revision history introduces a substantial bias.[14] This means that evaluation results on this benchmark are not truly representative of how a system would perform when applied to realistic online data and full-length articles.

GMEG Yahoo (Napoles et al., 2019) comprises paragraphs of informal web posts gathered from answers in the *Yahoo! Answers* platform. The style is informal, and contains slang terms and non-conventional mechanics.

AESW (Daudaravicius et al., 2016) was released as part of the Automated Evaluation of Scientific Writing Shared Task. It is a collection of text extracts from published journal articles (mostly in physics and mathematics) along with their (sentence-aligned) corrected counterparts.[15]

4 System Performance

We evaluate performance on GEC benchmarks for two approaches to GEC that currently have state-of-the-art performance on CoNLL14. The first approach, that we refer to as GEC-PSEUDODATA and is proposed by Kiyono et al. (2019),[16] uses a transformer-based seq2seq model. The second approach uses the PIE system (Awasthi et al., 2019)[17] which leverages a BERT-based architecture for local sequence transduction tasks. Both models are

---

[11] `https://www.cambridgeenglish.org/exams-and-tests/cefr/`

[12] Since error corrections on test sets are not publicly available, we carry out our analyses on the development sets.

[13] See footnote 12.

[14] Sentences that have been edited are more likely to contain grammatical errors, and grammatical errors will therefore be over-represented. This is reflected in the 82.3% erroneous sentence rate (see Table 3).

[15] We exclude sentences that use AESW's normalization scheme (e.g. citations replaced with _CITE_), as the models we use are not trained with these special tokens.

[16] `www.github.com/butsugiri/gec-pseudodata`; We use the PRETLARGE+SSE (finetuned) model.

Table 5: Scores of two SOTA GEC systems on each domain. For both systems performance is substantially lower on CWEB than ESL domains. Scores are calculated against each individual annotator and averaged

pre-trained on synthetic errors and fine-tuned on learner data from the train section of FCE (Yannakoudakis et al., 2011), Lang-8 (Mizumoto et al., 2011), and NUCLE (Dahlmeier et al., 2013) and for GEC-PSEUDODATA additionally on the W&I train split (Bryant et al., 2019).

Performance is evaluated using the $F_{0.5}$ metric calculated by ERRANT (Bryant et al., 2017).[18] However, the more annotators a dataset has, the higher score a system will get on this data (Bryant and Ng, 2015). In order to perform a fair comparison of systems across datasets with a different number of annotators, we calculate the ERRANT score against each individual annotator and then take the average to get the final score.

Evaluation results are presented in Table 5. Across all datasets, we observe lower scores with the PIE system (-6.05 $F_{0.5}$ on average), while GEC-PSEUDODATA is consistently better. Overall $F_{0.5}$ ranges from around 30 to 52 for most datasets; however, when the models are evaluated on CWEB and AESW, we observe a substantial drop in performance, with the lowest $F_{0.5}$ score being the PIE system on CWEB-S (6.15). Precision, in particular, suffers due to the systems over-correcting sentences that should remain unchanged.

Using the GEC-PSEUDODATA system, on average, we find a higher $F_{0.5}$ on ESL corpora (JFLEG, FCE, CoNLL, W&I) compared to non-ESL ones (47.4 vs. 29.0). This demonstrates that GEC systems trained on language learning data do not perform as well on other domains and further work is needed to improve their generalization.

	P	**R**	**$F_{0.5}$**
CWEB-G	42.09	16.56	32.01
CWEB-S	35.91	12.96	26.46
CWEB (G+S)	39.89	15.2	30.0

Table 6: Scores of the GEC-PSEUDODATA system fine-tuned on CWEB data. Fine-tuning yields substantial improvements, but scores are still worse than on ESL domains. Scores are calculated against each individual annotator and averaged.

4.1 Fine-tuning

We investigate the extent to which the GEC-PSEUDODATA system can be adapted to our domain, and fine-tune it using our development sets.[19] We take $1,000$ sentences from each of the development sets of CWEB-G and CWEB-S and use them as a development set for this experiment. The remaining $4,729$ sentences of our development sets are used as training data for fine-tuning the GEC system.

In Table 6, we can see that fine-tuning substantially improves performance (around $+10.0$ $F_{0.5}$ across all CWEB sets). In particular, precision is improved ($+20.8$/$+18.6$ on CWEB-G/S) at the expense of recall (-6.4/-2.8 on CWEB-G/S). However, performance is still low compared to the language learning domain ($F_{0.5}$ of at least 41), further indicating that there is scope for developing more robust and general-purpose, open-domain GEC systems. For the purpose of future benchmarking, Appendix B lists the system's ERRANT scores based on both annotators – as opposed to the average of individual annotator scores reported in Table 6.

---

[18] `www.github.com/chrisjbryant/errant`

[19] We use the fine-tuning parameters of Kiyono et al. (2019).

5 Analysis

In order to assess the impact our new dataset can have on the GEC field, we carry out analyses to show 1) to what degree the domain of our data is different from existing GEC corpora, and how existing GEC systems are affected by the domain shift; and 2) that a factor behind the performance drop on CWEB data is the inability of systems to rely on a strong internal language model in low error density domains.

5.1 Domain Shift

Moving from error correction in learner texts to error correction in diverse, online texts, many of which are written by professional writers, amounts to a drift in data distribution. In general, distributional drift comes in different flavors; given two distributions $P(\mathbf{X}, \mathbf{Y})$ and $Q(\mathbf{X}, \mathbf{Y})$:

Covariate shift concerns change in the marginal distribution of the independent variable, i.e., $P(\mathbf{X}) \neq Q(\mathbf{X})$. In the context of grammatical errors, this refers to the degree to which the type of sentences written varies between domains. Table 3 clearly shows covariate shift effects: see, for example, differences in vocabulary variation (measured by the type–token ratio) and the frequency of named entities.

Label bias describes the change in distribution of the dependent variable, i.e., $P(\mathbf{Y}) \neq Q(\mathbf{Y})$. In terms of GEC, this refers to the difference in error distributions across domains. In Table 3, we can see that CWEB data contains errors that are substantially more sparse than other domains – a smaller proportion of sentences are erroneous, and these erroneous sentences also contain fewer edits compared to other domains. Additionally, looking at Table 4, we can see that almost all error types are substantially less frequent in our data than in existing benchmarks – for example, spelling errors are 38 times more prevalent in GMEG Wiki compared to CWEB-S.

Moving from learner text to web data involves both forms of drift: covariate shift and label bias. We further analyze the effects of these shifts on system performance.

5.1.1 Impact of Error Density

To demonstrate that the error density of corpora has a substantial impact on the performance of GEC systems, we vary the proportion of erroneous sentences in each dataset by either removing correct sentences or by adding correct sentences of the same domain.[20] By fixing the frequency of errors across datasets, we can observe, in isolation, how the systems are affected by co-variate shift across domains. Precision as a function of the proportion of erroneous sentences for selected datasets[21] is presented in Figure 2 (recall is unchanged).

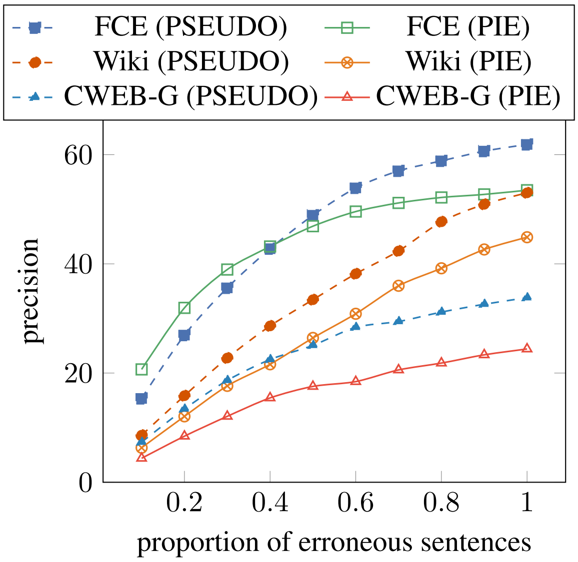

Figure 2: Precision as a function of the proportion of erroneous sentences in 3 different domains; comparing the GEC-PSEUDODATA (PSEUDO) and PIE systems.

For each domain, we observe precision being highly sensitive to the proportion of errors. This indicates that differences in error distribution across domains (i.e. label bias) is likely to be a large contributor to performance drop. We also observe the effect of covariate shift across the datasets: while the percentage of erroneous sentences is the same, precision differs for the different datasets which suggests that covariate shift across domains has an impact on the performance of the system.

5.1.2 Analysis of Gold Edits

In addition to error density, the type of errors present in the dataset also has an impact on the performance of GEC systems. We investigate how errors and their corresponding corrections differ across domains. In particular, we look at how gold edits in different domains change the sentence in terms of two factors: 1) How much do edits change the semantics of the sentence, and 2) to what degree do edits improve the sentence.

---

[20] For each dataset, we apply the gold corrections on incorrect sentences, creating new examples of in-domain, correct sentences, which are then randomly selected for inclusion.

[21] Scores for all datasets can be found in Appendix D.

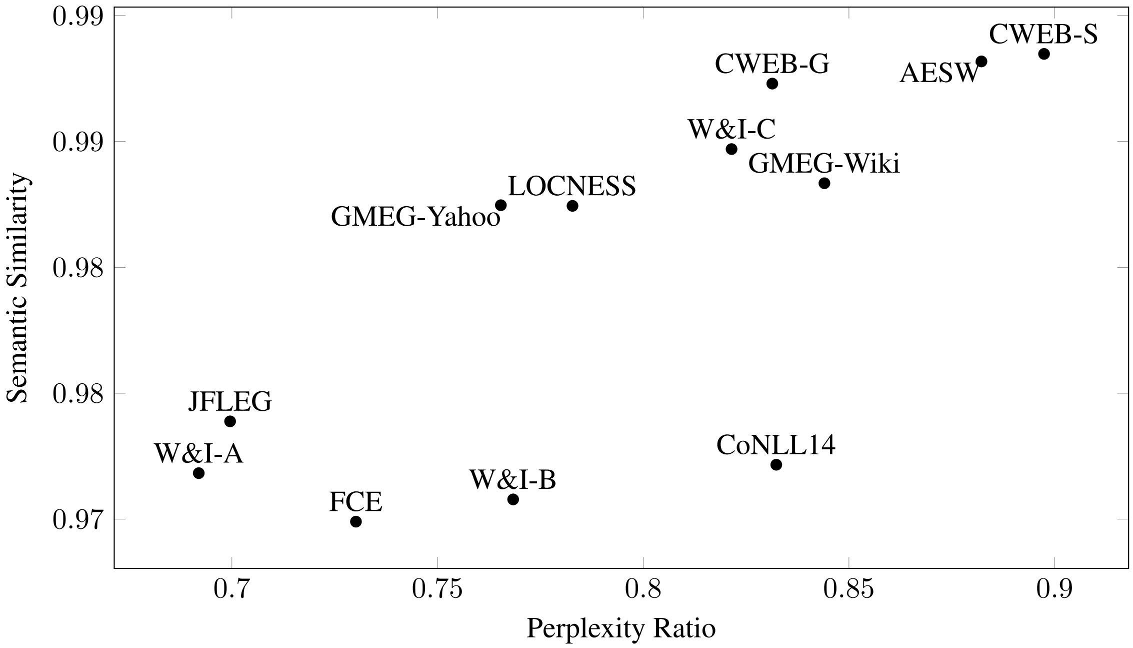

Figure 3: Average semantic similarity and perplexity ratio (sentence improvement) of sentences before and after being edited, plotted per dataset. The analysis is limited to sentences containing exactly one edit.

We limit our analysis to sentences containing exactly one edit, as we are interested in how individual edits change a sentence, regardless of how domains differ in amounts of erroneous sentences and in the number of edits per sentence (Table 3).

Regarding 1), to measure the semantic change of a sentence after an edit is introduced, we use sentence embeddings generated by Sentence-BERT (Devlin et al., 2019) and calculate the cosine similarity between the original sentence and its corrected counterpart. Regarding 2), the degree of sentence improvement is calculated as the ratio of the perplexity of GPT-2 (Radford et al., 2019) on a sentence after and before it has been edited.

$$\Delta P = \frac{PPL(edited\_sentence)}{PPL(original\_sentence)}$$

A lower ratio suggests that the edited sentence is an improvement, since its perplexity is lower than the original sentence.

Using the outputs of machine learning models as a proxy for semantic change and sentence improvement inevitably introduces biases, but nevertheless provide valuable insights into domain differences.

Corpus Level In Figure 3, the average semantic similarity and perplexity ratio is plotted for each dataset. It is evident that ESL datasets consist of edits with a higher degree of semantic change and sentence improvements than datasets from more advanced speakers. CWEB and AESW in particular stand out, with edits that largely retain the semantics of a sentence and that result in more subtle improvements.

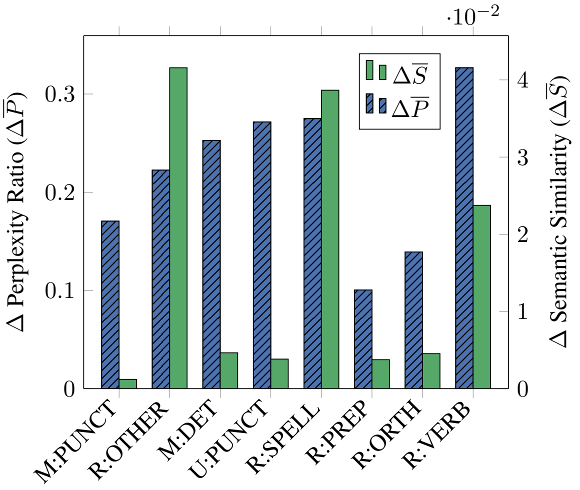

Figure 4: Difference in semantic similarity and perplexity ratio between CWEB-S and FCE for the most frequent error types (M: missing; R: replace; U: unnecessary).

Error type level In order to gain further insight on what is driving the differences between datasets, we look separately at how edits of each error type change the sentence. We compare FCE and CWEB-S, which lie at opposite ends in Figure 3. For each

	P	R	$F_{0.5}$
JFLEG	57.55	21.59	43.07
FCE	51.33	17.39	36.92
CoNLL14	40.30	16.56	31.17
W&I-A	45.79	15.10	32.55
W&I-B	43.17	14.46	30.90
W&I-C	33.02	9.81	22.42
LOCNESS	42.09	16.09	31.81
GMEG Wiki	52.36	13.35	32.99
GMEG Yahoo	62.50	16.45	39.45
AESW	10.18	3.58	7.44
CWEB-G	15.20	5.96	11.54
CWEB-S	8.94	1.33	4.17

Table 7: Scores of a language model based GEC system. The lower scores on CWEB and AESW indicate an inability to rely on language modelling in low error-density domains.

dataset, we obtain an average of semantic similarity, $\overline{S}$, and perplexity ratio, $\overline{P}$, separately for sentences of each error type. Then, for each error type, the difference, Δ, between scores in the two datasets is calculated.

$$\Delta\overline{S} = \overline{S}_{\text{CWEB-S}} - \overline{S}_{\text{FCE}}$$

$$\Delta\overline{P} = \overline{P}_{\text{CWEB-S}} - \overline{P}_{\text{FCE}}$$

Figure 4 plots these differences for the most common error types. We can observe that, for all error types, edits in CWEB-S result in both a lower degree of semantic change and sentence improvement than edits in FCE. This is particularly evident for the error types R:OTHER, R:SPELL and R:VERB. These are open class errors, where the error and correction can be quite different. It is therefore reasonable that differences in edits' degree of semantic change and perplexity improvement across domains are particularly observed in these cases.[22]

5.2 Language Model Importance

We also investigate the degree to which systems can rely on a strong internal language model representation when evaluated against different domains. We examine this by looking at the performance of a purely language model based GEC system over the different datasets.

We build on the approach of Bryant and Briscoe (2018), using confusion sets to generate alternative versions of an input sentence and then deciding if any of the alternatives are preferable to the original version, based on language model probabilities. The authors use an n-gram language model, which we replace with GPT-2 (Radford et al., 2019) to see how a strong neural language model performs – this approach is similar to Alikaniotis and Raheja (2019). Hyperparameters are tuned for each dataset (see Appendix C for details).

False Positive Examples	Perplexity ratio
All types of work are ~~callings~~ **called** to individuals.	0.34
Get started ~~at~~ **with** ACC	0.51
That ~~is~~ **was** actually kind of fun!	0.69

Table 8: Examples of false positives on the CWEB dataset that improve perplexity substantially – even more than the average gold edit in CWEB (0.86 perplexity ratio).

Table 7 displays the results on the different datasets. Recall and, in particular, precision is substantially lower on CWEB and AESW compared to other datasets. In general, scores are higher in domains with a higher proportion of errors and those containing edits which result in high perplexity improvements. In these cases systems can rely on a rough heuristic of replacing low probability sequences with high probability ones. However, in CWEB, where errors are fewer and more subtle, this leads to low precision, as perplexity alone cannot differentiate an erroneous sequence from a sequence that is rare but correct. Table 8 displays several examples of this, where false positive corrections suggested by the language model based GEC system have large perplexity improvements.

This analysis suggests that the inability to rely on a strong internal language model representation can negatively impact SOTA system performance on CWEB and on low error density domains in general. This would mean that having large amounts of error examples for training is more important in high-level domains.

6 Conclusion

We release a new GEC benchmark, CWEB, consisting of website text generated by English speakers at varying levels of proficiency. Comparisons against existing benchmarks demonstrate that CWEB differs in many respects: 1) in the distribution of sentences (higher vocabulary variation and named entity frequency); 2) in error density (lower); and 3)

---

[22] Score differences for the R:SPELL error type seem to be driven by a different propensity of spelling errors being of a typographical vs. phonetical nature in the two datasets.

in the types of edits and their impact on language model perplexity and semantic change.

We showed that existing state-of-the-art GEC models achieve considerably lower performance when evaluated on this new domain, even after fine-tuning. We argue that a factor behind this is the inability of systems to rely on a strong internal language model in low error density domains.

We hope that the dataset shall broaden the target domain of GEC beyond learner and/or exam writing and facilitate the development of robust GEC models in the open-domain setting.

C Language Model GEC Hyperparameter Tuning

A threshold, τ, determines the degree of probability improvement needed before an alternative sentence is preferred. For each dataset, we find τ, in the 0.9 to 1.0 range, resulting in the best development set $F_{0.5}$. For CoNLL14, we tune on CoNLL13; for W&I, we use the dedicated training sets; for LOCNESS, there is no training set available and so we tune on the W&I subset of advanced texts (W&I-C).

Abstract

Word embeddings are reliable feature representations of words used to obtain high quality results for various NLP applications. Uncontextualized word embeddings are used in many NLP tasks today, especially in resource-limited settings where high memory capacity and GPUs are not available. Given the historical success of word embeddings in NLP, we propose a retrospective on some of the most well-known word embedding algorithms. In this work, we deconstruct *Word2vec*, *GloVe*, and others, into a common form, unveiling some of the common conditions that seem to be required for making performant word embeddings. We believe that the theoretical findings in this paper can provide a basis for more informed development of future models.

1 Introduction

The advent of efficient uncontextualized word embedding algorithms (e.g., Word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014)) marked a historical breakthrough in NLP. Countless researchers employed word embeddings in new models to improve results on a multitude of NLP problems. In this work, we provide a retrospective analysis of these groundbreaking models of the past, which simultaneously offers theoretical insights for how future models can be developed and understood. We build on the theoretical work of Levy and Goldberg (2014), proving that their findings on the relationship between pointwise mutual information (PMI) and word embeddings go beyond Word2vec and singular value decomposition.

In particular, we generalize several word embedding algorithms into a common form by proposing the *low rank embedder* framework. We deconstruct each algorithm into its constituent parts, and find that, despite their many different hyperparameters, the algorithms collectively intersect upon the following two key design features. First, vector-covector dot products are learned to approximate PMI statistics in the corpus. Second, modulation of the loss gradient, directly or indirectly, is necessary to balance weak and strong signals arising from the highly imbalanced distribution of corpus statistics.

These findings can provide an informed basis for future development of both new embedding algorithms and deep contextualized models.

2 Fundamental concepts

We begin by formally defining embeddings, their vectors and covectors (also known as "input" and "output" vectors (Rong, 2014; Nalisnick et al., 2016)), and pointwise mutual information (PMI).

Embedding. In general topology, an embedding is understood as an injective structure preserving map, $f : X \to Y$, between two mathematical structures X and Y. A word embedding algorithm (f) learns an inner-product space (Y) to preserve a linguistic structure within a reference corpus of text, $\mathcal{D}$ (X), based on a vocabulary, $\mathcal{V}$. The structure in $\mathcal{D}$ is analyzed in terms of the relationships between words induced by their co-appearances, according to a certain definition of context. In such an analysis, each word figures dually: (1) as a focal element inducing a local context; and (2) as elements of the local contexts induced by focal elements. To make these dual roles explicit, we distinguish two copies of the vocabulary: the *focal*, or *term*, words $\mathcal{V}_T$, and the *context* words $\mathcal{V}_C$.

Word embedding consists of two maps:

$$\begin{aligned} \mathcal{V}_C &\longrightarrow \mathbb{R}^{1\times d} & \qquad \mathcal{V}_T &\longrightarrow \mathbb{R}^{d\times 1} \\ i &\longmapsto \langle i| & j &\longmapsto |j\rangle. \end{aligned}$$

We use Dirac notation to distinguish *vectors* $|j\rangle$, associated to focal words, from *covectors* $\langle i|$, asso-

ciated to context words. In matrix notation, $|j\rangle$ corresponds to a column vector and $\langle i|$ to a row vector. Their inner product is $\langle i|j\rangle$. We later demonstrate that many word embedding algorithms, intentionally or not, learn a vector space where the inner product between a focal word j and context word i aims to approximate their PMI in the reference corpus: $\langle i|j\rangle \approx \mathrm{PMI}(i,j)$.

Pointwise mutual information (PMI). PMI is a commonly used measure of association in computational linguistics, and has been shown to be consistent and reliable for many tasks (Terra and Clarke, 2003). It measures the deviation of the cooccurrence probability between two words i and j from the product of their marginal probabilities:

$$\mathrm{PMI}(i,j) := \ln \frac{p_{ij}}{p_i p_j} = \ln \frac{N N_{ij}}{N_i N_j}, \tag{1}$$

where p_{ij} is the probability of word i and word j cooccurring (for some notion of cooccurrence), and where p_i and p_j are marginal probabilities of words i and j occurring. The empirical PMI can be found by replacing probabilities with corpus statistics. Words are typically considered to cooccur if they are separated by no more than w words; N_{ij} is the number of counted cooccurrences between a *context* i and a *term* j; N_i, N_j, and N are computed by marginalizing over the N_{ij} statistics.

3 Word embedding algorithms

We will now introduce the *low rank embedder* framework for deconstructing word embedding algorithms, inspired by the theory of generalized low rank models (Udell et al., 2016). We unify several word embedding algorithms by observing them all from the common vantage point of their *global loss function*. Note that this framework is used for theoretical analysis, not necessarily implementation.

The global loss function for a *low rank embedder* takes the following form:

$$\mathcal{L} = \sum_{(i,j)\in\mathcal{V}_C\times\mathcal{V}_T} f_{ij}\Big(\ \psi(\langle i|, |j\rangle),\ \ \phi(i,j)\ \Big), \tag{2}$$

where $\psi(\langle i|, |j\rangle)$ is a kernel function of learned model parameters, and $\phi(i,j)$ is some scalar function (such as a measure of association based on how often i and j appear in the corpus); we denote these with ψ_{ij} and ϕ_{ij} for brevity. As well, f_{ij} are loss functions that take ψ_{ij} and ϕ_{ij} as inputs; all f_{ij} satisfy the property:

$$\frac{\partial f_{ij}}{\partial \psi_{ij}} = 0 \quad \text{at} \quad \psi_{ij} = \phi_{ij}. \tag{3}$$

The design variable ϕ_{ij} is some function of *corpus statistics*, and its purpose is to quantitatively measure some relationship between words i and j. The design variable ψ_{ij} is a function of *model parameters* that aims to approximate ϕ_{ij}; i.e., an embedder's fundamental objective is to learn $\psi_{ij} \approx \phi_{ij}$, and thus to train embeddings that capture the statistical relationships measured by ϕ_{ij}. The simplest choice for the kernel function ψ_{ij}, is to take $\psi_{ij} = \langle i|j\rangle$. But the framework allows any function that is symmetric and positive definite, allowing the inclusion of bias parameters (e.g. in GloVe) and subword parameterization (e.g. in FastText). We later demostrate that skip-gram with negative sampling takes $\phi_{ij} := \mathrm{PMI}(i,j) - \ln k$ and $\psi_{ij} := \langle i|j\rangle$, and then learns parameter values that approximate $\langle i|j\rangle \approx \mathrm{PMI}(i,j) - \ln k$.

To understand the range of models encompassed, it is helpful to see how the framework relates (but is not limited) to matrix factorization. Consider ϕ_{ij} as providing the entries of a matrix: $\mathbf{M} := [\phi_{ij}]_{ij}$. For models that take $\psi_{ij} = \langle i|j\rangle$, we can write $\hat{\mathbf{M}} = \mathbf{WV}$, where $\mathbf{W}$ is defined as having row i equal to $\langle i|$, and $\mathbf{V}$ as having column j equal to $|j\rangle$. Then, the loss function can be rewritten as:

$$\mathcal{L} = \sum_{(i,j)\in\mathcal{V}_C\times\mathcal{V}_T} f_{ij}\Big((\mathbf{WV})_{ij},\ \mathbf{M}_{ij}\Big).$$

This loss function can be interpreted as matrix reconstruction error, because the constraint in Eq. 3 means that the gradient goes to zero as $\mathbf{WV} \approx \mathbf{M}$.

Selecting a particular low rank embedder instance requires key design choices to be made: we must chose the embedding dimension d, the form of the loss terms f_{ij}, the kernel function ψ_{ij}, and the association function ϕ_{ij}. The derivative of f_{ij} with respect to ψ_{ij}, which we call the *characteristic gradient*, helps compare models because it exhibits the action of the gradient yet is symmetric in the parameters. In the Appendix we show how this derivative relates to gradient descent.

In the following subsections, we present the derivations of $\frac{\partial f_{ij}}{\partial \psi_{ij}}$, ψ_{ij}, and ϕ_{ij} for SVD (Levy and Goldberg, 2014; Levy et al., 2015), SGNS (Mikolov et al., 2013), FastText (Joulin et al., 2017), GloVe (Pennington et al., 2014), and LDS (Arora et al., 2016). The derivation for Swivel (Shazeer

Model	$\frac{\partial f_{ij}}{\partial \psi_{ij}}$	ψ_{ij}	ϕ_{ij}	$\langle i\vert j\rangle \approx$
SVD	$2 \cdot \left[\psi_{ij} - \phi_{ij}\right]$	$\langle i\vert j\rangle$	$\text{PMI}(i,j)$	$\text{PMI}(i,j)$
SGNS	$(N_{ij} + N_{ij}^-) \cdot \left[\sigma(\psi_{ij}) - \sigma(\phi_{ij})\right]$	$\langle i\vert j\rangle$	$\ln \frac{N_{ij}}{N_{ij}^-}$	$\text{PMI}(i,j) - \ln k$
GloVe	$2h(N_{ij}) \cdot \left[\psi_{ij} - \phi_{ij}\right]$	$\langle i\vert j\rangle + b_i + b_j$	$\ln N_{ij}$	$\text{PMI}(i,j)$
LDS	$4h(N_{ij}) \cdot \left[\psi_{ij} - \phi_{ij} + C\right]$	$\Vert\langle i\vert + \vert j\rangle^\intercal\Vert^2$	$\ln N_{ij}$	$d\text{PMI}(i,j) - d\gamma$
Swivel	$\sqrt{N_{ij}} \cdot \left[\psi_{ij} - \phi_{ij}\right]$	$\langle i\vert j\rangle$	$\text{PMI}(i,j)$	$\text{PMI}(i,j)$
	$1 \cdot \sigma\left(\psi_{ij} - \phi_{ij}\right)$		$\text{PMI}^*(i,j)$	$\text{PMI}^*(i,j)$

Table 1: Comparison of low rank embedders. Final column shows the value of $\langle i|j\rangle$ at $\frac{\partial f_{ij}}{\partial \psi_{ij}} = 0$. GloVe and LDS set $f_{ij} = 0$ when $N_{ij} = 0$; $h(N_{ij})$ is a weighting function sublinear in N_{ij}. Swivel takes one form when $N_{ij} > 0$ (first row) and another when $N_{ij} = 0$ (second row). N_{ij}^- is the number of negative samples; in SGNS, $N_{ij}^- \propto N_i N_j$, and both N_{ij} and N_{ij}^- are tempered by undersampling and unigram smoothing.

et al., 2016) as a low rank embedder is trivial, as it is already posed as a matrix factorization of PMI statistics. We summarize the derivations in Table 1.

3.1 SVD as a low rank embedder

Singular value decomposition (SVD) of the positive-PMI (PPMI) matrix is used by Levy and Goldberg (2014); Levy et al. (2015) to produce word embeddings that perform more or less equivalently to SGNS and GloVe. Converting the PMI matrix into PPMI is a trivial preprocessing step; ϕ is augmented according to a factor $\alpha = 0$ such that $\phi_{ij} = 0 \ \forall \phi_{ij} \leq \alpha$. We now prove why SVD of the PMI matrix results in word embeddings with dot products $\langle i|j\rangle \approx \text{PMI}(i,j)$, noting that this proof naturally holds for all augmentations of ϕ according to the α factor, including PPMI.

Proof. Truncated SVD provides an optimal solution to problem $\min_D \|D - A\|_F$ for some integer K less than the dimensionality of matrix A such that $\text{rank}(D) = K$ (Udell et al., 2016). The solution is the truncated SVD of A where $D = \sum_{k=1}^{K} \sigma_k u_k v_k^\intercal$ with σ being the k^{th} singular value and u_k and v_k as the k^{th} left and right singular vectors.

Within our framework, the truncated SVD of the PMI matrix thus solves the following loss function (note $A_{ij} = \phi_{ij} = \text{PMI}(i,j)$):

$$\mathcal{L} = -\sum_{(i,j)\in\mathcal{V}_C\times\mathcal{V}_T} \left(\psi_{ij} - \text{PMI}(i,j)\right)^2, \qquad (4)$$

where $\psi_{ij} = u_i^\intercal \Sigma v_j$. Allowing the square matrix of singular values Σ to be absorbed into the vectors (as in Levy et al. (2015)), we have $\langle i| = u_i$ and $|j\rangle = \Sigma v_j$. Thus, taking the derivative $\frac{\partial f_{ij}}{\partial \psi_{ij}}$ (noting that f_{ij} here is simply the squared difference between ψ_{ij} and ϕ_{ij}) and setting it equal to zero we observe:

$$\langle i|j\rangle = \text{PMI}(i,j). \qquad (5)$$

3.2 SGNS as a low rank embedder

Mikolov et al. (2013) proposed skip-gram with negative sampling with the following loss function:

$$\mathcal{L} = -\sum_{(i,j)\in D_2} \left\{ \ln \sigma\langle i|j\rangle + \sum_{\ell=1}^{k} \mathbb{E}\Big[\ln(1 - \sigma\langle i'_\ell|j\rangle)\Big] \right\},$$

where σ is the logistic sigmoid function, D_2 is a *list* containing each cooccurrence of a context-word i with a focal word j in the corpus, and the expectation is taken by drawing i'_ℓ from the (smoothed) unigram distribution to generate k "negative samples" for a given focal-word (Mikolov et al., 2013). We will demonstrate that SGNS is a low rank embedder with $\langle i|j\rangle \approx \text{PMI} - \ln k$.

Proof. We can transform the loss function by counting the number of times each pair occurs in the corpus, N_{ij}, and the number of times each pair is drawn as a negative sample, N_{ij}^-, while indexing the sum over the set $\mathcal{V}_C \times \mathcal{V}_T$:

$$\mathcal{L} = -\sum_{(i,j)\in\mathcal{V}_C\times\mathcal{V}_T} \Big\{ N_{ij} \ln \sigma\langle i|j\rangle + N_{ij}^- \ln(1 - \sigma\langle i|j\rangle) \Big\}.$$

The global loss is almost in the required form for a low rank embedder (Eq. 2), and the appropriate setting for the model approximation function is $\psi_{ij} = \langle i|j\rangle$. Calculating the partial derivative with respect to the model approximation function ψ_{ij}, following algebraic manipulation (using the identity $a \equiv (a+b)\sigma(\ln \frac{a}{b})$), we arrive at the following definition of the characteristic gradient for SGNS as a low rank embedder, where $\frac{\partial f_{ij}}{\partial \psi_{ij}} = \frac{\partial \mathcal{L}}{\partial \langle i|j\rangle}$:

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \langle i|j\rangle} &= N_{ij}^{-}\sigma\langle i|j\rangle - N_{ij}(1-\sigma\langle i|j\rangle) \\ &= (N_{ij}+N_{ij}^{-})\Big[\sigma\big(\langle i|j\rangle\big) - \sigma\Big(\ln\frac{N_{ij}}{N_{ij}^{-}}\Big)\Big] \\ &= (N_{ij}+N_{ij}^{-})\Big[\sigma\big(\psi_{ij}\big) - \sigma\big(\phi_{ij}\big)\Big]. \qquad (6)\end{aligned}$$

This provides that the association function for SGNS is $\phi_{ij} = \ln(N_{ij}/N_{ij}^{-})$, since the derivative will be equal to zero at that point (Eq. 3). However, recall that negative samples are drawn according to the unigram distribution (or a smoothed variant (Levy et al., 2015)). This means that $N_{ij}^{-} = kN_iN_j/N$. Therefore, in agreement with Levy and Goldberg (2014), we find that:

$$\phi_{ij} = \ln\frac{N_{ij}N}{N_iN_jk} = \mathrm{PMI}(i,j) - \ln k. \qquad (7)$$

3.3 FastText as a low rank embedder

Proposed by Joulin et al. (2017), FastText's motivation is orthogonal to the present work. Its purpose is to provide subword-based representation of words to improve vocabulary coverage and generalizability of word embeddings. Nonetheless, it can also be understood as a low rank embedder .

Proof. FastText uses a loss function that is identical to SGNS except that the vector for each word is taken as the sum of embeddings for all character n-grams appearing in the word, with $3 \le n \le 6$. Therefore, define $|j\rangle$ by $|j\rangle \equiv \sum_{g\in z(j)} |g\rangle$, where $|g\rangle$ is the vector for n-gram g, and $z(j)$ is the set of n-grams in word j. Covectors are accorded to words directly, so need not be redefined. The loss function and the derivation of entries for Table 1 is then formally identical to those for SGNS. This provides that $\psi_{ij} = \langle i|j\rangle$, and, $\phi_{ij} = \mathrm{PMI}(i,j) - \ln k$.

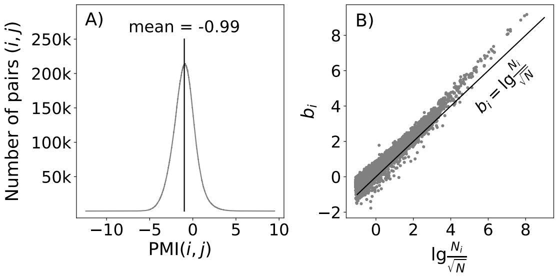

Figure 1: **A**) Histogram of $\mathrm{PMI}(i,j)$ values, for all pairs (i,j) with $N_{ij} > 0$. **B**) Scatter plot of GloVe's learned biases. Both from a Wikipedia 2018 corpus.

3.4 GloVe as a low rank embedder

GloVe was proposed as an algorithm halfway between sampling methods and matrix factorization (Pennington et al., 2014). Ignoring samples where $N_{ij} = 0$, GloVe uses the following loss function:

$$\mathcal{L} = \sum_{ij} h(N_{ij})\Big(\langle i|j\rangle + b_i + b_j - \ln N_{ij}\Big)^2 \qquad (8)$$

where b_i and b_j are learned bias parameters, and $h(N_{ij})$ is a weighting function sublinear in N_{ij}.

GloVe can be cast as a low rank embedder by using the model approximation function as a kernel with bias parameters, and setting the association measure to simply be the objective:

$$\begin{aligned}\psi_{ij} &= \big[\,\langle i|_1 \cdots \langle i|_d\; b_i\; 1\,\big]\cdot\big[\,|j\rangle_1 \cdots |j\rangle_d\;\; 1\;\; b_j\,\big]^{\intercal}, \\ &\text{and} \quad \phi_{ij} = \ln N_{ij}.\end{aligned}$$

Proof. Observe an optimal solution to the loss function, when $\frac{\partial f_{ij}}{\partial \psi_{ij}} = 0$:

$$\begin{aligned}\frac{\partial f_{ij}}{\partial \psi_{ij}} &= 2h(N_{ij})\Big[\langle i|j\rangle + b_i + b_j - \ln N_{ij}\Big] = 0 \\ &\implies \langle i|j\rangle + b_i + b_j = \ln N_{ij}.\end{aligned}$$

Multiplying the log operand by 1:

$$\begin{aligned}\langle i|j\rangle + b_i + b_j &= \ln\left(\frac{N_iN_j}{N}\frac{N}{N_iN_j}N_{ij}\right) \qquad (9) \\ &= \ln\frac{N_i}{\sqrt{N}} + \ln\frac{N_j}{\sqrt{N}} + \mathrm{PMI}(i,j). \qquad (10)\end{aligned}$$

On the right side, we have two terms that depend respectively only on i and j, which are candidates for the bias terms. Based on this equation alone, we cannot draw any conclusions. However, empirically the bias terms are in fact very near $\frac{N_i}{\sqrt{N}}$ and $\frac{N_j}{\sqrt{N}}$, and PMI is observed to be normally distributed, as can be seen in Fig. 1. This means that Eq. 10 provides $\langle i|j\rangle \approx \mathrm{PMI}(i,j)$.

Analyzing the optimum of GloVe's loss function yields important insights. First, GloVe can be added to the list of low rank embedders that learn a bilinear parameterization of PMI. Second, we can see why such a parameterization is advantageous. Generally, it helps to standardize features of low rank models (Udell et al., 2016), and this is essentially what transforming cooccurrence counts into PMI achieves. Thus, PMI can be viewed as a parameterization trick, providing an approximately normal target association to be modelled.

3.5 LDS as a low rank embedder

Arora et al. (2016) introduced an embedding perspective based on generative modelling with random walks through a latent discourse space (LDS). LDS provided a theoretical basis for the performant *SIF document embedding* algorithm, developed soon afterwards (Arora et al., 2017). We now demonstrate that LDS is also a low-rank embedder.

Proof. The low rank learning objective for LDS follows directly from **Corollary 2.3**, in Arora et al. (2016):

$$\mathrm{PMI}(i,j) = \frac{\langle i|j\rangle}{d} + \gamma + O(\epsilon).$$

$\frac{\partial f_{ij}}{\partial \psi_{ij}}$ can be found by straightforward differentiation of LDS's loss function:

$$\mathcal{L} = \sum_{ij} h(N_{ij})\big[\ln N_{ij} - \|\langle i| + |j\rangle^{\intercal}\|^2 - C\big]^2,$$

where $h(N_{ij})$ is as defined by GloVe. The quadratic term is a valid kernel function because:

$$\frac{\partial f_{ij}}{\partial \psi_{ij}} = \|\langle i| + |j\rangle^{\intercal}\|^2 = \langle \tilde{i}|\tilde{j}\rangle,$$

where

$$\begin{aligned}\langle \tilde{i}| &= \begin{bmatrix}\sqrt{2}\langle i|_1 & \cdots & \sqrt{2}\langle i|_d & \langle i|\langle i|^{\intercal} & 1\end{bmatrix},\\ |\tilde{j}\rangle &= \begin{bmatrix}\sqrt{2}|j\rangle_1 & \cdots & \sqrt{2}|j\rangle_d & 1 & |j\rangle^{\intercal}|j\rangle\end{bmatrix}^{\intercal}.\end{aligned}$$

4 Related work

Our derivation of SGNS's solution is inspired by the work of Levy and Goldberg (2014), who proved that *skip-gram with negative sampling* (SGNS) (Mikolov et al., 2013) was implicitly factorizing the $\mathrm{PMI} - \ln k$ matrix. However, they required additional assumptions for their derivation to hold. Li et al. (2015) explored relations between SGNS and matrix factorization, but their derivation diverges from Levy and Goldberg's result and masks the connection between SGNS and other low rank embedders. Other works have also explored theoretical or empirical relationships between SGNS and GloVe (Shi and Liu, 2014; Suzuki and Nagata, 2015; Levy et al., 2015; Arora et al., 2016).

5 Discussion

We observe common features between each of the algorithms (Table 1). In each case, $\frac{\partial f_{ij}}{\partial \psi_{ij}}$ takes the form $(\text{multiplier}) \cdot (\text{difference})$. The multiplier is always a "tempered" version of N_{ij} (or $N_i N_j$); that is, it increases sublinearly with N_{ij}.

For each algorithm, ϕ_{ij} is equal to PMI or a scaled log of N_{ij}. Yet, the choice of ψ_{ij} in combination with ϕ_{ij} provides that every model is optimized when $\langle i|j\rangle$ tends toward $\mathrm{PMI}(i,j)$ (with or without a constant shift or scaling). We demonstrated that the optimum for SGNS (and FastTest) is equivalent to the shifted PMI (§3.2). For GloVe, we showed that incorporation of the bias terms captures the unigram counts needed for PMI (§3.4). A similar property is found in LDS with regards to the L2 norm in its learning objective (Arora et al., 2016). Thus, these algorithms all converge on two key points: (1) an optimum in which model parameters are bilinearly related to PMI; and, (2) the weighting of $\frac{\partial f_{ij}}{\partial \psi_{ij}}$ by some tempered form of N_{ij}.

6 Conclusion

Our *low rank embedder* framework has evoked the commonalities between many word embedding algorithms. We believe a robust understanding of these algorithms is a prerequisite for theoretically motivated development of deeper models. Indeed, we offer the following conjectures: deep embedding models would benefit by incorporating PMI statistics into their training objective; such models will also benefit from sub-linear scaling of frequent word pairs during training; and, lastly, such models would benefit by learning representations with a dual character, as all of the embedding algorithms we described do by learning vectors *and* covectors.

A Appendix

A.1 On the characteristic gradient

The relationship between $\frac{\partial f_{ij}}{\partial \psi_{ij}}$ and the gradient descent actions taken during learning requires simply taking the next step in the chain rule during differentiation. For simplicity of exposition, we will assume, like SGNS and Swivel, that $\psi_{ij} = \langle i|j\rangle$, although the motivation of taking this derivative holds for any definition of ψ_{ij}, provided that it is a kernel function of the model parameters.

By examining the derivative $\frac{\partial f_{ij}}{\partial \langle i|j\rangle}$ we observe the primary objective of the model (to approximate dot products), and how this objective symmetrically updates vectors and covectors during learning.

Consider the generic update that occurs for a single (i, j) pair with the pairwise loss function f_{ij}. The gradient descent rule for a single update to the vector for word j, using some learning rate η, is:

$$|j\rangle \leftarrow |j\rangle - \eta \frac{\partial f_{ij}}{|j\rangle}, \tag{11}$$

However, since f_{ij} is a function of $\langle i|j\rangle$ and not of the vectors or covectors independently, we can use the chain rule to arrive at the following:

$$|j\rangle \leftarrow |j\rangle - \eta \frac{\partial f_{ij}}{\partial \langle i|j\rangle} \frac{\partial \langle i|j\rangle}{\partial |j\rangle} \tag{12}$$

$$|j\rangle \leftarrow |j\rangle - \eta \frac{\partial f_{ij}}{\partial \langle i|j\rangle} \langle i|^{\intercal}, \tag{13}$$

since $\frac{\partial \langle i|j\rangle}{\partial |j\rangle} = \langle i|$. Symmetrically, we also arrive at, for the updates to covectors:

$$\langle i| \leftarrow \langle i| - \eta \frac{\partial f_{ij}}{\partial \langle i|j\rangle} |j\rangle^{\intercal}. \tag{14}$$

Therefore, taking $\frac{\partial f_{ij}}{\partial \langle i|j\rangle}$ (more generally, $\frac{\partial f_{ij}}{\partial \psi_{ij}}$) to be the focal point of analysis in determining the objectives of the low rank embedders is well grounded.

Sequential Modelling of the Evolution of Word Representations for Semantic Change Detection

Adam Tsakalidis[1,3] Maria Liakata[1,2,3]

Abstract

Semantic change detection concerns the task of identifying words whose meaning has changed over time. Current state-of-the-art approaches operating on neural embeddings detect the level of semantic change in a word by comparing its vector representation in two distinct time periods, without considering its evolution through time. In this work, we propose three variants of sequential models for detecting semantically shifted words, effectively accounting for the changes in the word representations over time. Through extensive experimentation under various settings with synthetic and real data we showcase the importance of sequential modelling of word vectors through time for semantic change detection. Finally, we compare different approaches in a quantitative manner, demonstrating that temporal modelling of word representations yields a clear-cut advantage in performance.

1 Introduction

Identifying words whose lexical meaning has changed over time is a primary area of research at the intersection of natural language processing and historical linguistics. Through the evolution of language, the task of "semantic change detection" (Tahmasebi et al., 2018; Tang, 2018; Kutuzov et al., 2018) can provide valuable insights on cultural evolution over time (Michel et al., 2011). Measuring linguistic change is also relevant to understanding the dynamics in online communities (Danescu-Niculescu-Mizil et al., 2013) and the evolution of individuals (McAuley and Leskovec, 2013). Recent years have seen a surge in interest in this area since researchers are now able to leverage the increasing availability of historical corpora in digital form and develop models that detect the shift in a word's meaning through time.

However, two key challenges in the field still remain. Firstly, there is little work in existing literature on model comparison (Schlechtweg et al., 2019; Dubossarsky et al., 2019; Shoemark et al., 2019). Partially due to the lack of (longitudinal) labelled datasets, existing work assesses model performance mainly in a qualitative manner, without quantitative comparisons against prior work. Therefore, it becomes difficult to assess *what constitutes an appropriate approach for semantic change detection*. Secondly, on a methodological front, a large body of related work detects semantically shifted words by pairwise comparisons of their representations in distinct time periods, *ignoring the sequential modelling aspect of the task*. Since semantic change is a time-sensitive process (Tsakalidis et al., 2019), considering consecutive vector representations through time – instead of two bins of word representations (Schlechtweg et al., 2018, 2020) – can be crucial to improving model performance (Shoemark et al., 2019).

Here we tackle both challenges by approaching semantic change detection as an anomaly identification task. Working on embedding representations of words in the English language, we learn their evolution through time via an encoder-decoder architecture. We hypothesize that once such a model has been successfully trained on temporally sensitive sequences of word representations, it will accurately predict the evolution of the semantic representation of any word through time. Words that have undergone semantic change will be those that yield the highest errors by the prediction model. Our work makes the following contributions:

- we develop three variants of an LSTM-based architecture to measure the level of semantic change of a word by tracking its evolution through time in a sequential manner: (a) a word representation autoencoder, (b) a future word representation decoder and (c) a hybrid approach combining (a) and (b);

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8485–8497,
November 16–20, 2020.

- we show the effectiveness of our models under thorough experimentation with synthetic data;
- we compare our models against current practices and competitive baselines using real data, demonstrating important gains in performance and highlighting the importance of sequential modelling of word vectors through time;
- we release our code, to help set up a benchmark for model comparison within the domain in a quantitative fashion.[1]

2 Related Work

One can distinguish two directions within the literature on semantic change detection: (a) learning word representations over discrete time intervals (bins) and comparing the resulting vectors and (b) jointly learning word representations across time (Bamler and Mandt, 2017; Rosenfeld and Erk, 2018; Yao et al., 2018; Rudolph and Blei, 2018). Such representations can be generated via different approaches, such as topic- (Frermann and Lapata, 2016; Perrone et al., 2019), graph- (Mitra et al., 2014) and neural-based models (e.g., word2vec) – work by Tahmasebi et al. (2018) provides an overview of such approaches. In this work we focus on (a) due to scalability issues in learning diachronic representations from very large corpora, as in our case, and – without loss of generality – we utilise pre-trained, neural-based representations.

Related work in (a) derives word representations W_i ($i \in [0,..,|T-1|]$) across $|T|$ time intervals and performs pairwise comparisons for different values of i. Early work used frequency- or co-occurrence-based representations (Sagi et al., 2009; Cook and Stevenson, 2010; Gulordava and Baroni, 2011; Mihalcea and Nastase, 2012). However, leveraging word2vec-based representations (Mikolov et al., 2013) has become the common practice in recent years. Due to the stochastic nature of word2vec, Orthogonal Procrustes (OP) (Schönemann, 1966) is often applied to the resulting vectors, aiming at aligning the pairwise representations (Kulkarni et al., 2015; Hamilton et al., 2016; Del Tredici et al., 2019; Shoemark et al., 2019; Tsakalidis et al., 2019; Schlechtweg et al., 2019). Given two word matrices W_k, W_j at times k and j respectively, OP finds the optimal transformation matrix $R = \underset{\Omega;\Omega^T\Omega=I}{argmin} \|\Omega W_k - W_j\|_F$ and the semantic shift level of a word w during this time interval is defined as the cosine distance between the two aligned matrices (Hamilton et al., 2016). By operating in a linear pairwise fashion, such approaches ignore the time-sensitive and possibly non-linear nature of semantic change.

By contrast, Kim et al. (2014), Kulkarni et al. (2015), Dubossarsky et al. (2019) and Shoemark et al. (2019) derive time series of a word's level of semantic change to detect semantically shifted words. Even though these methods incorporate temporal modelling, they either rely heavily on the linear transformation R (Kulkarni et al., 2015; Shoemark et al., 2019) or focus primarily on the *generation* of temporally-sensitive representations as a means towards capturing semantic change (Kim et al., 2014; Dubossarsky et al., 2019). A key contribution of our work is that we do not base our methods on pre-defined transformations, but instead propose a model for learning how (any type of) pre-trained word representations vary across time, effectively exploiting the full sequence of a word's evolution.

Finally, the comparative evaluation of semantic change detection models is still in its infancy. Most related work assesses model performance based on artificial tasks (Cook and Stevenson, 2010; Kulkarni et al., 2015; Rosenfeld and Erk, 2018; Dubossarsky et al., 2019; Shoemark et al., 2019) or on a few hand-picked examples (Sagi et al., 2009), without cross-model comparison. The recently introduced shared tasks SemEval Task 1 (Schlechtweg et al., 2020) and DIACR-Ita (Basile et al., 2020) aim at bridging this gap; however, the respective datasets consist of documents split in two distinct time periods, thus not facilitating the study of the sequential nature of semantic change. Setting a benchmark for model comparison with real-world and sequential word representations is crucial in this field.

3 Methods

We formulate semantic change detection as an anomaly detection task in the evolution of pre-trained word embeddings. We assume that pre-trained word vectors $W_t \in [W_0, ..., W_{|T-1|}]$, where $W_t \in R^{|V| \times d}$ ($|V|$: vocabulary size; d: word representation size) in a historical corpus over $|T|$ time periods, evolve according to a non-linear function

---

[1] Code is available at: `https://github.com/adtsakal/semantic_change_evolution`

$f(W_t)$.[2] By approximating f, we obtain the level of semantic shift of a word w at time t by measuring the similarity between its word representation w_t against $f(w_t)$. A low similarity score for a given word implies an inaccurate model prediction (anomaly) and thus a high level of semantic change for the given word. Therefore, we can obtain a ranking of the words based on their semantic shift level by ordering them in ascending order of their similarity scores between w_t and $f(w_t)$. We approximate f via temporally sensitive deep neural models: (a) an autoencoder, which aims to reconstruct a word's trajectory up to a given point in time i $[w_0, ..., w_{|i|}]$ (section 3.1); and (b) a future predictor, which aims to predict future representations of the word $[w_{|i+1|}, ..., w_{|T-1|}]$ (section 3.2). The two models can be trained individually or (c) in a joint multi-task setting (section 3.3). These models benefit from accounting for sequential word representations across time $[W_0, ..., W_{|T-1|}]$, which is better suited for detecting semantically shifted words compared to the common practice of comparing only the first and last word representations $[W_0, W_{|T-1|}]$ (Shoemark et al., 2019).

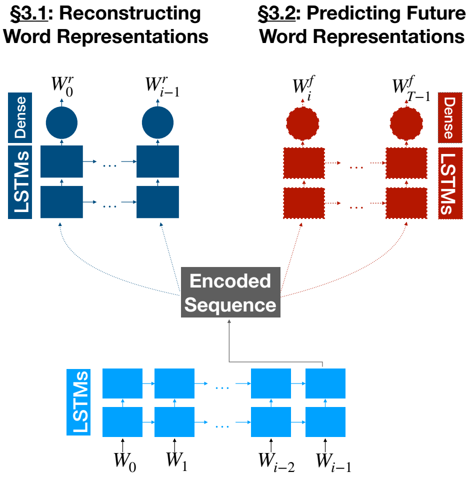

Figure 1: Overview of our proposed model: the sequence of the representation of a set of word vectors (vocabulary) over different time steps $W_{0:i-1}$ is encoded through two LSTM layers and then passed over to a reconstruction (3.1) decoder and a future prediction decoder (3.2). The model is trained by utilising **either decoder** in isolation, or **both** of them in parallel (3.3).

3.1 Reconstructing Word Representations

Given an input sequence of vectors representing the words in a vocabulary across i points in time $W_{0:i-1} = [W_0, W_1, ..., W_{i-1}]$, the goal of the autoencoder is to reconstruct the input sequence $W_{0:i-1}$. Since the task of semantic change includes a natural temporal dimension, we model our autoencoder via RNNs (see Figure 1). The encoder is composed of two LSTM layers (Hochreiter and Schmidhuber, 1997) with Dropout layers operating on their outputs, for regularisation (Srivastava et al., 2014). The first layer encodes the input sequence of $W_{0:i-1}$ and returns the hidden states as input to the second layer. The output of the second layer is the final encoded state, which is then copied $|i|$ times and fed as input to the decoder. The decoder has the same architecture as the encoder, albeit with additional dense layers on top of the second LSTM layer to make the final reconstruction $W^r_{0:i-1}$ on the $|i|$ time steps. The model is trained by minimising the mean squared error (MSE) loss function:

$$L_r = \frac{1}{i}\sum_{j=0}^{i-1} MSE(W_j, W^r_j). \quad (1)$$

After training, the words that yield the highest error rates in a given test set of word representations through time are considered to be the ones whose semantics have changed the most during the given time period. This is compatible with prior work based on word alignment (Hamilton et al., 2016; Tsakalidis et al., 2019), where the alignment error of a word indicates its level of semantic change.

3.2 Predicting Future Word Representations

Reconstructing the word vectors can reveal which words have changed their semantics in the past (i.e., up to time $i-1$, see 3.1). If we are interested in predicting changes in the semantics of future word representations (i.e., after time $i-1$), we can consider a future word representation prediction task: given the sequence of past word representations $W_{0:i-1} = [W_0, W_1, ..., W_{i-1}]$ over the first i time points, we predict the future representations of the words in the vocabulary $W_{i:T-1} = [W_i, W_{i+1}, ..., W_{T-1}]$, for a sequence of overall length $|T|$ (see Figure 1). We follow the same model architecture as in section 3.1, with the only difference being the number of time steps $(T-i)$ used in the decoder to make $|T-i|$ predictions. The model is trained using the loss function L_f:

$$L_f = \frac{1}{T-i}\sum_{j=i}^{T-1} MSE(W_j, W^f_j). \quad (2)$$

---

[2] Note: t in W_t indicates the time period from when the associated pre-trained word vectors are taken (e.g., year 2000).

3.3 Joint Model

The two models can be combined into a joint one, where, given an input sequence of representations of the vocabulary $W_{0:i-1}$ over i points in time, the goal is both to (a) reconstruct the input sequence and (b) predict the future word $|T-i|$ representations $W_{i:T-1}$. The complete model architecture is provided in Figure 1: the encoder is identical to the one used in 3.1 and 3.2. However, the bottleneck is now copied $|T|$ times and passed to the decoders of the reconstruction ($|i|$ times) and future prediction ($|T-i|$ times). The loss function L_{rf} here is the summation of the individual losses in Eq. 1 and 2:

$$\begin{aligned} L_{rf} = &\frac{1}{i}\sum_{j=0}^{i-1} MSE(W_j, W_j^r) \\ &+ \frac{1}{T-i}\sum_{j=i}^{T-1} MSE(W_j, W_j^f). \end{aligned} \quad (3)$$

There are two main reasons for modelling semantic change in this multi-task setting. Firstly, we benefit from the finer granularity of the two decoders due to their handling of only part of the sequence in a more fine-grained manner, compared to the individual task models. Secondly, the joint model is insensitive to the value of i in Eq. 3 compared to Eq. 1 and 2, as discussed next.

3.4 Model Equivalence

The three models perform different operations; however, setting the operational time periods appropriately in Eq. 1-3 can result in model equivalence (i.e., performing the same task). Specifically, to detect the words whose semantics have changed during [0, $T-1$], the autoencoder (Eq. 1) needs to be fed and reconstruct the full sequence across [0, $T-1$] (i.e., i=T-1). Reducing this interval (reducing i) would limit its operational time period. On the contrary, an increase in the value of i in Eq. 2 of the future prediction model shortens the time period during which it can detect the words whose semantics have changed the most – to detect the words whose semantics have changed within the full sequence [1, $T-1$], it requires only the word representations W_0 in the first time interval. Therefore, setting the parameter i can be crucial for the performance of the individual models. By contrast, the joint model in section 3.3 is able to detect the words that have undergone semantic change, regardless of the value of i (see Eq. 3), since it is still able to operate on the full sequence – we showcase these effects in section 5.2.

4 Experiments with Synthetic Data

Tasks run on artificial data have been used for evaluation purposes in related work (Gale et al., 1992; Schütze, 1998; Cook and Stevenson, 2010; Kulkarni et al., 2015; Rosenfeld and Erk, 2018; Dubossarsky et al., 2019; Shoemark et al., 2019). In this section, we work with artificial data as a proof-of-concept of our proposed models – we compare against state-of-the-art and other baseline methods with real data in the next section. Here we employ a longitudinal dataset of word representations (4.1) and artificially alter the representations of a small set of words across time (4.2). We then train (4.3) our models and evaluate them on the basis of their ability to identify those words that have undergone (artificial) semantic change (4.4).

4.1 Dataset

We employ the UK Web Archive dataset (Tsakalidis et al., 2019), which contains 100-dimensional representations of 47.8K words for each year in the period 2000-2013. These were obtained by employing word2vec (i.e., skip-gram with negative sampling (Mikolov et al., 2013)) on the documents published in each year independently. Note that our models can be applied to any type of pre-trained embeddings. Each year corresponds to a time step in our modelling. The dataset contains 65 words whose meaning has changed within 2001-13, as indicated by the Oxford English Dictionary. These are removed for the purposes of this section, to avoid interference with the artificial data modeling. We use one subset (80%) of the remaining longitudinal word representations for training our models and the rest (20%) for evaluation purposes.

4.2 Artificial Examples of Semantic Change

We generate artificial examples of words with changing semantics, by following a paradigm inspired by Rosenfeld and Erk (2018). We uniformly at random select 5% of the words in the test set to alter their semantics. For every selected "source" word α, we select a "target" word β (details about the selection process of β are provided in the next paragraph). We then alter the representation $w_t^{(\alpha)}$ of the source word α at each point in time t so that it shifts towards the representation $w_t^{(\beta)}$ of the target word at this point in time as:

$$w_t^{*(\alpha)} = \lambda_t w_t^{(\alpha)} + (1-\lambda_t) w_t^{(\beta)}. \tag{4}$$

Following Rosenfeld and Erk (2018), we model λ_t via a sigmoid function. λ_t receives values within [0, 1] and acts as a decay function that controls the speed of change in the source word's semantics towards the target. Thus, the semantic representation of α is not altered during the first time points and then it gradually shifts towards the representation of β (for middle values of t), where it stabilizes towards the last time points. Since the duration of the semantic shift of a word may vary, we experiment under different scenarios (see "Conditioning on Duration of Change" below). Alternative modelling approaches of artificial semantic change have been presented in Shoemark et al. (2019) – e.g., forcing a word to acquire a new sense while also retaining its original meaning. We opted for the "stronger" case of semantic shift (Eq. 4) as a proof-of-concept for our models. In section 5 we experiment with real-world data, without any assumptions about the form of the function underlying semantic change.

Conditioning on Target Words The selection of the target words should be such that they allow the representation of the source word to change through time (Dubossarsky et al., 2019). This will not be the case if we select a pair of $\{\alpha, \beta\}$ {source, target} words whose representations are very similar (e.g., synonyms). Thus, for each source word α we select uniformly at random a target word β s.t. the cosine similarity of their representations at the initial time point (i.e., in the year 2000) falls within a certain range $(c-0.1, c]$. Higher values of c enforce a lower semantic change level for α through time, since its representation will be shifted towards a similar word β, and vice versa. To assess model performance across different levels of semantic change, we experiment with varying $c = \{0.0, 0.1, ..., 0.5\}$.

Conditioning on Duration of Change The duration of semantic change affects the value of λ_t in Eq. 4. We conventionally set $\lambda_{07} = 0.5$, s.t. the artificial word representation $w_{07}^{*(\alpha)}$ of a source word α in 2007 (i.e., the midpoint between 2001-2013) to be equal to $0.5(w_{07}^{(\alpha)} + w_{07}^{(\beta)})$. We then experiment with four different duration [start, end] ranges for the semantic change: (a) "Full" [2001-13], (b) "Half" [2005-10], (c) "OT" (One-Third) [2006-09] and (d) "Quarter" [2007-08]. A longer lasting semantic change duration implies a smoother transition of word α towards the meaning of word β, and vice versa (see Figure 2). By generating synthetic examples of varying semantic change duration we are able to measure model performance under different conditions.

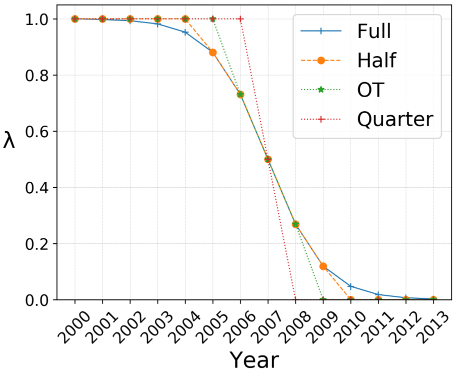

Figure 2: The different functions used to model λ_t in Eq. 4, indicating the speed and duration of semantic change of our synthetic examples (see section 4.2).

4.3 Artificial Data Experiment

Our task is to rank the words in the test set by means of their level of semantic change. We first train our three models on the training set and then we apply them on the test set. Finally, we measure the level of semantic change of a word by means of the average cosine similarity between the predicted and actual word representations at each time step of the decoder. Model performance is assessed via rank-based metrics (Basile and McGillivray, 2018; Tsakalidis et al., 2019; Shoemark et al., 2019).

Model Training We define and train our models as follows:

- `seq2seq`$_r$: the autoencoder (section 3.1) receives and reconstructs the full sequence of the word representations in the training set: $[W_{00}, ..., W_{13}] \rightarrow [W^r_{00}, ..., W^r_{13}]$.
- `seq2seq`$_f$: the future prediction model (section 3.2) receives the representation of the words in the training set in the year 2000 and learns to predict the rest of the sequence: $[W_{00}] \rightarrow [W^f_{01}, ..., W^f_{13}]$.
- `seq2seq`$_{rf}$: the multi-task model (section 3.3) is fed with the first half of the sequence of the word representations in the training set and jointly learns to (a) reconstruct the input sequence and (b) predict the word representations in the future: $[W_{00}, ..., W_{06}] \rightarrow \{[W^r_{00}, ..., W^r_{06}], [W^f_{07}, ..., W^f_{13}]\}$.

We have a different number of timesteps for $\texttt{seq2seq}_r$ and $\texttt{seq2seq}_f$ in their input, so that the decoder in each model operates on the maximum possible output sequence, thus exploiting the semantic change of the words over the whole time period (see section 3.4). $\texttt{seq2seq}_{rf}$ is expected to be insensitive to the number of input time steps, therefore we conventionally set it to half of the overall sequence. We keep 25% of our training set for validation purposes and train our models using the Adam optimiser (Kingma and Ba, 2015). We select the best parameters after 25 trials using the Tree of Parzen Estimators algorithm of the hyperopt module (Bergstra et al., 2013), by means of the maximum average (i.e., per time step) cosine similarity in the validation set.[3]

Testing and Evaluation After training, each model is applied to the test set, yielding its predictions for every word through time.[4] The level of semantic change of a word is then calculated via the average cosine similarity between the actual and the predicted word representations through time, with higher values indicating a better model prediction (thus, a lower level of semantic change). The words are ranked on ascending order of their average cosine similarity, with the first ranks indicating words whose representations have changed the most (low cosine similarity). For evaluation, similarly to Tsakalidis et al. (2019), we employ the average rank across all of the semantically changed words (in %, denoted here as μ_r), with lower scores indicating a better model. We prefer μ_r to the mean reciprocal rank, because the latter emphasises the first rankings. Since semantic change detection is an under-explored task in quantitative terms, we aim at getting better insights on model performance by working with an averaging metric. For the same reason we avoid using classification-based metrics that are based on a cut-off point (e.g., recall at k (Basile and McGillivray, 2018)). We do make use of such metrics in the cross-model comparison with real data (section 5.2).

4.4 Results

Model Comparison Figure 3 presents the results of the three models on our synthetic data across all (c, λ) combinations. $\texttt{seq2seq}_{rf}$ performs consistently better than the individual ($\texttt{seq2seq}_r$, $\texttt{seq2seq}_f$) models in μ_r, showing that combining the two models under a multi-task setting benefits from the joint and finer-grained parameter tuning of the two components. $\texttt{seq2seq}_r$ performs slightly better than $\texttt{seq2seq}_f$, probably due to the autoencoder having to output a longer sequence (i.e., due to W_{00}^r), which helps explore the temporal variation of the words more effectively.

Figure 4 shows the cosine similarity between the predicted and actual representation of each synthetic word per time step for the "Full" case when c=0.0 (highest level of change, see section 4.2). $\texttt{seq2seq}_r$ reconstructs the input sequence of synthetic examples more accurately than the future prediction component (average cosine similarity per year (avg_cos): .65 vs .50). It particularly manages to reconstruct the synthetic word representations *during* the years 2006-2008 ($avg\_cos_{06:08}$=.75), which are the points when λ_t varies more rapidly (see Figure 2); however, it fails to reconstruct equally well their representations before ($avg\_cos_{00:05}$= .65) and after ($avg\_cos_{09:13}$= .59) this sharp change. On the contrary, $\texttt{seq2seq}_f$ predicts more accurately the synthetic word representations during the first years ($avg\_cos_{01:05}$ = .74), when the change in their semantics is minor, but (correctly) fails after the semantic change is almost complete (i.e., when $\lambda_t \leq .25$, $avg\_cos_{09:13}$= .24). $\texttt{seq2seq}_{rf}$ benefits from the individual components' advantage: it appropriately reconstructs the artificial examples in the first years ($avg\_cos_{00:05}$ = .85) so that their semantic shift is highlighted more clearly during ($avg\_cos_{06:08}$= .62) and after the process is almost complete ($avg\_cos_{09:13}$= .26). Finally, avg_cos in $\texttt{seq2seq}_{rf}$ highly correlates with λ_t (ρ=.987), potentially providing insights on how to measure the speed of semantic change of a word.

Effect of Conditioning Parameters Regardless of the duration of the semantic change process, an increase in the value of c results in model performance degradation. This is expected, since the increase of c implies that the level of semantic change of the source words is lower, as discussed in 4.2, thus making the task of detecting them more difficult. Nevertheless, our worst performing model in the most challenging setting (c=0.5, Full, seq2seq_f) achieves μ_r=28.17, which is clearly better than the μ_r expected by a random baseline (μ_r=50.00).

The decrease of the duration of semantic change

(a) $\texttt{seq2seq}_r$ (b) $\texttt{seq2seq}_f$ (c) $\texttt{seq2seq}_{rf}$

Figure 4: Cosine similarity between the actual and the predicted vectors of the synthetic words that have undergone artificial semantic change (rows), per year (columns). Light colours indicate inaccurate model predictions of the word vectors – i.e., indicating that the associated words have undergone semantic change.

has a positive effect on our models (see Figure 3). This is more evident in the cases of high value of c, where $\texttt{seq2seq}_r$ (μ_r: 26.09-18.21 in the Full-to-Quarter cases), $\texttt{seq2seq}_f$ (μ_r: 28.17-22.48) and $\texttt{seq2seq}_{rf}$ (μ_r:20.38-13.09) show clear gains in performance. This indicates that our models can capture the semantic change in small subsequences of the time-series. Studying this effect in datasets of longer duration is an important future direction.

5 Model Comparison with Real Data

5.1 Experimental Setting

We approach the task in a rank-based manner, as in section 4. However, here we are interested in detecting real-world examples of semantic change in words and comparing our models against strong baselines and current practices.

Data and Task We employ the UK Web Archive dataset (see section 4.1). We keep the same 80/20 train/test split as in section 4 and incorporate in the test set the 65 words with known changes in meaning according to the Oxford English Dictionary. We train our models as in section 4.3, aiming at detecting the 65 words in the test set. We use μ_r (as in section 4) and recall at k (Rec@k, k=5%, 10%, 50%) as our evaluation metrics. We refrain from using precision at k, since Oxford English Dictionary is not expected to have a full coverage of the semantically shifted words. Lower μ_r and higher Rec@k scores indicate better models.

Models We compare the three variants from section 3 against four types of baselines:

– *A random word rank generator* (`RAND`). We report average metrics after 1K runs on the test set.

– *Variants of Procrustes Alignment*, as a common practice in past work: Given word representations in two different years $[W_0, W_i]$ centered around the origin and s.t. $tr(W_k W_k^T) = 1$, `PROCR` transforms W_i into W_i^* s.t. the squared differences between W_0 and W_i^* are minimised. We also use the $\texttt{PROCR}_k$ and $\texttt{PROCR}_{kt}$ variants (Tsakalidis et al., 2019), which first detect the k most stable words across either $[W_0, W_i]$ ($\texttt{PROCR}_k$) or $[W_0, ..., W_{T-1}]$ ($\texttt{PROCR}_{kt}$) to learn the alignment and then transform W_i into W_i^*. Words are ranked based on the cosine distance between $[W_0, W_i^*]$.

– *Models leveraging the first and last word representations only*. We use a Random Forest (Breiman, 2001) regression model (`RF`) that predicts W_i, given W_0. We also use the same architectures presented in sections 3.1-3.2, trained on $[W_0, W_i]$ (ignoring the full sequence): $\texttt{LSTM}_r$ reconstructs the sequence $[W_0, W_i]$; $\texttt{LSTM}_f$ predicts W_i, given W_0, similarly to `RF`. Words are ranked in ascending order of the (average, for $\texttt{LSTM}_r$) cosine similarity between their predicted and actual representations.

– *Models operating on the time series of distances*. Given a sequence of vectors $[W_0, ..., W_i]$, we construct the time series of cosine distances that result by `PROCR`. Then, we use two global trend models (Shoemark et al., 2019): $\texttt{GT}_c$ ranks the words by means of the absolute value of the Pearson correlation of their time series; $\texttt{GT}_\beta$ fits a linear regression model for every word and ranks the words by the absolute value of the slope. Finally, we

Table 1: Model comparison when operating on the entire time sequence (2000-13) and averaged across time (2000-01, ..., 2000-13). Past work and baseline models shown in the table are defined in section 5.1 ("Models").

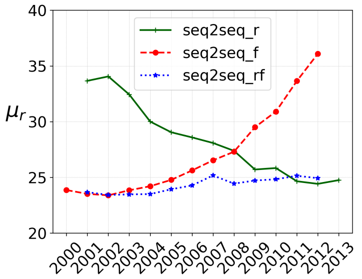

Figure 5: μ_r of our models for varying value of i (Eq. 1–3).[5]For the complete results, refer to Appendix B.

employ PROCR$_*$, ranking words based on the average cosine distance within $[0, i]$; this is similar to the "Mean Distances" model used in Rodina et al. (2019), with the difference that the distances at time point i are calculated by measuring the cosine distance resulting from the alignment against the initial time point 0 and not against $i - 1$.[6]

We report the performance of the models (a) when they operate on the full interval [2000-13] and (b) averaged across all intervals [2000-01, ..., 2000-13]. In (b), our models use additional (future) information compared to our baselines; when `seq2seq`$_f$ is fed with the word sequences of [2000, 2001], it makes a prediction for the years [2002, ..., 2013] – such information cannot be leveraged by the baselines. Thus, for (b), we only perform intra-model (and intra-baseline) comparisons.

5.2 Results

Our models *vs* baselines Results are shown in Table 1. The three proposed models consistently achieve the lowest μ_r and highest Rec@k when working on the whole time sequence ('00-'13 columns). The comparison between {`seq2seq`$_r$, `LSTM`$_r$} and {`seq2seq`$_f$, `LSTM`$_f$} in the years 2000-13 showcases the benefit of modelling the full sequence of the word representations across time, compared to using the first and last representations only. Our models provide a relative boost of 4.6% in μ_r and [35.7%, 42.8%, 5.8%] in Rec@k (for k=[5, 10, 50]) compared to the best performing baseline. `seq2seq`$_f$ and `seq2seq`$_{rf}$ models outperform the autoencoder (`seq2seq`$_r$) in most metrics, while `seq2seq`$_{rf}$ yields the most stable results across all runs. We explore these differences in detail in the last paragraph of this section.

Intra-baseline comparison Models operating only on the first and last word representations fail to confidently outperform the Procrustes-based baselines, demonstrating again the weakness of operating in a non-sequential manner. The `LSTM` models achieve low μ_r on the 2000-13 experiments; however, the difference with the rest of the baselines in μ_r across all years is negligible. The intra-Procrustes model comparison shows that the benefit of selecting a few anchor words to learn a better alignment (`PROCR`$_k$, `PROCR`$_{kt}$) shown in Tsakalidis et al. (2019) in examining semantic change over two consecutive years might not apply when examining a longer time period. Finally, contrary to Shoemark et al. (2019), we find that time sensitive models operating on the word distances across time (`GT`$_c$, `GT`$_\beta$) perform worse than the baselines that leverage only the first and last word representations. This difference is attributed to the low number of time steps in our dataset that does not allow the `GT` models to exploit long-term correlations (i.e., considering the average distance across time (`PROCR`$_*$) performs better), but also highlights the importance of leveraging the full word sequence across time.

Effect of input/output lengths Figure 5 shows the μ_r of our three variants when we alter the length of the input and output (see section 3.4). The performance of `seq2seq`$_r$ increases with the input size since by definition the decoder is able to detect words whose semantics have changed over a longer period of time (i.e., within $[2000, i]$, with i increasing), while also modelling a longer se-

---

[5] Example (2005 in x-axis): The sequence of the word representations until 2005 is the input to all of our models. Then, `seq2seq`$_r$ reconstructs the word representations up to 2005, `seq2seq`$_f$ predicts the future representations (2006, ..., 2013) and `seq2seq`$_{rf}$ performs both tasks jointly.

[6] We refrain from evaluating the `GT` models when $i \leq 2$, due to the very short time interval that does not allow for correlations to appear in the data, leading to very poor performance.

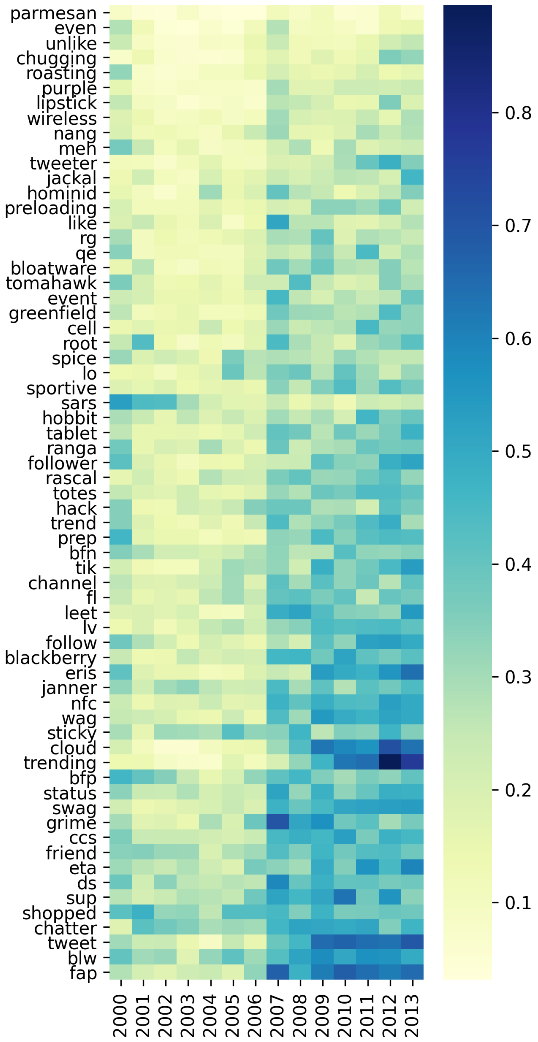

Figure 6: Cosine distances (actual *vs* predicted vectors) of each semantically shifted word (as indicated by the Oxford English Dictionary), per year. Lighter colours indicate better model performance – thus, lower level of semantic change predicted by our joint model.

quence of a word's representation through time. On the contrary, the performance of $\texttt{seq2seq}_f$ increases alongside the decrease of the number of input time steps. This is expected since, as i decreases, $\texttt{seq2seq}_f$ encodes a shorter input sequence and the decoding (and hence the semantic change detection) is applied on the remaining (and increased number of) time steps within $[i+1, 2013]$. These findings provide empirical evidence that both models can achieve better performance if trained over longer sequences of time steps. Finally, the stability of $\texttt{seq2seq}_{rf}$ showcases its input length-invariant nature, which is also clearly evident in all of the averaged results (standard deviation in avg±std columns) in Table 1: in its worst performing setting, $\texttt{seq2seq}_{rf}$ still manages to achieve results that are close to the best performing model (μ_r=25.17, Rec@k=[21.54, 36.92, 83.08] for the three thresholds) and always better (or equal to) the best performing baseline shown in Table 1 in Rec@k. This is a very attractive aspect of the model as it removes the need to manually define the number of time steps to be fed to the encoder.

Words with shifted meaning Figure 6 shows the cosine distances between the actual and predicted vectors of the 65 words that acquired a new meaning between 2001-2013. The distances are calculated by applying the $\texttt{seq2seq}_{rf}$ model (trained as in section 4.3) on the test set. The words are ranked based on their average cosine distance throughout the years such that the words in the first rows form more challenging examples for detecting their semantic shift. Despite that some of these words have acquired an additional meaning in the context of social networks (e.g., "like", "unlike"), this is not effectively captured by their vectors. Utilising contextual representations (Giulianelli et al., 2020) in our models can be more effective for capturing such cases in future work.

6 Conclusion and Future Work

We introduce three sequential models for semantic change detection that effectively exploit the full sequence of a word's representations through time to determine its level of semantic change. Through extensive experiments on synthetic and real data we showcase the effectiveness of the proposed models under various settings and in comparison to state-of-the-art on the UK Web Archive dataset. Importantly, we show that their performance increases alongside the duration of the time period under study, confidently outperforming competitive models and common practices on semantic change.

Future work can use anomaly detection approaches operating on our model's predicted word vectors to detect anomalies in a word's representation across time. We also plan to investigate different architectures, such as Variational Autoencoders (Kingma and Welling, 2014), and incorporate contextual representations (Devlin et al., 2019; Hu et al., 2019) to detect new senses of words. A limitation of our work is that it has been tested on a single dataset, where 65 words have undergone semantic change; testing our models in datasets of different duration and in different languages will provide clearer evidence of their effectiveness.

A List of Hyperparameters

Our models We test the following hyper-parameters for our $\texttt{seq2seq}_{r/f/rf}$ models:

- encoder_LSTM$_0$, number of units: [128, 256, 512] ([32,64,128,256,512] for seq2seq$_f$).
- encoder_LSTM$_1$, number of units: [32, 64]
- decoder_LSTM$_0$, number of units: [32, 64] (x2, for the case of $\texttt{seq2seq}_{rf}$ – for (a) the autoencoding and (b) future prediction component)
- decoder_LSTM$_1$, number of units: [128, 256, 512] (x2, for the case of $\texttt{seq2seq}_{rf}$; [32,64,128,256,512] for seq2seq$_f$).
- dropout rate in dropout layers: [.1, .25, .5]
- batch size: [32, 64, 128, 256, 512, 1024]
- number of epochs: [10, 20, 30, 40, 50]

We optimise our parameters using the Adam optimiser in `keras`, using the default learning rate (.001).

Baselines We experiment with the following hyper-parameters per model:

- $\texttt{LSTM}_{r/f}$: we follow the exact same settings as in our seq2seq$_r$ and seq2seq$_f$ models, respectively.
- `RF`: we experiment with the number of trees ([50, 100, 150, 200]) and select the best model based on the maximum average cosine similarity across all predictions, as in our models.
- $\texttt{PROCR}_{k/kt}$: we experiment with different rate [.001, .01, .05, .1, .2, ...9] of anchor (or diachronic anchor) words on the basis of the size of the test set. We select to display in our results the best model based on the average performance in the test set (k=.9 for $\texttt{PROCR}_k$, k=.5 for $\texttt{PROCR}_{kt}$).
- $\texttt{GT}_c$: we explore different correlation metrics (Spearman Rank, Pearson Correlation, Kendall Tau) and select to display the best one (Pearson Correlation) on the basis of its average performance on the test set across all experiments. Due to the very poor performance of all metrics when operating on a small number of time-steps (≤ 2), we only provide the results in Table 1 (avg±std columns) when these models operate on longer sequences.
- `PROCR`, $\texttt{PROCR}_*$, $\texttt{GT}_\beta$, `RAND`: there are no hyper-parameter to tune in these models. In terms of preprocessing, for all `PROCR`-based baselines, we first subtract the mean and then we divide each matrix by its Frobenius norm, so that the resulting (transformed) matrices are in the same space.

B Complete Results on Real Data

The complete list of results (μ_r) of all models in all of the experiments with real data (section 5, Table 1 and Figure 5) are provided in Table 2. The interpretation of the "year" for each model is provided in Table 3.

year	PROCR	PROCR$_k$	PROCR$_{kt}$	RF	LSTM$_r$	LSTM$_f$	GT$_\beta$	GT$_c$	PROCR$_*$	seq2seq$_r$	seq2seq$_f$	seq2seq$_{rf}$
2000	-	-	-	-	-	-	-	-	-	-	23.86	-
2001	34.26	34.54	34.43	37.35	33.67	36.43	-	-	34.26	33.66	23.52	23.67

Sparsity Makes Sense: Word Sense Disambiguation Using Sparse Contextualized Word Representations

Gábor Berend[1,2]
[1]Institute of Informatics, University of Szeged
[2]MTA-SZTE Research Group on Aartificial Intelligence
berendg@inf.u-szeged.hu

Abstract

In this paper, we demonstrate that by utilizing sparse word representations, it becomes possible to surpass the results of more complex task-specific models on the task of fine-grained all-words word sense disambiguation. Our proposed algorithm relies on an overcomplete set of semantic basis vectors that allows us to obtain sparse contextualized word representations. We introduce such an information theory-inspired synset representation based on the co-occurrence of word senses and non-zero coordinates for word forms which allows us to achieve an aggregated F-score of 78.8 over a combination of five standard word sense disambiguating benchmark datasets. We also demonstrate the general applicability of our proposed framework by evaluating it towards part-of-speech tagging on four different treebanks. Our results indicate a significant improvement over the application of the dense word representations.

1 Introduction

Natural language processing applications have benefited remarkably form language modeling based contextualized word representations, including CoVe (McCann et al., 2017), ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), inter alia. Contrary to standard “static” word embeddings like `word2vec` (Mikolov et al., 2013) and Glove (Pennington et al., 2014), contextualized representations assign such vectorial representations to mentions of word forms that are sensitive to the entire sequence in which they are present. This characteristic of contextualized word embeddings makes them highly applicable for performing word sense disambiguation (WSD) as it has been investigated recently (Loureiro and Jorge, 2019; Vial et al., 2019).

Another popular line of research deals with sparse overcomplete word representations which differ from typical word embeddings in that most coefficients are exactly zero. Such sparse word representations have been argued to convey an increased interpretability (Murphy et al., 2012; Faruqui et al., 2015; Subramanian et al., 2018) which could be advantageous for WSD. It has been shown that sparsity can not only favor interpretability, but it can contribute to an increased performance in downstream applications (Faruqui et al., 2015; Berend, 2017).

The goal of this paper is to investigate and quantify what synergies exist between contextualized and sparse word representations. Our rigorous experiments show that it is possible to get increased performance on top of contextualized representations when they are post-processed in a way which ensures their sparsity.

In this paper we introduce an information theory-inspired algorithm for creating sparse contextualized word representations and evaluate it in a series of challenging WSD tasks. In our experiments, we managed to obtain solid results for multiple fine-grained word sense disambiguation benchmarks. All our source code for reproducing our experiments are made available at `https://github.com/begab/sparsity_makes_sense`.[1]

Our contributions can be summarized as follows:

- we propose the application of contextualized sparse overcomplete word representation in the task of word sense disambiguation,
- we carefully evaluate our information theory inspired approach for quantifying the strength of the connection between the individual dimensions of (sparse) word representations and

---

human interpretable semantic content such as fine grained word senses,

- we demonstrate the general applicability of our algorithm by applying it for POS tagging on four different UD treebanks.

2 Related work

One of the key difficulties of natural language understanding is the highly ambiguous nature of language. As a consequence, WSD has long-standing origins in the NLP community (Lesk, 1986; Resnik, 1997a,b), still receiving major recent research interest (Raganato et al., 2017a; Trask et al., 2015; Melamud et al., 2016; Loureiro and Jorge, 2019; Vial et al., 2019). A thorough survey on WSD algorithms of the pre-neural era can be found in (Navigli, 2009).

A typical evaluation for WSD systems is to quantify the extent to which they are capable of identifying the correct sense of ambiguous words in their contexts according to some sense inventory. One of the most frequently applied sense inventory in the case of English is the Princeton WordNet (Fellbaum, 1998) which also served the basis of our evaluation.

A variety of WSD approaches has evolved ranging from unsupervised and knowledge-based solutions to supervised ones. Unsupervised approaches could investigate the textual overlap between the context of ambiguous words and their potential sense definitions (Lesk, 1986) or they could be based on random walks over the semantic graph providing the sense inventory (Agirre and Soroa, 2009).

Supervised WSD techniques typically perform better than unsupervised approaches. IMS (Zhong and Ng, 2010) is a classical supervised WSD framework which was created with the intention of easy extensibility. It trains SVMs for predicting the correct sense of a word based on traditional features, such as surface forms and POS tags of the ambiguous words as well as its neighboring words.

The recent advent of neural text representations have also shaped the landscape of algorithms performing WSD. Iacobacci et al. (2016) extended the classical feature-based IMS framework by incorporating word embeddings. Melamud et al. (2016) devised context2vec, which relies on a bidirectional LSTM (biLSTM) for performing supervised WSD. Kågebäck and Salomonsson (2016) also proposed the utilization of biLSTMs for WSD. Raganato et al. (2017b) tackled all-words WSD as a sequence learning model and solved it using LSTMs. Vial et al. (2019) introduced a similar framework, but replaced the LSTM decoder with an ensemble of transformers. (Vial et al., 2019) additionally relied on BERT contextual word representations as input to their all-words WSD system.

Contextual word embeddings have recently superseded traditional word embeddings due to their advantageous property of also modeling the neighboring context of words upon determining their vectorial representations. As such, the same word form gets assigned a separate embedding when mentioned in different contexts. Contextualized word vectors, including (Devlin et al., 2019; Yang et al., 2019), typically employ some language modelling-inspired objective and are trained on massive amounts of textual data, which makes them generally applicable in a variety of settings as illustrated by top-performing entries at the SuperGLUE leaderboard (Wang et al., 2019).

Most recently, Loureiro and Jorge (2019) have proposed the usage of contextualized word representations for tackling WSD. Their framework builds upon BERT embeddings and performs WSD relying on a k-NN approach of query words towards the sense embeddings that are derived as the centroids of contextual embeddings labeled with a certain sense. The framework also utilizes static fasttext (Bojanowski et al., 2017) embeddings, and averaged contextual embeddings derived from the definitions attached to WordNet senses for mitigating the problem caused by the limited amounts of sense-labeled training data.

Kumar et al. (2019) proposed the EWISE approach which constructs sense definition embeddings also relying on the network structure of WordNet for performing zero-shot WSD in order to handle words without any sense-annotated occurrence in the training data. Bevilacqua and Navigli (2020) introduces EWISER as an improvement over the EWISE approach by providing a hybrid knowledge-based and supervised approach via the integration of explicit relational information from WordNet. Our approach differs from both (Kumar et al., 2019) and (Bevilacqua and Navigli, 2020) in that we are not exploiting the structural properties of WordNet.

SenseBERT (Levine et al., 2019) extends BERT (Devlin et al., 2019) by incorporating an auxiliary task into the masked language modeling objective for predicting word supersenses besides word identities. Our approach differs from SenseBERT as we do not propose an alternative way for training contextualized embeddings, but introduce an algorithm for extracting a useful representation from pretrained BERT embeddings that can effectively be used for WSD. Due to this conceptual difference, our approach does not need a large transformer model to be trained, but it can be steadily applied over pretrained models.

GlossBERT (Huang et al., 2019) framed WSD as a sentence pair classification task between the sentence containing an ambiguous target token and the contents of the glosses for the potential synsets of the ambiguous token and fine-tuned BERT accordingly. GlossBERT hence requires a fine-tuning stage, whereas our approach builds directly on the pre-trained contextual embeddings, which makes it more resource efficient.

Our work also relates to the line of research on sparse word representations. The seminal work on obtaining sparse word representations by Murphy et al. (2012) applied matrix factorization over the co-occurrence matrix built from some corpus. Arora et al. (2018) investigated the linear algebraic structure of static word embedding spaces and concluded that “simple sparse coding can recover vectors that approximately capture the senses”. Faruqui et al. (2015); Berend (2017); Subramanian et al. (2018) introduced different approaches for obtaining sparse word representations from traditional static and dense word vectors. Our work differs from all the previously mentioned papers in that we create sparse *contextualized* word representations.

3 Approach

Our algorithm is composed of two important steps, i.e. we first make a sparse representation from the dense contextualized ones, then we derive a succinct representation describing the strength of connection between the individual basis of our representation and the sense inventory we would like to perform WSD against. We elaborate on these components next.

3.1 Sparse contextualized embeddings

Our algorithm first determines contextualized word representations for some sense-annotated corpus. We shall denote the surface form realizations in the corpus as $\mathcal{X} = \left\{\left[x_j^{(i)}\right]_{j=0}^{N_i}\right\}_{i=0}^{M}$, with $x_j^{(i)}$ standing for the token at position j within sentence i, supposing a total of M sequences and N_i tokens in sentence i. We refer to the contextualized word representation for some token in boldface, i.e. $\boldsymbol{x}_j^{(i)}$ and the collection of contextual embeddings as $\mathbb{X} = \left\{\left[\boldsymbol{x}_j^{(i)}\right]_{j=0}^{N_i}\right\}_{i=0}^{M}$.

Likewise to the sequence of sentences and their respective tokens, we also utilize a sequence of annotations that we denote as $\mathbb{S} = \left\{\left[\boldsymbol{s}_j^{(i)}\right]_{j=0}^{N_i}\right\}_{i=0}^{M}$, with $\boldsymbol{s}_j^{(i)}$ indicating the labeling of token j within sentence i. We have $\boldsymbol{s}_j^{(i)} \in \{0,1\}^{|\mathcal{S}|}$ with $\mathcal{S}$ denoting the set of possible labels included in our annotated corpus. That is, we have an indicator vector conveying the annotation for every token. We allow for the $\boldsymbol{s}_j^{(i)} = \boldsymbol{0}$ case, meaning that it is possible that certain tokens lack annotation. In the case of WSD, the annotation is meant in the form of sense annotation, but in general, the token level annotations could convey other types of information as well.

The next step in our algorithm is to perform sparse coding over the contextual embeddings of the annotated corpus. Sparse coding is a matrix decomposition technique which tries to approximate some matrix $X \in \mathbb{R}^{v\times m}$ as a product of a sparse matrix $\alpha \in \mathbb{R}^{v\times k}$ and a dictionary matrix $D \in \mathbb{R}^{k\times m}$, where k denotes the number of basis vectors to be employed.

We formed matrix X by stacking and unit normalizing the contextual embeddings comprising $\mathbb{X}$. We then optimize

$$\min_{\substack{D\in\mathcal{C}\\ \boldsymbol{\alpha}_j^{(i)}\in\mathbb{R}^k_{\geq 0}}} \sum_{i=1}^{M}\sum_{j=1}^{N_i}\|\boldsymbol{x}_j^{(i)} - \boldsymbol{\alpha}_j^{(i)}D\|_2^2 + \lambda\|\boldsymbol{\alpha}_j^{(i)}\|_1, \quad (1)$$

where $\mathcal{C}$ denotes the convex set of matrices with row norm at most 1, λ is the regularization coefficient and the sparse coefficients in $\boldsymbol{\alpha}_j^{(i)}$ are required to be non-negative. We imposed the non-negativity constraint on α as it has been reported to provide increased interpretability (Murphy et al., 2012).

3.2 Binding basis vectors to senses

Once we have obtained a sparse contextualized representation for each token in our annotated corpus, we determine the extent to which the individual bases comprising the dictionary matrix D bind to the elements of our label inventory $\mathcal{S}$. In order to do so, we devise a matrix $\Phi \in \mathbb{R}^{k\times|\mathcal{S}|}$, which contains a ϕ_{bs} score for each pair of basis vector b and a particular label s. We summarize our algorithm for obtaining Φ in Algorithm 1.

The definition of Φ is based on a generalization of co-occurrence of bases and the elements of the label inventory $\mathcal{S}$. We first define our co-occurrence matrix between bases and labels as

$$C = \sum_{i=1}^{M} \sum_{j=1}^{N_i} \boldsymbol{\alpha}_j^{(i)} \boldsymbol{s}_j^{(i)\intercal}, \tag{2}$$

i.e. C is the sum of outer products of sparse word representations ($\boldsymbol{\alpha}_j^{(i)}$) and their respective sense description vector ($\boldsymbol{s}_j^{(i)}$). The definition in (2) ensures that every $c_{bs} \in C$ aggregates the sparse nonnegative coefficients words labeled as s has received for their coordinate b. Recall that we allowed certain $\boldsymbol{s}_j^{(i)}$ to be the all zero vector, i.e. tokens that lack any annotation are conveniently handled by Eq. (2) as the sparse coefficients of such tokens do not contribute towards C.

We next turn the elements of C into a matrix representing a joint probability distribution P by determining the ℓ_1-normalized variant of C (line 5 of Algorithm 1). This way we devise a sparse matrix, the entries of which can be used for calculating Pointwise Mutual Information (PMI) between semantic bases and the presence of symbolic senses of our sense inventory.

For a pair of events (i, j) PMI is measured as $\log\left(\frac{p_{ij}}{p_{i*}p_{*j}}\right)$, with p_{ij} referring to their joint probability, p_{i*} and p_{*j} denoting the marginal probability of i and j, respectively. We determine these probabilities from the entries of P that we obtain from C via ℓ_1 normalization.

Employing Positive PMI Negative PMI values for a pair of events convey the information that they repel each other. Multiple studies have argued that negative PMI values are hence detrimental (Bullinaria and Levy, 2007; Levy et al., 2015) . To this end, we could opt for the determination of positive PMI (pPMI) values as indicated in line 7 of Algorithm 1.

Employing normalized PMI An additional property of (positive) PMI is that it favors observations with low marginal frequency (Bouma, 2009), since for events with low $p(x)$ marginal probability $p(x|y) \approx p(x)$ tend to hold, which results in high PMI values. In our setting, it would result in rarer senses receiving higher ϕ_{bs} scores towards all the bases.

In order to handle low-frequency senses better, we optionally calculate the normalized (positive) PMI (Bouma, 2009) between a pair of base and sense as $\log\left(\frac{p_{ij}}{p_{i*}p_{*j}}\right) \Big/ -\log\left(p_{ij}\right)$. That is, we normalize the PMI scores by the negative logarithm of the joint probability (cf. line 8 of Algorithm 1). This step additionally ensures that the normalized PMI (nPMI) ranges between -1 and 1 as opposed to the $(-\infty, \min(-\log(p_i), -\log(p_j)))$ range of the unnormalized PMI values.

Algorithm 1 Calculating Φ

 9:     return $\Phi, D$
10: end procedure
```

3.3 Inferring senses

We now describe the way we assign the most plausible sense to any given token from a sequence according to the sense inventory employed for constructing D and Φ.

For an input sequence of N tokens accompanied by their corresponding contextualized word representations as $[\boldsymbol{x}_j]_{j=1}^{N}$, we determine their corresponding sparse representations $[\boldsymbol{\alpha}_j]_{j=1}^{N}$ based on D that we have already determined upon obtaining Φ. That is, we solve an ℓ_1-regularized convex optimization problem with D being kept fixed for all the unit normalized vectors $\boldsymbol{x}_j$ in order to obtain the sparse contextualized word representation $\boldsymbol{\alpha}_j$ for every token j in the sequence.

We then take the product between $\boldsymbol{\alpha}_j \in \mathbb{R}^k$ and $\Phi \in \mathbb{R}^{k \times |\mathcal{S}|}$. Since every column in Φ corresponds to a sense from the sense inventory, every scalar in the resulting product $\boldsymbol{\alpha}_j^\intercal \Phi \in \mathbb{R}^{|\mathcal{S}|}$ can be interpreted as the quantity indicating the extent to which token j – in its given context – pertains to the individual senses from the sense inventory. In other words, we assign that sense s to a particular token j which maximizes $\boldsymbol{\alpha}_j^\intercal \Phi_{*s}$, where Φ_{*s} indicates the column vector from Φ corresponding to sense s.

4 Experiments and results

We evaluate our approach towards the unified WSD evaluation framework released by Raganato et al. (2017a) which includes the sense-annotated SemCor dataset for training purposes. SemCor (Miller et al., 1994) consists of 802,443 tokens with more than 28% (226,036) of its tokens being sense-annotated using WordNet sensekeys.

For instance `bank%1:14:00::` is one of the possible sensekeys the word *bank* can be assigned to according to one of the 18 different synsets it is included in WordNet 3.0. WordNet 3.0 contains all together 206,949 distinct senses for 147,306 unique lemmas grouped into 117,659 synsets. We constructed Φ relying on the synset-level information of WordNet.

4.1 Sparse contextualized embeddings

For obtaining contextualized word representations, we rely on the pretrained `bert-large-cased` model from (Wolf et al., 2019). Each input token $x_j^{(i)}$ gets assigned 25 contextual vectors $[\boldsymbol{x}_{j,l}^{(i)}]_{l=0}^{24}$ according to the input and the 24 inner layers of the BERT-large model. Each vector $\boldsymbol{x}_{j,l}^{(i)}$ is 1024-dimensional.

BERT relies on WordPiece tokenization, which means that a single token, such as *playing*, could be broken up into multiple subwords (*play* and *##ing*). We defined token-level contextual embeddings to be the average of their subword-level contextual embeddings.

Sparse coding as formulated in (1) took the stacked 1024-dimensional contextualized BERT embeddings for the 802,443 tokens from SemCor as input, i.e. we had $X \in \mathbb{R}^{1024 \times 802443}$. We used the SPAMS library (Mairal et al., 2009) to solve our optimization problems. Our approach has two hyperparameters, i.e. the number of basis vectors included in the dictionary matrix (k) and the regularization coefficient (λ). We experimented with $k \in \{1500, 2000, 3000\}$ in order to investigate the sensitivity of our proposed algorithm towards the dimension of the sparse vectors and we employed $\lambda = 0.05$ throughout all our experiments.

Figure 1 includes the average number of nonzero coefficients for the sparse word representations from the SemCor database when using different values of k and different layers of BERT as input. The average time for determining sparse contextual word representations for one layer of BERT was 40 minutes on an Intel Xeon 5218 for $k = 3000$.

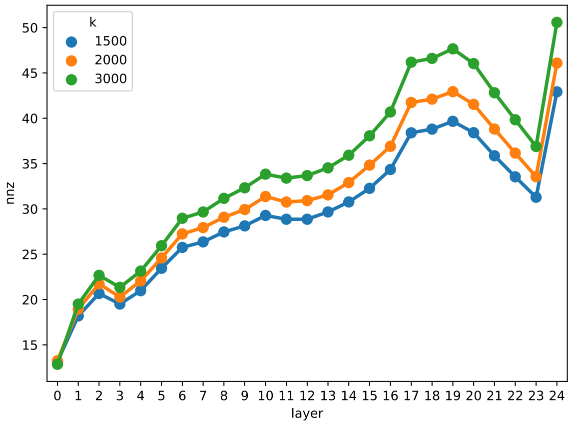

Figure 1: Average number of nonzero coefficients per SemCor tokens when relying on contextualized embeddings from different layers of BERT as input.

4.2 Evaluation on all-words WSD

The evaluation framework introduced in (Raganato et al., 2017a) contains five different all-words WSD benchmarks for measuring the performance of WSD systems. The dataset includes the SensEval2 (Edmonds and Cotton, 2001), SensEval3 (Mihalcea et al., 2004), SemEval 2007 Task 17 (Pradhan et al., 2007), SemEval 2013 Task 12 (Navigli et al., 2013), SemEval 2015 Task 13 (Moro and Navigli, 2015) datasets each containing 2282, 1850, 455, 1644 and 1022 sense annotated tokens, respectively.

The concatenation of the previous datasets is also included in the evaluation toolkit, which is commonly referred as the ALL dataset that includes 7253 sense-annotated test cases. We relied on the official scoring script included in the evaluation framework from (Raganato et al., 2017a). Unless stated otherwise, we report our results on the combination of all the datasets for brevity as results for all the subcorpora behaved similarly.

In order to demonstrate the benefits of our proposed approach, we develop a strong baseline similar to the one devised in (Loureiro and Jorge, 2019). This approach employs the very same contextualized embeddings that we use otherwise in our algorithm for providing identical conditions for the different approaches. For each synset s, we then determine its centroid based on the contextualized word representations pertaining to sense s accord-

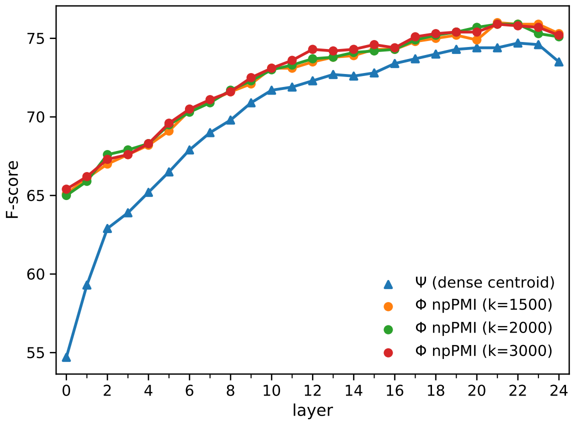

Figure 2: Comparative results of relying on the dense and sparse word representations of different dimensions for WSD using the SemCor dataset for training.

ing to the training data. We then use this matrix Ψ as a replacement over Φ when making predictions for some token with its dense contextualized embedding $\boldsymbol{x}_j$.

The way we make our fine-grained sensekey predictions towards the test tokens are identical when utilizing dense and sparse contextualized embeddings, the only difference is whether we base our decision on $\boldsymbol{x}_j^\intercal \Psi$ (for the dense case) or $\boldsymbol{\alpha}_j^\intercal \Phi$ (for the sparse case). In either case, we choose the best scoring synset a particular query lemma can belong to. That is, we perform argmax operation described in Section 3.3 over the set of possible synsets a query lemma can belong to.

Figure 2 includes comparative results for the approach using dense and sparse contextualized embeddings derived from different layers of BERT. We can see that our approach yields considerable improvements over the application of dense embeddings. In fact, applying sparse contextualized embeddings provided significantly better results ($p \ll 0.01$ using McNemar's test) irrespective of the choice of k when compared against the utilization of dense embeddings.

Additionally, the different choices for the dimension of the sparse word representations does not seem to play a decisive role as illustrated by Figure 2 and also confirmed by our significance tests conducted between the sparse approaches using different values of k. Since the choice of k does not severely impacted results, we report our experiments for the $k = 3000$ case hereon.

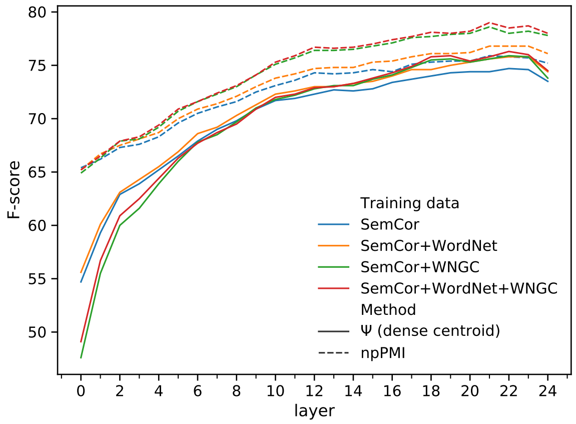

Figure 3: The effects of employing additional sources of information besides SemCor during training.

4.2.1 Increasing the amount of training data

We also measured the effects of increasing the amount of training data. We additionally used two sources of information, i.e. the WordNet synsets themselves and the Princeton WordNet Gloss Corpus (WNGC) for training. The WordNet synsets were utilized in an identical fashion to the LMMS approach (Loureiro and Jorge, 2019), i.e. we determined a vectorial representation for each synset by taking the average of the contextual representations that based on the concatenation of the definition and the lemmas belonging to the synsets.

WNGC includes a sense-annotated version of WordNet itself containing 117,659 definitions (one for each synset in WordNet), consisting of 1,634,691 tokens out of which 614,435 has a corresponding sensekey attached to. We obtained this data from the Unification of Sense Annotated Corpora (UFSAC) (Vial et al., 2018).

For this experiment all our framework was kept intact, the only difference was that instead of solely relying on the sense-annotated training data included in SemCor, we additionally relied on the sense representations derived from WordNet glosses and sense annotations included in WNGC upon the determination of Φ and Ψ for the sparse and dense cases, respectively. For these experiments we used the same set of semantic basis vectors D that we determined earlier for the case when we relied solely on SemCor as the source of sense annotated dataset. Figure 3 includes our results when increasing the amount of sense-annotated training data. We can see that the additional training data consistently improves performance for both the dense and the sparse case. Figure 3 demon-

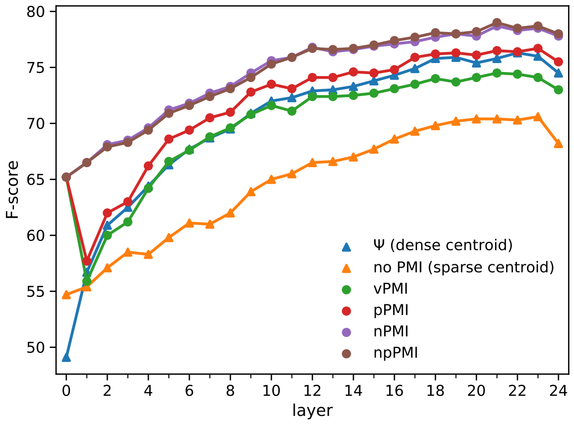

Figure 4: Ablation experiments regarding the different strategies to calculate Φ using the combined (SemCor+WordNet+WNGC) training data.

strates that our proposed method when trained on the SemCor data alone is capable of achieving the same or better performance as the approach which is based on dense contextual embeddings using all the available sources of training signal.

4.2.2 Ablation experiments

We gave a detailed description of our algorithm in Section 3.2. We now report our experimental results that we conducted in order to see the contribution of the individual components of our algorithms. As mentioned in Section 3.2, determining normalized positive PMI (`npPMI`) between the semantic bases and the elements of the sense inventory plays a central role in our algorithm.

In order to see the effects of normalizing and keeping only the positive PMI values, we evaluated 3 further *PMI-based variants for the calculation of Φ, i.e. we had

- `vPMI` vanilla PMI without normalization or discarding negative entries,
- `pPMI`, which discards negative PMI values but does not normalize them and
- `nPMI` which performs normalization, however does not discard negative PMI values.

Additionally, we evaluated the system which uses sparse contextualized word representations for determining Φ, however, does not involve the calculation of PMI scores at all. In that case we calculated a centroid for every synset similar to the calculation of Ψ for the case of contextualized embeddings that are kept dense. The only difference is that for the approach we refer to as `no PMI`, we calculated synset centroids based on the sparse contextualized word representations.

Figure 4 includes our results for the previously mentioned variants of our algorithm when relying on the different layers of BERT as input. Figure 4 highlights that calculating PMI is indeed a crucial step in our algorithm (cf. the `no PMI` and `⋆PMI` results). We also tried to adapt the `⋆PMI` approaches for the dense contextual embeddings, but the results dropped severely in that case.

We can additionally observe that normalization has the most impact on improving the results, as the performance of `nPMI` is at least 4 points better than that of `vPMI` for all layers. Not relying on negative PMI scores also had an overall positive effect (cf. `vPMI` and `pPMI`), which seems to be additive with normalization (cf. `nPMI` and `npPMI`).

4.2.3 Comparative results

We next provide detailed performance results broken down for the individual subcorpora of the evaluation dataset. Table 1 includes comparative results to previous methods that also use SemCor and optionally WordNet glosses as their training data. In Table 1 we report our results obtained by our model which derives sparse contextual word embeddings based on the averaged representations retrieved from the last four layers of BERT identical to how it was done in (Loureiro and Jorge, 2019). Figure 4 illustrates that reporting results from any of the last 4 layers would not change our overall results substantially.

Table 1 reveals that it is only the LMMS_{2348} (Loureiro and Jorge, 2019) approach which performs comparably to our algorithm. LMMS_{2348} determines dense sense representations relying on the large BERT model as well. The sense representations used by LMMS_{2348} are a concatenation of the 1024-dimensional centroids of each senses encountered in the training data, an 1024-dimensional vectors derived from the glosses of WordNet synsets and a 300-dimensional static fasttext embeddings. Even though our approach does not rely on static fasttext embeddings, we still managed to improve upon the best results reported in (Loureiro and Jorge, 2019). The improvement of our approach which uses the SemCor training data alone is 1.9 points compared to the LMMS_{1024}, i.e. such a variant of the LMMS system (Loureiro and Jorge, 2019) which also relies solely on BERT representations for the SemCor training set.

approach	SensEval2	SensEval3	SemEval2007	SemEval2013	SemEval2015	ALL
Most Frequent Sense (MFS)	66.8	66.2	55.2	63.0	67.8	65.2
IMS (Zhong and Ng, 2010)	70.9	69.3	61.3	65.3	69.5	68.4
IMS+emb-s (Iacobacci et al., 2016)	72.2	70.4	62.6	65.9	71.5	69.6
context2Vec (Melamud et al., 2016)	71.8	69.1	61.3	65.6	71.9	69.0
LMMS$_{1024}$ (Loureiro and Jorge, 2019)	75.4	74.0	66.4	72.7	75.3	73.8
LMMS$_{2348}$ (Loureiro and Jorge, 2019)	76.3	75.6	68.1	75.1	77.0	75.4
GlossBERT(Sent-CLS-WS) (Huang et al., 2019)	77.7	75.2	72.5	76.1	80.4	77.0

Ours (using SemCor + WordNet)	77.9	**77.8**	68.8	76.1	77.5	76.8
Ours (using SemCor + WordNet + WNGC)	**79.6**	77.3	**73.0**	**79.4**	**81.3**	**78.8**

Table 1: Comparison with previous supervised results in terms of F measure computed by the official scorer provided in (Raganato et al., 2017a).

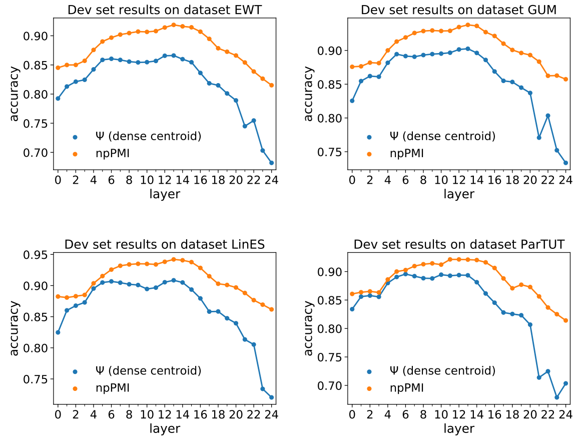

Figure 5: POS tagging results evaluated over the development set of four English UD v2.5 treebanks.

4.3 Evaluation towards POS tagging

In order to demonstrate the general applicability of our proposed algorithm, we evaluated it towards POS tagging using version 2.5 of Universal Dependencies. We conducted experiments over four different subcorpora in English, namely the EWT (Silveira et al., 2014), GUM (Zeldes, 2017), LinEs (Ahrenberg, 2007) and ParTut (Sanguinetti and Bosco, 2015) treebanks.

For these experiments, we used the same approach as before. We also used the same dictionary matrix D for obtaining the sparse word representations that we determined based on the SemCor dataset. The only difference for our POS tagging experiments is that this time the token level labels were replaced by the POS tags of the individual tokens as opposed to their sense labels. This means that both Ψ and Φ had 17 columns, i.e. the number of distinct POS tags used in these treebanks.

Figure 5 reveals that the approach utilizing sparse contextualized word representations outperform the one that is based on the adaptation of the LMMS approach for POS tagging by a fair margin, again irrespective of the layer of BERT that is used as input. A notable difference compared to the results obtained for all-words WSD that for POS tagging the intermediate layers of BERT seem to deliver the most useful representation.

Treebank	Centroid (Ψ)	`npPMI` (Φ)	p-value
EWT	86.66	**91.81**	7e-193
GUM	89.58	**92.93**	2e-63
LinES	91.24	**94.64**	1e-87
ParTUT	90.73	**92.99**	4e-7

Table 2: Comparison of the adaptation of the LMMS approach and ours on POS tagging over the test sets of four English UD v2.5 treebanks. The last column contains the p-value for the McNemar test comparing the different behavior of the two approaches.

We used the development set of the individual treebanks for choosing the most promising layer of BERT to employ the different approaches over. For the `npPMI` approach we selected layer 13, 13, 14 and 11 for the EWT, GUM, LinES and ParTut treebanks. As for the dense centroid based approach we selected layer 6 for the ParTUT treebank and layer 13 for the rest of the treebanks. After doing so, our results for the test set of the four treebanks are reported in Table 2. Our approach delivered significant improvements for POS tagging as well as indicated by the p-values of the McNemar test.

5 Conclusions

In this paper we investigated how the application of sparse word representations obtained from contextualized word embeddings can provide a substantially increased ability for solving problems that require the distinction of fine-grained word senses. In our experiments, we managed to obtain solid results for multiple fine-grained word sense disambiguation benchmarks with the help of our information theory-inspired algorithm. We additionally carefully investigated the effects of increasing the amount of sense-annotated training data and the different design choices we made. We also demonstrated the general applicability of our approach by evaluating it in POS tagging. Our source code is made available at `https://github.com/begab/sparsity_makes_sense`.

Abstract

We introduce and study semantic capacity of terms. For example, the semantic capacity of *artificial intelligence* is higher than that of *linear regression* since *artificial intelligence* possesses a broader meaning scope. Understanding semantic capacity of terms will help many downstream tasks in natural language processing. For this purpose, we propose a two-step model to investigate semantic capacity of terms, which takes a large text corpus as input and can evaluate semantic capacity of terms if the text corpus can provide enough co-occurrence information of terms. Extensive experiments in three fields demonstrate the effectiveness and rationality of our model compared with well-designed baselines and human-level evaluations.

1 Introduction

Terms are not all considered equal. For instance, in computer science, the meaning scope of *artificial intelligence* or *computer architecture* is broader than that of *linear regression*. To study this phenomenon, in this paper, we introduce *Semantic Capacity*, which is a scalar value to characterize the meaning scope of a term. A good command of semantic capacity will give us more insight into the granularity of terms and allow us to describe things more precisely, which is a crucial step for downstream tasks such as keyword extraction (Hulth, 2003; Beliga et al., 2015; Firoozeh et al., 2020) and semantic analysis (Landauer et al., 1998; Goddard, 2011).

Figure 1 shows the fingerprint visualization of a computer scientist, which is generated by Elsevier Fingerprint Engine[1], a popular system that creates an index of weighted terms for research profiling. From the example, we can find that there exist some non-ideal terms, such as *learning* whose semantic capacity is too high, *backpropagation* whose semantic capacity is too low, and even irrelevant terms such as *color*. Understanding semantic capacity of terms will help us to choose better terms to describe entities. Besides, combining with other techniques like word similarity, semantic capacity can also help keyword replacement. For instance, to describe the computer scientist depicted in Figure 1, if the audience is a layman of computer science, we should use terms with high semantic capacity like *artificial intelligence*. But for an expert in the corresponding domain, we can select terms with low semantic capacity like *object recognition* to make the fingerprint more precise.

However, there are countless terms in human language, which means that it is extremely hard to investigate semantic capacity for all existing terms. Besides, semantic capacity of terms is also ambiguous in different domains. For instance, *cheminformatics* may be considered as a term with low semantic capacity in computer science and a term with high semantic capacity in chemistry.

On the other hand, the information on terms we acquire is usually very limited and/or noisy. Although semantic taxonomies such as WordNet (Miller, 1995) provide rich semantic relations between words, the information is still limited, and these knowledge bases are expensive to maintain and extend. Besides, there exists some research work that models hierarchical structures of terms automatically, but most of them suffer from low recall or insufficient precision. For instance, hypernymy discovery (Hearst, 1992; Snow et al., 2005; Roller et al., 2018) aims at finding *is-a* relations in textual data. If we can find all the hypernymy pairs and construct a perfect tree structure that includes every term, the problem of semantic capacity can

---

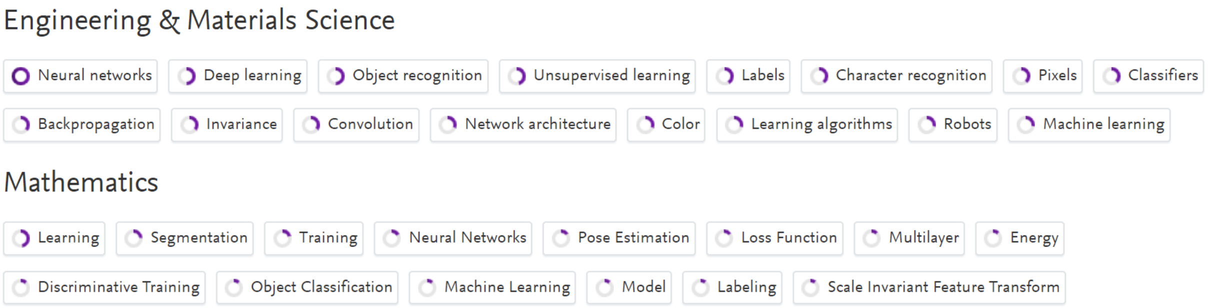

Figure 1: Snapshot of a fingerprint visualization generated by Elsevier Fingerprint Engine.

be solved to some extent. However, as far as we know, this is almost impossible in state of the art.

The above analysis shows that we should focus the problem on a specific domain and cover as many terms as possible with easily accessible information. Besides, we should also consider user requirements and deal with terms that are not included at first. Therefore, we propose a two-step model that only takes a text corpus as input and can evaluate semantic capacity of terms, provided that the text corpus can give enough co-occurrence signals. Our model consists of the offline construction process and the online query process. The offline construction process measures semantic capacity of terms in a specific semantic space, which narrows the problem to a specific domain and reduces the complexity of the problem to a practical level. The online query process deals with users' queries and evaluates newly added terms that users are interested in. To learn semantic capacity of terms with simple co-occurrences between terms, we introduce the *Semantic Capacity Association Hypothesis* and propose the *Lorentz Model with Normalized Pointwise Mutual Information*, where terms are placed in the hyperbolic space with a novel combination of normalized pointwise mutual information. Finally, norms of embeddings are interpreted as semantic capacity of terms.

The main contributions of our work are summarized as follows:

- We study semantic capacity of terms. As far as we know, we are the first to introduce and clarify the definition of semantic capacity.
- We propose a two-step model to learn semantic capacity of terms with unsupervised methods. Theoretically, our model can evaluate semantic capacity of any terms appearing in the text corpus as long as the corpus can provide enough co-occurrence signals.
- We introduce the *Semantic Capacity Association Hypothesis* and propose the Lorentz model with NPMI, which is a novel application of NPMI to help place terms in the hyperbolic space. We also conceive a novel idea to interpret norms of embeddings as semantic capacity of terms.
- We conduct extensive experiments on three scientific domains. Results show that our model can achieve performance comparable to scientific professionals, with a small margin to experts, and much better than laymen.

The code and data are available at `https://github.com/c3sr/semantic-capacity`.

2 Methodology

In this section, we introduce the definition of semantic capacity and describe our model in detail. The overview of our model is shown in Figure 2.

2.1 Definition

The semantic capacity of a term depends on its inherent semantics, the context it is used in, and its associations to other terms in the context. For example, *computer science* is a term with a broad meaning, and it is considered parallel to other terms with broad meanings like *physics* and *materials science*. Besides, *computer science* is also the parent class of some terms with broad meaning scopes like *artificial intelligence* and *computer architecture*.

However, understanding the inherent semantics of terms and modeling the associations between all terms found in human language are impractical due to limited resources. Therefore, in this paper, we focus on modeling semantic capacity for terms in a specific domain. The problem is defined as follows:

Definition 1 *(Semantic Capacity) The semantic capacity* $SC(\cdot)$ *of a term is a scalar value that*

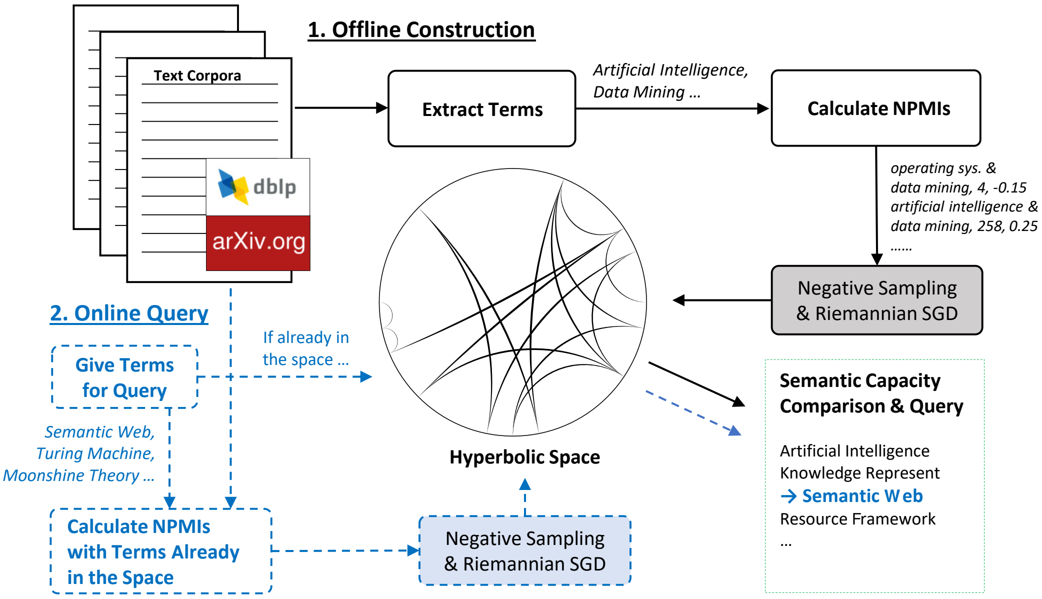

Figure 2: The overview of the two-step model. The model first takes a text corpus as input, and a set of terms are extracted from the corpus. After that, with the training process, terms are placed in the hyperbolic space, and norms of embeddings are interpreted as semantic capacity of terms. For terms that users are interested in but have not already been in the hyperbolic space, the model trains online and returns the corresponding results.

evaluates the relative semantic scope of a term in a specific domain. And the larger the value, the broader the semantic scope.

Semantic capacity reflects the generality of the term in a specific domain of interests, and the larger the value, the more general of such a term. According to the *Distributional Inclusion Hypotheses (DIH)* (Geffet and Dagan, 2005), if X is the superclass of Y, then all the syntactic-based features of Y are expected to appear in X. Therefore, a term with a broad meaning scope is expected to contain all features of its subclasses, and these subclasses are also expected to contain features of other terms with narrow meaning scopes. Associations between terms can be considered as some kind of syntactic-based features. Therefore, terms with higher semantic capacity are more likely to associate with more terms. Besides, in addition to DIH, we also have a new observation that terms like *artificial intelligence* are more likely to have a strong association with its direct subclasses like *machine learning* than descendant classes like *support vector machine*, which means that terms with broader meaning scopes are more likely to associate with terms with broader meaning scopes. Therefore, we propose the *Semantic Capacity Association Hypothesis* as follows:

Hypothesis 1 *(Semantic Capacity Association Hypothesis) Terms with higher semantic capacity will be associated with 1) more terms, and 2) terms with higher semantic capacity than terms with lower semantic capacity.*

2.2 Offline Construction Process

According to the analysis in the introduction, a feasible solution to measure semantic capacity is to focus on a specific domain. Therefore, we first introduce the offline construction process, which aims at learning semantic capacity of terms by taking a large text corpus as input with a number of domain-specific terms extracted from the corpus.

In this paper, to simplify the process and for easier evaluation, we use the public knowledge base Wikipedia Category[2] as a simple method to extract terms in a specific domain (more details are stated in Section 3.1). We can also extract terms from the domain-specific corpus directly by taking some term/phrase extraction methods (Velardi et al., 2001; Shang et al., 2018). After this process, our focus turns to learn semantic capacity of these extracted terms using the text corpus.

According to the *Semantic Capacity Association Hypothesis*, the key to measuring semantic capacity is to model associations between terms and then put terms in the proper place based on associations among them. Specifically, we aim to capture

---

[2] `https://en.wikipedia.org/wiki/Wikipedia:Categorization`

two types of associations between terms: semantic similarity, e.g., the association between AI (artificial intelligence) and ML (machine learning) is stronger than that between AI and DB (database) since ML is closer to AI than DB in meaning; and status similarity, e.g., the association between AI and ML is stronger than that between AI and SVM (support vector machine) since ML is more parallel to AI than SVM. On the other hand, the number of terms grows exponentially as semantic capacity gets lower, which means we need an exponentially increasing space to place terms. Therefore, we would like to design a method based on associations between terms to place terms in the hyperbolic space where circle circumference and volumes grow exponentially with radius.

Hyperbolic space is a kind of non-Euclidean geometry space represented by the unique, complete, simply connected Riemannian manifold with constant negative curvature. Recently, Nickel and Kiela (2017) proposed a hierarchical representation learning model, named the *Poincaré ball model*, based on the Riemannian manifold $\mathcal{P}^n = (\mathbf{B}^n, g_p)$, where $\mathbf{B}^n = \{\mathbf{x} \in \mathbb{R}^n : \|\mathbf{x}\| < 1\}$ is an open n-dimensional unit ball and g_p is the Riemannian metric tensor, which is defined as

$$g_p(\mathbf{x}) = \left(\frac{2}{1 - \|\mathbf{x}\|^2}\right)^2 g^E, \tag{1}$$

where $\mathbf{x} \in \mathbf{B}^n$ and g^E is the Euclidean metric tensor. The distance function on $\mathcal{P}^n$ is given as

$$d_p(\mathbf{x}, \mathbf{y}) = \cosh^{-1}\left(1 + \frac{2 \cdot \|\mathbf{x} - \mathbf{y}\|^2}{(1 - \|\mathbf{x}\|^2)(1 - \|\mathbf{y}\|^2)}\right). \tag{2}$$

Given a set of terms and a text corpus, we can count the frequency of co-occurrences $freq(x, y)$ between term x and y by traversing the corpus with a fixed window size. We can then learn representations of terms by using co-occurrence information directly based on the Poincaré ball model. Because of the restriction of hyperbolic space and the distance function, minimizing the loss described in (Nickel and Kiela, 2017) will be more likely placing terms co-occurring with more terms, especially those with higher co-occurrences, near the center of the Poincaré ball. If co-occurrences capture associations between terms well, according to the *Semantic Capacity Association Hypothesis*, semantic capacity of terms can be interpreted by norms of embeddings to some extent: $SC(x) = 1/\|\mathbf{x}\|$.

However, co-occurrences between terms are very common. There are many valid reasons that terms co-occur. For instance, two terms may co-occur because they are parallel (e.g., *machine learning* and *data mining*), or one term includes the other term (e.g., *artificial intelligence* and *machine learning*). Meanwhile, more generally, irrelevant or distant terms may also co-occur. Therefore, the associations modeled by co-occurrences between terms are very noisy, leading to the result that terms with high frequency will co-occur with more terms; thus, they are more likely to be placed near the center.

However, the high frequency of a term cannot guarantee the term's semantic capacity also high. In contrast, there are cases in which terms with less frequency turn out to possess high semantic capacity. For instance, *theoretical computer science* is a term with high semantic capacity. However, it is much less commonly used than its subfield term such as *graph theory*.

With this in mind, to filter noise and better model associations between terms, we introduce *normalized pointwise mutual information (NPMI)* (Bouma, 2009) to help place terms in the hyperbolic space. Letting $\mathcal{W}$ represent the term set, the NPMI value of term x and y is given as

$$npmi(x, y) = -\log \frac{p(x, y)}{p(x)p(y)} / \log p(x, y), \tag{3}$$

where $p(x, y) = 2 \cdot freq(x, y)/Z$ and $p(x) = freq(x)/Z$ with $freq(x) = \sum_{y \in \mathcal{W}} freq(x, y)$ and $Z = \sum_{x \in \mathcal{W}} freq(x)$.

Compared to pointwise mutual information (PMI), NPMI scales the value between -1 and 1, where -1 means x and y never co-occur, 0 means x and y occur independently, and 1 means x and y co-occur completely. If x and y possess a positive relation, given term y, term x will be more likely to occur in the window; thus the NPMI value will be positive. Therefore, in our model, we set a threshold $\delta > 0$ to filter out pairs with negative or weak relations and use the remaining pairs to build the set of associations, which is $\mathcal{D} = \{(x, y) : npmi(x, y) > \delta\}$.

According to (Nickel and Kiela, 2018), the Poincaré ball model is not optimal to optimize; therefore, we apply the Lorentz model (Nickel and Kiela, 2018) that can perform Riemannian optimization more efficiently and avoid numerical instabilities. The Lorentz model learns representations in $\mathbf{H}^n = \{\mathbf{x} \in \mathbb{R}^{n+1} : x_0^2 - \sum_{i=1}^n x_i^2 =$

$1, x_0 > 0\}$, where the distance function is defined as

$$d_\ell(\mathbf{x}, \mathbf{y}) = \cosh^{-1}(x_0 y_0 - \sum_{i=1}^{n} x_i y_i). \quad (4)$$

The Lorentz model and the Poincaré ball model are equivalent since points in one space can be mapped to the other space (Nickel and Kiela, 2018). Compared to the Lorentz model, the Poincaré ball model is more intuitive to interpret the embeddings. Therefore, we adopt the Lorentz model in our training process and use the Poincaré ball to interpret semantic capacity of terms.

To learn semantic capacity of terms, we modify the classic loss function of the Lorentz model and propose a new version that considers the strength of association, named *the Lorentz model with NPMI*. Letting

$$s(x, y) = \frac{\exp(-d_\ell(\mathbf{x}, \mathbf{y}))}{\sum_{y' \in \mathcal{N}(x)} \exp(-d_\ell(\mathbf{x}, \mathbf{y'}))}, \quad (5)$$

the loss function is given as

$$\mathcal{L}(\Theta) = - \sum_{(x,y) \in \mathcal{D}} npmi(x, y) \cdot \log s(x, y), \quad (6)$$

where $\mathcal{N}(x) = \{y | (x, y) \notin \mathcal{D}\} \cup \{x\}$ is the set of negative examples for x, and $\Theta = \{\boldsymbol{\theta}_i\}_{i=1}^{|\mathcal{W}|}$ represents the embeddings of terms, where $\boldsymbol{\theta}_i \in \mathbf{H}^n$. For training, we randomly select a fixed number of negative samples for each associated pair and then try to minimize the distance between points in this pair, against the negative samples.

Therefore, we aim to solve the optimization problem as

$$\min_{\Theta} \mathcal{L}(\Theta) \quad \text{s.t. } \forall \boldsymbol{\theta}_i \in \Theta : \boldsymbol{\theta}_i \in \mathbf{H}^n. \quad (7)$$

For optimization, we follow (Nickel and Kiela, 2018) and perform Riemannian SGD (Bonnabel, 2013).

2.3 Online Query Process

Since the terms that we are interested in may not be in the term set $\mathcal{W}$ extracted from the corpus, to evaluate the semantic capacity of newly added terms, we need an online training process to incorporate them into the system.

Assuming a number of terms are already placed in the hyperbolic space, adding a few new terms has little impact on the semantic space and original embeddings. Therefore, we can treat already trained terms as *anchor points* and add new terms into the space dynamically. More specifically, given a new term a, we find its co-occurrences with the original terms in $\mathcal{W}$ in the large corpus and calculate the NPMI values for a according to Eq. (3). And the optimization problem is then given as

$$\min_{\mathbf{a}} \quad - \sum_{(a,y) \in \mathcal{D}_a} npmi(a, y) \cdot \log s(a, y), \quad (8)$$

where $\mathcal{D}_a$ is the set of associations that contain a.

The online query process is illustrated in the blue part of Figure 2, where users provide a set of terms. The model first examines whether those terms are already in the space; if so, the system returns the semantic capacity directly. For terms that are not in the space, the system calculates the associations between them and the anchor points in the corpus and solves the optimization problem in Eq. (8) by the Lorentz model with NPMI. Finally, semantic capacity of these new terms will be returned as the reciprocal of embedding norms in the Poincaré ball. To make the online process more efficient, we can save the statistical information (e.g., co-occurrences with the anchor points) of all terms appearing in the corpus. By doing this, each query can be finished in a short time.

All in all, combining the offline construction and the online query process, we not only deal with the computational problem by focusing on a specific domain, but also have the ability to evaluate semantic capacity of any terms appearing in the text corpus as long as the text corpus can provide enough co-occurrence information. Besides, the online training process can also be considered as a way to extend the semantic space.

3 Experiments

In this section, we conduct experiments to validate the effectiveness of our model.

3.1 Datasets

We conduct experiments in three fields, including *computer science*, *physics*, and *mathematics*.

Computer Science We use DBLP text corpus[3] as input and extract terms from the corpus via Wikipedia Category. More specifically, we use terms appearing in both the corpus and the top k levels in Wikipedia Category of Computer Science[4]

---

Physics	1393	105	452	1090	14	127
Mathematics	1070	158	399	826	18	153

Table 1: Statistics of the dataset for $\mathcal{W}_5$.

to build the set of terms $\mathcal{W}_k$, which is considered as a simple term extraction process from the corpus. Since there are some irrelevant terms (considered as noise) in the category, we filter out terms whose "Page views in the past 30 days" ≤ 500 and length of words > 3. Besides, we filter out terms that contain numbers or special symbols. For evaluation, we also extract hypernym-hyponym pairs from Wikipedia Category.

Physics We use arXiv Papers Metadata Dataset[5] as input and extract terms from the corpus via Wikipedia Category of Physics[6] in the same way as computer science.

Mathematics We also use arXiv Papers Metadata Dataset as input and extract terms from the corpus via Wikipedia Category of Mathematics[7]. Other settings are the same as computer science.

Statistics of the data with respect to $\mathcal{W}_5$ are listed in Table 1. Taking Physics as an example, we extract 1090 terms, including 14 at the top 1 level and 127 at the top 2. Among these terms, there are 1393 pairs of hypernym-hyponym, including 105 pairs whose hypernym is at the top 1 level and 452 at the top 2.

3.2 Experimental Setup

Since our tasks on semantic capacity are brand new and there is no existing baseline that uses co-occurrences between terms to evaluate semantic capacity of terms, we build or adapt the following models for our experiments:

- **Popularity**: A simple method which uses the frequency $freq(\cdot)$ to evaluate the semantic capacity of each term, i.e., $SC(x) \propto freq(x)$.
- **Poincaré GloVe**: Poincaré GloVe (Tifrea et al., 2019) is the state-of-the-art model for hierarchical word embedding and hypernymy discovery, which adapts the GloVe algorithm to the hyperbolic space. In our experiments, we use the reciprocal of embedding norms as the semantic capacity of terms.

We also design the following models for ablation study:

- **Euclidean Model (Co-occurrences)**: A variant of our model which uses the Euclidean space instead of the hyperbolic space and models associations between terms by frequency of co-occurrences instead of NPMI.
- **Euclidean Model (NPMI)**: A variant of our model which uses the Euclidean space instead of the hyperbolic space.
- **Lorentz Model (Co-occurrences)**: A variant of our model which models associations between terms by frequency of co-occurrences instead of NPMI.
- **Lorentz Model (NPMI)**: Our model described in Section 2.

Parameter Settings We performed manual tuning for all models and adopted the following values for the hyperparameters. For all tasks and datasets, to find the co-occurrences between terms, we set window size as 20. For the training of our models, we set embedding size as 20, batch size as 512, number of negative samples as 50, and NPMI threshold δ as 0.1. We repeated our experiments for 5 random seed initializations.

All experiments were finished on one single NVIDIA GeForce RTX 2080 GPU under the PyTorch framework.

3.3 Evaluation on Offline Construction

In this section, we test whether the offline construction part of our model can preserve semantic

capacity of terms well. Wikipedia Category can be considered as tree-structured, where each edge is a hypernym-hyponym (broader/narrower) pair so that we can use these pairs for our evaluation. We first conduct our experiments on the semantic capacity comparison task with term set $\mathcal{W}_5$: given a pair (x, y), determine whether the semantic capacity of x is higher than that of y. For each field, we evaluate the accuracy for all pairs (all), pairs with hypernym at the top 1 level (top 1), pairs with hypernym at the top 2 levels (top 2). The results are shown in Table 2.

From the results, we find that the Lorentz model with NPMI outperforms all the baselines significantly, which achieves satisfactory performances in all fields, especially for pairs with hypernym at the top 1 level. Here we should mention that disagreements exist in the evaluation. For instance, in Wikipedia Category, *programming language theory* is the parent class of *programming language* and *computational neuroscience* is the parent class of *artificial intelligence*. However, people may also agree that *programming language* is the superclass of *programming language theory* and *artificial intelligence* is broader than *computational neuroscience*.

Besides, compared with these variants of our model, the Lorentz model with NPMI has a significant performance improvement over them, which indicates the effectiveness of using filtered NPMI to characterize associations between terms and shows the superiority of placing terms in the hyperbolic space. In terms of training speed, taking the offline construction in computer science as an example, compared with the run time of the Lorentz model with co-occurrences (51s), the Lorentz model with NPMI also has an improvement in efficiency (30s).

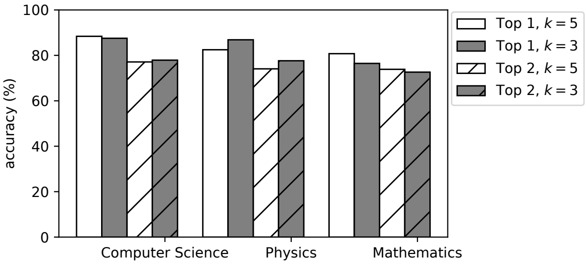

Figure 3: Top 1 and Top 2 accuracies when $\mathcal{W} = \mathcal{W}_k$.

To compare with methods based on lexico-syntactic patterns, we also try Hearst patterns (with extended patterns) (Hearst, 1992) to find the hypernymy relations for physical terms. The result shows that only 2.5% (35/1393) of the hypernymy pairs are detected, i.e., almost impossible to measure semantic capacity of terms.

In addition to evaluating on the pairs, we introduce a metric to evaluate the performance in a different way. Since semantic capacity is not strictly divided by levels of terms, it is possible that the semantic capacity of a term at the higher level is lower than that of a term at the lower level. But in general, the average rank of terms at the higher level should be higher than that of terms at the

Table 4: Results (%) of semantic capacity query tasks.

lower level. Therefore, we use the average rank of terms at the top k levels (AR_k) as a metric to evaluate the performance, which is defined as

$$AR_k = \frac{1}{|\mathcal{W}_k|} \sum_{x \in \mathcal{W}_k} \frac{rank(x)}{|\mathcal{W}|}, \qquad (9)$$

where $|\mathcal{W}|$ denotes the cardinality of the term set and $rank(x)$ is the ranking (being the top rank or the highest semantic capacity) of term x evaluated by the model. In other words, when k is small, the smaller AR_k, the better. For terms at the top 1 level, the metric is sensitive to misordered terms, and the value will grow a lot when a term is ranked low. Again, semantic capacity is not strictly divided by levels of terms, but in general, terms at the higher level should have higher ranks (smaller in value). Results in Table 3 show that our model achieves the best performance, and the results are consistent with the results of the semantic comparison task.

Sensitivity to Term Set The training process is affected by the term extraction process. Therefore, we want to detect model sensitivity with respect to the term set. For this purpose, we use $\mathcal{W}_5$ and $\mathcal{W}_3$ in each field as the term set respectively and conduct the semantic capacity comparison task for pairs with hypernym at the top 1 level and pairs with hypernym at the top 2 levels.

From Figure 3, we can see the results are relatively stable. On the one hand, compared to $\mathcal{W}_3$, $\mathcal{W}_5$ contains more terms, which means term set $\mathcal{W}_5$ is more complete, but the training time also increases with the number of terms. On the other hand, since noise increases with the level in Wikipedia Category, $\mathcal{W}_5$ contains more noisy terms than $\mathcal{W}_3$. In short, how to choose the term set depends on many factors, such as the task we care about and the noise contained in the term set we acquire.

3.4 Evaluation on Online Query

In this section, experiments are conducted to validate the performance of the online query process on evaluating semantic capacity of newly added terms. We randomly select 100 hypernym-hyponym pairs at the top 3 levels of each evaluation set for online query and use the remaining terms in $\mathcal{W}_3$ for offline construction. We compare our model with human annotation by three groups of people, where each pair is labeled by three unique people. Details of human annotation are listed as follows:

- **Human Annotation (Layman)**: Human annotation by workers on Amazon Mechanical Turk[8] with "HIT Approval Rate" $\geq$ 95% (considered as high quality).
- **Human Annotation (Professional)**: Human annotation by non-major students in the United States. Specifically, we ask math, computer science, physics students to conduct annotation tasks for physics, math, computer science, respectively.
- **Human Annotation (Expert)**: Human annotation by corresponding major students.

From the results shown in Table 4, we find that our model far outperforms human annotation by laymen in all fields. And the performance of our model is comparable to that of human annotation by professionals, with a small margin to experts. The results also imply disagreements exist in the evaluation since experts cannot achieve accuracies close to 100%. Besides, for both our model and human annotation, the top 1 accuracy is usually higher than top 2 accuracy, and the top 2 accuracy is higher than accuracy for all pairs, which is in line with common sense that semantic capacity of terms at the top levels is usually easier to evaluate. In short, the results demonstrate the effectiveness of our model for evaluating semantic capacity of newly added terms. Furthermore, our model can be applied to semantic capacity query for terms that are not included in the offline process.

4 Related Work

Our work is related to research on lexical semantics (Cruse, 1986). Among them, hypernymy, also known as *is-a* relation, has been studied for a long time. A well-known method is the Hearst patterns (Hearst, 1992), which extracts hypernymy pairs from a text corpus by hand-crafted lexico-syntactic patterns. Inspired by the Hearst patterns, some other pattern-based-methods like (Snow et al., 2005; Roller et al., 2018) are proposed successively. On the other hand, hypernymy discovery based on distributional approaches has also attracted widespread interest (Weeds et al., 2004; Lenci and Benotto, 2012; Chang et al., 2018).

The techniques our model based on are related to research on learning representations of symbolic data in the hyperbolic space (Krioukov et al., 2010; Nickel and Kiela, 2017, 2018). Since text preserves natural hierarchical structures, Dhingra et al. (2018) design a framework that learns word and sentence embeddings in an unsupervised manner from text corpora, Tifrea et al. (2019) propose Poincaré GloVe to learn word embeddings based on the GloVe algorithm in the hyperbolic space, Aly et al. (2019) use Poincaré embeddings to improve exiting methods to domain-specific taxonomy induction, and Le et al. (2019) propose a method to predict missing hypernymy relations and correct wrong extractions for Hearst patterns based on the hyperbolic entailment cones (Ganea et al., 2018).

5 Conclusion

In this paper, we explore semantic capacity of terms. We first introduce the definition of semantic capacity and propose the *Semantic Capacity Association Hypothesis*. After that, we propose a two-step model to investigate semantic capacity of terms, which consists of the offline construction and the online query processes. The offline construction process places domain-specific terms in the hyperbolic space by our proposed Lorentz model with NPMI, and the online query process deals with user requirements, where semantic capacity is interpreted by norms of embeddings. Extensive experiments with datasets from three fields demonstrate the effectiveness and rationality of our model compared with well-designed baselines and human-level evaluations.

In addition, while semantic capacity studied in this paper is restricted to a specific domain, we believe the notion of semantic capacity can be extended to all terms in human language. The extension of the scope will be the future work.

Abstract

Long document coreference resolution remains a challenging task due to the large memory and runtime requirements of current models. Recent work doing incremental coreference resolution using just the global representation of entities shows practical benefits but requires keeping all entities in memory, which can be impractical for long documents. We argue that keeping all entities in memory is unnecessary, and we propose a memory-augmented neural network that tracks only a small bounded number of entities at a time, thus guaranteeing a linear runtime in length of document. We show that (a) the model remains competitive with models with high memory and computational requirements on OntoNotes and LitBank, and (b) the model learns an efficient memory management strategy easily outperforming a rule-based strategy.

1 Introduction

Long document coreference resolution poses runtime and memory challenges. Current best models for coreference resolution have large memory requirements and quadratic runtime in the document length (Joshi et al., 2019; Wu et al., 2020), making them impractical for long documents.

Recent work revisiting the entity-mention paradigm (Luo et al., 2004; Webster and Curran, 2014), which seeks to maintain explicit representations only of entities, rather than all their constituent mentions, has shown practical benefits for memory while being competitive with state-of-the-art models (Xia et al., 2020). In particular, unlike other approaches to coreference resolution which maintain representations of both mentions *and* their corresponding entity clusters (Rahman and Ng, 2011; Stoyanov and Eisner, 2012; Clark and Manning, 2015; Wiseman et al., 2016; Lee et al., 2018) , the entity-mention paradigm stores representations only of the entity clusters, which are updated incrementally as coreference predictions are made. While such an approach requires less memory than those that additionally store mention representations, the number of entities can still become impractically large when processing long documents, making the storing of all entity representations problematic.

Is it necessary to maintain an unbounded number of mentions or entities? Psycholinguistic evidence suggests it is not, as human language processing is incremental (Tanenhaus et al., 1995; Keller, 2010) and has limited working memory (Baddeley, 1986). In practice, we find that most entities have a small spread (number of tokens from first to last mention of an entity), and thus do not need to be kept persistently in memory. This observation suggests that tracking a limited, small number of entities at any time can resolve the computational issues, albeit at a potential accuracy tradeoff.

Previous work on finite memory models for coreference resolution has shown potential, but has been tested only on short documents (Liu et al., 2019; Toshniwal et al., 2020). Moreover, this previous work makes token-level predictions while standard coreference datasets have span-level annotations. We propose a finite memory model that performs quasi-online coreference resolution,[1] and test it on LitBank (Bamman et al., 2020) and OntoNotes (Pradhan et al., 2012). The model is trained to manage its limited memory by predicting whether to "forget" an entity already being tracked in exchange for a new (currently untracked) entity. Our empirical results show that: (a) the model is competitive with an unbounded memory version, and (b) the model's learned memory management outperforms a strong rule-based baseline.[2]

---

[1] "Quasi-online" because document encoding uses bidirectional transformers with access to future tokens.

Table 1: Max. Total Entity Count vs. Max. Active Entity Count.

	LitBank	OntoNotes
Max. Total Entity Count	199	94
Max. Active Entity Count	18	24

2 Entity Spread and Active Entities

Given input document $\mathcal{D}$, let $(x_n)_{n=1}^{N}$ represent the N mention spans corresponding to M underlying entities $(e_m)_{m=1}^{M}$. Let $\text{START}(x_i)$ and $\text{END}(x_i)$ denote the start and end token indices of the mention span x_i in document $\mathcal{D}$. Let $\text{ENT}(x_i)$ denote the entity of which x_i is a mention. Given this notation we next define the following concepts.

Entity Spread Entity spread denotes the interval of token indices from the first mention to the last mention of an entity. The entity spread $\text{ES}(e)$ of entity e is given by:

$$\text{ES}(e) = [\min_{\text{ENT}(x)=e} \text{START}(x), \max_{\text{ENT}(x)=e} \text{END}(x)]$$

Active Entity Count Active entity count $\text{AE}(t)$ at token index t denotes the number of unique entities whose spread covers the token t, i.e., $\text{AE}(t) = |\{e \mid t \in \text{ES}(e)\}|$.

Maximum Active Entity Count Maximum active entity count $\text{MAE}(\mathcal{D})$ for a document $\mathcal{D}$ denotes the maximum number of active entities at any token index in $\mathcal{D}$, i.e., $\text{MAE}(\mathcal{D}) = \max_{t \in [|\mathcal{D}|]} \text{AE}(t)$. This measure can be simply extended to a corpus $\mathcal{C}$ as: $\text{MAE}(\mathcal{C}) = \max_{\mathcal{D} \in \mathcal{C}} \text{MAE}(\mathcal{D})$.

Table 1 shows the MAE and the maximum total entity count in a single document, for LitBank and OntoNotes. For both datasets the maximum active entity count is much smaller than the maximum total entity count. Thus, rather than keeping all the entities in memory at all times, models can in principle simply focus on the far fewer active entities at any given time.

3 Model

Based on the preceding finding, we will next describe models that require tracking only a small, bounded number of entities at any time.

To make coreference predictions for a document, we first encode the document and propose candidate mentions. The proposed mentions are then processed sequentially and are either: (a) added to an existing entity cluster, (b) added to a new cluster, (c) ignored due to limited memory capacity (for bounded memory models), or (d) ignored as an invalid mention.

Document Encoding is done using the SpanBERT$_{\text{LARGE}}$ model finetuned for OntoNotes and released as part of the coreference model of Joshi et al. (2020). We don't further finetune the SpanBERT model. To encode long documents, we segment the document using the *independent* and *overlap* strategies described in Joshi et al. (2019).[3] In *overlap* segmentation, for a token present in overlapping BERT windows, the token's representation is taken from the BERT window with the most neighboring tokens of the concerned token. For both datasets we find that *overlap* slightly outperforms *independent*.

Mention Proposal Given the encoded document, we next predict the top-scoring mentions which are to be clustered. The goal of this step is to have high recall, and we follow previous work to threshold the number of spans chosen (Lee et al., 2017). Given a document $\mathcal{D}$, we choose $0.3 \times |\mathcal{D}|$ top spans for LitBank, and $0.4 \times |\mathcal{D}|$ for OntoNotes.

Note that we pretrain the mention proposal model before training the mention proposal and mention clustering pipeline end-to-end, as done by Wu et al. (2020). The reason is that without pretraining, most of the mentions proposed by the mention proposal model would be invalid mentions, i.e., spans that are not mentions, which would not provide any training signal to the mention clustering stage. For both datasets, we sample invalid spans with 0.2 probability during training, so as to roughly equalize the number of invalid spans and actual mentions, as suggested by Xia et al. (2020).

Mention Clustering Let $(x_i)_{i=1}^{K}$ represent the top-K candidate mention spans from the mention proposal step and let $s_m(x_i)$ represent the mention score for span x_i, which indicates how likely it is that a span constitutes a mention. Assume that the mentions are already ordered based on their position in the document and are processed sequentially in that order.[4] Let $E = (e_m)_{m=1}^{M}$ represent the M

`long-doc-coref`

[3] We modify the *overlap* segmentation to respect sentence boundary or token boundary when possible.

[4] Specifically, they are ordered based on START(·) index with ties broken using END(·).

entities currently being tracked by the model (initially $M = 0$). For ease of discussion, we will overload the terms x_i and e_j to also correspond to their respective representations.

In the *first* step, the model decides whether the span x_i refers to any of the entities in E as follows:

$$s_c(x_i, e_j) = f_c([x_i; e_j; x_i \odot e_j; g(x_i, e_j)]) + s_m(x_i)$$
$$s_c^{top} = \max_{j=1\ldots M} s_c(x_i, e_j)$$
$$e^{top} = \arg\max_{j=1\ldots M} s_c(x_i, e_j)$$

where $\odot$ represents the element-wise product, and $f_c(\cdot)$ corresponds to a learned feedforward neural network. The term $g(x_i, e_j)$ correponds to a concatenation of feature embeddings that includes embeddings for (a) number of mentions in e_j, (b) number of mentions between x_i and last mention of e_j, (c) last mention decision, and (d) document genre (only for OntoNotes).

Now if $s_c^{top} > 0$ then x_i is considered to refer to e^{top}, and e^{top} is updated accordingly.[5] Otherwise, x_i does not refer to any entity in E and a *second* step is executed, which will depend on the choice of memory architecture. We test three memory architectures, described below.

1. **Unbounded Memory (U-MEM)**: If $s_m(x_i) > 0$ then we create a new entity $e_{M+1} = x_i$ and append it to E. Otherwise the mention is ignored as invalid, i.e., it doesn't correspond to an entity. This differs from Xia et al. (2020) who append all non-coreferent mentions. The reason for the change is that appending all mentions can hurt performance on LitBank where singletons are explicitly marked and used for evaluation.

2. **Bounded Memory**: Suppose the model has a capacity of tracking C entities at a time. If $C > M$, i.e., the memory capacity has not been fully utilized, then the model behaves like U-MEM. Otherwise, the bounded memory models must decide between: (a) evicting an entity already being tracked, (b) ignoring x_i due to limited capacity, and (c) ignoring the mention as invalid. We test two bounded memory variants that are described below.

Table 2: Results for LitBank (CoNLL F1).

Model	Dev F1	Test F1
U-MEM	76.5	75.9
LB-MEM		
5 cells	70.6	69.5
10 cells	75.4	74.9
20 cells	76.3	75.7
RB-MEM		
5 cells	67.5	66.7
10 cells	72.2	71.8
20 cells	73.1	72.6
Bamman et al. (2020)	-	68.1

(a) **Learned Bounded Memory (LB-MEM)**: The proposed LB-MEM architecture tries to predict a score $f_r(.)$ corresponding to the anticipated number of remaining mentions for any entity or mention, and compares it against the mention score $s_m(x_i)$ as follows:

$$d = \arg\min[f_r(e_1), \ldots, f_r(e_M), f_r(x_i), s_m(x_i)]$$

where $f_r(\cdot)$ is a learned feedforward neural network. If $1 \leq d \leq M$ then then the model evicts the previous entity e_d and reinitialize it to x_i. Otherwise if $d = M + 1$ then the model ignores x_i due to limited capacity. Finally if $d = M + 2$ then the model predicts the mention to be invalid.

(b) **Rule-based Bounded Memory (RB-MEM)** The Least Recently Used (LRU) principle is a popular choice among memory models (Rae et al., 2016; Santoro et al., 2016). While LB-MEM considers all potential entities for eviction, with RB-MEM this choice is restricted to just the LRU entity, i.e., the entity whose mention was least recently seen. The rest of the steps are similar to the LB-MEM model.

Training All the models are trained using teacher forcing. The ground truth decisions for bounded memory models are chosen to maximize the number of mentions tracked by the model (details in Appendix A.3). Finally, the training loss is calculated via the addition of the cross-entropy losses for the two steps of mention clustering.

4 Experimental Setup

4.1 Datasets

LitBank is a recent coreference dataset for literary texts (Bamman et al., 2020). The dataset consists of prefixes of 100 novels with an average length of 2100 words. Singletons are marked and used for evaluation. Evaluation is done via 10-fold cross-validation over 80/10/10 splits.[6]

---

[5] We use weighted averaging where the weight for e^{top} corresponds to the number of previous mentions seen for e^{top}.

[6] `https://github.com/dbamman/lrec2020-coref/tree/master/data`

Table 3: Results for OntoNotes (CoNLL F1) .

Model	Dev F1	Test F1
U-MEM	77.7	77.4
LB-MEM		
5 cells	73.1	73.0
10 cells	76.6	76.2
20 cells	77.7	77.3
RB-MEM		
5 cells	69.0	68.8
10 cells	75.2	75.0
20 cells	77.5	77.5
U-MEM (Xia et al., 2020)	78.7	78.2
Joshi et al. (2020)	80.1	79.6
Wu et al. (2020)	83.4	83.1

OntoNotes consists of 2802/343/348 documents in the train/development/test splits, respectively (Pradhan et al., 2012). The documents span 7 genres and have an average length of 463 words. Singletons are not marked in the dataset.

4.2 Hyperparameters

Document encoding is done using the SpanBERT$_{\text{LARGE}}$ model of Joshi et al. (2020) which was finetuned for OntoNotes. The SpanBERT model is not further finetuned. The other model parameters are trained using the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 5×10^{-4}. For span representation, we use the embedding function described in Lee et al. (2017). For OntoNotes we follow the setup of Xia et al. (2020). We differ, however, in training all the model parameters, except SpanBERT, from scratch. The models are trained for 10 epochs with a patience of 3 epochs, i.e., reduce learning rate by a 0.1 factor if the validation loss doesn't improve for 3 epochs. For LitBank the models are trained for 25 epochs with a patience of 3 epochs. For more details see Appendix A.2.

5 Results

Tables 2 and 3 show results of all the proposed models for LitBank and OntoNotes respectively. As expected, the bounded memory models improve with increase in memory. For both datasets, the LB-MEM model with 20 memory cells is competitive with the U-MEM model. The RB-MEM model with 20 memory cells is competitive on OntoNotes but is significantly worse than the other two on LitBank. Comparing among the bounded memory models, the LB-MEM model is significantly better than RB-MEM for lower numbers of memory cells.

Table 4: Peak memory and inference time statistics for the LitBank cross-validation split zero.

Model	Peak training mem. (in GB)	Peak inference mem. (in GB)	Inference time (in s)
U-MEM	11.6	3.1	29.25
LB-MEM			
5 cells	8.0	3.2	27.31
10 cells	8.4	3.2	27.44
20 cells	9.1	3.2	27.86
RB-MEM			
5 cells	8.0	3.2	26.19
10 cells	8.3	3.2	26.50
20 cells	8.9	3.2	26.19

Table 5: Comparison of number of entities in memory.

Model	LitBank		OntoNotes	
	Avg	Max	Avg	Max
U-MEM	97.0	198	16.3	87
LB-MEM				
5 cells	5.0	5	4.6	5
10 cells	10.0	10	8.1	10
20 cells	20.0	20	12.4	20
RB-MEM				
5 cells	5.0	5	4.6	5
10 cells	10.0	10	8.1	10
20 cells	20.0	20	12.4	20

We analyze the reasons for this in the next section.

Between the two datasets, we see that the increase in memory results in larger improvement for LitBank. We also establish a new state-of-the-art for LitBank with the U-MEM memory model. For OntoNotes, our models are competitive with comparable models such as Xia et al. (2020). The performance difference between the two U-MEM models might be because we try to predict invalid mentions which, while beneficial for LitBank, can lead to lower mention recall for OntoNotes. We expect gains by further finetuning the SpanBERT model and learning a parameterized global entity representation, but we leave them for future work.

6 Analysis

In this section we analyze the behavior of the three memory models on LitBank and OntoNotes.

Memory Utilization Table 4 compares the memory and inference time statistics for the different memory models for the LitBank cross-validation split zero.[7] For training, the bounded memory models are significantly less memory intensive than the U-MEM model. The table also shows that the

---

[7] Peak memory usage estimated via `torch.cuda.max_memory_allocated()`

Table 6: Average number of mentions ignored by the two bounded memory models.

Memory size	LitBank LB-MEM	LitBank RB-MEM	OntoNotes LB-MEM	OntoNotes RB-MEM
5	18.3	83.2	0.5	5.4
10	0.0	34.5	0.0	0.7
20	0.0	7.0	0.0	0.0

bounded memory models are faster than the U-MEM memory model during inference (inference time calculated by averaging over three runs). This is because the number of entities tracked by the U-MEM memory model grows well beyond the maximum of 20 memory slots reserved for the bounded models as shown in Table 5.

Surprisingly, for inference we see that the bounded models have a slightly larger memory footprint than the U-MEM model. This is because the document encoder, SpanBERT, dominates the memory usage during inference (as also observed by Xia et al., 2020). Thus the peak memory usage during inference is determined by the mention proposal stage rather than the mention clustering stage. And during the mention proposal stage, the additional parameters of bounded memory models, which are loaded as part of the whole model, cause the slight uptick in peak inference memory. Note that using a cheaper encoder or running on a sufficiently long document, such as a book, can change these results.

Number of Entities in Memory Table 5 compares the maximum number of entities kept in memory by the different memory models for the LitBank cross-validation dev sets and the OntoNotes dev set. As expected, the U-MEM model keeps more entities in memory than the bounded memory models on average for both datasets. For LitBank the difference is especially stark with the U-MEM model tracking about 5/10 times more entities in memory on average/worst case, respectively. Also, while some OntoNotes documents do not use even the full 5 memory cell capacity, all LitBank documents fully utilize even the 20 memory cell capacity. This is because LitBank documents are more than four times as long as OntoNotes documents, and LitBank has singletons marked. These results also justify our initial motivation that with long documents, the memory requirement will increase even if we only keep the entity representations.

Table 7: Error Analysis for OntoNotes dev set. CE=Conflated Entities, DE=Divided Entity, EM=Extra Mention, EE=Extra Entity, MM=Missing Mention, ME=Missing Entity.

Model	CE	DE	EM	EE	MM	ME
U-MEM	950	901	635	621	493	542
LB-MEM						
5 cells	722	1020	394	426	982	1058
10 cells	863	988	499	505	637	719
20 cells	894	905	571	542	513	631
RB-MEM						
5 cells	724	1166	386	406	989	1335
10 cells	851	1088	474	547	702	749
20 cells	880	903	559	561	531	634

LB-MEM vs. RB-MEM Table 6 compares the number of mentions ignored by LB-MEM and RB-MEM. The LB-MEM model ignores far fewer mentions than RB-MEM. This is because while the RB-MEM model can only evict the LRU entity, which might not be optimal, the LB-MEM model can choose any entity for eviction. These statistics combined with the fact that the LB-MEM model typically outperforms RB-MEM mean that the LB-MEM model is able to anticipate which entities are important and which are not.

Error Analysis Table 7 presents the results of automated error analysis done using the Berkeley Coreference Analyzer (Kummerfeld and Klein, 2013) for the OntoNotes dev set. As the memory capacity of models increases, the errors shift from missing mention, missing entity, and divided entity categories, to conflated entities, extra mention, and extra entity categories. For the 5-cell configuration, the LB-MEM model outperforms RB-MEM in terms of tracking more entities.

7 Conclusion and Future Work

We propose a memory model which tracks a small, bounded number of entities. The proposed model guarantees a linear runtime in document length, and in practice significantly reduces peak memory usage during training. Empirical results on LitBank and OntoNotes show that the model is competitive with an unbounded memory version and outperforms a strong rule-based baseline. In particular, we report state of the art results on LitBank. In future work we plan to apply our model to longer, book length documents, and plan to add more structure to the memory.

Acknowledgments

We thank David Bamman for help with the LitBank setup, and Patrick Xia for answering questions about their coreference model. We also thank the anonymous ACL reviewers for their valuable feedback. A Appendix

A.1 Maximum Active Entities

Figure 1 visualizes the histograms of length of Entity Spread (ES), defined in Section 2, as a fraction of document length for documents in LitBank and OntoNotes. For LitBank we only visualize the entity spread of non-singleton clusters because otherwise the histogram is too skewed towards one. Figure 2 visualizes the histograms of Maximum Active Entity Count (MAE), defined in Section 2, for documents in LitBank and OntoNotes.

A.2 Model Details

Other hyperparameters We stick with the hyperparameters for feedforward neural network (FFNN) size and depth, and dropout from Joshi et al. (2020). One hyperparameter that we find to be important is the weight of the non-coreferent term in the cross-entropy loss for the first step of mention clustering. We find that placing a higher weight of 2.0 on that term leads to consistent performance gains. This might be because of that term's significance, as the value of that term decides whether the next step of mention clustering is triggered or not.

Table 8: Hyperparameter options with the bold choices highlighted as bold.

Parameter	Range
Dropout	{0.3}
FFNN hidden layer	{3000}
FFNN # of hidden layers	1
Document Encoding	{Independent, **Overlap**}
Non-coreferent entity weight	{1.0, **2.0**, 5.0}

Expected Validation Performance Since LitBank has 10 cross-validation splits, the grid search based tuning process was limited to a few cross-validation splits. For LitBank, in our initial experiments with gold mention clustering we find that *overlap* segmentation gave a gain of about 0.5% F1 and we stuck with the choice from then onwards. For non-coreferent entity weight, we see an improvement of 0.5-1% F1 on going from 1.0 to 2.0 but the performance with 5.0 weight drops below of that with 1.0.

For OntoNotes, we find that deviating from *overlap* to *independent* results in a drop of about 1% F1 absolute performance for the LB-MEM model with 5 and 10 memory cells, the other two models are almost unaffected. The reason why *overlap* is crucial to the LB-MEM model is because on average the tokens get more future context which helps the model in “anticipating" which entities are important and need to be kept in the memory.

A.3 Ground Truth Generation

In this section we explain how the ground truth action sequence is generated corresponding to the predicted mention sequence. The ground truth for U-MEM model is fairly straight forward. For the bounded memory models, we keep growing the number of entities till we hit the memory ceiling. For all the entities in memory, we maintain the number of mentions remaining in the ground truth cluster. For example, a cluster with a total of five mentions, two of which have already been processed by the model, has three remaining mentions.

Suppose now a mention corresponding to a currently untracked entity comes in and the memory is already at full capacity. Then for the LB-MEM model, we compare the number of mentions of this new entity (along with the current mention) against the number of mentions remaining for all the entities currently being tracked. If there are entities in memory with number of remaining mentions less than or equal to the number of mentions of this currently untracked entity, then the untracked entity replaces the entity with the least number of remaining mentions. Ties among the entities with least number of remaining mentions are broken by the least recently seen entity. If there’s no such entity in the memory, then the mention is ignored. For the RB-MEM model, the comparison is done in a similar way but is limited to the LRU entity.

A.4 Miscellaneous

Computing Infrastructure & Runtime All the models for a single cross validation split of LitBank can be trained within 4 hours. The U-MEM models require 24GB memory GPUs and are trained on TitanRTX. The LB-MEM and RB-MEM models can be trained on 12GB memory GPUs.

As in LitBank, the U-MEM model for OntoNotes require 24GB memory GPUs. The LB-MEM and RB-MEM models can be trained on 12GB memory GPUs. Training on OntoNotes finishes within 12 hours.

Table 9: Number of model parameters (in millions).

	LitBank	OntoNotes
U-MEM	37.36	37.42
LB-MEM	46.83	46.95
RB-MEM	46.83	46.95

Table 10: Spearman correlation of F1 score with document length and # of entities in OntoNotes dev set.

Model	Document Length	# of Entities
U-MEM	-0.31	-0.27
LB-MEM		
5 cells	-0.38	-0.39
10 cells	-0.37	-0.35
20 cells	-0.30	-0.27
RB-MEM		
5 cells	-0.42	-0.47
10 cells	-0.36	-0.37
20 cells	-0.33	-0.30

Number of model parameters. Table 9 shows the number of trainable parameters for all the model and dataset combinations. LB-MEM and RB-MEM have additional parameters in comparison to U-MEM for predicting a score corresponding to the number of remaining mentions for an entity. Comparing across datasets, the OntoNotes models have a few additional parameters than their LitBank counterparts for modeling the document genre.

Evaluation Metric Code. We use the coreference scorer Perl script available at `https://github.com/conll/reference-coreference-scorers`. We also use the Python implementation by Kenton Lee available at `https://github.com/kentonl/e2e-coref/blob/master/metrics.py`. The two scripts can have some rounding differences.

Effect of Document Length and Number of Entities. Table 10 presents the Spearman correlation between document F1 score and both document length and number of entities in the document. The correlations are negative because the problem becomes more challenging with increase in document length and entities. The increase in memory for bounded models results in less negative correlation, suggesting improved performance for challenging documents. The slightly less negative correlation for LB-MEM models than RB-MEM models for 20 memory cells (when their dev performance is similar) implies that LB-MEM models perform better for longer OntoNotes documents.

Revealing the Myth of Higher-Order Inference in Coreference Resolution

Abstract

This paper analyzes the impact of higher-order inference (HOI) on the task of coreference resolution. HOI has been adapted by almost all recent coreference resolution models without taking much investigation on its true effectiveness over representation learning. To make a comprehensive analysis, we implement an end-to-end coreference system as well as four HOI approaches, attended antecedent, entity equalization, span clustering, and cluster merging, where the latter two are our original methods. We find that given a high-performing encoder such as SpanBERT, the impact of HOI is negative to marginal, providing a new perspective of HOI to this task. Our best model using cluster merging shows the Avg-F1 of 80.2 on the CoNLL 2012 shared task dataset in English.

1 Introduction

Coreference resolution has always been considered one of the unsolved NLP tasks due to its challenging aspect of document-level understanding (Wiseman et al., 2015, 2016; Clark and Manning, 2015, 2016; Lee et al., 2017). Nonetheless, it has made a tremendous progress in recent years by adapting contextualized embedding encoders such as ELMo (Lee et al., 2018; Fei et al., 2019) and BERT (Kantor and Globerson, 2019; Joshi et al., 2019, 2020). The latest state-of-the-art model shows the improvement of 12.4% over the model introduced 2.5 years ago, where the major portion of the improvement is derived by representation learning (Figure 1).

Most of these previous models have also adapted higher-order inference (HOI) for the global optimization of coreference links, although HOI clearly has not been the focus of those works, for the fact that gains from HOI have been reported marginal. This has inspired us to analyze the impact of HOI on modern coreference resolution models in order to envision the future direction of this research. To make thorough ablation studies among different approaches, we implement an end-to-end coreference system in PyTorch (Sec 3.1), and two HOI approaches proposed by previous work, attended antecedent and entity equalization (Sec 3.2), along with two of our original approaches, span clustering and cluster merging (Sec 3.3). These approaches are experimented with two Transformer encoders, BERT and SpanBERT, to assess how effective HOI is even when coupled with those high-performing encoders (Sec 4). To the best of our knowledge, this is the first work to make a comprehensive analysis on multiple HOI approaches side-by-side for the task of coreference resolution.[1]

(2018), F-19: Fei et al. (2019), K-19: Kantor and Globerson (2019), J-19: Joshi et al. (2019), J-20: Joshi et al. (2020).

2 Related Work

Most neural network-based coreference resolution models have adapted antecedent-ranking (Wiseman et al., 2015; Clark and Manning, 2015; Lee et al., 2017, 2018; Joshi et al., 2019, 2020), which relies on the local decisions between each mention and its

November 16–20, 2020.

antecedents. To achieve deeper global optimization, Wiseman et al. (2016); Clark and Manning (2016); Yu et al. (2020) built entity representations in the ranking process, whereas Lee et al. (2018); Kantor and Globerson (2019) refined the mention representation by aggregating its antecedents' information.

There is no secret that the integration of contextualized embeddings has played the most critical role in this task. While the followings are based on the same end-to-end coreference model (Lee et al., 2017), Lee et al. (2018); Fei et al. (2019), Peters et al. (2018) reported 3.3% improvement by adapting ELMo in the encoders. Kantor and Globerson (2019); Joshi et al. (2019) gained additional 3.3% by adapting BERT (Devlin et al., 2019). Joshi et al. (2020) introduced SpanBERT that gave another 2.7% improvement over Joshi et al. (2019). Most recently, Wu et al. (2020) proposes a new model that adapts question-answering framework on coreference resolution, and achieves state-of-the-art result of 83.1 on the CoNLL'12 shared task.

3 Approach

3.1 End-to-End Coreference System

We reimplement the end-to-end *c2f-coref* model introduced by Lee et al. (2018) that has been adapted by every coreference resolution model since then. It detects mention candidates through span enumeration and aggressive pruning. For each candidate span x, the model learns the distribution over its antecedents $y \in \mathcal{Y}(x)$:

$$P(y) = \frac{e^{s(x,y)}}{\sum_{y' \in \mathcal{Y}(x)} e^{s(x,y')}} \tag{1}$$

where $s(x, y)$ is the local score involving two parts: how likely the spans x and y are valid mentions, and how likely they refer to the same entity:

$$\begin{aligned} s(x,y) &= s_m(x) + s_m(y) + s_c(x,y) \\ s_m(x) &= w_m \texttt{FFNN}_m(g_x) \\ s_c(x,y) &= w_c \texttt{FFNN}_c(g_x, g_y, \phi(x,y)) \end{aligned} \tag{2}$$

g_x, g_y are the span embeddings of x and y, $\phi(x, y)$ is the meta-information (e.g., speakers, distance), and w_m, w_c are the mention and coreference scores, respectively (`FFNN`: feedforward neural network). We use different Transformers-based encoders, and follow the "*independent*" setup for long documents as suggested by Joshi et al. (2019).

3.2 Span Refinement

Two HOI methods presented by recent coreference work are based on span refinement that aggregates non-local features to enrich the span representation with more "global" information. The updated span representation g'_x can be derived as in Eq. 3, where g'_x is the interpolation between the current and refined representation g_x and a_x, and W_f is the gate parameter. g'_x is used to perform another round of antecedent-ranking in replacement of g_x.

$$\begin{aligned} g'_x &= f_x \circ g_x + (1 - f_x) \circ a_x \\ f_x &= \sigma(W_f[g_x, a_x]) \end{aligned} \tag{3}$$

The following two methods share the same updating process for g'_x, but with different ways to obtain the refined span representation a_x.

Attended Antecedent (`AA`) takes the antecedent information to enrich g'_x (Lee et al., 2018; Fei et al., 2019; Joshi et al., 2019, 2020). The refined span a_x is the attended antecedent representation over the current antecedent distribution $P(y)$, where $g_{y \in \mathcal{Y}(x)}$ is the antecedent representation:

$$a_x = \sum_{y \in \mathcal{Y}(x)} P(y) \cdot g_y \tag{4}$$

Entity Equalization (`EE`) takes the clustering relaxation as in Eq. 5 to model the entity distribution (Kantor and Globerson, 2019), where $Q(x \in E_{y'})$ is the probability of the span x referring to an entity $E_{y'}$ in which the span y' is the first mention. $P(y)$ is the current antecedent distribution.

$$Q(x \in E_{y'}) = \begin{cases} \sum_{k=y'}^{x-1} P(y = k) \cdot Q(k \in E_{y'}) & y' < x \\ P(y = \epsilon) & y' = x \\ 0 & y' > x \end{cases} \tag{5}$$

The refined span a_x is the attended entity representation, where $e_y^{(x)}$ is the entity representation to which the span y belongs till the span x:

$$e_x^{(t)} = \sum_{y=1}^{t} Q(y \in E_x) \cdot g_y \tag{6}$$

$$a_x = \sum_{y=1}^{x} Q(x \in E_y) \cdot e_y^{(x)} \tag{7}$$

3.3 HOI with Clustering

This section introduces two new HOI methods for a more extensive study in HOI.

Span Clustering (`SC`) is also based on span refinement, and it constructs the actual clusters and obtains the "true" predicted entities using $P(y)$ instead of modeling the "soft" entity clusters through the relaxation as in `EE` (Section 3.2). This way, although we lose the differentiable property, the obtaining of true entities with the same empirical inference time as `EE` has made `SC` desirable.
The entity representation e_i for an entity cluster C_i is given by the attended spans in this cluster:

$$\begin{aligned}\alpha_t &= w_\alpha \text{FFNN}_\alpha(g_t)\\ \alpha_{i,t} &= \frac{\exp(\alpha_t)}{\sum_{k\in C_i}\exp(\alpha_k)}\\ e_i &= \sum_{t\in C_i}\alpha_{i,t}\cdot g_t\end{aligned}$$

The entity clusters C_i are constructed in the same way as in the final cluster prediction. The refined span a_x is then equal to the representation of entity e_i to which it belongs ($g_x \in C_i$).

Cluster Merging (`CM`) performs sequential antecedent ranking combining both antecedent and entity information to gradually build up the entity clusters, which is distinguished from span refinement methods that simply re-rank antecedents. Algorithm 1 describes the ranking process for `CM`. g_i is the i'th span, $\mathcal{Y}(i)$ is the indices of g_i's antecedents, and C_i is the cluster that g_i belongs to. The ranking score $s_x(y)$ consists of both antecedent score f_a (see Eq. 2) and cluster score f_c. To avoid overlapping between f_a and f_c, we set f_c as 0 if the cluster is the initial cluster (L6). Thus, f_c becomes the consultation such that when $f_c > 0$, the span g_x is likely to match the cluster C_y, and vice versa. f_c is computed by `FFNN` similar to f_a, and $\phi(C_y)$ is the meta-feature such as the cluster size.

Algorithm 1 Antecedent Ranking for `CM`

```
 1: procedure RANKING($g_1, \cdots, g_N$)
 2:     $C_{i=1,\cdots,N} \leftarrow g_i$
 3:     $R \leftarrow$ ranking_order($g_1, \cdots, g_N$)
 4:     for $x = R_1 \cdots R_N$ do
 5:         for $y \in \mathcal{Y}(x)$ do                ▷ Parallelized
 6:             $f_c(g_x, C_y) \leftarrow 0$ if $C_y = g_y$
 7:             $s_x(y) \leftarrow f_a(g_x, g_y) + f_c(g_x, C_y, \phi(C_y))$
 8:         $y' \leftarrow \text{argmax}_{y\in\mathcal{Y}(x)} s_x(y)$
 9:         if $y' \neq \epsilon$ then
10:             merge $C_x$ and $C_{y'}$
11:     return $s_1, \cdots, s_N$
```

Two simple configurations can be tuned for `CM`. We can have the sequential left-to-right ranking order or the easy-first order (L3) whose sequence is ordered by each span's max antecedent score, building the most confident clusters first (Ng and Cardie, 2002; Clark and Manning, 2016). There can be element-wise mean or max-reduction among the spans in the two merging clusters (L10).

Distinguished from Wiseman et al. (2016), clusters in `CM` are searched and merged in training without the use of oracle clusters, closing the gap between training and test time.

4 Experiments

For our experiments, the CoNLL 2012 English shared task dataset is used (Pradhan et al., 2012). Given the end-to-end coreference system in Section 3.1, six models are developed as follows:[2]

- `BERT`: BERT (Devlin et al., 2019) as the encoder
- `SpanBERT`: SpanBERT (Joshi et al., 2020) as the encoder
- `+AA`: `SpanBERT` with attended antecedent (§3.2)
- `+EE`: `SpanBERT` with entity equalization (§3.2)
- `+SC`: `SpanBERT` with span clustering (§3.3)
- `+CM`: `SpanBERT` with cluster merging (§3.3)

Note that `BERT` and `SpanBERT` completely rely on only local decisions without any HOI. Particularly, `+AA` is equivalent to Joshi et al. (2020).

4.1 Results

Table 1 shows the best results in comparison to previous state-of-the-art systems. We also report the mean scores and standard deviations from 5 repeated developments, which we could not find from the previous works.

The impact of SpanBERT over BERT is clear, showing 2.4% improvement on average. However, none of the HOI models shows a clear advantage over `SpanBERT` which adapts no HOI. In fact, all HOI models except for `CM` show negative impact. The best result is achieved by `CM` with the Avg-F1 of 80.2, surpassing the previous best result of 79.6 based on *c2f-coref* reported by Joshi et al. (2020).

4.2 Impact Analysis of HOI

Three HOI methods based on span refinement, `AA`, `EE`, and `SC`, show negative impact upon local decisions. We suspect that error propagation from antecedent-ranking may downgrade the quality of refinement. On the other hand, `CM` shows marginal improvement, suggesting that maintaining entity clusters can be superior to span refinement, at the

+ CM	85.9	**85.5**	**85.7**	79.0	**78.9**	**79.0**	76.7	**75.2**	**75.9**	**80.2**	**79.9** (±0.2)

Table 1: Best results on the test set of the CoNLL'12 English shared task. The averaged F1 of MUC, B^3, CEAF_{ϕ_4} is the main evaluation metric. Avg-M: the mean Avg-F1 and its standard deviation from five developments. The mean and stdev of other metrics are provided in Appendix A.2. See Figure 1 for acronyms of the previous works.

cost of more inference time from the sequential ranking process. To analyze the direct impact of HOI, we take the trained models of each HOI method and evaluate them on the test set while turning off HOI, making it compatible to SpanBERT.

The averaged performance drop with respect to Avg-F1 after turning off HOI is less than 0.2 for all methods (Appendix A.3), implying that none of the HOI method has a significantly direct impact to the final performance of the model using SpanBERT. In further investigation, we examine the change of coreferent links with respect to correctness. Specifically, Table 2 shows the four types of link changes before and after HOI. It demonstrates that the benefits from HOI is diminished because the effects are two-sided: there are roughly same amounts of links (about 1%) becoming correct or wrong after HOI, therefore neither HOI method leads to much improvement overall.

	W2C	C2W	C2C	W2W
+ AA	240.8 (1.3)	241.2 (1.3)	16262.2	2168.4
+ EE	244.1 (1.3)	245.3 (1.3)	16183.3	2136.3
+ SC	248.2 (1.3)	262.0 (1.4)	16184.4	2146.0
+ CM	226.4 (**1.2**)	235.0 (**1.2**)	16446.0	2180.0

Table 2: Averaged statistics on the test set prediction of four HOI approaches. W2C represents the number of mentions that are linked to a **W**rong antecedent before HOI and are linked to a **C**orrect antecedent after HOI; vice versa for C2W. C2C/W2W is the number of mentions that are both linked to **C**orrect/**W**rong antecedents before and after HOI. Parentheses indicate the percentage of corresponding numbers per row.

It is worth mentioning that the impact of HOI is not limited to only global decisions. HOI implicitly serves as a way of regularization that impacts local decisions as well, since HOI and local ranking are mutually dependent during training. Such indirect influence of HOI makes it difficult to assess its true impact, which we will explore more in the future.

4.3 Analysis of Pronoun Resolution

Direct Inference For the error analysis, we examine the direct inference between two personal pronouns.[3] SP/PS in Table 3 shows the numbers of links that one pronoun incorrectly selects another pronoun with different plurality as its antecedent. We find that adapting HOI shows slightly higher impact than switching to a more advanced encoder. AA can reinforce the pronoun representation to bias towards singularity and lead to lower SP error and higher PS error, while the difference between BERT and SpanBERT is trivial on SP/PS.

We also look at the general types of coreferent errors involving two pronouns. False Link (FL) falsely links a non-anaphoric pronoun to another pronoun as antecedent; Wrong Link (WL) links an anaphoric pronoun to another wrong pronoun as antecedent. Table 3 shows that EE and CM reduce FL errors by 4+%, suggesting that the aggregation of non-local features indeed leads to more conservative linking decisions. However, adapting an advanced encoder shows higher impact on WL errors, as SpanBERT reduces almost 10% compared to BERT, implying that representation learning is still more important for semantic matching.

---

[3] Ambiguous pronouns such as "you" are excluded in direct inference analysis, and included in indirect inference analysis.

Indirect Inference The plurality of ambiguous pronouns such as *you* depends on the context. Two indirect links of (*he*, *you*) and (*you*, *they*) can be common to induce incorrect clusters that contain both singular and plural pronouns (Wiseman et al., 2016; Lee et al., 2018). Table 3 shows the numbers of these erroneous clusters in prediction. Surprisingly, very few of these clusters contain ambiguous pronouns in either approach. This observation moderates the long-standing movitation of HOI.

Additionally, the change of representation from BERT to SpanBERT has far more impact that reduces 10% of these erroneous clusters, while the four HOI methods fail to show significant difference compared to `SpanBERT`.

	SP	PS	FL	WL	BC
`BERT`	2.3	6.5	213.8	186.3	48.8 (3.5)
`SpanBERT`	2.8	6.6	218.3	168.0	**43.8** (2.7)
+ `AA`	**1.8**	8.8	214.2	**159.4**	44.8 (2.4)
+ `EE`	**1.8**	**5.5**	210.0	165.3	44.0 (2.5)
+ `SC`	3.8	7.2	223.6	170.0	45.4 (3.0)
+ `CM`	3.0	6.6	**208.0**	162.2	**43.8** (2.6)

Table 3: Averaged statistics on the test set prediction of different approaches. SP is the number of coreferent links from **S**ingular to **P**lural personal pronouns; vice versa for PS. FL (False Link) and WL (Wrong Link) is the number of conreferent link errors that involve two personal pronouns. BC is the number of clusters that contain both singular and plural pronouns, and the parentheses indicate the numbers of BC that contain ambiguous pronouns such as "you".

5 Conclusion

We implement the end-to-end coreference resolution model and investigate four higher-order inference methods, including two of our own methods. Our best model shows the new result of 80.2 on the CoNLL 2012 dataset. We thoroughly analyze the empirical effectiveness of HOI and demonstrate why it fails to boost performance on the CoNLL 2012 dataset compared to the improvement from encoders. We show that current HOI does not meet up with the original motivation, suggesting that a new perspective of HOI is needed for this task in the era of deep learning-based NLP.

A Appendices

A.1 Experimental Settings

We implement the experimented models using PyTorch. $\text{BERT}_{\text{Large}}$ and $\text{SpanBERT}_{\text{Large}}$ are used as encoders. For each experiment, the best performed model on the development set is selected and evaluated on the test set.

Hyperparameters and Implementation Similar to Joshi et al. (2019, 2020), documents are split into independent segments with maximum 384 word pieces for $\text{BERT}_{\text{Large}}$ and 512 for $\text{SpanBERT}_{\text{Large}}$. In our final setting, BERT-parameters and task-parameters have separate learning rates (1×10^{-5} and 3×10^{-4} respectively), separate linear decay schedule, and separate weight decay rates (10^{-2} and 0 respectively). Models are trained 24 epochs with dropout rate 0.3.

The implementation of `EE` is based on the Tensorflow implementation from Kantor and Globerson (2019) which requires $\mathcal{O}(k^2)$ memory with k being the number of extracted spans, while other HOI approaches only requires $\mathcal{O}(k)$ memory [4]. To keep the GPU memory usage within 32GB, we limit the maximum number of span candidates for `EE` to be 300, which may have a negative impact on the performance.

Experiments are conducted on Nvidia Tesla V100 GPUs with 32GB memory. The average training time is around 7 hours for `BERT` and `SpanBERT` without HOI, and ranges from 9 - 15 hours with HOI methods.

A.2 Results

Table 4 reports the macro-average F1 scores out of 5 repeated developments of each approach. `CM` still has the best performance with 79.9 averaged F1 score. Span refinement-based HOI approaches, `AA`, `EE`, and `SC`, still have lower F1 scores than the local-only `SpanBERT`.

We do not find different configurations for `CM` make any huge impact to the performance. The final configuration for `CM` is sequential order and max reduction (Algorithm 1).

A.3 Analysis

`AA`	-0.02 (± 0.06)
`EE`	0.03 (± 0.07)
`SC`	0.11 (± 0.10)
`CM`	0.04 (± 0.04)

Table 5: Performance drop on CoNLL'12 English test set after turning off the corresponding HOI in trained models.

Table 5 shows the averaged performance drop and its standard deviations w.r.t Avg-F1 after turning off the corresponding HOI in trained models, to see the direct performance impact of HOI over local decisions.

Pronoun Resolution In our analysis, the following personal pronouns are regarded as ambiguous pronouns: "you", "your", "yours".

	MUC	B^3	CEAF_{ϕ_4}	
	F1	F1	F1	Avg. F1
`BERT`	83.7 (± 0.1)	75.5 (± 0.1)	72.6 (± 0.1)	77.3 (± 0.1)
`SpanBERT`	85.3 (± 0.1)	78.4 (± 0.1)	75.5 (± 0.3)	79.7 (± 0.1)
+ `AA`	85.2 (± 0.2)	78.1 (± 0.2)	75.0 (± 0.2)	79.4 (± 0.2)
+ `EE`	85.0 (± 0.1)	77.7 (± 0.2)	74.7 (± 0.2)	78.9 (± 0.4)
+ `SC`	85.1 (± 0.2)	77.9 (± 0.3)	74.7 (± 0.3)	79.2 (± 0.3)
+ `CM`	**85.5** (± 0.2)	**78.5** (± 0.3)	**75.6** (± 0.2)	**79.9** (± 0.2)

Table 4: Results on the test set of the CoNLL'12 English shared task data. Macro-average is reported for each F1 score from 5 repeated developments of each approach. See Section 4 for the approaches.

[4] The maximum number of antecedents for all models is set to 50 which is constant.

Pre-training Mention Representations in Coreference Models

Yuval Varkel

Amir Globerson
Tel Aviv University and Google Research

Abstract

Collecting labeled data for coreference resolution is a challenging task, requiring skilled annotators. It is thus desirable to develop coreference resolution models that can make use of unlabeled data. Here we provide such an approach for the powerful class of neural coreference models. These models rely on representations of mentions, and we show these representations can be learned in a self-supervised manner towards improving resolution accuracy. We propose two self-supervised tasks that are closely related to coreference resolution and thus improve mention representation. Applying this approach to the GAP dataset results in new state of the arts results.

1 Introduction

Coreference resolution models cluster mentions by their referring entities. Almost all such models rely on vector representations of mentions (Clark and Manning, 2016; Lee et al., 2017, 2018; Denis and Baldridge, 2008; Rahman and Ng, 2009; Durrett et al., 2013; Chang et al., 2013; Wiseman et al., 2016; Martschat and Strube, 2015). The representations for all mentions are then compared (usually sequentially) and mention pairs judged to be most similar are considered coreferent.

Thus, the mention representation is a key component in modern coreference resolution models. Indeed, it has recently been shown that improving this representation leads to improved resolution performance. For example, BERT embeddings were used in (Joshi et al., 2019b) and SpanBERT (Joshi et al., 2019a) further improved performance.

However, both BERT and SpanBERT representations are trained on self-supervised tasks that seem quite distant from coreference resolution (e.g., masked-word-prediction in BERT, and masked-whole-span-prediction in SpanBERT). This suggests the possibility that unlabeled data can be used for further improving coreference resolution if we use self-supervised tasks that are more closely related to coreference resolution.

Motivated by the above, we ask: which self-supervised tasks should be used to improve mention representation for coreference resolution.

Two recent attempts for pre-training coreference models have focused on tasks such as language modeling (Liu et al., 2019) and masked-word-prediction for name resolution (Kocijan et al., 2019). Here we propose self-supervision tasks that train the coreference model directly (rather than just the underlying BERT), resulting in improved mention representations and resolution accuracy.

We identify two signals in a text that are highly informative for coreference resolution and show how to use them for self-supervision. The first signal is that the same name can appear multiple times in a text, and these mentions very likely corefer. Thus we can train mention representations to be similar for these mentions. The second signal is pronouns. Since each pronoun is likely to refer to *some* mention, we optimize mention representations to maximize the accuracy of this prediction.

We describe a training procedure for both these losses and show that together they result in new state of the art results on the GAP coreference dataset. Importantly this is a fairly small dataset, and thus our results demonstrate the power of unsupervised pre-training of mention representations.

2 Baseline Model

The coreference resolution task corresponds to extracting the set of mentions from a text and clustering these, such that clusters correspond to all mentions of a specific entity.

As a baseline model, we use the work of Joshi et al. (2019b), which builds on top of Lee et al. (2018) and uses SpanBERT (Joshi et al., 2019a). SpanBERT has the same architecture as BERT (Devlin et al., 2018) but is trained with a different objective, where whole spans are masked and span

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8534–8540,
November 16–20, 2020.

boundary representations are optimized to predict all tokens of the masked span. This feature proves useful for coreference since, in many cases, entity mentions are spans of tokens, and span ranking models benefit from improved span representations.

The input to the coreference model is a span representation $\boldsymbol{r}_i$ for each mention i. In what follows, dependence on $\boldsymbol{r}_i$ is implied from dependence on i. A scoring function $s_m(i)$ is defined to score whether a span i is a mention. Only a portion of the top-scored mentions are kept for antecedent matching. An antecedent scoring function $s(i,j)$ is defined to score whether j is an antecedent of i. Using the pairwise function, for each span i, a distribution $P(y_i)$ over antecedents is defined:

$$P(y_i) = \frac{e^{s(i,y_i)}}{\sum_{y \in \mathcal{Y}(i)} e^{s(i,y)}} ,$$

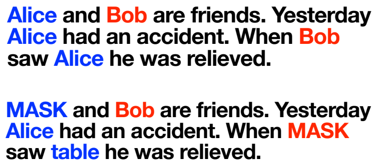
where $\mathcal{Y}(i) = \{\epsilon, 1, \ldots, i-1\}$ and ϵ is a dummy antecedent to represent the event that span i is not a mention or it has no antecedents. Note that both the $s_m(i)$ and the pairwise function $s(i,j)$ depend on span representations.

Next, span representations are "refined" using the antecedent distribution as an attention mechanism (see Lee et al., 2018) which in turn affects $P(y_i)$. Finally, to cluster mentions, the antecedent distribution is queried for the most probable antecedent for each mention. The mention clusters are induced by these links. Mentions with ϵ as most probable antecedent indicate a new cluster, but if no other mention links to them as antecedents, they are pruned. Training on labeled data is done by maximizing the probability of ground-truth antecedents.

3 Pre-training Process

Our goal is to propose an approach for pre-training mention representations on unlabeled data, such that they can be more readily used for coreference resolution. Namely, the goal is that after pre-training, we can use the mention representation to train a coreference resolution system with relatively little labeled data. Next, we propose two objectives for this pre-training process.

Most previous approaches to pre-training (Joshi et al., 2019a) use only the BERT model while pre-training on unlabeled data. Here we propose to pre-train the coreference model in Sec. 2. The motivation is that we want to directly train the mention representation and scores of this model such that it will be "ready" for training on labeled data.



Alice and Bob are friends. Yesterday
Alice had an accident. When Bob
saw Alice he was relieved.

MASK and Bob are friends. Yesterday
Alice had an accident. When MASK
saw table he was relieved.

Figure 1: An illustration of the name masking objective. On the top is the original sentence with colors corresponding to repeated names. Bottom is the same sentence with some of the mentions replaced with random tokens and [MASK]. The self-supervision task is to cluster the red and blue mentions using the coreference model.).

3.1 Pre-training via Name Masking

Texts typically contain multiple appearances of the same-named entity. For example: "Alice was late. When Bob saw Alice he was relieved". In these cases, it is almost certain that the two occurrences of Alice correspond to the same cluster. Our key observation is that this signal persists even in the sentence "Alice was late. When [MASK] saw [MASK] he was relieved". In this case, the information that the two mentions have the same name is no longer available, but sentence context is sufficient for understanding that the second [MASK] corefers with Alice. Here we further consider a more challenging setup where instead of [MASK] we use a random token.

The above intuition provides a highly effective task for training coreference models: take sentences with multiple names, mask some of the occurrences, and train a coreference model to place the masked names in the correct cluster. To implement this idea, we need to decide on the candidate mentions set. We do not want to use all mentions in the text since, for most of these, we don't have ground-truth clusters. Thus, we only consider mentions that contain proper names that appear one or more times. We set the ground truth for these mentions according to their names, and then replace some of these with [MASK] or random tokens.

To summarize, given a text, we find mention clusters based on repeated names, create ground truth clusters based on those, and replace some of the mentions with [MASK] or random tokens. Finally, we use as loss the standard coreference loss of the model in Sec. 2 when restricted only to these mentions. See Fig. 1 for an illustration.

3.2 Pre-training via Pronoun Masking

Pronouns are abundant in text, and of course highly informative about coreference structure. Next, we show that pronouns can provide a simple yet effective self-supervision signal. Consider the sentence "Bob knew Alice and thought very highly of [MASK]", and assume we know that [MASK] is a pronoun. In this case, we have enough information about Alice to correctly predict the masked pronoun is "her". In particular, we would like the mention representation of [MASK] to be sufficient for predicting the pronoun since this reflects that the representation carries information about the mention that is relevant for coreference decisions.

Formally, let S denote the set of personal pronouns. Given a sentence with pronoun $w \in S$ in the ith mention, replace the pronoun with [MASK], and obtain the representation $\boldsymbol{r}_i$. Next, predict a pronoun from $\boldsymbol{r}_i$ using a feed-forward neural network with one hidden layer, FFNN, and take the cross-entropy loss for the ground-truth pronoun w. Formally, we optimize: $\text{CE}(\text{softmax}(\text{FFNN}(\boldsymbol{r}_i)), w)$.

4 Fine-tuning

After the pre-training process in Sec. 3, we fine-tune the model on the GAP dataset. Unlike Ontonotes, GAP is partially labeled: only one pronoun and two names are labeled, even if additional entities exist in the text. Partial labeling poses a challenge for coreference models that have a learnable mention detection phase, since the ground truth excludes mentions, and during training the model learns to falsely label their spans as non-mentions. To accommodate this, we change the baseline loss to consider only gold mentions, i.e., we optimize the log-likelihood of the correct antecedent filtered only for the gold mentions. We define it as $\mathcal{L}_1(D)$ for a document D.

We found it useful to additionally train for correct mention detection in the objective. We add a mention auxiliary loss $\mathcal{L}_2(D)$ in the form of cross-entropy on the predicted mention score s_m. Finally, we optimize:

$$\mathcal{L}_1(D) + \lambda \cdot \mathcal{L}_2(D) \tag{1}$$

5 Related Work

Several works have set out to improve mention representations for coreference resolution (Lee et al., 2018; Kantor and Globerson, 2019; Joshi et al., 2019b). Lee et al. (2018) have refined the mention representation using attention over the antecedents of each mention. Kantor and Globerson (2019) showed the Entity Equalization approach to represent each mention in a cluster via an approximation of the sum of all mentions in its cluster. Employing Devlin et al. (2018) to extract mention representations boosts coreference resolution accuracy (Joshi et al., 2019b). Joshi et al. (2019a) increased it even further using masked whole-span prediction.

Several works have explored pre-training for coreference resolution. The recent work of Wu et al. (2019) uses Question Answering as part of the model and can thus train on QA datasets.

Other works explored self-supervision for this goal. Liu et al. (2019) uses a language model objective to train a memory network, which can resolve coreference links. Kocijan et al. (2019) finds pairs of sentences with at least two distinct personal names such that one of them is repeated. One non-first occurrence of the repeated candidate is masked, and the goal is to predict the masked name, given the correct and one incorrect candidates. They collect examples with no more than two sentences, limiting the background context the model can extract. Since only one name occurrence is masked and needs to be inferred, the model is not forced to resolve all person clusters.

Ye et al. (2020) use an approach similar to Kocijan et al. (2019), but include a Language Modeling objective. Emami et al. (2019) use names and pronouns gender information to generate links between a pronoun and a name. Again, the model needs to resolve a single coreference link for each example, instead of resolving multiple clusters.

Our proposed name masking is conceptually different since we do not try to predict names or single links, but rather use masking and random tokens to create hard coreference problems from the data. Our proposed pre-training procedure generates rich examples with multiple clusters and mentions. This lets us train a coreference model directly rather than just a BERT model.

6 Experiments

Dataset: The GAP dataset (Webster et al., 2018) is a corpus of Wikipedia snippets. Each snippet is annotated with one gender-balanced pronoun, two names, and two flags indicating whether the pronoun is coreferent with the first name, the second name, or neither (if both flags are false). The goal of the model is to detect mentions in the snippet and group them into coreference clusters. The model is then evaluated on the coreference links between the two names and the pronoun. We note that training on GAP alone is challenging since it contains only 2000/2000/454 snippets for development/test/validation sets.

The above evaluation scheme does not use the fact that there are only three marked mentions in each snippet. There are however previous works (Attree, 2019; Chada, 2019) that consider the *gold-two-mention* task (Webster et al., 2018), where the locations of the gold names and pronoun are used during inference as well[1]. We will compare our results in both scenarios: *detected-mentions*, where models need to detect the mentions by themselves, and *gold-two-mention*.

The metrics measured in this task are the overall F1, F1 on feminine and masculine examples, and bias defined as $\frac{\text{Feminine F1}}{\text{Masculine F1}}$. We use the official scorer.[2]

Training: Our experimental setup and code is built on top of the code in Joshi et al. (2019b) and SpanBERT (Joshi et al., 2019a). We pre-train on English Wikipedia unlabeled text[3] for 700k steps on the objectives defined in 3 using SpaCy NER[4] for person names extraction. See masking strategy and model's hyperparameters in Appendix A.

7 Results

We report masculine, feminine and overall F1 and feminine F1 to masculine F1 bias (Webster et al., 2018). All fine-tuning results are averages of 5 runs. Test set results for the *detected-mentions* scenario are shown in Table 1. Our baseline is the SpanBERTCoref based model from Joshi et al. (2019b), trained on GAP using the filtered loss in Sec. 4, which achieves 83.88 and 86.64 overall F1 for the base and large models, respectively. Pre-training the model before fine-tuning on GAP improves overall F1 by 2.02 and 1.92 for the base and large models. Ablation tests on the validation set shown in Table 3 indicate that each of the pre-training objectives has a significant contribution.

Test set results for the *gold-two-mention* task are shown in Table 2. The large pretrained SpanBERTCoref model achieves 92.86 overall F1, improving on Attree (2019) best single model by 0.36. Our results set a new state of the art for the GAP coreference resolution task for both the scenarios, *detected-mentions* and *gold-two-mention* for single models.

Fine-Tuning on Ontonotes: We explore another training setting of Joshi et al. (2019b), where training is only on Ontonotes (Pradhan et al., 2012) and not GAP. In this setting SpanBERT Base and Large yield an overall F1 of 85.76 and 87.5 on GAP, respectively. Our pre-training, followed by Ontonotes training, improves these to 86.12 and 87.66. Improvement is smaller than when training only on GAP, since Ontonotes is a much larger labeled dataset than GAP, thus reducing the effect of pre-training. We can also compare our results to the recent work of Wu et al. (2019). They also consider the setting of fine-tuning on Ontonotes, and report an F1 of 87.5 on GAP, as compared to our 87.66 in the same setting. However, the models are not completely comparable because Wu et al. (2019) pre-train on Quoref and SQUAD, whereas we pre-train on Wikipedia.

	F_1^M	F_1^F	$\frac{F_1^F}{F_1^M}$	F_1
Parallelism	69.4	64.4	0.93	66.9
+ URL	72.3	68.8	0.95	70.6
Lee et al. (2017)	67.8	66.3	0.98	67.0

+ Our Pre-training	88.06	83.72	0.95	85.9
SpanBERTCoref Large	87.48	85.78	0.98	86.64
+ Our Pre-training	90.2	86.9	0.96	**88.56**

Table 1: Results on the GAP test set for the *detected-mentions* task. An average of 5 runs is reported. Parallelism is Webster et al. (2018)'s baseline. Lee et al. (2017) result is re-trained and reported in Liu et al. (2019). SpanBERTCoref is Joshi et al. (2019b) using SpanBERT, trained on GAP with the filtered loss defined in Sec. 4. Improvements on base and large models are significant at $p < 0.001$ (t-test).

8 Conclusion

We proposed two self-supervision tasks to improve span representations of coreference resolution models. Our approach directly optimizes the mention representations used by the coreference model, allowing it to be fine-tuned on relatively little data,

A Training

A.1 Masking

For names and pronouns, we use the stochastic masking strategy of BERT: mask with 80% probability, replace with a random token with 10% probability, and keep the original tokens with 10% probability. Perturbing almost all names and pronouns mandates the coreference model to store contextual information in each mention representation. We down-sample masculine pronouns to reduce gender-bias by excluding 60% of them from the objective. Following these steps, we are able to generate 10M examples.

A.2 Simultaneous Optimization of Objectives

Masking names and pronouns in the same text would render the pronoun completion task extremely difficult and, in most cases, impossible. Instead, we defined an objective per each self-supervised task and alternate between masked names examples with the coreference resolution objective and masked pronouns examples with the pronoun completion objective. Practically, we have examples of both types in the same batch. This strategy allows for simultaneous optimization of both objectives without feeding the model a text segment with all its names and pronouns masked.

A.3 Model

The feed-forward neural network for pronoun completion is defined with the same hyperparameters of the FFNN defined in the baseline model (Joshi et al., 2019b,a): one hidden layer with 3000 units. We implemented gradient accumulation, i.e., we run a forward and backward pass for n examples sequentially, sum the gradients, and only then apply them on the model's weights. Using this process, we multiply the effective batch size by n. While the actual batch size is 1 in each forward and backward pass, using gradient accumulation, we increased the effective batch size to 16 and 18 for the base and large models, respectively. The base model, containing 160M parameters, was pre-trained using a V100 GPU for 24 days, and the large model, containing 409M parameters, was pre-trained on 6 V100 for 12 days. For fine-tuning, λ is set to 32, maximizing overall F1 on the validation set (λ's search space is $\{\frac{1}{16}, \frac{1}{8}, \frac{1}{4}, ..., 64\}$). We fine-tune the model with the original training configuration, with our objective as defined in (1). The base model is fine-tuned using a Titan X GPU for

4 hours, and large using V100 for 10 hours. For both pre-training and fine-tuning, the rest of the hyperparameters are kept from previous work.

Learning Collaborative Agents with Rule Guidance for Knowledge Graph Reasoning

Abstract

Walk-based models have shown their advantages in knowledge graph (KG) reasoning by achieving decent performance while providing interpretable decisions. However, the sparse reward signals offered by the KG during traversal are often insufficient to guide a sophisticated walk-based reinforcement learning (RL) model. An alternate approach is to use traditional symbolic methods (e.g., rule induction), which achieve good performance but can be hard to generalize due to the limitation of symbolic representation. In this paper, we propose *RuleGuider*, which leverages high-quality rules generated by symbolic-based methods to provide reward supervision for walk-based agents. Experiments on benchmark datasets show that *RuleGuider* improves the performance of walk-based models without losing interpretability. [1]

1 Introduction

While knowledge graphs (KGs) are widely adopted in natural language processing applications, a major bottleneck hindering its usage is the sparsity of facts (Min et al., 2013), leading to extensive studies on KG completion (or reasoning) (Trouillon et al., 2016; Dettmers et al., 2018; Das et al., 2017; Xiong et al., 2017; Lin et al., 2018; Meilicke et al., 2019). Many traditional approaches on the KG reasoning task are based on logic rules (Landwehr et al., 2007, 2010; Galárraga et al., 2013, 2015). These methods are referred to as *symbolic-based methods*. Although they showed good performance (Meilicke et al., 2019, 2020), they are inherently limited by their representations and generalizability of the associated relations of the given rules.

To ameliorate such limitations, *embedding-based methods* (Bordes et al., 2013; Socher et al., 2013; Wang et al., 2014; Yang et al., 2014; Trouillon et al., 2016; Dettmers et al., 2018, 2017; Sun et al., 2019; Zhang et al., 2019) were proposed. They learn distributed representations for entities and relations and make predictions using the representations. Despite their superior performance, they fail to make human-friendly interpretations.

To improve the interpretability, many recent efforts formulate the task as a multi-hop reasoning problem using reinforcement learning (RL) techniques (Xiong et al., 2017; Das et al., 2017; Shen et al., 2018; Chen et al., 2018; Lin et al., 2018), referred to as *walk-based methods*. A major issue of these methods is the reward function. A "hit or not" reward is too sparse while a shaped reward using an embedding-based distance measurement Lin et al. (2018) may not always result in desirable paths.

In this paper, we propose *RuleGuider* to tackle the aforementioned reward issue in walk-based methods with the help of symbolic rules. We aim to improve the performance of walk-based methods without losing their interpretability. The RuleGuider is composed of a symbolic-based model fetching logic rules and a walk-based agent searching reasoning paths with the guidance of the rules. We also introduce a way to separate the walk-based agent to allow for further efficiency. We experimentally show the efficiency of our model without losing the interpretability.

2 Problem and Preliminaries

In this section, we review the KG reasoning task. We also describe the symbolic-based and walk-based methods used in RuleGuider.

Problem Formulation. A KG consisting of fact triples is represented as $\mathcal{G} = \{(e_i, r, e_j)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where $\mathcal{E}$ and $\mathcal{R}$ are the set of entities and relations, respectively. Given a query $(e_s, r_q, ?)$ where e_s is a subject entity and r_q is a query re-

November 16–20, 2020.

Figure 1: Rule quality difference between datasets. There are exists high quality rules on WN18RR.

lation, the task of KG reasoning is to find a set of object entities E_o such that (e_s, r_q, e_o) , where $e_o \in E_o$, is a fact triple missing in $\mathcal{G}$. We denote the queries $(e_s, r_q, ?)$ as *tail queries*. We note that we can also perform *head queries* $(?, r_q, e_o)$. To be consistent with most existing works, we only consider tail queries in this paper.

Symbolic-based Methods. Some previous methods mine Horn rules from the KG and predict missing facts by grounding these rules. A recent method AnyBURL (Meilicke et al., 2019) showed comparable performance to the state-of-the-art embedding-based methods. It first mines rules by sampling paths from the $\mathcal{G}$, and then make predictions by matching queries to the rules. Rules are in the format: $r(X, Y) \leftarrow b_1(X, A_2) \wedge$ ... $\wedge\, b_n(A_n, Y)$, where upper-case letters represent variables. A *rule head* is denoted by $r(\cdots)$ and a *rule body* is denoted by the conjunction of atoms $b_1(\cdots), \ldots, b_n(\cdots)$. We note that $r(c_i, c_j)$ is equivalent to the fact triple (c_i, r, c_j).

However, these methods have limitations. For example, rules mined from different KGs may have different qualities, which makes the reasoner hard to select rules. Figure 1 shows such difference. Rules are sorted based on accuracy of predicting the target entities. The top rules from WN18RR are much more valuable than those from FB15K-237.

Walk-based Methods. Given a query $(e_s, r_q, ?)$, walk-based methods train an RL agent to find a path from e_s to the desired object entity e_o that implies the query relation r_q. At step t, the current state is represented by a tuple $s_t = (e_t, (e_s, r_q))$, where e_t is the current entity. The agent then samples the next relation-entity pair to visit from possible actions $A_t = \{(r', e') | (e_t, r', e') \in \mathcal{G}\}$. The agent receives a reward when it reaches e_o.

3 Proposed Method: RuleGuider

RuleGuider consists of a symbolic-based method (see Section 2), referred to as *rule miner*, and a walk-based method, referred to as *agent*. The rule miner first mines logic rules and the agent traverses over the KG to learn the probability distribution of reasoning paths with the guidance (via the reward) of the rules. As the agent walks through relations and entities alternatively, we propose to separate the agent into two sub-agents: a relation and entity agents. After the separation, the search space is significantly pruned. Figure 2 shows the structure of these two agents in detail.

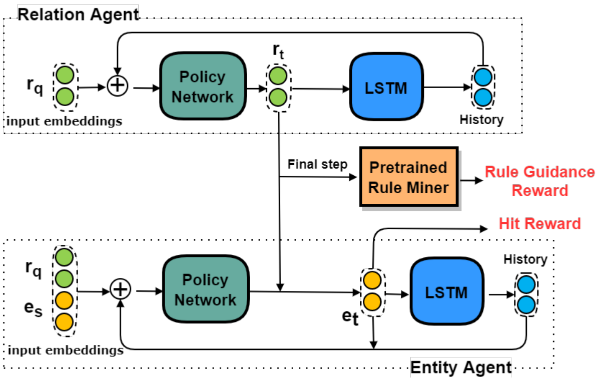

Figure 2: **The architecture of two agents**. The relation and entity agent interact with each other to generate a path. At each step, the entity agent first selects an entity from valid entities. The relation agent then samples a relation based on the selected entity. At the final step, they receive a hit reward based on the last selected entity and a rule guidance reward from the pre-mined rule set based on the selected path.

3.1 Model Architecture

Relation Agent. At step t ($t = 1, \cdots, T$, T is the number of hops), the relation agent selects a single relation r_t which is incident to the current entity e_{t-1}, where e_0=e_s. Given a query $(e_s, r_q, ?)$ and a set of rules $\mathbf{R}$, this process can be formulated as $r_t = P^R(r_q, e_{t-1}, \mathbf{R}, \boldsymbol{h}_t^R)$ where $\boldsymbol{h}_t^R$ is the relation history. The agent first filter out rules whose heads are not same as r_q, and then it selects r_t from the t^{th} atoms of the remaining rule bodies, i.e. $b_t(\cdots)$ in the rule pattern.

Since the rule miner provides confidence scores of rules, we first use RL techniques to pre-train this agent using the scores. During training, the agent applies the pre-trained strategy (distribution) and keeps tuning the distribution by utilizing semantic information provided by embeddings. In another words, the relation agent leverages both confidence scores of pre-mined rules as well as embedding shaped hit rewards.

Entity Agent. At step t, the agent generates the distribution of all candidate entities based on e_s,

r_q, and the entity history $\boldsymbol{h}_t^E$. Given the current relation r_t, this process can formally be represented as $e_t = P^E(e_s, r_q, r_t, \boldsymbol{h}_t^E)$. The agent selects an entity from all entities that incident on r_t. In this way, the entity and relation agent can reason independently.

In experiments, we have also tried to let the entity agent generate distribution based on relation agent pruned entity space. In this way, the entity agent takes in the selected relation and can leverage the information from the relation agent. However, the entity space may be extremely small and hard to learn. It makes the entity agent less effective, especially on large and dense KG.

Policy Network. The relation agent's search policy is parameterized by the embedding of $\boldsymbol{r}_q$ and $\boldsymbol{h}_t^R$. The relation history is encoded using an LSTM(Hochreiter and Schmidhuber, 1997): $\boldsymbol{h}_t^R = \text{LSTM}(\boldsymbol{h}_{t-1}^R, \boldsymbol{r}_{t-1})$, where $\boldsymbol{r}_{t-1} \in \mathbb{R}^d$ is the embedding of the last relation. We initialize $\boldsymbol{h}_0^R = \text{LSTM}(\boldsymbol{0}, \boldsymbol{r}_s)$, where $\boldsymbol{r}_s$ is a special start relation embedding to form an initial relation-entity pair with source entity embedding $\boldsymbol{e}_s$. Relation space embeddings $\boldsymbol{R}_t \in \mathbb{R}^{|R_t| \times d}$ consist embeddings of all the relations in relation space R_t at step t. Finally, relation agent outputs a probability distribution $\boldsymbol{d}_t^R$ and samples a relation from it. $\boldsymbol{d}_t^R = \sigma(\boldsymbol{R}_t \times \boldsymbol{W}_1 \text{ ReLU}(\boldsymbol{W}_2[\boldsymbol{h}_t^R; \boldsymbol{r}_q]))$ where σ is the softmax operator, $\boldsymbol{W}_1$ and $\boldsymbol{W}_2$ is trainable parameters. We design relation agent's history-dependent policy as $\boldsymbol{\pi}^R = (\boldsymbol{d}_1^R, \boldsymbol{d}_2^R, \ldots, \boldsymbol{d}_T^R)$.

Similarly, entity agent's history-dependent policy is $\boldsymbol{\pi}^E = (\boldsymbol{d}_1^E, \boldsymbol{d}_2^E, \ldots, \boldsymbol{d}_T^E)$. Entity agent can acquire its embedding of last step $\boldsymbol{e}_{t-1}$, entity space embeddings $\boldsymbol{E}_t$, its history $\boldsymbol{h}_t^E = \text{LSTM}(\boldsymbol{h}_{t-1}^E, \boldsymbol{e}_{t-1})$, and the probability distribution of entities $\boldsymbol{d}_t^E$ as follows. $\boldsymbol{d}_t^E = \sigma(\boldsymbol{E}_t \times \boldsymbol{W}_3 \text{ReLU}(\boldsymbol{W}_4[\boldsymbol{h}_t^E; \boldsymbol{r}_q; \boldsymbol{e}_s; \boldsymbol{e}_t]))$ where $\boldsymbol{W}_3$ and $\boldsymbol{W}_4$ is trainable parameters. Note that entity agent uses a different LSTM to encode the entity history.

3.2 Model Learning

We train the model by letting the two aforementioned agents to start from specific entities and traverse through the KG in a fixed number of hops. The agents receive rewards at their final step.

Reward Design. Given a query, the relation agent prefers paths which direct the way to the correct object entity. Thus, given a relation path, we give reward according to its confidence retrieved from the rule miner, referred to as *rule guidance reward* R_r. We also add a Laplace smoothing $p_c = 5$ to the confidence score for the final R_r.

In addition to R_r, the agent will also receive a *hit reward* R_h, which is 1 if the predicted triple $\epsilon = (e_s, r_q, e_T) \in \mathcal{G}$. Otherwise, we use the embedding of ϵ to measure reward as in Lin et al. (2018). $R_h = \mathbb{I}(\epsilon \in \mathcal{G}) + (1 - \mathbb{I}(\epsilon \in \mathcal{G})f(\epsilon)$ where $\mathbb{I}(\cdot)$ is an indicator function, $f(\epsilon)$ is a composition function for reward shaping using embeddings.

Training Procedure. We train the model in four stages. 1) Train relation and entity embeddings using an embedding-based method. 2) Apply a rule miner to retrieve rules and their associated confidence scores. 3) Pre-train the relation agent by freezing the entity agent and asking the relation agent to sample a path. We only use the rule miner to evaluate the path and compute R_r based on the pre-mined confidence score. 4) Jointly train the relation and entity agent to leverage the embeddings to compute R_h. The final reward R involves R_r and R_h with a constant factor λ: $R = \lambda R_r + (1-\lambda) R_h$. The policy networks of two agents are trained using the REINFORCE (Williams, 1992) algorithm to maximize R.

4 Experiments

In this section, we compare RuleGuider with other approaches on three datasets. We describe the experiment setting, results, and analysis.

4.1 Experimental Setup

Datasets. We evaluate different methods on three benchmark datasets. (1) FB15k-237 (Toutanova et al., 2015), (2) WN18RR (Dettmers et al., 2018), and (3) NELL-995 (Xiong et al., 2017).

Hyperparameters. We set all embedding size to 200. Each history encoder is a three-layer LSTM with a hidden state dimension 200. We use AnyBURL (Meilicke et al., 2019) as the rule miner and set the confidence score threshold to be 0.15. Other hyperparameters are shown in appendix.

4.2 Results

Table 1 shows the evaluation results. RuleGuider achieves the state-of-the-art results over walk-based methods on WN18RR and NELL-995, and also competitive results on FB15k-237. One possible reason is: compared to the other two datasets, the relation space in FB15k-237 is much larger and the rules is relatively sparse in the large relational

path space, which makes it harder for the relation agent to select a desired rule.

We find symbolic-based models perform strongly on WN18RR and we set λ higher to receive stronger rule guidance. We also observe that embedding-based methods have consistently good performance on all datasets compared to walk-based methods despite their simplicity. One possible reason is that embedding-based methods implicitly encode the connectivity of the whole graph into the embedding space (Lin et al., 2018). Embedding-based methods are free from the strict traversing in the graph and sometimes benefit from this property due to incompleteness of the graph. By leveraging rules, we also incorporate some global information as guidance to make up for the potential searching space loss during the discrete inference process.

Table 2 shows the percentage of rules used on the development set using ComplEx embedding in the pre-training and training phase. It shows that our model abandons a few rules to further improve hit performance during the training phase.

4.3 Ablation Study

We run different variants of RuleGuider on the development set of WN18RR. We use ComplEx hit reward shaping for consistency. Table 3 shows the results. Freezing pre-trained agent performing worse indicates that hit reward is necessary. Removing pre-training performing worse shows that the walk-based agents benefit from logic rules. The single agent variant performing worse shows the effectiveness of pruning action space.

4.4 Human Evaluation

Besides the evaluation metrics, we further analyze whether the reasoning path that leads to correctly predicted entity is reasonable. We perform human evaluation on the Amazon Mechanical Turk. We randomly sample a evaluation set with 300 triples from development set using uniform distribution on FB15k-237. During evaluation, given the ground truth triple, three judges are asked to choose which path is a better explanation/decomposition of it between: 1. path generated by our method. 2. paths generated by Multihop's method. 3. Draw or none of them are reasonable. Note that there are 2.6% of the predicted paths are the same and they are excluded from the evaluation set. For each triple, we count majority vote as the evaluation result. As it's possible that the three judges each choose a different option which leads to one vote on each choice. In this case, we do not count it in the final evaluation result (table 4). Unexpectedly, no triple get more than one vote on Tie. RuleGuider achieves a better performance and the reasoning path makes more sense to human judges comparing to Multihop with ComplEx reward shaping.

5 Conclusions

In this paper, we proposed a collaborative framework utilizing both symbolic-based and walk-based models. We separate the walk-based agent into an entity and relation agent to effectively leverage the symbolic rules and significantly reduce the action space. Experimentally, our approach improved the performance of the state-of-the-art walk-based models on two benchmark KGs.

In future work, we would like to study how to introduce acyclic rules to the walk-based systems.

A Appendix

A.1 Datasets

We use the same training, development and testing set splits as Lin et al. (2018). Following Lin et al. (2018), we restrict the output degree of an entity by selecting top η neighbors according to their PageRank score (Page et al., 1999). We remove unseen entities in test set for NELL-995. We also add reverse links from object entity e_o to subject entity e_s.

The detailed datasets statistics is shown in Table 5 and Table 6.

Dataset	#Ent	#Rel	#Fact
FB15k-237	14,505	237	272,115
WN18RR	40,945	11	86,835
NELL-995	75,492	200	154,213

Table 5: Number of relations, entities and fact triples on three datasets.

Dataset	Degree		Relation Degree		Entity Degree	
	mean	median	mean	median	mean	median
FB15k-237	37.52	22	10.32	10	29.17	18
NELL-995	4.03	1	1.79	1	3.47	1
WN18RR	4.28	3	2.55	2	3.54	2

Table 6: Output degree of each entity on three datasets. Degree is the total edges incident to each entity. Relation degree is the number of relations on each entity's output edges. Entity degree is the number of entities that each entity connects to.

A.2 Training Details

A.2.1 Hardware and Runtime

We trained our model on one NVIDIA GeForce 1080 Ti GPU. Table 7 shows the runtime detail of our model training.

	WN18RR	NELL-995	FB15k-237
number of epochs	50	1000	30
time/epoch	360s	50s	1800s
trainable parameters	26M	47M	11M

Table 7: Running time and model parameters.

A.2.2 Hyperparamters Search

We use Adam to train our model and use beam search during inference to give the ranked prediction of object entities. We run grid search on a bunch of hyperparameters to select the best configuration. The bounds for searched hyperparameters are shown in Table 8. An exception is rule guidance reward ratio λ, which are manually tuned. Table 10 shows the configurations of our best performing model.

Hyperparameter	Search Bounds
regularization weight β	[0.0, 0.1]
embedding dropout rate	[0.0, 0.3]
hidden layer dropout rate	[0.0, 0.3]
relation dropout rate	[0.0, 0.95]
entity dropout rate	[0.0, 0.95]
bandwidth	{200, 256, 400, 512}
mini-batch size	{64, 128, 256, 512}
learning rate	[0.001, 0.003]
number of hops	{2, 3}

Table 8: Searched hyperparameters using grid search. Following (Lin et al., 2018), we add an entropy regularization term in the training objective and the term is weighted by regularization weight β. Bandwidth is the entity output degree.

A.2.3 Confidence Score Threshold

We analyze the performance of our model with different confidence score thresholds of the rule miner (AnyBURL). We set the maximum threshold to be 0.15. Table 9 shows the results. The results do not present any observable pattern. One potential reason is that walk-based reasoning paths and less confident rules may have similar performance on certain queries.

Confidence	> 0.00	> 0.05	> 0.10	> 0.15
@1	42.7	42.7	42.4	**42.9**

Table 10: Hyperparameter used in our model.

A.2.4 Evaluation Metrics

During inference, the model gives a ranked list of predicted entities as the result. We use Hit@N (H@N) and Mean Reciprocal Rank (MRR) to evaluate the model performance based on the ranked list. Hit@N measures the percentage of test triples for which the correct object entity is ranked in top N in the candidate entities list. MRR measures the average reciprocal of the rank of the object entity.

A.3 Development Set Performance

The result of RuleGuilder with complex embedding hit reward shaping on development set is shown in Table 11.

Abstract

Extracting temporal relations between events and time expressions has many applications such as constructing event timelines and time-related question answering. It is a challenging problem which requires syntactic and semantic information at sentence or discourse levels, which may be captured by deep contextualized language models (LMs) such as BERT (Devlin et al., 2019). In this paper, we develop several variants of BERT-based temporal dependency parser, and show that BERT significantly improves temporal dependency parsing (Zhang and Xue, 2018a). We also present a detailed analysis on why deep contextualized neural LMs help and where they may fall short. Source code and resources are made available at `https://github.com/bnmin/tdp_ranking`.

1 Introduction

Temporal relation extraction has many applications such as constructing event timelines for news articles or narratives as well as time-related question answering. Recently, Zhang and Xue (2018b) presented Temporal Dependency Parsing (TDP), which organizes time expressions and events in a document to form a Temporal Dependency Tree (TDT). Given a previous step which detects time expressions and events, TDP extracts the temporal structure between them. Consider this example:

Example 1: *Kuchma and Yeltsin signed a cooperation plan on February 27, 1998. Russia and Ukraine share similar cultures, and Ukraine was ruled from Moscow for centuries. Yeltsin and Kuchma called for the ratification of the treaty, saying it would create a "strong legal foundation".*

Figure 1 shows the corresponding TDT. Compared to previous pairwise approaches for temporal relation extraction based on TimeML (Pustejovsky et al., 2003a) which require $\binom{n}{2}$ pairs of temporal relations to be annotated, TDT significantly reduces the annotation complexity while still preserving the essential temporal structure between events and temporal relations. TDP is still challenging because it requires syntactic and semantic information at sentence and discourse levels.

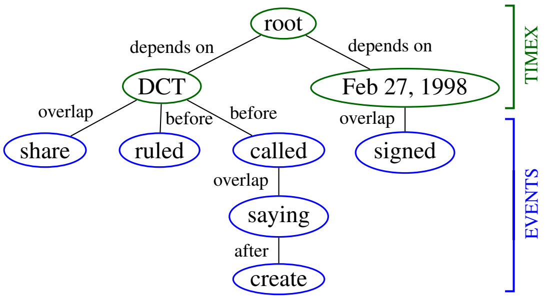

Figure 1: Temporal Dependency Tree of Example 1. DCT is Document Creation Time (March 1, 1998)

Recently, deep language models such as BERT (Devlin et al., 2019) have been shown to be successful at many NLP tasks, because (1) they provide contextualized word embeddings that are pre-trained with very large corpora, and (2) BERT in particular is shown to capture syntactic and semantic information (Tenney et al., 2019, Clark et al., 2019), which may include but is not limited to tense and temporal connectives. Such information is relevant for TDP.

In this paper, we present BERT-based TDP models, and empirical evidence demonstrating that BERT significantly improves TDP. We summarize the contributions of this paper as follows:

- We develop temporal dependency parsers that incorporate BERT, from a straightforward usage of pre-trained BERT word embeddings, to using BERT's multi-layer multi-head self-attention architecture as an encoder trained within an end-to-end system.

A previous version is available at `https://arxiv.org/abs/2004.14577`.

† Work done during an internship at BBN.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8548–8553,
November 16–20, 2020.

- We present experiments showing significant advantages of the BERT-based TDP models. Experiments show that BERT improves TDP performance in all models, with the best model achieving a 13 absolute F1 point improvement over our re-implementation of the neural model in (Zhang and Xue, 2018a)[1].
- We lay out a detailed analysis on BERT's strengths and limitations for this task.

We present technical details, experiments, and analysis in the rest of this paper.

2 Related Work

Much previous work has been devoted to classification and annotation of relations between events and time expressions, notably TimeML (Pustejovsky et al., 2003a) and TimeBank (Pustejovsky et al., 2003b), as well as many extensions of it (see Derczynski, 2017 for an overview). TimeML annotates all explicit relations in the text; at the extreme, TimeBank-Dense (Cassidy et al., 2014) annotates all $\binom{n}{2}$ pairs of relations. Pair-wise annotation has three problems: $O(n^2)$ complexity; the possibility of inconsistent predictions such as A before B, B before C, C before A; and forcing annotation of relations left unclear by the document.

While extracting time expressions and events is well handled (e.g. Strötgen and Gertz, 2010, Lee et al., 2014), relating them is still a challenging task. Previous research on extracting these relations (e.g. Bethard et al., 2017, Ning et al., 2017, Lin et al., 2019) almost always uses pair-wise TimeML-annotated data which has rich annotation but also inherits the above three complexity and consistency issues. To address these issues, Zhang and Xue (2018b) present a tree structure of relations between time expressions and events (TDT), along with a BiLSTM model (Zhang and Xue, 2018a) for parsing text into TDT and a crowd-sourced corpus (Zhang and Xue, 2019).

Organizing time expressions and events into a tree has a number of advantages over traditional pair-wise temporal annotation. It reduces the annotation complexity to $O(n)$ and avoids cyclic inconsistencies both in the annotation and the model output. Despite the apparent reduction in labeled edges, many additional edge labels can be deduced from the tree: in Figure 1, we can deduce e.g. that *ruled* is before *share* because *ruled* is before DCT but *share* overlaps DCT. A final advantage of TDTs is that they allow underspecification where the source document does not explicitly specify an order, such as the relation between *signed* and *called* (likely to be *overlap*, but it is not certain). Zhang and Xue (2019) is currently the only English-language TDP corpus, comprising 196 newswire articles.

In addition, this paper capitalizes on the now well-documented recent advances provided by BERT (Devlin et al., 2019). Besides offering richer contextual information, BERT in particular is shown to capture syntactic and semantic properties (Tenney et al., 2019, Clark et al., 2019) relevant to TDP, which we show yield improvements over Zhang and Xue's original model.

3 BERT-based Neural Models for Temporal Dependency Parsing

Following Zhang and Xue (2018a), we transformed temporal dependency parsing (TDP) to a ranking problem: given a child mention (event or time expression) x_i extracted by a previous system, the problem is to select the most appropriate parent mention from among the root node, DCT or an event or time expression from the window $x_{i-k}, \ldots, x_i, \ldots, x_{i+m}$ [2] around x_i, along with the relation label (*before*, *after*, *overlap*, *depends on*). That is, for each x_j in the window, the model judges the child-parent candidate pair $\langle x_i, x_j \rangle$. A Temporal Dependency Tree (TDT) is assembled with an incremental algorithm which selects, for each event and time expression in sequence in the document, the highest-ranked prediction ⟨parent, relation type⟩. The tree structure is enforced by selecting the highest probability parent which does not introduce a cycle[3].

We developed three models that share a similar overall architecture (Figure 2): the model takes a pair of mentions (child and potential parent) as input and passes each pair through an encoder which embeds the nodes and surrounding context into a dense representation. All models use the same window approach described above to source parent candidates. Following Zhang and Xue (2018a), linguistic features are concatenated onto the dense representation, which is then passed to a feed-forward

---

[1] We were unable to replicate the F1-score reported for this corpus in Zhang and Xue (2019). The improvement over the reported, state-of-the-art result is 8 absolute F1 points.

[2] We set $k = 10, m = 3$ in all experiments.

[3] In practice, this step to avoid cyclic edges is rare: it is required for less than 4% of the predicted edges.

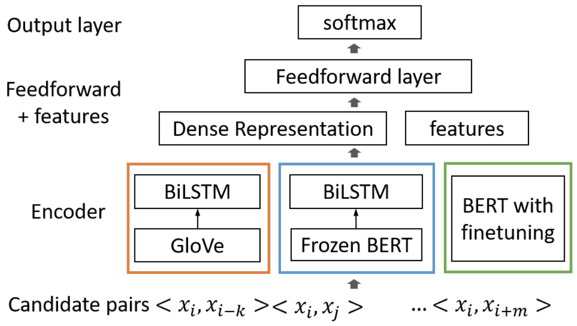

Figure 2: Model architecture for TDP with three different encoders (orange, blue, green boxes). Shown with the ⟨parent, child⟩ input pairs for a given child (event or time expression) x_i. For simplicity, we did not show $\langle x_i, root \rangle$ and $\langle x_i, DCT \rangle$, which are included as candidate pairs for all x_i.

layer and a softmax function to generate scores for each relation label for each pair.

We developed three types of encoder:

- BILSTM and BILSTM-GLOVE feed the document's word embeddings to a BiLSTM to encode the pair as well as the surrounding context. The word embeddings can be either randomly initialized (identical to Zhang and Xue, 2018a) (in BILSTM), or pre-trained from a large corpus – we used GloVe (Pennington et al., 2014) (in BILSTM-GLOVE).
- BILSTM-BERT replaces the word embeddings with frozen (pre-trained) BERT contextualized word embeddings. We used the BERT-base uncased model[4], which has been trained on English Wikipedia and the BookCorpus.
- BERT-FT: BERT's multi-layer multi-head self-attention architecture (with pre-trained weights) is used directly to encode the pairs. Its weights are fine-tuned in the end-to-end TDP training process.

All models use the same loss function and scoring as in Zhang and Xue (2018a). We present more details about the two BERT-based models below.

3.1 Model BILSTM-BERT

The first model adjusts the model architecture from Zhang and Xue (2018a) to replace its word embeddings with frozen BERT embeddings. That is, word embeddings are computed via BERT for every sentence in the document; then, these word embeddings are processed as in the original model. More details about the BiLSTM model can be found in Zhang and Xue (2018a).

3.2 Model BERT-FT

This model takes advantage of BERT's multi-layer multi-head self-attention architecture (Vaswani et al., 2017) to learn feature representations for classification. The embedding of the first token `[CLS]` is interpreted as a classification output and fine-tuned.

To represent a child-parent pair with context, BERT-FT constructs a pseudo-sentence for the (potential) parent node and a pseudo-sentence for the child node. The pair of pseudo-sentences are concatenated and separated by the `[SEP]` token, and then fed into the BERT model. Each pseudo-sentence is formed of the word(s) of the node, the node's label (TIMEX or EVENT), a separator token ':' and the sentence containing the node, as shown in Table 1.

word(s)	label	sep	sentence
February 27, 1998	TIMEX	:	*Kuchma and Yeltsin signed a cooperation plan on February 27 1998.*
called	EVENT	:	*Yeltsin and Kuchma called for the ratification . . .*

Table 1: A pair of pseudo-sentences in BERT-FT, for potential parent *February 27, 1998* and child *called* in Example 1 (The correct parent here is DCT).

4 Experiments

We use the training, development and test datasets from Zhang and Xue (2019) for all experiments (182 train / 5 development / 9 test documents, total 2084 sentences). The documents in the datasets are already annotated with events and temporal expressions. This allows us to focus on evaluating the task of constructing temporal dependency trees.

We evaluated four configurations of the encoders above. Firstly BILSTM (RE-IMPLEMENTED) re-implements Zhang and Xue (2018a)'s model[5] in TensorFlow (Abadi et al., 2016) for fair comparison. Replacing its randomly-initialized embeddings with GloVe (Pennington et al., 2014) yields BILSTM-GLOVE. We also test the models BILSTM-BERT and BERT-FT as described in Section 3.

We used Adam (Kingma and Ba, 2014) as the optimizer and performed coarse-to-fine grid search for key parameters such as learning rate and number of epochs using the dev set [6]. We observed

---

[4] `https://github.com/google-research/bert`

[5] Originally implemented in DyNet (Neubig et al., 2017).

[6] We tried all parameter configurations with learning rates in $\{0.001, 0.0001, 0.0005, 0.00025\}$ and numbers of epochs in $\{50, 75, 100\}$, and perform 5 runs for each configuration. We observed a mean F1 of 0.58 with variance=0.002 across

that when fine-tuning BERT in the BERT-FT model, a lower learning rate (0.0001) paired with more epochs (75) achieves top performance, compared to using learning rate 0.001 with 50 epochs for the BiLSTM models. We used NVIDIA Tesla P100 GPUs for training the models. On a single GPU, one epoch takes 7.5 minutes for the BERT-FT model and 0.8 minutes for the BILSTM-BERT model.

	F1 score	
Model	dev	test
Rule-based baseline (Zhang and Xue, 2019)	0.15	0.18
BiLSTM (Zhang and Xue, 2019)	0.53	0.60
BILSTM (re-impl., Zhang and Xue, 2019)	0.45	0.55
BILSTM-GLOVE	0.50	0.58
BILSTM-BERT	0.54	0.61
BERT-FT	0.59	**0.68**

Table 2: Performance of the models.

Table 2 summarizes the F1 scores[7] of our models. Results are averaged over 5 runs. We also include the rule-based baseline and the performance reported in Zhang and Xue (2019), which applies the model of Zhang and Xue (2018a) to the 2019 corpus, as a baseline[8].

BILSTM-BERT outperforms the re-implemented BILSTM model by 6 points and BILSTM-GLOVE by 3 points in F1-score, respectively. This indicates that the frozen, pre-trained BERT embeddings improve temporal relation extraction compared to either kind of non-contextualized embedding. Fine-tuning the BERT-based encoder (BERT-FT) resulted in an absolute improvement of as much as 13 absolute F1 points over the BiLSTM re-implementation, and 8 F1 points over the reported results in Zhang and Xue (2019). This demonstrates that contextualized word embeddings and the BERT architecture, pre-trained with large corpora and fine-tuned for this task, can significantly improve TDP.

We also calculated the models' accuracies on time expressions or events subdivided by their type of parent: DCT, a time expression other than DCT, or another event. Difficult categories are children of DCT and children of events. We see that the main difference between BILSTM and BILSTM-BERT is its performance on children of DCT: with BERT, it scores 0.48 instead of 0.38. Conversely BERT-FT sees improvements across the board over BILSTM, with a 0.21 increase on children of DCT, a 0.14 increase for children of other time expressions, and a 0.11 increase for children of events.

5 Analysis

Why BERT helps: A detailed manual comparison of the dependency trees produced by the different models for articles in the test set shows BERT's advantages for TDP. The following phenomena are attested by many sentences in many documents and correspond to known properties of BERT.

Firstly, unlike BILSTM, BERT-FT is able to properly relate time expressions occurring syntactically after the event, such as *Kuchma and Yeltsin signed a cooperation plan on February 27, 1998* in Example 1. (BILSTM falsely relates *signed* to the "previous" time expression DCT). This shows BERT's ability to "look forward" with its self-attention, attending to parents appearing after the child.

Secondly, BERT-FT is able to capture verb tense and use it to determine the correct relation for both DCT and chains of events. For example, it knows that present tense (*share similar cultures*) overlaps DCT, while past perfect events (*was ruled from Moscow*) happen either before DCT or before the event adjacent (salient) to them.

Thirdly, BERT-FT captures syntactic constructions with implicit temporal relations such as reported speech and gerunds (e.g. in Example 1, *Yeltsin and Kuchma called for the ratification [. . .], saying it would create* . . . , it identifies that *called* and *saying* overlap and *create* is after *saying*).

Similarly, BERT's ability to handle syntactic properties (Tenney et al., 2019, Clark et al., 2019) such as embedded clauses may allow it to detect the direction of connectives such as *since*. While all models may identify the matrix clause verb as the correct parent, BERT-FT is much more likely to choose the correct label. (BILSTM almost always chooses 'before' for DCT or 'after' for children of events, ignoring the connective.)

Lastly, both BERT-FT and BILSTM-BERT are much better than the BILSTM at identifying context changes (new "sections") and linking these events to DCT rather than to a time expression in the previous sections (evidenced by the scores on children of DCT). Because BERT's word embeddings use the sentence as context, the models using BERT may be able to "compare" the sentences and judge that they are unrelated despite being adjacent.

---

all configurations for all models.

[7] Following (Zhang and Xue, 2019), F1 scores are reported. For a document with n nodes, the TDP task constructs a tree of $n + 1$ edges, so F1 is essentially the same as the accuracy.

[8] We were unable to replicate the F1-score reported in Zhang and Xue (2019) despite using similar hyperparameters. Therefore, we include performances for our re-implementation and the reported score in Zhang and Xue (2019) in Table 2.

Equivalent TDP trees: In cases where BERT-FT is incorrect, it sometimes produces an equivalent or very similar tree (since relations such as *overlap* are transitive, there may be multiple equivalent trees). Future work could involve developing a more flexible scoring function to account for this.

Limitations: There are also limitations to BERT-FT. For example, it is still fooled by syntactic ambiguity. Consider this example:

Example 2: *Foreign ministers agreed to set up a panel to investigate who shot down the Rwandan president's plane on April 6, 1994.*

A human reading this sentence will infer based on world knowledge that *April 6, 1994* should be attached to the embedded clause (*who shot down*), not to the matrix clause (*agreed*), but a syntactic parser would produce both parses. BERT-FT incorrectly attaches *agreed* to *April 6, 1994*: even BERT's contextualized embeddings are not sufficient to identify the correct parse.

6 Conclusion and Future Work

We present two models that incorporate BERT into temporal dependency parsers, and observe significant gains compared to previous approaches. We present an analysis of where and how BERT helps with this challenging task.

For future research, we plan to explore other types of deep neural LMs such as Transformer-XL (Dai et al., 2019) and XLNet (Yang et al., 2019). As discussed in Section 5, we also plan to develop a more flexible scoring function which can handle equivalent trees. Finally, we plan to evaluate BERT-FT on other temporal relation datasets as part of a larger pipeline, which will include a mapping between TDTs and other temporal relation annotation schemas such as the TempEval-3 dataset (UzZaman et al., 2013).

Abstract

The goal of open information extraction (OIE) is to extract facts from natural language text, and to represent them as structured triples of the form ⟨*subject*, *predicate*, *object*⟩. For example, given the sentence »*Beethoven composed the Ode to Joy.*«, we are expected to extract the triple ⟨*Beethoven*, *composed*, *Ode to Joy*⟩. In this work, we systematically compare different neural network architectures and training approaches, and improve the performance of the currently best models on the OIE16 benchmark (Stanovsky and Dagan, 2016) by 0.421 F_1 score and 0.420 AUC-PR, respectively, in our experiments (i.e., by more than 200% in both cases). Furthermore, we show that appropriate problem and loss formulations often affect the performance more than the network architecture.

1 Introduction

The field of information extraction (IE) focuses on the automatic acquisition of information from text in a structured format (Jurafsky and Martin, 2009; Niklaus et al., 2018), and methods from this field are used to automatically collect desired information from large corpora of text. Traditionally, IE methods were developed for specific domains with homogeneous corpora and fixed sets of predicates and entities (Niklaus et al., 2018). Such methods are unable to generalize beyond their domains, as they are limited by their predefined collections of entities and predicates.

The area of open information extraction (OIE) was introduced as an alternative approach to IE (Banko et al., 2007), where predicates and entities are not restricted to a specific domain. More formally, the aim of an OIE algorithm is to extract all facts entailed by the input text in the format of ⟨*subject*, *predicate*, *object*⟩ triples. Alternative formulations allow for longer tuples, however, most of the work (including ours) focuses on binary predicates only. Given a sentence »*Sam succeeded in convincing John.*«, an OIE system should extract a tuple: ⟨*Sam*, *succeeded in convincing*, *John*⟩. The relation phrase »*succeeded in convincing*« indicates the semantic relationship between »*Sam*« and »*John*«. OIE plays a key role in several downstream natural language processing (NLP) applications, such as knowledge base construction from text (Soderland et al., 2010), question answering (Fader et al., 2014), information retrieval (Etzioni, 2011), text comprehension, and natural language understanding (Mausam, 2016).

In this work, we focus on the extraction of binary relations, and introduce several novel neural approaches to OIE. We construct our models from three blocks, namely, an embedding block, an encoding block, and a prediction block, and introduce several possible implementations of each of them. Furthermore, we exhaustively test all possible combinations of their use, and show that output encoding and loss function strongly influence the results. To that end, we introduce and test three different training schemes, and investigate their influence on the performance of a model.

All experiments have been conducted on the OIE16 benchmark by Stanovsky and Dagan (2016). As part of the systematic architecture search, several existing neural architectures for OIE (Stanovsky et al., 2018; Zhan and Zhao, 2019; Cui et al., 2018) have been tested and compared under equal conditions.

The main contributions of this work are:

- We introduce and compare different possible training schemes for OIE as a sequence tagging problem.
- We provide a large-scale study of existing and new OIE models, and compare them under the various introduced training schemes.
- We obtain our best results with a novel model based on transformers (Vaswani et al., 2017) and long short-term memories (LSTMs), and

improve the current state of the art on the OIE16 benchmark (Stanovsky et al., 2018) by 0.421 F_1 score and 0.420 AUC-PR, respectively, i.e., by more than 200% in both cases.

2 Related Work

TextRunner (Banko et al., 2007) stands out as the first OIE system. After TextRunner, a number of OIE systems have been developed, such as ClauseIE (Corro and Gemulla, 2013), ProPS (Stanovsky et al., 2016), and OpenIE4 (Angeli et al., 2015). These systems are mostly rule-based and use the language syntax to extract triples from sentences. For example, ClauseIE makes use of linguistic knowledge of the grammar of a sentence to detect clauses, and to identify the type of any such. OpenIE4 uses semantic role labeling to extract tuples from a sentence, and PropS relies on the proposition structure of syntax and dependency trees of the input sentence. However, rule-based systems suffer from severe error propagation when applied to examples outside of expected language patterns (Cui et al., 2018).

Recently, several approaches based on neural network (NN) architectures have been introduced (Stanovsky et al., 2018; Cui et al., 2018; Zhan and Zhao, 2019; Jia and Xiang, 2019). As one of the first neural methods, Stanovsky and Dagan (2016) treat OIE as a sequence-tagging task, and use a bidirectional long short-term memory (BiLSTM) architecture with a softmax layer to predict a BIO tag (Ratinov and Roth, 2009), as defined below, for each word in the input sentence. In contrast to this, Cui et al. (2018) consider OIE as a problem of neural machine-translation (NMT) from English into a triple, and approach it with an attention-based sequence-to-sequence model (Bahdanau et al., 2015). Jia and Xiang (2019) use the same sequence-tagging problem formulation as Stanovsky et al. (2018) and extend their work with systematic tests of various NN architectures, such as (Bi)LSTMs, convolutional neural networks (CNNs), and their combinations with conditional random fields (CRFs). Finally, they develop a hybrid model that combines BiLSTMs, CNNs, and CRFs to achieve a maximal performance.

Zhan and Zhao (2019) introduce a span model for n-ary OIE to replace the previously adopted sequence-tagging formulation. Their BiLSTM-based model finds predicate spans separately and uses a separate BiLSTM module to find arguments (entities), given a predicate as an input.

3 Task Formulation

As defined earlier, we aim to extract binary relations from single sentences. Each fact is represented as a triple ⟨*subject*, *predicate*, *object*⟩ and elements have to be non-overlapping contiguous phrases in the sentence.

Following Stanovsky et al. (2018), we treat OIE as a sequence-tagging task, where each word is labelled with a BIO tag. To that end, each element of a triple is implicitly extracted by labeling the according sequence of words with a **B**eginning-tag followed by an arbitrary number of **I**nside-tags, and words that are not part of any extracted phrase are marked with the **O**utside-tag. Tags are prefixed with A0 if they refer to a triple's subject, P for the predicate, and A1 to refer to the object of the extracted triple. We use a total of seven different labels, denoted as $\mathcal{L} = \{A0\text{-}B, A0\text{-}I, P\text{-}B, P\text{-}I, A1\text{-}B, A1\text{-}I, O\}$, and Figure 1 illustrates how they are used to extract triples from text.

More recently, Zhan and Zhao (2019) introduced an alternative formulation that is based on spans rather than sequence tags. A span is a subsequence of the sentence and an extracted triple is a set of three disjunct spans, corresponding to subject, predicate, and object. They generate all possible candidate triples and use a model to score them. To restrict the exponentially growing number of possible triples, additional restrictions are put into place, such as maximum length or syntactic requirements (cf. Zhan and Zhao (2019).

Unlike its formal counterpart, semantic parsing, the task of OIE is defined more vaguely, and hence leaves some space for interpretation. For instance, one could generally consider both ⟨*Ludwig van Beethoven*, *was*, *a world-famous composer*⟩ and ⟨*Ludwig van Beethoven*, *was*, *a world-famous composer* ***of classical music***⟩ valid extractions for the first example provided in Figure 1, but ultimately, this is a design choice that depends on the concrete application. Also, there is no fixed schema of relations to be extracted. This introduces another level of complexity, as memorization of encountered patterns for a given set of relations is insufficient for a good performance and generalization.

We highlight that single sentences frequently induce more than one triple. As an example of this, consider the lower part of Figure 1, which illustrates a sentence that consolidates two different pieces of information.

Based on the preceding deliberations, we can view

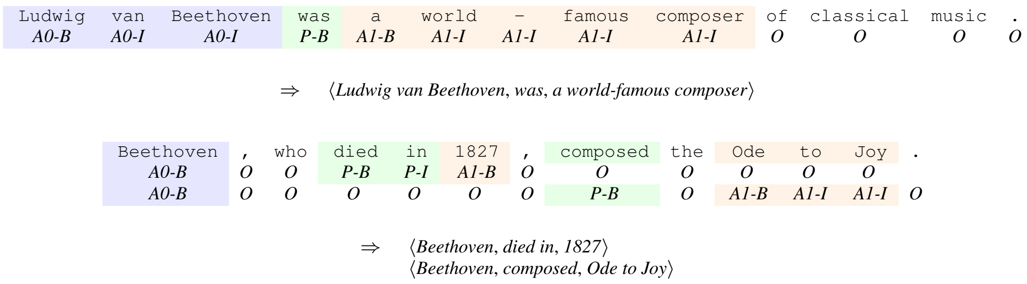

Figure 1: Two examples of the kind of data extraction that is considered in OIE.

any problem instance as a tuple $\langle X, Y \rangle$, where $X = \langle w_1, w_2, \dots, w_m \rangle$ describes a sentence as a sequence of words, and $Y = \{y_1, y_2, \dots, y_n\}$ defines a set of valid extractions. Depending on the problem definition being used, the elements in Y are either sequences of BIO tags, i.e., $y_i \in \mathcal{L}^m$ for $1 \leq i \leq n$, or triples specified in terms of spans. Independently of the employed input and output formulation, our aim in this work is to model the conditional distribution $\mathbb{P}\{y \mid X\}$.

4 Methodology

In this work, we consider several variations and extensions of existing architectures for OIE viewed both as sequence-tagging and as span-prediction task. To that end, we subdivide models conceptually into three blocks, which we call embedding, encoding, and prediction (listed from the bottom to the top), and investigate the impact of different NN modules for each of them below. The blocks serve the obvious purposes indicated by the according designations, and are described in detail in the rest of this section.

Embedding. The embedding block represents the bottom part of our models, and serves the purpose of mapping text, given as sequence of tokens, to a sequence of embedding vectors. Traditionally, embedding vectors were (pre-)trained for a fixed vocabulary of tokens, and used directly in place of any actual tokens in a processed input sequence (Pennington et al., 2014). More recently, however, different models for computing contextualized vector representations of tokens in an input sequence have been used to represent text input (Alec et al., 2018; Devlin et al., 2018; Howard and Ruder, 2018), which induced notable progress on a multitude of NLP tasks.

We consider both approaches, and use either just word-piece embeddings (Wu et al., 2016), which we refer to as simple embedding block, or ALBERT (Lan et al., 2019) for computing contextualized representations.

For the task of OIE, it is a common practice to make use of part-of-speech (PoS) tags in addition to the actual input text (Stanovsky et al., 2018; Jia and Xiang, 2019; Zhan and Zhao, 2019). We follow this, and append an embedding representing the according PoS tag to every vector produced by the used embedding block. In the case of word pieces, each sub-word token was attributed the same PoS tag as the full word it belongs to.

Encoding. The encoding block constitutes the middle part of the considered models, which processes an embedded input sequence, as provided by the module used in the embedding block, and outputs an encoded sequence of equal length. In this work, we make use of three different NN modules for encoding embedded sequences: a BiLSTM, the encoder part of a transformer, and a BiLSTM combined with a CNN, as introduced by Jia and Xiang (2019). For the simple BiLSTM encoder, we concatenate the top-layer hidden states of both directions, and use these as encodings of the respective tokens in the input sequence. The LSTM-CNN encoder processes a provided sequence in parallel with a BiLSTM and a CNN that are independent of each other. The used CNN consists of just one convolutional layer followed by max-pooling, and maps the entire embedded input sequence, viewed as matrix, to a single output vector. This vector is then concatenated with every step in the encoded sequence that is provided by the BiLSTM to yield the final output. Again, the encoding provided by the BiLSTM consists of the concatenated top-layer hidden states.

Prediction. The top block of a model takes an encoded sequence as input, and computes a probability distribution over all possible triples to extract. We consider four different model architectures as prediction blocks, three for the sequence-tagging setting, based on LSTMs, CRFs, and multi-layer perceptrons (MLPs), and the recently introduced

SpanOIE model (Zhan and Zhao, 2019), which considers OIE as a span-prediction task.

We use LSTMs for predicting label sequences left-to-right such that every step models the conditional distribution of the next label given the encoded input sequence up to the current step as well as all previously predicted labels, i.e.,

$$\mathbb{P}\left\{\langle y_1, \dots, y_m \rangle \mid \langle \mathbf{e}_1, \dots, \mathbf{e}_m \rangle\right\} = \prod_i \mathbb{P}\left\{y_i \mid \mathbf{e}_1, \dots, \mathbf{e}_i, y_1, \dots, y_{i-1}\right\}, \quad (1)$$

where $\langle \mathbf{e}_1, \dots, \mathbf{e}_m \rangle$ is an encoded sequence, as provided by the used encoding block, and $\langle y_1, \dots, y_m \rangle \in \mathcal{L}^m$ a sequence of labels.

CRFs are commonly used in combination with sequential models, such as recurrent neural networks (RNNs), since they provide a convenient way of modeling the joint distribution of entire label sequences rather than just step-wise conditional distributions. Furthermore, using CRFs on top of a recurrent model frequently results in an increased prediction accuracy (e.g., Huang et al., 2015). For our purposes, we employ a standard linear-chain CRF as prediction block.

MLPs are another family of NN modules that is frequently used for predicting labels in the context of OIE. In contrast to the previously mentioned predictors, however, they compute labels independently for each step of an input sequence, disregarding those computed for any surrounding positions. Hence, employing MLPs is based on the simplifying assumption that

$$\mathbb{P}\left\{\langle y_1, \dots, y_m \rangle \mid \langle \mathbf{e}_1, \dots, \mathbf{e}_m \rangle\right\} = \prod_i \mathbb{P}\left\{y_i \mid \mathbf{e}_i\right\}, \quad (2)$$

using the same terminology as above.

Finally, we use the SpanOIE model as the only prediction block that is based on the span-formulation of OIE. For an encoded input sequence, this model computes scores independently for each triple in a set of candidates to extract, which are then normalized to yield a probability distribution. We defer the interested reader to Zhan and Zhao (2019) for any details.

Training Loss. Since prediction blocks aim to model the probability distribution over all candidate triples to extract, the negative log-likelihood (NLL) lends itself as the natural loss function to use. If we consider OIE as a sequence-tagging task, however, then optimizing the NLL requires us to deal with one problematic aspect. Among all BIO tags, the *O*-tag, indicating tokens that are not part of subject, predicate, or object, tends to appear at a much higher frequency than other tags. This, in turn, means that the ability to correctly predict *O*-tags has the strongest direct influence on the NLL, and encourages models to focus too much on this label.

To account for this issue, we explore three novel training schemes, which disregard the probabilities of certain positions in a sequence for computing the NLL, as illustrated in Figure 2. A straightforward attempt to decrease the influence of *O*-tags on the loss term is to disregard them entirely (cf. Figure 2a). Since we model probability distributions over tag sequences as opposed to computing unnormalized scores, the law of total probability allows for a network to still learn when to predict *O*-tags, even though it is not explicitly trained to do so. Informally, this means that $\mathbb{P}\{O\} = 1 - \mathbb{P}\{B\} - \mathbb{P}\{I\}$, which is why the trained network learns to predict *O*-tags when the probabilities of all remaining tags are small.

The second training scheme is based on the observation that the critical aspect of predicting a sequence of tags is identifying transitions between a block of *O*-tags and an element of the triple, i.e., the subject, the predicate, and the object, or directly between two of the latter. Hence, this training scheme disregards all probabilities except for those of positions that appear right before or right after a transition (cf. Figure 2b). Intuitively, this makes sense, as all the disregarded tags can be determined immediately, once we know the boundaries of the subject, the predicate, and the object.

Combining the two previously outlined ideas results in our third trained scheme, which optimizes only the first and the last position of every element of the extracted triple (cf. Figure 2c). Again, remaining tags can be determined from the knowledge of these tags only.

Finally, notice that the presented schemes are used during the training of a model only. For inference and sampling, we make use of all probabilities, including those of *O*-tags.

5 Experimental Evaluation

Dataset. For our experiments, we made use of the OIE16 benchmark dataset (Stanovsky and Dagan, 2016). With a total of 5,078 training samples, the dataset is rather small, though, making it hard to train models that generalize to unseen problem instances. For this work, we thus augmented the OIE16 training data with samples from

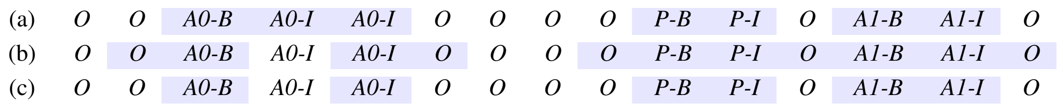

Figure 2: (a) Excluding all *O* tags when computing the loss. (b) Considering only the tags in the transitions between different tags (c) Considering only the tags in the transitions between different tags that are not *O*.

another dataset created by Cui et al. (2018). The latter is a huge dataset, consisting of more than 36M training samples that have been generated using OpenIE4 (Angeli et al., 2015), and contains examples with lower quality than the OIE16 data. Furthermore, there is usually just one target triple to extract per sentence in this dataset, while OIE models are generally expected to find all of them.

To make effective use of the low-quality dataset, we had to perform a number of preprocessing steps (described in detail in Appendix A, which left us with a total of 1.7M training samples that were combined with the training partition of the OIE16 benchmark dataset.

Experimental Evaluation. We conducted a large-scale study in which we trained and evaluated all combinations of embedding, encoding, and prediction blocks introduced above. For those models containing an ALBERT embedding block, we made use of a pretrained ALBERT model (`albert-base-v1`) provided by Wolf et al. (2019). Due to resource constraints, we had to freeze the parameters of the ALBERT blocks to speed up the training of our models. For models containing a simple embedding block, we used word-piece embeddings (Wu et al., 2016) rather than word embeddings, since these yielded better results in our experiments, and employed the embedding vectors that were pretrained with the same ALBERT model used in the ALBERT embedding blocks to initialize the model.

Notice that the architectures considered in our study also cover all the currently most important methods of OIE that are based on deep learning (DL) (Angiras, 2018; Cui et al., 2018; Stanovsky et al., 2018; Zhan and Zhao, 2019; and a slightly modified version the model by Jia and Xiang 2019, as described in Appendix C). We do not compare to any rule-based OIE systems, though, as they have been shown to consistently achieve inferior results than DL-based approaches in related work (Angiras, 2018; Cui et al., 2018; Stanovsky and Dagan, 2016).

Models that use either the LSTM or the MLP prediction block were trained and evaluated for all the training schemes presented above. Other predictors cannot be used with any of the newly introduced schemes, though, and were thus trained by minimizing the standard NLL only.

All considered models were evaluated on the test partition of the OIE16 dataset with respect to both F_1 score and the area under the precision-recall curve (AUC-PR). To that end, we computed the top-20 predictions for each of the samples in the test data, using either beam search or, in the case of the CRF predictor, the Viterbi algorithm, and considered all predictions with a probability above a certain threshold as extractions of the model evaluated. As the prediction threshold, we chose the one that achieved the maximum F_1 score on the validation partition of the OIE16 dataset separately for each model. Notice that the prediction threshold was well below 0.5 in all our experiments, usually around 0.1, and thus allowed for extracting multiple triples per sample.

To determine whether a predicted triple matches any of the target triples in the test data, we employed the evaluation scheme that is typically used in the context of OIE (He et al., 2015; Stanovsky and Dagan, 2016).[1] To that end, a predicted triple is considered correct, if each of its elements, i.e., subject, predicate, and object, contains the syntactic head of the corresponding element in the target triple. For instance, if the test set contains a triple ⟨*Donald Trump*, *is*, *president of the U.S.*⟩, then the prediction ⟨*Trump*, *is*, *president of the U.S.*⟩ is considered correct, as »*Trump*« is the syntactic head of the subject phrase »*Donald Trump*«.

Occasionally, OIE models are evaluated with predicate-head hinting (Stanovsky et al., 2018), which means that the beginning of the predicate in the target triple is marked as part of the input. More precisely, a special token is inserted into the input sequence right before the first token that is part of the predicate to extract, the so-called predicate head. This, obviously, makes the task of OIE considerably easier, and does not reflect the typical problem scenario. Nevertheless, we run all experiments a second time with predicate-head hinting, and provide the according results in Appendix B.

---

[1] This is the same evaluation scheme that is used by the well-known benchmark script by Stanovsky and Dagan (2016).

Due to the great number of experiments that have been conducted, it was not possible for us to perform grid search for every one of them separately. Instead, we chose a set of hyperparameters that we found to work well across a multitude of initial training runs, and kept them constant over all performed experiments. The exact hyperparameter values are reported in Appendix A. Furthermore, the code that was written for our experimental evaluation is available for download on GitHub. [2]

Results. Table 1 summarizes the results of our comparative study, and provides a number of interesting insights. First and foremost, we see that the model with the transformer encoding and the LSTM prediction block achieved the best F_1 score both with and without ALBERT embedding block. The prior is also the overall best model with respect to both F_1 score and AUC-PR, and outperformed all the considered state-of-the-art approaches by a significant margin of at least 0.421 F_1 score and 0.420 AUC-PR, respectively. While one might have expected to see the transformer encoding block at the top of the score board, it is surprising that the CRF predictor performed significantly worse than the LSTM and MLP prediction blocks, as CRFs have previously achieved strong results on different task of sequence prediction (e.g., Huang et al., 2015). What comes less at surprise, though, is that using an ALBERT embedding block led to an increased performance in almost all cases, which is in line with the existing research on BERT and related models. Another important insight is that the newly introduced training schemes for sequence-tagging models helped to boost performance significantly in comparison with the usual way of computing the training loss. In this context, optimizing the first and the final tokens of subject, predicate, and object only proved particularly useful (column (d) in the table), and led to the best results for almost all encoding and prediction blocks.

At this point, we want to emphasize that the results that we have achieved for models from related work differ significantly from those reported in the respective papers, which is easily explained by the difference in how models were evaluated in the same. In the context of OIE, it is common practice to pre-select candidate triples during inference, and subsequently use a model to score each of them. While this might make sense for optimizing a system in a production environment, it obfuscates a model's true ability to some extent, which is why we decided to not use any kind of pre-selection at all.

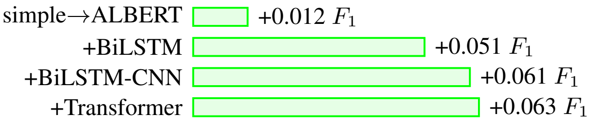

Figure 3: The average improvements caused by using an ALBERT embedding block in place of a simple one and by adding an encoding block to a model in terms of F_1 score, computed across all experiments performed.

Analysis and Ablation Studies. In this section, we further analyze the results presented above, including the ablations that have been performed as part of our comparative study already. Furthermore, we present additional ablation studies for the best-performing model.

At the bare minimum, a model consists of a simple embedding block as well as one of the prediction blocks presented above, while encoding blocks are generally optional. Hence, we first investigate the effect of moving from a simple to an ALBERT embedding block on the one hand and how adding an encoding block influences a model's performance on the other—Figure 3 summarizes our insights. First and foremost, we observed that encoding blocks, on average, cause much higher improvements than using an ALBERT embedding block in place of a simple one. More precisely, ALBERT caused just a small mean improvement of 0.012 F_1. Encoding blocks, however, pushed performance notably by 0.058 F_1, on average, and, as expected, transformers performed best among all considered encoding blocks.

Next, we compare the various prediction blocks used in our experiments. To that end, Figure 4 illustrates the mean performance of each prediction block contrasted with the mean F_1 score computed over all experiments performed. Surprisingly, the LSTM prediction block preformed, on average, by far best among all predictors considered, and outperformed all other prediction blocks for each of the training schemes considered. Another surprise is that even the MLP predictor achieved better results than the CRF prediction block for all training schemes except (a). This contrasts previous findings on the use of CRFs for sequence-tagging (Huang et al., 2015), and suggests that the training scheme, which is analyzed next, is a much bigger impact on a model's performance than certain choices about its architecture for the task of OIE. Therefore, when trained in the right way, a simple predictor, such as an MLP, can outperform

Table 1: The results of our experimental evaluation, where the different columns correspond with the different training schemes: (a) standard NLL (i.e., considering all labels), (b) disregarding O-tags, (c) optimizing transitions only, and (d) considering start and end of a triple's elements only. The best results are underlined for each of the encoding blocks, and printed boldface for each prediction block.

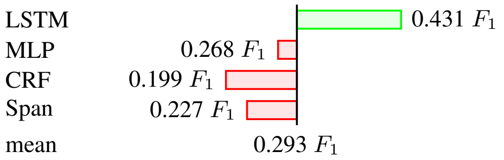

Figure 4: The average F_1 score achieved by each of the different prediction blocks in comparison with the overall mean F_1.

a more powerful one, such as a CRF, which does not allow for using the introduced training schemes. Finally, the mean performance of the SpanOIE prediction block was found to be in between those values observed for the CRF and the MLP predictor.

Finally, Figure 5 compares the mean performance achieved for each of the different training schemes with the overall mean F_1 score computed over all experiments with sequence-tagging models (as schemes (b) to (d) can be used with these models only). As illustrated in the figure, we observed significant differences among the training schemes. First and foremost, we see that training scheme (d), which optimizes the first and last positions of subjects, predicates, and objects only, clearly outperformed all other schemes. Intuitively, this makes sense, as this view reduces the problem of OIE to the absolute minimum, which is the question of where elements start and end, respectively. In contrast to this, optimizing the NLL on entire label sequences, i.e., scheme (a), led to the worst mean performance. This suggests that O-tags, which appear most frequently among all labels, are attributed too much importance in general, and steer away attention from important aspects such as the boundaries of triples' elements, which are emphasized by the other training schemes. Schemes (b) and (c) resulted in similar mean F_1 scores, close to the overall mean performance, and hence performed significantly worse than (d). Since the parts of a label sequence considered by each of these three schemes allow for reconstructing the entire sequence, one possible explanation for this is, once again, that training scheme (d) reduces the task to the absolute minimum, which might also render the according learning task as easy as possible.

We want to emphasize that the lenient evaluation scheme that is used in the context of OIE allows models to »*cheat*« in the sense that they can learn

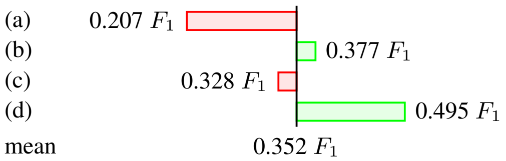

Figure 5: The average F_1 score achieved by each of the different training schemes, computed just for sequence-tagging models in comparison with the overall mean F_1 for the according experiments.

Table 2: The average number of O-tags predicted as part of subject, predicate, and object, respectively. To that end, we refer to O-tags that were prepended to a target element as prefix, and those that were appended as suffix.

to not predict O-tags at all to improve the chances that very long subjects, predicates, and objects actually cover the syntactic heads of some target triples. To show that this does not happen with our models, we computed how often the top model predicted an O-tag correctly (as O-tag) and how many it labelled as part of subjects, predicates, and objects, respectively. Table 2 summarizes our findings, and shows that the model is highly accurate on subjects and predicates, with less than one O-tag prepended and appended to any target subject or predicate on average. For objects, we find similar numbers for prepended, but slightly higher ones for appended O's. Manual inspection of the data reveals, however, that this is justified in most cases. A good example for this is the one that has been used above: if the target object »*a composer*« is predicted as »*a composer of classical music*«, then »*of classical music*« is a suffix that is represented as series of O-tags in the dataset, but which may very well be considered as part of the object. Overall, the model predicted on average 78.7% of all O-tags correctly as such for each sample in the test data, which together with the other statistics supports the conclusion that it did not learn to cheat by generating overly long elements.

For our best-performing model, we conducted additional ablation studies, looking at how its performance changes when the number of layers in the encoder (1 in the top model) and the used hidden-layer size, in both encoder and predictor, (512 in the top model) is varied, as summarized in Table 3. To that end, we noted that increasing the number of layers in the transformer encoding block resulted in lower values of both F_1 score and AUC-PR. The same was the case for both increasing and decreasing the used hidden size. Since our training data consists of a total of about 1.7M samples only, a likely explanation is that there is balance between under- and overfitting the data, which our top model seems to address well. Finally, we notice a similar pattern with respect to the different training schemes as the one discussed above.

enc. layers	**hidden size**	**score**	**training scheme**			
			(a)	**(b)**	**(c)**	**(d)**
6	128	F_1	0.360	0.402	0.306	0.426
		AUC-PR	0.200	0.201	0.196	0.213
1	128	F_1	0.347	0.428	0.301	0.431
		AUC-PR	0.212	0.303	0.223	0.209
1	**512**	F_1	0.351	0.555	0.362	**0.628**
		AUC-PR	0.242	0.515	0.278	**0.644**
1	1024	F_1	0.418	0.424	0.426	0.446
		AUC-PR	0.195	0.204	0.206	0.223

Table 3: Results achieved for different configurations of our best-performing model, which consists of an ALBERT embedding block, a transformer encoding block, and an LSTM prediction block. The best configuration is printed boldface.

Some of the existing works on neural OIE employ correction of malformed predicted label sequences (Stanovsky et al., 2018). To that end, orphan intermediate labels, i.e., ones that are preceeded neither by the according head nor by the same intermediate label, are corrected to O-tags. In our experiments, this approach did not lead to any improvements, and is thus not further elaborated on. Finally, Appendix B provides additional insights gained in our experiments with predicate-head hinting, which led to an average improvement of 0.074 F_1 score and 0.077 AUC-PR, respectively.

6 Conclusion

In this work, we systematically compared a range of different NN architectures for OIE as well as different schemes for training them. In doing so, we improved the state of the art on the OIE16 benchmark by 0.421 F_1 and 0.420 AUC-PR, respectively, (i.e., by more than 200% in both cases) with a novel model, consisting of an ALBERT embedding block, a transformer encoding block, and an LSTM prediction block, which was trained by means of a training scheme using a newly introduced loss formulation. Subsequent analysis revealed that choosing the right training scheme is as important as selecting the neural model architecture, as the standard NLL loss attributes too much importance to non-essential aspects of the data, and consistently leads to inferior results.

Appendices

A Data Preprocessing

For this work, we augmented the OIE16 training data with samples from another dataset created by Cui et al. (2018). The latter is a huge dataset, consisting of more than 36M training samples that have been generated using OpenIE4 (Angeli et al., 2015), and contains examples with lower quality than the OIE16 data. Furthermore, there is usually just one target triple to extract per sentence in this dataset, while OIE models are generally expected to find all of them.

To make effective use of the low-quality dataset, we had to perform a number of preprocessing steps. First and foremost, some samples make use of additional tags for specifying label sequences. Following Cui et al. (2018), we discarded these tags, which results in samples that are still valid and compatible with the standard set of BIO tags, as presented above. Furthermore, Angiras (2018) observed that models trained on the huge low-quality dataset tend to saturate in the first training epoch already, usually resulting in low training, but high test error. To obtain better results, we thus filtered the dataset with respect to the distribution of predicates in the target triples. We observed that just about 8K out of more than 71K predicates appear at least 50 times, and pruned all training samples with predicates below this threshold, which left us with a dataset consisting of about 28M sentences. Next, we observed highly uneven occurrence statistics of the remaining predicates, and, following Cui et al. (2018), further down-sampled the data to avoid training on a dataset with highly imbalanced target predicates. In doing so, we proceeded as follows:

- for predicates appearing less than 500 times, we sampled 50 examples,
- for those with 500 to 1K occurrences, we selected 200 examples,
- predicates with 1K to 10K occurrences were down-sampled to 500 examples,
- for predicates with 10K and 100K occurrences, we sampled 1K examples, and
- for all predicates that appear more than 100K times, we sampled 3K examples.

Sampling was performed uniformly at random, and reduced the training data to a total of 1.7M training samples, which were combined with the training partition of the OIE16 benchmark dataset. The resulting dataset can be downloaded from our GitHub repository.

B Hyperparameters

Table 4 summarizes the hyperparameters that were used in our experiments. These were determined over a number of initial experiments, and kept constant throughout all training runs conducted for this paper.

C Analysis with Predicate-head Hinting

Table 5 summarizes the results of our experiments with predicate-head hinting, and, as expected, we observed an average improvement of 0.089 F_1 and 0.078 AUC-PR, respectively. Surprisingly, however, the top model in terms of F_1 score in this setting was the one that uses an ALBERT embedding block, a BiLSTM encoding block, and an LSTM prediction block, followed by the model that performed best without predicate-head hinting, which uses a transformer encoding block instead. The latter was once again the top model in terms of AUC-PR, though. In the remainder of this appendix, we have a closer look at these results, which provide a few more interesting insights.

First and foremost, we observed that adding an

model block	number of layers
ALBERT embedder	12
BiLSTM Encoder	2
BiLSTM-CNN Encoder	1
Transformer Encoder	1
MLP Predictor	1
CRF Predictor	1
LSTM Predictor	1

hyperparameter	value
batch size	128
dropout rate	0.3
hidden size (except ALBERT)	128
hidden size (ALBERT)	768
learning rate	0.0005
maximum gradient norm	2
weight decay λ	10^{-5}
word-piece embedding size	128
PoS embedding size	100
transformer heads	6
transformer query/key/value size	50
transformer encoder hidden size	512
vocab size	30K

Table 4: The hyperparameters that were used throughout all our experiments.

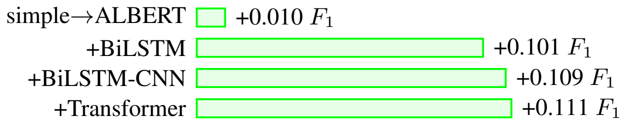

Figure 6: The average improvements caused by using an ALBERT embedding block in place of a simple one and by adding an encoding block to a model in terms of F_1 score, computed across all experiments performed **with** predicate-head hinting.

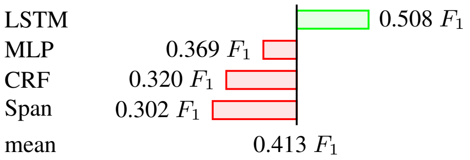

Figure 7: The average F_1 score achieved **with** predicate-head hinting by each of the different prediction blocks in comparison with the overall mean F_1.

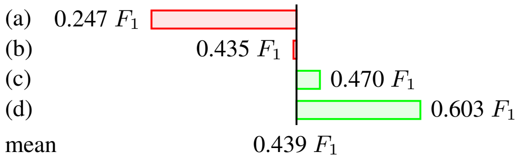

Figure 8: The average F_1 score achieved **with** predicate-head hinting by each of the different training schemes, computed just for sequence-tagging models in comparison with the overall mean F_1 for the according experiments.

embedding block to a model led, on average, to a much bigger improvement than this was the case without predicate-head hinting, as illustrated in Figure 6. More precisely, we found an average improvement of 0.107 F_1, which is about 0.047 F_1 greater than without predicate-head hinting, while the differences among the considered embedding blocks remained about the same. This suggests that all embedding blocks are able to effectively leverage provided details about the predicate head, and, in turn, create better encodings of an input sequence. Furthermore, we see that the transformer encoding block still leads to the greatest average improvement. In contrast to this, using ALBERT instead of a simple embedding block induced an equally small improvement as before.

Figure 7 provides a comparison of the different prediction blocks, and, interestingly, we see that the differences among the predictors are smaller with predicate-head hinting. One possible explanation for this is that, in this setting, the encoding block accounts for additional details of an input sequence as part of the computed encoding, which becomes possible given that the predicate head is provided as input to the model. This, in turn, reduces the impact of the employed prediction block. Furthermore, we observed that, unlike before, the CRF predictor performed, on average, slightly better than the SpanOIE prediction block, whereas LSTM and MLP predictors performed notably better, albeit with a slightly smaller gap between them as without predicate-head hinting.

Finally, Figure 8 provides a comparison of the different training schemes, and we see that the impact of the same has become bigger than this was the case without predicate-head hinting. This is somewhat surprising, but emphasizes once again that the introduced schemes are more effective than optimizing the standard NLL, and focus on relevant aspects of the considered problem, while paying less attention to incidental details.

D Adjustments of the Model by Jia and Xiang (2019)

As indicated in the main text already, our BiLSTM-CNN encoding block is a slightly modified version of the hybrid BiLSTM-CNN network introduced by Jia and Xiang (2019). In the original work, the word embeddings were passed through a BiLSTM network to give $[L_f, L_b]$, where L_f is a collection of hidden states from the forward part of the BiLSTM, and L_b are the hidden states from the according backward part. In addition to this, the word representations were also passed through a

Table 5: The results of our evaluation **with** predicate-head hinting, where the different columns correspond with the different training schemes: (a) standard NLL (i.e., considering all labels), (b) disregarding O-tags, (c) optimizing transitions only, and (d) considering start and end of a triple's elements only. The best results are underlined for each of the encoding blocks, and printed boldface for each prediction block.

CNN to compute a representation vector C. Then, all vectors in L_f and L_b as well as C were concatenated into a single vector, and fed into a dense layer with a softmax activation to compute predictions. In this work, however, we concatenate the CNN output with every pair of forward and backward hidden-states from the BiLSTM separately, resulting in a sequence of hidden representations that is of equal length as processed input sequence. These hidden representations are then fed into the subsequent prediction block.

SeqMix: Augmenting Active Sequence Labeling via Sequence Mixup

Abstract

Active learning is an important technique for low-resource sequence labeling tasks. However, current active sequence labeling methods use the queried samples alone in each iteration, which is an inefficient way of leveraging human annotations. We propose a simple but effective data augmentation method to improve label efficiency of active sequence labeling. Our method, SeqMix, simply augments the queried samples by generating extra labeled sequences in each iteration. The key difficulty is to generate plausible sequences along with token-level labels. In SeqMix, we address this challenge by performing mixup for both sequences and token-level labels of the queried samples. Furthermore, we design a discriminator during sequence mixup, which judges whether the generated sequences are plausible or not. Our experiments on Named Entity Recognition and Event Detection tasks show that SeqMix can improve the standard active sequence labeling method by 2.27%–3.75% in terms of F_1 scores. The code and data for SeqMix can be found at `https://github.com/rz-zhang/SeqMix`.

1 Introduction

Many NLP tasks can be formulated as sequence labeling problems, such as part-of-speech (POS) tagging (Zheng et al., 2013), named entity recognition (NER) (Lample et al., 2016), and event extraction (Yang et al., 2019). Recently, neural sequential models (Lample et al., 2016; Akbik et al., 2018; Vaswani et al., 2017) have shown strong performance for various sequence labeling task. However, these deep neural models are *label hungry*—they require large amounts of annotated sequences to achieve strong performance. Obtaining large amounts of annotated data can be too expensive for practical sequence labeling tasks, due to token-level annotation efforts.

Active learning is an important technique for sequence labeling in low-resource settings. Active sequence labeling is an iterative process. In each iteration, a fixed number of unlabeled sequences are selected by a query policy for annotation and then model updating, in hope of maximally improving model performance. For example, Tomanek et al. (2007); Shen et al. (2017) select query samples based on data uncertainties; Hazra et al. (2019) compute model-aware similarity to eliminate redundant examples and improve the diversity of query samples; and Fang et al. (2017); Liu et al. (2018) use reinforcement learning to learn query policies. However, existing methods for active sequence labeling all use the queried samples *alone* in each iteration. We argue that the queried samples provide limited data diversity, and using them alone for model updating is inefficient in terms of leveraging human annotation efforts.

We study the problem of enhancing active sequence labeling via data augmentation. We aim to generate augmented labeled sequences for the queried samples in each iteration, thereby introducing more data diversity and improve model generalization. However, data augmentation for active sequence labeling is challenging, because we need to generate sentences and token-level labels jointly. Prevailing generative models (Zhang et al., 2016; Bowman et al., 2016) are inapplicable because they can only generate word sequences without labels. It is also infeasible to apply heuristic data augmentation methods such as context-based words substitution (Kobayashi, 2018), synonym replacement, random insertion, swap, and deletion (Wei and Zou, 2019), paraphrasing (Cho et al., 2019) or back translation (Xie et al., 2019), because label composition is complex for sequence labeling. Directly using these techniques to manipulate tokens may inject incorrectly labeled sequences into training data and harm model performance.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8566–8579,
November 16–20, 2020.

We propose SeqMix, a data augmentation method for generating sub-sequences along with their labels based on *mixup* (Zhang et al., 2018). Under the active sequence labeling framework, SeqMix is capable of generating plausible pseudo labeled sequences for the queried samples in each iteration. This is enabled by two key techniques in SeqMix: (1) First, in each iteration, it searches for pairs of eligible sequences and mixes them both in the feature space and the label space. (2) Second, it has a discriminator to judge if the generated sequence is plausible or not. The discriminator is designed to compute the perplexity scores for all the generated candidate sequences and select the low-perplexity sequences as plausible ones.

We show that SeqMix consistently outperforms standard active sequence labeling baselines under different data usage percentiles with experiments on Named Entity Recognition and Event Detection tasks. On average, it achieves $2.95\%, 2.27\%, 3.75\%$ F_1 improvements on the CoNLL-2003, ACE05 and WebPage datasets. The advantage of SeqMix is especially prominent in low-resource scenarios, achieving $12.06\%, 8.86\%, 16.49\%$ F_1 improvements to the original active learning approach on the above three datasets. Our results also verify the proposed mixup strategies and the discriminator are vital to the performance of SeqMix.

2 Preliminaries

2.1 Problem Definition

Many NLP problems can be formulated as sequence labeling problems. Given an input sequence, the task is to annotate it with token-level labels. The labels often consist of a position prefix provided by a labeling schema and a type indicator provided by the specific task. For example, in the named entity recognition task, we can adopt the `BIO` (Beginning, Inside, Outside) tagging scheme (Màrquez et al., 2005) to assign labels for each token: the first token of an entity mention with type `X` is labeled as `B-X`, the tokens inside that mention are labeled as `I-X` and the non-entity tokens are labeled as `O`.

Consider a large unlabeled corpus $\mathcal{U}$, traditional active learning starts from a small annotated seed set $\mathcal{L}$, and utilizes a query function $\psi(\mathcal{U}, K, \gamma(\cdot))$ to obtain K most informative unlabeled samples $\mathcal{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_K\}$ along with their labels $\mathcal{Y} = \{y_1, \cdots, y_K\}$, where $\gamma(\cdot)$ is the query policy. Then, we remove $\mathcal{X}$ from the unlabeled data $\mathcal{U}$ and repeat the above procedure until the satisfactory performance achieved or the annotation capacity reached.

In SeqMix, we aim to further exploit the annotated set $\langle\mathcal{X}, \mathcal{Y}\rangle$ to generate augmented data $\langle\mathcal{X}^*, \mathcal{Y}^*\rangle$. Then the labeled dataset is expanded as $\mathcal{L} = \mathcal{L} \cup \langle\mathcal{X}, \mathcal{Y}\rangle \cup \langle\mathcal{X}^*, \mathcal{Y}^*\rangle$. Formally, we define our task as: (1) construct a generator $\phi(\cdot)$ to implement sequence and label generation based on the actively sampled data $\mathcal{X}$ and its label $\mathcal{Y}$, (2) set a discriminator $d(\cdot)$ to yield the filtered generation, then (3) augment the labeled set as $\mathcal{L} = \mathcal{L} \cup \langle\mathcal{X}, \mathcal{Y}\rangle \cup d(\phi(\mathcal{X}, \mathcal{Y}))$.

2.2 Active Learning for Sequence Labeling

Active sequence labeling selects K most informative instances $\psi(\cdot, K, \gamma(\cdot))$ in each iteration, with the hope of maximally improving model performance with a fixed labeled budget. With the input sequence $\mathbf{x}$ of length T, we denote the model output as $f(\cdot|\mathbf{x};\theta)$. Our method is generic to any query policies $\gamma(\cdot)$. Below, we introduce several representative policies.

Least Confidence (LC) Culotta and McCallum (2005) measure the uncertainty of sequence models by the most likely predicted sequence. For a CRF model (Lafferty et al., 2001), we calculate γ with the predicted sequential label $\mathbf{y}^*$ as

$$\gamma^{\mathrm{LC}}(\mathbf{x}) = 1 - \max_{y^*}(P(\mathbf{y}^*|\mathbf{x};\theta), \qquad (1)$$

where $\mathbf{y}^*$ is the Viterbi parse. For BERT (Devlin et al., 2019) with a token classification head, we adopt a variant of the least confidence measure:

$$\gamma^{\mathrm{LC'}}(\mathbf{x}) = \sum_{t=1}^{T}(1 - \max_{\mathbf{y}_t} P(\mathbf{y}_t|\mathbf{x};\theta)), \qquad (2)$$

where $P(\mathbf{y}_t|\mathbf{x};\theta) = \mathrm{softmax}(f(\mathbf{y}_t|\mathbf{x};\theta))$.

Normalized Token Entropy (NTE) Another uncertainty measure for the query policy is normalized entropy (Settles and Craven, 2008), defined as:

$$\gamma^{\mathrm{TE}}(\mathbf{x}) = -\frac{1}{T}\sum_{t=1}^{T}\sum_{m=1}^{M} P_m(\mathbf{y}_t|\mathbf{x},\theta)\log P_m(\mathbf{y}_t|\mathbf{x},\theta), \qquad (3)$$

where $P_m(\mathbf{y}_t|\mathbf{x},\theta) = [\mathrm{softmax}(f(\mathbf{y}_t|\mathbf{x};\theta))]_m$.

Disagreement Sampling Query-by-committee (QBC) (Seung et al., 1992), is another approach for specifying the policy, where the unlabeled data can be sampled by the disagreement of the base models. The disagreement can be defined in several ways, here we take the vote entropy proposed by (Dagan and Engelson, 1995). Given a committee consist of C models, the vote entropy for input $\mathbf{x}$ is:

$$\gamma^{\mathrm{VE}}(\mathbf{x}) = -\frac{1}{T}\sum_{t=1}^{T}\sum_{m=1}^{M}\frac{V_m(\mathbf{y}_t)}{C}\log\frac{V_m(\mathbf{y}_t)}{C}, \tag{4}$$

where $V_m(\mathbf{y}_t)$ is the number of models that predict the t-th token $\mathbf{x}_t$ as the label m.

3 The SeqMix Method

3.1 Overview

Given a corpus for sequence labeling, we assume the dataset contains a small labeled set $\mathcal{L}$ and a large unlabeled set $\mathcal{U}$ initially. We start from augmenting the seed set $\mathcal{L}$ with SeqMix. First, we adopt a pairing function $\zeta(\cdot)$ to find paired samples by traversing $\mathcal{L}$. Next, we generate mixed-labeled sequences via latent space linear interpolation with one of the approaches mentioned in Section 3.2. To ensure the semantic quality of the generated sequences, we use a discriminator $d(\cdot)$ to measure the perplexity of them and filter low-quality sequences out. Then we generate the extra labeled sequences $\mathcal{L}^* = \mathit{SeqMix}(\mathcal{L}, \alpha, \zeta(\cdot), d(\cdot))$ and get the augmented training set $\mathcal{L} = \mathcal{L} \cup \mathcal{L}^*$. The sequence labeling model θ is initialized on this augmented training set $\mathcal{L}$.

After that, the iterative active learning procedure begins. In each iteration, we actively select instances from $\mathcal{U}$ with a query policy $\gamma(\cdot)$ (Section 2.2) to obtain the top K samples $\mathcal{X} = \psi(\mathcal{U}, K, \gamma(\cdot))$. The newly selected samples will be labeled with $\mathcal{Y}$, and the batch of samples $\langle\mathcal{X}, \mathcal{Y}\rangle$ will be used for SeqMix. Again, we generate $\mathcal{L}^* = \mathit{SeqMix}(\langle\mathcal{X}, \mathcal{Y}\rangle, \alpha, \zeta(\cdot), d(\cdot))$ and expand the training set as $\mathcal{L} = \mathcal{L} \cup \mathcal{L}^*$. Then we train the model θ on the newly augmented set $\mathcal{L}$. The iterative active learning procedure terminates when a fixed number of iterations are reached. We summarize the above procedure in Algorithm 1.

Algorithm 1 The procedure of active sequence labeling augmentation via SeqMix

Input: Labeled seed set $\mathcal{L}$; Unlabeled set $\mathcal{U}$; Query function $\psi(\cdot, K, \gamma(\cdot))$; The sequence labeling model θ; Beta distribution parameter α; Pairing function $\zeta(\cdot)$; Discriminator function $d(\cdot)$.

```
// seed set augmentation
        $\mathcal{L}^* = \mathit{SeqMix}(\mathcal{L}, \alpha, \zeta(\cdot), d(\cdot))$
        $\mathcal{L} = \mathcal{L} \cup \mathcal{L}^*$
// model initialization
        $\theta$ = train $(\theta, \mathcal{L})$
// active learning iterations with augmentation
for round in active learning rounds do
    $\mathcal{X} = \psi(\mathcal{U}, K, \gamma(\cdot))$
    $\mathcal{U} = \mathcal{U} - \mathcal{X}$
    Annotate $\mathcal{X}$ to get $\langle\mathcal{X}, \mathcal{Y}\rangle$
    $\mathcal{L}^* = \mathit{SeqMix}(\langle\mathcal{X}, \mathcal{Y}\rangle, \alpha, \zeta(\cdot), d(\cdot))$
    $\mathcal{L} = \mathcal{L} \cup \langle\mathcal{X}, \mathcal{Y}\rangle \cup \mathcal{L}^*$
    $\theta$ = train $(\theta, \mathcal{L})$
end
```

Output: The sequence model trained with active data augmentation: θ

3.2 Sequence Mixup in the Embedding Space

Mixup (Zhang et al., 2018) is a data augmentation method that implements linear interpolation in the input space. Given two input samples x_i, x_j along with the labels y_i, y_j, the mixing process is:

$$\tilde{x} = \lambda x_i + (1-\lambda)x_j, \tag{5}$$

$$\tilde{y} = \lambda y_i + (1-\lambda)y_j, \tag{6}$$

where $\lambda \sim \mathit{Beta}(\alpha, \alpha)$ is the mixing coefficient. Through linear combinations on the input level of paired examples and their labels, Mixup regularizes the model to present linear behavior among the training data.

Mixup is not directly applicable to generate interpolated samples for text data, because the input space is discrete. To overcome this, SeqMix performs token-level interpolation in the embedding space and selects a token closest to the interpolated embedding. Specifically, SeqMix constructs a table of tokens $\mathcal{W}$ and their corresponding contextual embeddings $\mathcal{E}$[1]. Given two sequences $\mathbf{x_i} = \{\mathbf{w}_i^1, \cdots, \mathbf{w}_i^T\}$ and $\mathbf{x_j} = \{\mathbf{w}_j^1, \cdots, \mathbf{w}_j^T\}$ with their embedding representations $\mathbf{e}_{\mathbf{x_i}} = \{\mathbf{e}_i^1, \cdots, \mathbf{e}_i^T\}$ and $\mathbf{e}_{\mathbf{x_j}} = \{\mathbf{e}_j^1, \cdots, \mathbf{e}_j^T\}$, the t-th mixed token is the token whose embedding $\mathbf{e}^t$ is closest to the mixed embedding:

$$\mathbf{e}^t = \operatorname*{arg\,min}_{\mathbf{e}\in\mathcal{E}} \left\| \mathbf{e} - (\lambda \mathbf{e}_\mathbf{i}^\mathbf{t} + (1-\lambda)\mathbf{e}_\mathbf{j}^\mathbf{t}) \right\|_2 . \tag{7}$$

---

[1] The construction of $\{\mathcal{W}, \mathcal{E}\}$ are discussed in Appendix.

To get the corresponding $\mathbf{w}^t$, we can query the table $\{\mathcal{W}, \mathcal{E}\}$ using $\mathbf{e}^t$. The label generation is straightforward. For two label sequences $\mathbf{y}_i = \{\mathbf{y}_i^1, \cdots, \mathbf{y}_i^T\}$ and $\mathbf{y}_j = \{\mathbf{y}_j^1, \cdots, \mathbf{y}_j^T\}$, we get the t-th mixed label as:

$$\mathbf{y}^t = \lambda \mathbf{y}_i^t + (1-\lambda)\mathbf{y}_j^t, \tag{8}$$

where $\mathbf{y}_i^t$ and $\mathbf{y}_j^t$ are one-hot encoded labels.

Along with the above sequence mixup procedure, we also introduce a pairing strategy that selects sequences for mixup. The reason is that, in many sequence labeling tasks, the labels of interest are scarce. For example, in the NER and event detection tasks, the "O" label is dominant in the corpus, which do not refer to any entities or events of interest. We thus define the labels of interest as *valid labels*, *e.g.*, the non-"O" labels in NER and event detection, and design a sequence pairing function to select more informative parent sequences for mixup. Specifically, the sequence pairing function $\zeta(\cdot)$ is designed according to *valid label density*. For a sequence, its valid label density is defined as $\eta = \frac{n}{s}$, where n is the number of valid labels and s is the length of the sub-sequence. We set a threshold η_0 for $\zeta(\cdot)$, and the sequence will be considered as an eligible candidate for mixup only when $\eta \geq \eta_0$.

Based on the above token-level mixup procedure and the sequence pairing function, we propose three different strategies for generating interpolated labeled sequences. These strategies are shown in Figure 1 and described below:

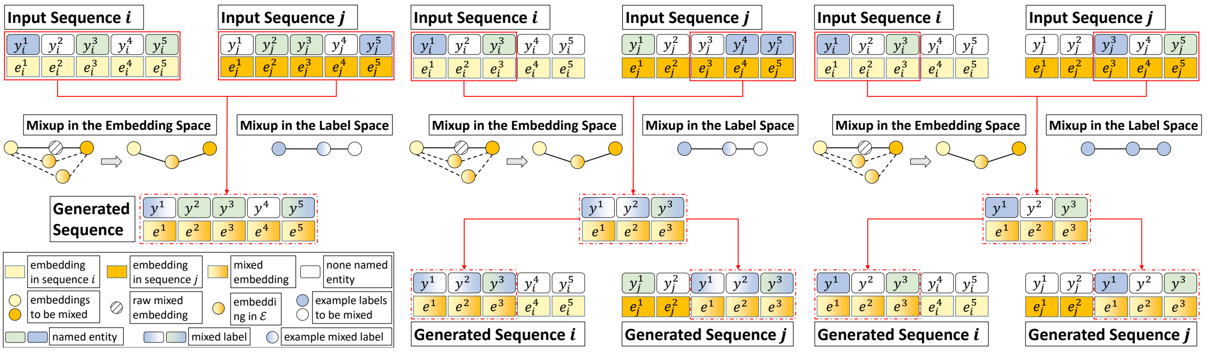
Whole-sequence mixup As the name suggests, whole-sequence mixup (Figure 1(a)) performs sequence mixing at the whole-sequence level. Given two sequences $\langle \mathbf{x_i}, \mathbf{y_i} \rangle, \langle \mathbf{x_j}, \mathbf{y_j} \rangle \in \mathcal{L}$, they must share the same length without counting padding words. Besides, the paring function $\zeta(\cdot)$ requires that both the two sequences satisfy $\eta \geq \eta_0$. Then we perform mixup at all token positions, by employing Equation 7 to generate mixed tokens and Equation 8 to generate mixed labels (note that the mixed labels are soft labels).

Algorithm 2 The generation procedure of SeqMix

```
Input: Labeled set $\mathcal{L} = \langle \mathcal{X}, \mathcal{Y} \rangle$; Beta distribution parameter $\alpha$; Pairing function $\zeta(\cdot)$; Discriminator function $d(\cdot)$; Number of expected generation $N$.
for $\langle \mathbf{x_i}, \mathbf{y_i} \rangle, \langle \mathbf{x_j}, \mathbf{y_j} \rangle, (i \neq j)$ in $\mathcal{L}$ do
    if $\zeta(\langle \mathbf{x_i}, \mathbf{y_i} \rangle, \langle \mathbf{x_j}, \mathbf{y_j} \rangle)$ then
        $\lambda \sim Beta(\alpha, \alpha)$
        // mixup the target sub-sequences
        for $t = 1, \cdots, T$ do
            Calculate $\mathbf{e}^t$ by Eq. (7);
            Get corresponding token $\mathbf{w}^t$ for $\mathbf{e}^t$;
            Calculate $\mathbf{y}^t$ by Eq. (8).
        end
        $\tilde{\mathbf{x}}_{sub} = \{\mathbf{w}^1, \cdots, \mathbf{w}^T\}$
        $\tilde{\mathbf{y}}_{sub} = \{\mathbf{y}^1, \cdots, \mathbf{y}^T\}$
        // replace the original sequences
        for $k$ in $\{i, j\}$ do
            $\tilde{\mathbf{x}}_k = \mathbf{x}_k - \mathbf{x}_{\mathbf{k}sub} + \tilde{\mathbf{x}}_{sub}$
            $\tilde{\mathbf{y}}_k = \mathbf{y}_k - \mathbf{y}_{\mathbf{k}sub} + \tilde{\mathbf{y}}_{sub}$
            if $d(\tilde{\mathbf{x_k}})$ then
                $\mathcal{L}^* = \mathcal{L}^* \cup \langle \tilde{\mathbf{x}}_k, \tilde{\mathbf{y}}_k \rangle$
            end
            if $|\mathcal{L}^*| \geq N$ then
                break
            end
        end
    end
end
Output: Generated sequences and labels $\mathcal{L}^*$
```

Sub-sequence mixup One drawback of the whole-sequence mixup is that it indiscriminately mixes over all tokens, which may include incompatible subsequences and generate implausible sequences. To tackle this, we consider sub-sequence mixup (Figure 1(b)) to mix sub-sequences of the parent sequences. It scans the original samples with a window of fixed-length s to look for paired sub-sequences. Denote the sub-sequences of $\langle \mathbf{x_i}, \mathbf{y_i} \rangle, \langle \mathbf{x_j}, \mathbf{y_j} \rangle$ as $\mathbf{X}_{\mathbf{i}sub} = \{\mathbf{x}^1_{\mathbf{i}sub}, \ldots, \mathbf{x}^s_{\mathbf{i}sub}\}$, $\mathbf{X}_{\mathbf{j}sub} = \left\{\mathbf{x}^1_{\mathbf{j}sub}, \ldots, \mathbf{x}^s_{\mathbf{j}sub}\right\}$. If $\exists\ \mathbf{x}_{\mathbf{i}sub} \in \mathbf{X}_{\mathbf{i}sub}$, $\mathbf{x}_{\mathbf{j}sub} \in \mathbf{X}_{\mathbf{j}sub}$, such that their $\eta \geq \eta_0$, we have $\zeta(\langle \mathbf{x_i}, \mathbf{y_i} \rangle, \langle \mathbf{x_j}, \mathbf{y_j} \rangle) =$ True. Then the sub-sequences $\mathbf{x}_{\mathbf{i}sub}$ and $\mathbf{x}_{\mathbf{j}sub}$ are mixed as Figure 1(b). The mixed sub-sequence and labels will replace the original parts of the parent samples, and the other parts of the parent samples remain unchanged. In this way, sub-sequence mixup is expected to keep the syntax structure of the original sequence, while providing data diversity.

Label-constrained sub-sequence mixup can be considered as a special case of sub-sequence mixup, where the constraints inherit sub-sequence mixup, and further require that the sub-sequence labels are consistent. As Figure 1(c) shows, after mixing such paired samples, the generation will just update the tokens of the sub-sequences while keeping the labels the same as before. Hence, this



(a) Whole sequence mixup (b) Sub-sequence mixup (c) Label-constrained sub-sequence mixup

Figure 1: Illustration of the three variants of SeqMix. We use $s = 5, \eta_0 = \frac{3}{5}$ for whole-sequence mixup and $s = 3, \eta_0 = \frac{2}{3}$ for sub-sequence mixup and label-constrained sub-sequence mixup. The solid red frames indicate paired sequences or sub-sequences, and the red dotted frames indicate generated sequence or sub-sequence. In the original sequences, the parts not included in the solid red frames will be unchanged in the generated sequences. For the mixup in the embedding space, we take the embedding in $\mathcal{E}$ which is closest to the raw mixed embedding as the generated embedding. For the mixup in the label space, the mixed label can be used as the pseudo label.

version is called label-constrained sub-sequence mixup.

Comparing the three variants, label-constrained sub-sequence mixup gives the most restrictions to pairing parent samples, sub-sequence mixup sets the sub-sequence-level pattern, while whole-sequence mixup just requires $\eta \geq \eta_0$ for the sequences with the same length.

3.3 Scoring and Selecting Plausible Sequences

During sequence mixup, the mixing coefficient λ determines the strength of interpolation. When λ approximates 0 or 1, the generated sequence will be similar to one of the parent sequences, while the λ around 0.5 produces relatively diverse generation. However, generating diverse sequences means low-quality sequences can be generated, which can provide noisy contextual information and hurt model performance.

To maintain the quality of mixed sequences, we set a discriminator to score the perplexity of the sequences. The final generated sequences will consist of only the sequences that pass the sequence quality screening. For the screening, we utilize a language model GPT-2 (Radford et al., 2019) to score sequence $\mathbf{x}$ by computing its perplexity:

$$\text{Perplexity}(\mathbf{x}) = 2^{-\frac{1}{T}\sum_{i=1}^{T}\log p(w_i)}, \tag{9}$$

where T is the number of tokens before padding, w_i is the i-th token of sequence $\mathbf{x}$. Based on the perplexity and a score range $[s_1, s_2]$, the discriminator can give judgment for sequence $\mathbf{x}$:

$$d(\mathbf{x}) = \mathbb{1}\left\{s_1 \leq \text{Perplexity}\left(\mathbf{x}\right) \leq s_2\right\}. \tag{10}$$

The lower the perplexity score, the more natural the sequence. However, the discriminator should also consider the regularization effectiveness and the generation capacity. Hence, a blind low perplexity setting is undesirable. The overall sequence mixup and selection procedure is illustrated in Algorithm 2.

4 Experiments

4.1 Experiment Setup

Datasets. We conduct experiments on three sequence labeling datasets for the named entity recognition (NER) and event detection tasks.

(1) **CoNLL-03** (Tjong Kim Sang and De Meulder, 2003) is a corpus for NER task. It provides four named entity types: persons, locations, organizations, and miscellaneous.[2]

(2) **ACE05** is a corpus for event detection. It provides 8 event types and 33 subtypes. We study the event trigger detection problem, which aims to identify trigger tokens in a sentence.

(3) **Webpage** (Ratinov and Roth, 2009) is a NER corpus with 20 webpages related to computer science conference and academic websites. It inherits the entity types from CoNLL-03.

Data Split. To investigate low-resource sequence labeling, we randomly take 700 labeled sentences

---

[2] We take the English version as our target corpus.

from the original CoNLL-03 dataset as the training set. For ACE05 and WebPage dataset, the annotation is sparse, so we conduct experiments on their original dataset without further slicing.

We set 6 data usage percentiles for the training set in each corpus. The sequence model is initialed on a small seed set, then it performs five iterates of active learning. For the query policy, we use random sampling and the three active learning policies mentioned in Section 2.2. The machine learning performance is evaluated by F_1 score for each data usage percentile.

Parameters. We use BERT-base-cased for the NER task as the underlying model, and BERT-base-multilingual-cased for the event trigger detection task. We set the max length as 128 to pad the varying-length sequences. The learning rate of the underlying model is 5e-5, and the batch size is 32. We train them for 10 epochs at each data usage percentile. For the parameters of SeqMix, we set $\alpha = 8$ to sample λ from $Beta(\alpha, \alpha)$. We use the sub-sequence window length $s = \{5, 5, 4\}$, the valid label density $\eta_0 = \{0.6, 0.2, 0.5\}$ for CoNLL-03, ACE05 and Webpage, respectively. The augment rate is set as 0.2, and the discriminator score range is set as $(0, 500)$. We also perform a detailed parameter study in Section 4.4.

4.2 Results

The main results are presented in Figure 2, where we use NTE sampling as the default active learning policy. From the result, it is clear that our method achieves the best performance consistently at each data usage percentile for all three datasets. The best SeqMix method (sub-sequence mixup with NTE sampling) outperforms the strongest active learning baselines by 2.95% on CoNLL-03, 2.27% on ACE05 and 3.75% on WebPage in terms of F_1 score on average. Moreover, the augmentation advantage is especially prominent for the seed set initialization stage where we only have a very limited number of labeled data. Through the augmentation, we improve the model performance from 68.65% to 80.71%, where the seed set is 200 labeled sequences and the augmentation provides extra 40 data points for CoNLL-03. The improvement is also significant on ACE05 (40.65% to 49.51%), and WebPage (55.18% to 71.67%), which indicates that our SeqMix can largely resolve the label scarcity issue in low-resource scenarios.

Data Usage	200	300	400	500	600	700
(0, $+\infty$)	**81.15**	82.32	82.74	83.66	83.79	85.05
(0, 2000)	80.20	82.24	83.21	83.67	83.90	85.11
(0, 1000)	80.13	81.86	83.58	84.22	84.81	85.16
(0, 500)	80.71	**82.82**	**84.05**	**85.28**	**86.04**	**86.24**

Table 1: The $F_1(\%)$ of sub-sequence mixup with NTE sampling in different discriminator score range, evaluated on CoNLL-03 with 700 data.

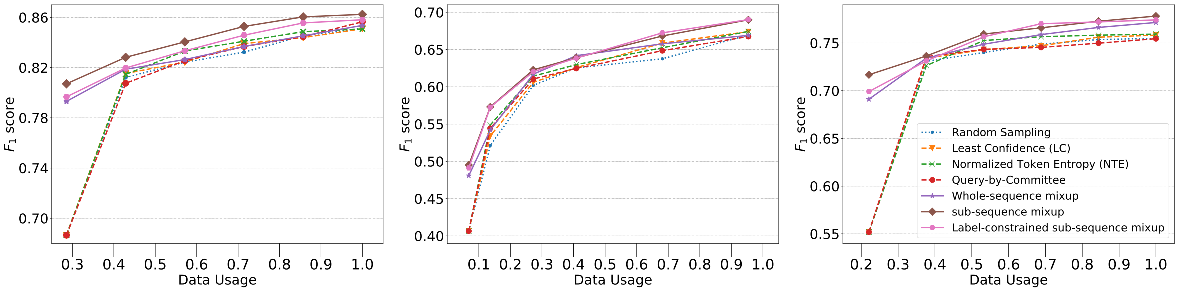
We also perform statistical significance tests for the above results. We use Wilcoxon Signed Rank Test (Wilcoxon, 1992), a non-parametric alternative to the paired t-test. This significance test fits our task as F-score is generally assumed to be not normally distributed (Dror et al., 2018), and non-parametric significance tests should be used in such a case. The results show that sub-sequence mixup and label-constrained sub-sequence mixup can provide a statistical significance (the confidence level $\alpha = 0.05$ and the number of data points $N = 6$) for all the comparisons with active learning baselines on used datasets. The whole-sequence mixup passes the statistical significance test with $\alpha = 0.1$ and $N = 6$ on CoNLL-03 and WebPage, but fails on ACE05.

Among all the three SeqMix variants, sub-sequence mixup gives the overall best performance (label-constrained sub-sequence mixup achieves very close performance with sub-sequence mixup on ACE05 dataset), but whole-sequence mixup does not yield a consistent improvement to the original active learning method. This is because the whole-sequence mixup may generate semantically poor new sequences. Instead, the sub-sequence-level process reserves the original context information between the sub-sequence and the other parts of the whole sequence. Meanwhile, the updated sub-sequences inherit the original local informativeness, and introduce linguistic diversity to enhance the model's generalization ability.

To justify that SeqMix can provide improvement to the active learning framework with various query policies, we employ different query policies with SeqMix augmentation under the same experiment setting as Figure 2(a). From Figure 3, we find that there is a consistent performance improvement when employing SeqMix with different query policies. As SeqMix achieves $\{2.46\%, 2.85\%, 2.94\%\}$ performance gain for random sampling, LC sampling and NTE sampling respectively.

4.3 Effect of Discriminator

To verify the effectiveness of the discriminator, we conduct the ablation study on a subset of CoNLL-



(a) CoNLL-03 (700 labeled data) (b) ACE05 (14k labeled data) (c) WebPage (385 labeled data)

Figure 2: The F_1 score of test set in terms of data usage on CoNLL-03, ACE05 and WebPage.

Data Usage	200	300	400	500	600	700	**Average**
$r = 0.2$	**80.22 (+0.76)**	82.23(+0.43)	**83.61 (+0.61)**	84.62 (+0.53)	85.16 (+0.10)	85.22 (-0.11)	**+ 0.39**
$r = 0.4$	79.71 (+0.25)	**82.48(+0.68)**	82.66 (-0.34)	83.46 (-0.63)	84.79 (-0.27)	85.24 (-0.09)	- 0.07
$r = 0.6$	79.40 (-0.06)	82.07(+0.27)	83.34 (+0.34)	**84.75 (+0.66)**	**85.43 (+0.37)**	**85.50 (+0.17)**	+ 0.29
$r = 0.8$	79.48 (+0.02)	81.63(-0.17)	82.80 (-0.20)	83.29 (-0.80)	84.54 (-0.52)	85.32 (-0.01)	- 0.28
$r = 1.0$	78.51 (-0.95)	80.58(-1.22)	82.59 (-0.41)	84.31 (+0.22)	85.36 (+0.30)	85.37 (+0.04)	- 0.34

Table 2: The F_1 score with variant augment rate r. The value in the parentheses is the difference with the average F_1 for corresponding data usage. The last column presents the average F_1 difference for each learning rate r.

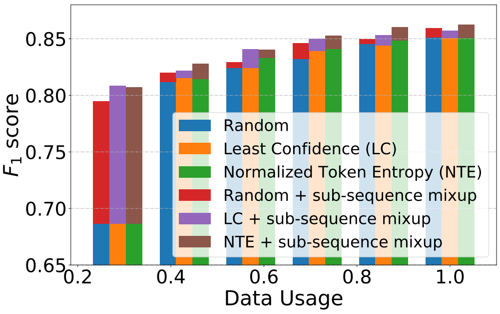


Figure 3: The improvements to various active learning approaches provided by SeqMix.

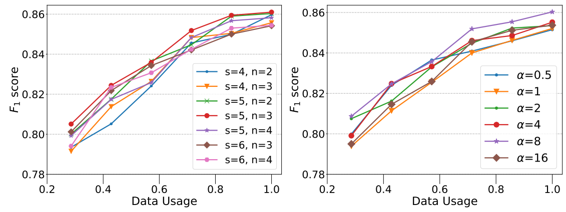
03 with 700 labeled sequences. We use sub-sequence mixup with NTE sampling as the backbone and change the perplexity score range of the discriminator. We start from the seed set with 200 labeled data, then actively query 100 data in each learning round and repeat 5 rounds in total.

The result in Table 1 demonstrates the discriminator provides a stable improvement for the last four data usage percentiles, and the discriminator with score range $(0, 500)$ can boost the model by 1.07% F_1 score, averaged by all the data usage percentiles. The comparison between 3 different score thresholds demonstrates the lower the perplexity, the better the generation quality. As a result, the final F_1 score becomes higher with the better generated tokens. Actually, we can further narrow down the score range to get more performance improvement in return, but the too strict constraints will slow down the generation in practice and reduce the number of generated samples.



(a) F_1 with several combination of s and n (b) F_1 with different α

Figure 4: Parameter Search for SeqMix

4.4 Parameter Study

In this subsection, we study the effect of several key parameters.

Augment rate r. We vary the augment rate $r = \frac{|\mathcal{L}^*|}{|\psi(\mathcal{U},K,\gamma(\cdot))|}$ in $\{0.2, 0.4, 0.6, 0.8, 1.0\}$ and keep the number of initial data usage same to investigate the effect of augment rate for data augmentation. Table 2 shows that $r \le 0.6$ can provide better F_1 improvement. The model with $r = 0.2$ surpasses the model with $r = 1.0$ by 0.73%, evaluated by the average F_1 score for all the data usage percentiles. This result indicates that the model appreciates moderate augmentation more. However, the performance variance based on the augment rate is not prominent compared to the improvement provided by SeqMix to the active learning framework.

Valid tag density η_0. We search the valid tag density η_0 as Section 3.2 defined by varying the sub-sequence window length s and the required number of valid tag n within the window. The results in Figure 4(a) illustrate the combination $(s = 5, n = 3)$ outperforms other settings. When s is too small, the window usually truncates the continuous clause, thus cutting off the local syntax or semantic information. When s is too large, sub-sequence mixup tends to behave like whole-sequence mixup, where the too long sub-sequence generation can hardly maintain the rationality of syntax and semantics as before. The high η_0 with long window length may result in an insufficient amount of eligible parent sequences. Actually, even with a moderate augment rate $\alpha = 0.2$, the combination $(s = 6, n = 5)$ has been unable to provide enough generation.

Mixing parameter α. We show the performance with different α in Figure 4(b). The parameter α decides the distribution $\lambda \sim Beta(\alpha, \alpha)$, and the coefficient λ directly involved the mixing of tokens and labels. Among the values $\{0.5, 1, 2, 4, 8, 16\}$, we observed $\alpha = 8$ presents the best performance. It outperforms the second-best parameter setting 0.49% by average. From the perspective of Beta distribution, larger α will make the sampled λ more concentrated around 0.5, which assigns more balance weights to the parent samples to be mixed. In this way, the interpolation produces encoded token with further distance to both the parent samples, thus introduces a more diverse generation.

4.5 Case Study

Figure 5 presents a generation example via sub-sequence mixup. For the convenience of presentation, we set the length of sub-sequence $s = 3$ and the valid label density threshold $\eta_0 = \frac{2}{3}$. The two input sequences get paired for their eligible sub-sequences "`COLORADO 10 St`" and "`Slovenia , Kwasniewski`". The sub-sequences are mixed by $\lambda = 0.39$ in this case, which is sampled from $Beta(\alpha, \alpha)$. Then the generated sub-sequence "`Ohio ( novelist`" replaces the original parts in the two input sequences. Among the generated tokens, "`Ohio`" inherits the label `B-ORG` from "`COLORADO`" and the label `B-LOC` from "`Slovenia`", and the distribution $Beta(\alpha, \alpha)$ assigns the two labels with weights $\lambda = 0.39$ and $(1 - \lambda) = 0.61$. The open parenthesis is produced by the mixing of a digit and a punctuation mark, and keeps the label `O` shared by its parents. Similarly, the token "`novelist`" generated by "`St`" and "`Kwasniewski`" gets a mixed label from `B-ORG` and `B-PER`.

The discriminator then evaluates the two generated sequences. The generated sequence i is not reasonable enough intuitively, and its perplexity score 877 exceeds the threshold, so it is not added into the training set. The generated sequence j retains the original syntax and semantic structure much better. Although the open parenthesis seems strange, it plays a role as the comma in the original sequence to separate two clauses. This generation behaves closely to a normal sequence and earns 332 perplexity score, which permits its incorporation into the training set.

5 Related Work

Active Sequence Labeling Sequence labeling has been studied extensively for different NLP problems. Different neural architectures has been proposed (Huang et al., 2015; Lample et al., 2016; Peters et al., 2018; Akbik et al., 2018) in recent years, which have achieved state-of-the-art performance in a number of sequence labeling tasks. However, these neural models usually require exhaustive human efforts for generating labels for each token, and may not perform well in low-resource settings. To improve the performance of low-resource sequence labeling, several approaches have been applied including using semi-supervised methods (Clark et al., 2018; Chen et al., 2020b), external weak supervision (Lison et al., 2020; Liang et al., 2020; Ren et al., 2020; Zhang et al., 2019; Yu et al., 2020) and active learning (Shen et al., 2017; Hazra et al., 2019; Liu et al., 2018; Fang et al., 2017; Gao et al., 2019). In this study, we mainly focus on active learning approaches which select samples based on the query policy design. So far, various uncertainty-based (Scheffer et al., 2001; Culotta and McCallum, 2005; Kim et al., 2006) and committee-based approaches (Dagan and Engelson, 1995) have been proposed for improving the sample efficiency. More recently, Shen et al. (2017); Hazra et al. (2019); Liu et al. (2018); Fang et al. (2017) further improve the aforementioned active learning approaches to improve the sampling diversity as well as the generalization ability of models on low-resource scenarios. These works mainly claim the sample efficiency provided by the active learning approach but do not study data augmentation for active sequence labeling.

Interpolation-based Regularizations Mixup implements interpolation in the input space to regularize models (Zhang et al., 2018). Recently,

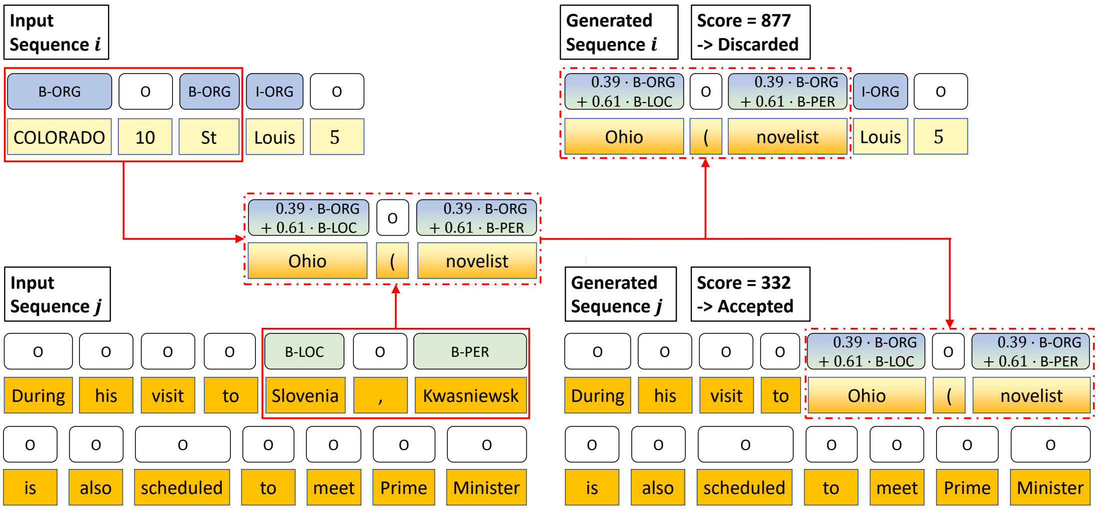


Figure 5: A generation case of sub-sequence mixup.

the Mixup variants (Verma et al., 2019; Summers and Dinneen, 2019; Guo et al., 2019b) turn to perform interpolation in the hidden space to capture higher-level information. Guo et al. (2019a); Chen et al. (2020a) apply hidden-space Mixup for text classification. These works, however, have not explored how to perform mixup for sequences with token-level labels, nor do they consider the quality of the mixed-up samples.

Text Augmentation Our work is also related to text data augmentation. Zhang et al. (2015); Wei and Zou (2019) utilize heuristic approaches including synonym replancement, random insertion, swap and deletion for text augmentation, Kafle et al. (2017); Silfverberg et al. (2017) employ heuristic rules based on specific task, Hu et al. (2017) propose to augment text data in an encoder-decoder manner. Very recently, (Anaby-Tavor et al., 2020; Kobayashi, 2018) harness the power of pre-trained language models and augmenting the text data based on contextual patterns. Although these methods can augment the training set and improve the performance of text classification model, they fail to *generate sequences and labels simultaneously*, thus cannot be adapted to our problem where token-level labels are required during training. Instead, in our study, we propose a new framework SeqMix for data augmentation to facilitate sequence labeling task. Our method can generate token-level labels and preserve the semantic information in the augmented sentences. Moreover, it can be naturally combined with existing active learning approaches and further promote the performance.

6 Conclusion

We propose a simple data augmentation method SeqMix to enhance active sequence labeling. By performing sequence mixup in the latent space, SeqMix improves data diversity during active learning, while being able to generate plausible augmented sequences. This method is generic to different active learning policies and various sequence labeling tasks. Our experiments demonstrate that SeqMix can improve active learning baselines consistently for NER and event detection tasks; and its benefits are especially prominent in low-data regimes. For future research, it is interesting to enhance SeqMix with language models during the mixup process, and harness external knowledge for further improving diversity and plausibility.

A Information for Dataset

A.1 Dataset Collection

Here we list the link to datasets used in our experiments.

- **CoNLL-03**: `https://github.com/synalp/NER/tree/master/corpus/CoNLL-2003`.
- **ACE05**: We are unable to provide the downloadable version due to it is not public. This corpus can be applied through the website of LDC: `https://www.ldc.upenn.edu/collaborations/past-projects/ace`.
- **Webpage**: Please refer the link in the paper (Ratinov and Roth, 2009).

A.2 Dataset Split

All the mentioned dataset has been split into **train/validate/test** set in the released version. We keep consistent with the validation set and the test set in our experiment. For the active learning paradigm, we split the training set as Table 3. The active learners are initialized on the seed set, then they implement 5 active learning rounds.

B Baseline Settings

For the baselines, we take random sampling and 3 active learning approaches – LC sampling, NTE sampling, and QBC sampling as Section 2.2.

C Implementation Details of SeqMix

We implement bert-base-cased as the underlying model for the NER task and bert-base-multilingual-cased as the underlying model for the event detection task. We use the model from Huggingface Transformer codebase[3], and the repository[4] to fine-tune our model for sequence labeling task.

C.1 Number of Parameters

In our model, we use **bert-base-cased** and **bert-base-multilingual-cased** both of them occupy 12-layer, 768-hidden, 12-heads with 110M parameters.

C.2 Adapting BERT for sequence labeling task

To fine-tune on sequence labeling tasks, a dropout layer ($p = 0.1$) and a linear (token-level) classification layer is built upon the pre-trained model.

C.3 SeqMix Details

In Section 3.2, we construct a table of tokens $\mathcal{W}$ and their corresponding contextual embedding $\mathcal{E}$. For our underlying BERT model, we use the vocabulary provided by the tokenizer to build up $\mathcal{W}$, and the embedding initialized on the training set as $\mathcal{E}$.

We also need to construct a special token collection to exclude some generation in the process of sequence mixing. For example, BERT places token `[CLS]` and `[SEP]` at the starting position and the ending position for sentence, and pad the inputs with `[PAD]`. We exclude these disturbing tokens and the parent tokens.

C.4 Parameter Settings

The key parameters setting in our framework are stated here: (1) The number of active learning round is 5 for all the three datasets, but the size of seed set and the number of samples in each round differs from the dataset. We list the specific numbers as Table 3. (2) The sub-sequence window length s and the valid label density threshold η_0 vary from the datasets. For CoNLL-03, $s = 5$, $\eta_0 = 0.6$; for ACE05, $s = 5$, $\eta_0 = 0.2$; for WebPage, $s = 4$, $\eta_0 = 0.5$. (3) We set $\alpha = 8$ for the *Beta* distribution. (4) The discriminator score range is set as $(0, 500)$ for all the datasets. (5) For BERT configuration, we choose 5e-5 for learning rate, 128 for padding length, 32 for batch size, 0.1 for dropout rate, 1e-8 for ϵ in Adam. At each data usage point, we train the model for 10 Epochs. (6) We set $\mathcal{C} = 3$ for the QBC query policy.

D Details of Experiments

We take following criteria to evaluate the sequence labeling task. A named entity is correct only if it is an exact match of the corresponding entity in the data file. An event trigger is correct only if the span and type match with golden labels. Based on the above metric, we evaluate F_1 score in our experiments.

D.1 Performance on Development Set

Table 4 to Table 6 shows the model performance on the validation set. The data usage in these tables

QBC Sampling	48.16	59.01	62.79	64.89	66.20	66.91
Sub-sequence mixup	56.51	61.62	63.65	65.83	67.54	67.98

Table 5: Validation F_1 of ACE05

refers to the number of labeled data, excluding the augmentation data. Sub-sequence mixup is trained with $(1+\alpha)$ times data, where the α denotes the augment rate. Note that WebPage is a very limited dataset, there is a big difference between the performance on the validation set and the test set. We average each experiment by 5 times.

D.2 Computing Infrastructure

We implement our system on *Ubuntu 18.04.3 LTS* system. We run our experiments on an Intel(R) Xeon(R) CPU @ 2.30GHz and NVIDIA Tesla P100-PCIe with 16 GB HBM2 memory. The NVIDIA-SMI version is 418.67 and the CUDA version is 10.1.

D.3 Average Runtime

For the 5-round active learning with SeqMix augmentation, our program runs about 500 seconds for WebPage dataset, 1700 seconds for the CoNLL slicing dataset, and 3.5 hours for ACE 2005. If the QBC query policy used, all the runtime will be multiplied about 3 times.

D.4 Hyper parameter Search

For the discriminator score range, we first examine the perplexity score distribution of the CoNLL training set. Then determine an approximate score range $(0, 2000)$ first. We linearly split score ranges below 2000 to conduct parameter study and report the representative ranges in Section 4.3. Given the consideration to the generation speed and the augment rate setting, we finally choose 500 as the upper limit rather than a too narrow score range setting.

For the mixing coefficient λ, we follow (Zhang et al., 2018) to sample it from $Beta(\alpha, \alpha)$ and explore α ranging from $[0.5, 16]$. We present this parameter study in Section 4.4. The result shows different α did not influence the augmentation performance much.

For the augment rate and the valid tag density, we also have introduced the parameter study in Section 4.4.

AxCell: Automatic Extraction of Results from Machine Learning Papers

Abstract

Tracking progress in machine learning has become increasingly difficult with the recent explosion in the number of papers. In this paper, we present AxCell, an automatic machine learning pipeline for extracting results from papers. AxCell uses several novel components, including a table segmentation subtask, to learn relevant structural knowledge that aids extraction. When compared with existing methods, our approach significantly improves the state of the art for results extraction. We also release a structured, annotated dataset for training models for results extraction, and a dataset for evaluating the performance of models on this task. Lastly, we show the viability of our approach enables it to be used for semi-automated results extraction in production, suggesting our improvements make this task practically viable for the first time. Code is available on GitHub.[1]

1 Introduction

Machine learning studies how machines learn with respect to a task, a performance metric, and a dataset (Mitchell, 2006). The (task, dataset, metric name, metric value) tuple can therefore be seen as representing a single result of a machine learning paper. To make progress as a field we need to make comparisons between results achieved with different methodologies. In light of the explosion in the number of machine learning publications in recent years, such comparisons have become more difficult.[2] This poses serious challenges to peer review, among others. For instance, across ten language modelling papers submitted to ICLR 2018, the perplexity score of the best baseline differed by more than 50 points (Ruder, 2018).

One way to deal with the deluge of papers is to develop automatic approaches for extracting results from papers and aggregating them into leaderboards. Authors typically publish their results in a tabular format in the paper, including a selection of comparisons between their approach and past papers. Automatic extraction of result tuples from tables—and optionally metadata such as model names—enables a full comparison between published methods.

Online leaderboards for comparison have become increasingly common in the research community. But these are only available for a few tasks and do not aid the comparison of models across tasks. To fill the gap, result aggregation tools such as Papers With Code[3] and NLP-Progress[4] utilise crowdsourced community contributions to populate paper leaderboards. However, human annotation of results can be laborious and error-prone, leading to omission or misreporting of paper results. Automating at least some parts of the process can speed-up the annotation, reduce number of errors and lower the expert knowledge required to correctly annotate a paper. This motivates the need for a machine learning approach to create a comprehensive results resource for the field.

Existing state-of-the-art approaches for results extraction are brittle and noisy, relying on text formatting hints and tables extraction from PDF files (Hou et al., 2019). In contrast, we propose AxCell, a pipeline for automatic extraction of results from machine learning papers. AxCell breaks down the results extraction task into several subtasks including table type classification, table semantic segmentation and linking results to leaderboards. We employ an ULMFiT-based classifier

architecture (Howard and Ruder, 2018) to make full use of paper and table context to interpret tabular content, and extract results accordingly.

As a whole, this paper makes three main contributions to the literature. First, we significantly improve over the state-of-the-art for results extraction with our AXCELL system. On the subset of the NLP-TDMS dataset of Hou et al. (2019) where LaTeX code is available, our approach achieves a micro F_1 score of 25.8 compared to the state of the art of 7.5. Secondly, we release a structured, annotated dataset for training models for results extraction, and an evaluation dataset for evaluating the performance of models on this task. Lastly, our approach is used in an in-production setting at paperswithcode.com to semi-automatically (by aiding the human review) extract results from papers and track progress in machine learning.

2 Related Work

Results Extraction. Previous works have studied the problem of extracting results tuples (task, dataset, metric name, metric value) from papers. Singh et al. (2019) perform search over publications and compose a leaderboard for a queried triplet. Similar to our approach, they use tables extracted from LaTeX sources. In contrast, they do not extract absolute metric values but rank papers and do not appear to utilise the text content of publications. Our goal in this paper is to extract complete results to create leaderboards, so unlike Singh et al. (2019), we focus on extracting raw metric values. Additionally we make use of the content of the publication as context for entity recognition and linking.

Closer to our formulation, Hou et al. (2019) extract absolute metric values alongside the metric name, task and dataset. They also use text excerpts as well as direct tabular information to make inferences for table contents. They frame extraction as a natural language inference problem and apply an NLI model based on a BERT architecture (Devlin et al., 2019) to extract results from PDF files. The disadvantage of this approach is that using PDFs leads to a lot of noise in structural information such as the partition of a table into cells. In our work, we explicitly utilise the structural information from the LaTeX source to extract entire tables in order to perform semantic segmentation. We demonstrate that this structural information and segmentation are crucial for boosting extraction performance.

Table Extraction. The more general problem of retrieving information from tables has been studied in past works (Milosevic et al., 2019; Ghasemi-Gol and Szekely, 2018; Wei et al., 2006; Herzig et al., 2020). Our focus in this paper is on the problem of extracting and interpreting content of tables characteristic to machine learning papers. The goal of our table semantic segmentation model is to classify cells into categories. That is, instead of performing structural segmentation where one tries to distinguish between captions, headers and rows in a stream of text (Pinto et al., 2003) we focus on semantic segmentation (i.e., assigning roles to each cell) of tables.

3 Our Approach

The task of paper results extraction is to take a machine learning paper as an input and extract results contained within the paper, specifically tuples of the form (task, dataset, metric name, metric value). As an example, if we were to take the EfficientNet paper of Tan and Le (2019) as an input, some example results tuples we would want to extract would be (Image Classification, ImageNet, Top 1 Accuracy, 84.4%), (Image Classification, ImageNet, Top 5 Accuracy, 97.1%) and (Image Classification, Stanford Cars, Accuracy, 94.7%).

To tackle this problem effectively we define subtasks that take us from paper to results. In particular, we introduce the AXCELL pipeline that consists of the following subtasks: (i) **table type classification**, identifying whether a table in a paper has relevant results; (ii) **table segmentation**, segmenting and classifying table cells according to whether they hold metrics, datasets, models, etc.; and (iii) **linking results to leaderboards**, taking the result tuples and matching them to an existing leaderboard of results. The end-to-end system is shown in Figure 1 with reference to an example. We now introduce the different components of AXCELL.

3.1 Table Type Classification

The first stage of AXCELL is to categorize tables from papers into one of three categories: `leaderboard` tables, `ablation` tables and `irrelevant` tables. A `leaderboard` table contains the principal results of the paper on a selected benchmark, including comparisons with other papers. An `ablation` table compares different permutations of the paper's methodology.

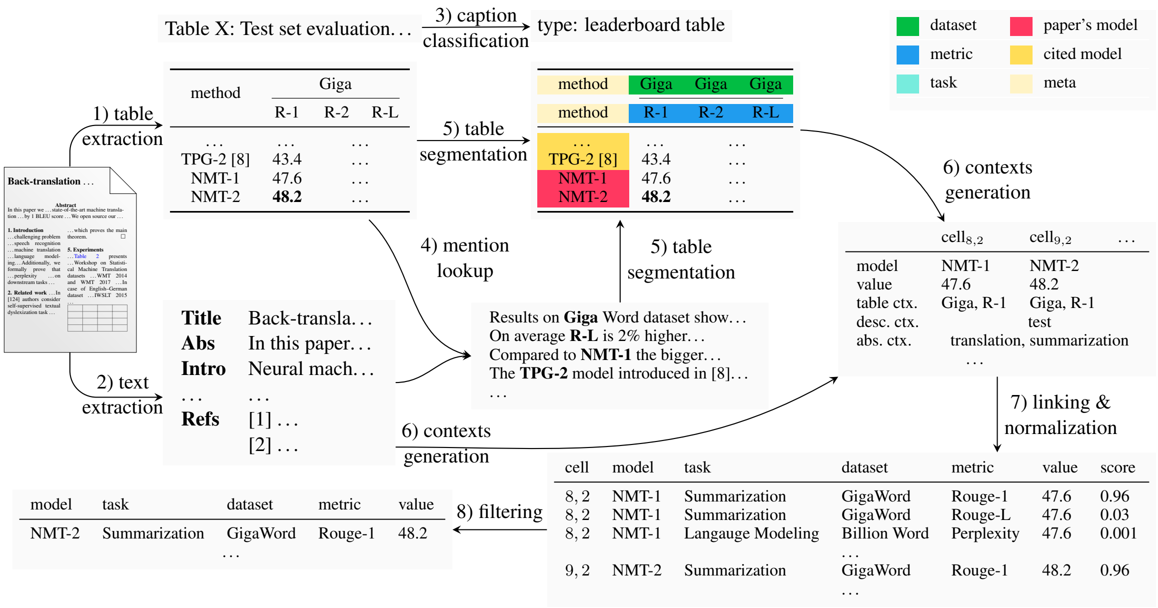

Figure 1: Graphical depiction of AXCELL. The extraction starts with LaTeX source code of a paper, from which we extract 1) tables and 2) text. 3) We classify the caption to filter out irrelevant tables. 4) The content of each cell is looked up in the paper's text. Retrieved mentions are used to 5) segment cells based on their meaning (see the legend in the top-right corner). The segmented table and the paper's text are used to 6) obtain contexts for each numeric cell. 7) Results tuples are scored based on contexts and numeric values are normalized to match required format. 8) Inferior results or results below a confidence threshold are filtered out.

Lastly, `irrelevant` tables include hyperparameters, dataset statistics and other information that is not directly relevant for result extraction.

For this stage we employ a classifier with a ULMFiT architecture (Howard and Ruder, 2018) with LSTM layers and a SentencePiece unigram model (Kudo, 2018) for tokenization.[5] We train the SentencePiece model and pretrain a left-to-right ULMFiT language model on text of papers from an unlabelled dataset of arXiv articles (see Section 4). Table 5 in the Appendix contains details on the hyperparameters and training regime.[6]

The classifier head is a standard ULMFiT classifier with a pooling layer followed by two linear layers. We treat the problem as a two-label classification with labels: `leaderboard` and `ablation`. A table is considered irrelevant if it is neither a leaderboard nor ablation (we use a confidence threshold of 0.5). In practice it is common for a single table to include both principal results introduced in a given paper as well as results of ablation studies. For this reason we extract results from both `leaderboard` and `ablation` tables and pick only the best results during filtering (see Section 3.6). We train the model on the SEGMENTEDTABLES dataset (see Section 4.2).

3.2 Table Segmentation

The second stage of AXCELL is to pass relevant tables to a table segmentation subtask. The goal is to annotate each non-numeric cell of a table with a label denoting what type of data a given cell contains. To this end, we classify each table cell into one of: `dataset` name, `metric` name, `paper model`, `cited model`, and `other` (containing meta and task cells). An example of a segmented table is shown in Figure 1.

To help classify each table cell, we provide a context in which the cell content is mentioned. We search for cell content in the full paper content using a BM25 scoring algorithm. Retrieved text fragments are then passed to a ULMFiT-based classifier with some handcrafted features for the cell. These features include information such as the position of the cell in the table, whether the cell is a header, and cell styles. A full list is available in the Appendix. For processing the retrieved text fragments, the retrieved term from the cell is replaced

---

[5] Our classifier uses the fast.ai implementation (Howard and Gugger, 2020).

[6] We experimented with finetuning alternative language models such as BERT and SciBERT but our initial experiments did not yield superior results. A full investigation of alternative models, including pretraining from scratch, is left for future research.

```
On TREC-6, <MASK> significantly
improves upon training from
scratch; as examples are shorter
and fewer, supervised and
semi-supervised <MASK> achieve
similar results.
```

Figure 2: An example of a text excerpt from the paper by Howard and Ruder (2018) used as evidence for a cell content query with *ULMFiT* (covered with `<MASK>` token) as `paper model`.

with a special mask `<MASK>` token to inhibit memorization of common names (see Figure 2 for an example). Table segmentation can then be treated as a classification problem with 5 exclusive labels. We use the same pre-trained language model to train the table type classifier. Results for this stage of the model are outlined in Table 3.

3.3 Cell Context Generation

The next stage after table segmentation is to generate contexts for numeric cells. As an example, if we know a numeric cell has a dataset cell somewhere in its row, and a model cell somewhere in its column, then this table context is informative for deciding the dataset and model for this result. But there is much broader context in the paper that is useful for linking.

For example, a paper studying semantic segmentation with models evaluated on KITTI and CamVid datasets could mention *semantic segmentation* in the introduction, *test set* in a subsection referring to a results table, *KITTI* in the description of that table and *class IoU* in the column header. Figure 3 shows a visual representation of this hierarchy of context.

To reflect this hierarchy we generate several types of contexts for each cell. The `table context`, as discussed, looks at a numeric cell and other cells in its row or column labeled as model, dataset or metric. We also define text contexts: a `caption context`, the table caption; a `mentions context`, text fragments referencing the table; an `abstract context`, the paper abstract; and a global `paper context`, containing the entire paper text. The gathered contexts are then used to link potential results to predefined leaderboards of results.

3.4 Linking Cells to Leaderboards

Once we have the cell contexts, the next stage of AXCELL is to link them to leaderboards to form performance records. The goal is to take a metric value associated with a `paper model` cell and infer the leaderboard it is connected to. A leaderboard is defined by a (task, dataset, metric name) triplet. For example: (Image Classification, ImageNet, Top 1 Accuracy) can capture papers that report performance on Image Classification for ImageNet and report Top 1 Accuracy. To simplify the problem, we assume a closed-domain with all leaderboards known in advance. To match results to leaderboards we look for evidence in cell contexts, which we now explain.

Pieces of evidence are words or phrases that correspond to a task, dataset or metric. For example, *SST-2*, *binary* and *polarity* could all serve as evidence for the two-class *Stanford Sentiment Treebank* dataset (Socher et al., 2013). Pieces of evidence allow us to infer whether an entity has been mentioned in a given context. Using the same example, if "SST-2" appears in the table caption then this is evidence that a numeric value in the table could be linked to the *Stanford Sentiment Treebank* dataset.

3.5 Model

Our goal is to determine the probability $p(k|E)$ of a leaderboard $k \in \{1 \ldots K\}$ being associated with a given cell, conditioned on the evidence E we have collected for this cell. Instead of modelling this directly using a discriminative model, we opt for a simple generative model $p(k, E)$ that can be adapted to new leaderboards as well as types of evidence without additional training data. While this should be possible for discriminative models as well, we leave this open for future work.

Let $E = \{e_1, \dots, e_s\}$ consist of pieces of evidence e_j of the form $e_j = (m, t, c)$ where m is a mention such as "acc", t is a type of entity such as "Metric" and c is the type of context the evidence was found in, such as "Table." Our model generates leaderboard and evidence using $p(k, E) = p(k)p(E|k)$. To model the likelihood of evidence, we make a Naive Bayes assumption and set $p(E|k) = \prod_{e \in E} p(e|k)$.

We assume that the type of context c controls the generation of the remainder of the evidence m and t:

$$p(e|k) = p(m, t, c|k) = p(c)p(m, t|c, k).$$

Once we know the context type c, using a latent noise variable n we generate evidence either independent or dependent of the actual leaderboard:

$$\begin{aligned} p(m, t|c, k) = &p(t|c, k)\Big[p(n|t, c)p(m|n, t) \\ &+ (1 - p(n|t, c))p(m|\neg n, t, k)\Big]. \end{aligned}$$

Finally, we assume that a leaderboard generates its mention as follows:

$$p(m|\neg n, t, k) = p(m|\neg n, t, \text{property}(t, k))$$

where property(t, k) is the t property of the leaderboard k. For example if the leaderboard k consists of (Image Classification, ImageNet, Accuracy) then property(Metric, k) = Accuracy .

Inference To score a leaderboard k given evidence E, we calculate $p(k, E)/\sum_{k'} p(k', E)$ summing over all leaderboards in the taxonomy. This is feasible as we assume a closed-domain scenario.

Estimation Most of our parameters are hand-set to uniform distributions. In particular, we set $p(k) = \frac{1}{K}$, $p(t|c, k) = \frac{1}{3}$, $p(c) = \frac{1}{5}$. We set $p(m|\neg n, t, \text{property}(t, k))$ to be inversely proportional to the number of other entities of type t with the same mention evidence m (see Appendix C for details).

The probabilities $p(n|t, c)$ of a mention of type t in context c being noisy are tuned manually for each of 15 (t, c) pairs. The probabilities $p(m|n, t)$ of a noisy mention are assumed to be the same for all mentions of a given type t and are tuned as well. We tune 18 parameters in total.

3.6 Filtering

The final step of AXCELL is to filter out (i) results for cited models, (ii) results with a linking score that is too low and (iii) inferior results (to avoid extraction of ablation results).

First, we filter out records not associated with models introduced in a paper being processed. We then remove records for which a linking score is below some given threshold. The remaining records are grouped by leaderboard and for each leaderboard only the best result is kept, based on *higher is better* annotation available in taxonomy; e.g., *Accuracy* would keep higher values, *Error Rate* would keep lower values. Finally, we remove all results with a linking score below the second threshold. This gives us the final list of results tuples extracted from the paper.

4 Dataset

In this section we explain the datasets we used for training and evaluating AXCELL for results extraction. The primary input we use for a training dataset is LaTeX source code of machine learning papers from arXiv.org. Over 90% of considered papers have source code available. This allows us to obtain a high quality dataset without common artifacts that arise from extracting data directly from PDF files.

For training our models we use two main datasets:

- ARXIVPAPERS: An unlabelled dataset of over 100,000 machine learning papers. Used for language model pre-training.
- SEGMENTEDTABLES: A table segmentation dataset where each cell is annotated according to whether it is a paper, metric, dataset, and so on. Used for table segmentation and table type classification.

We manually tune the linking and filtering performance of our method using a validation dataset:

- LINKEDRESULTS: An annotated dataset of over 200 papers with results tuples, capturing the performance of models in the papers, and links to tables.

Lastly we evaluate the end-to-end performance of AXCELL on our test set:

- PWC LEADERBOARDS: An annotated dataset of over 2,000 leaderboards with results tuples. Used for end-to-end performance evaluation.

We now describe in detail these datasets.

4.1 arXiv Papers

The dataset contains $104,710$ papers published on arXiv.org between 2007–2020. $93,811$ papers are available with LaTeX sources, from which we extracted $277,946$ tables in total. Due to licensing limitations the dataset we release with this paper contains only metadata (available in the public domain) and links to articles. The dataset is unlabeled, designated for use in self-supervised pretraining.

4.2 Segmented Tables

This is a dataset for table classification and segmentation, containing 1994 annotated tables from 352 articles. The dataset provides data on dataset mentions in captions, the type of table (`leaderboard`, `ablation`, `irrelevant`) and ground truth cell annotations into classes: `dataset`, `metric`, `paper model`, `cited model`, `meta` and `task`.

4.3 Linked Results

This is a set of 239 papers we annotated with 1591 results tuples, capturing the performance of models in the papers. Additionally we include metrics scores in a normalized form. We also record metadata such as the names of the models used in papers. Each results tuple (task, dataset, metric name, metric value) is linked to a particular table, row and cell it originates from. Note that results that appear outside of a table, for instance in the paper's text or graphs, are not present in this dataset.

4.4 PWC Leaderboards

This is a dataset of 2,291 leaderboards, where the data is collected from the Papers with Code labelling interface (see Figure 5 in Appendix). This interface allows annotators on Papers with Code to take a paper and label it with results tuples. Annotations are then reviewed by the community and revised if necessary. Since this is the biggest and most diverse curated ground-truth dataset, it is a good test for evaluating the end-to-end performance of our solution.

Table 1: End-to-end extraction results on subset of NLP-TDMS (Exp) dataset.

Method	Micro			Macro		
	P	R	F_1	P	R	F_1
(task, dataset, metric)						
TDMS-IE	53.4	66.3	59.2	57.1	66.1	58.5
AXCELL	65.8	58.5	61.9	56.0	55.8	54.1
(task, dataset, metric, score)						
TDMS-IE	6.8	8.4	7.5	8.6	9.5	8.8
AXCELL	27.4	24.4	25.8	20.2	20.6	19.7

5 Experiments

We now evaluate the end-to-end performance of AXCELL on the results extraction task. We evaluate on two datasets: the NLP-TDMS dataset introduced in Hou et al. (2019), in order to compare our method to the state of the art, and on our PWC LEADERBOARDS dataset, which contains many more leaderboards and acts as a more challenging benchmark.

5.1 NLP-TDMS Results

We compare AXCELL to the TDMS-IE model from Hou et al. (2019) on the NLP-TDMS dataset in Table 1. The NLP-TDMS (Full) dataset contains 332 papers related to Natural Language Processing with 848 performance annotations of task, dataset, metric and score and 168 unique leaderboards. The subset NLP-TDMS (Exp) is limited to 77 leaderboards appearing in at least 5 papers. See Table 10 in the Appendix for dataset statistics. To compare with Hou et al. (2019), we use the Exp dataset.

Hou et al. (2019) extract records directly from PDF, so the methods are not fully comparable. In order to run AXCELL on that dataset we limit the dataset to papers for which LaTeX source code is available. Table 1 shows results on that subset with TDMS-IE performance computed based on published predictions. Our solution yields significantly better results for whole records retrieval despite not being trained on their taxonomy (i.e., the zero-shot scenario in Hou et al. (2019)).

5.2 PWC LEADERBOARDS Results

Having validated the performance of our approach compared to the state of the art, we now apply it to our much larger dataset of leaderboards. Compared

Table 2: Extraction results of AXCELL on PWC LEADERBOARDS dataset (restricted to our taxonomy) for entire records (TDMS), records without score (TDM) and individual entities.

Entity	Micro			Macro		
	P	R	F_1	P	R	F_1
TDMS	37.4	23.2	28.7	24.0	21.8	21.1
TDM	67.8	47.8	56.1	47.9	46.4	43.5
Task	70.6	57.3	63.3	60.7	62.6	59.7
Dataset	70.2	48.4	57.3	53.5	52.7	49.9
Metric	68.8	58.5	63.3	58.4	60.4	56.5

to the NLP-TDMS dataset, whose taxonomy consists of 77 leaderboards, our taxonomy consists of 3,445 leaderboards making prediction much more challenging.

The results of our approach for extracting each entity are detailed in Table 2. We achieve reasonable performance on extracting the full TDMS (task, dataset, metric, score) tuple, which is the most challenging setting and the highest scores for extracting task and metric information. The lower scoring entities are generally the ones that depend on the quality of extraction of other entities. For example, extracting leaderboards depends on how well we extract task, dataset and metric entities.

The large difference in performance between extraction of TDM and full TDMS tuples is due to the fact that in order to get the score right, the model needs to correctly predict the table, column and row the score value is present in. Additionally, the extracted value needs to be normalized. On the other hand, the right TDM can often be inferred from other results reported in a paper.

6 Performance Studies

Due to working with machine learning papers from multiple domains (from CV to NLP to biology) and a multistep approach (where errors compound) the errors are characterized by a long-tail distribution and it is difficult to pin-point the biggest source of errors. In this section, we analyze the various steps of AXCELL in order to better understand their relative importance.

6.1 Table Type Classification

The biggest issue of table type classification is in distinguishing between leaderboard and ablation tables (see Figure 7 in Appendix). These tables can be very similar structurally: ablations may even compare on the same split of data as the primary result. As the distinction is not always clear, during results retrieval we extract results from both types of tables and pick only the best results during filtering (i.e., the highest or lowest based on predicted metric).

6.2 Table Segmentation

One goal of table segmentation is to generalise to tables from unseen tasks. To study this, we partitioned SEGMENTEDTABLES dataset into 11 folds, based on the task name extracted from paper abstracts. The fold with tables from Image Classification papers is always used as a validation set. For each of the remaining 10 folds we train 5 models with a given fold used as a test set and the other 9 folds used as training data. The final table segmentation model used in AXCELL is the one with the highest micro F_1 score on the validation set.

Table 3 shows micro precision, recall and F_1 score of classifying each non-numeric cell into one of 5 exclusive classes: dataset, metric, competing model, paper's model or other.

We can see that we achieve strong results on all tasks, although some tasks perform better than others. A task like semantic segmentation has less table and benchmark diversity, so benchmark tables for datasets like Cityscapes and PASCAL VOC 2012 are fairly standardised across papers. This makes extraction fairly straightforward. In contrast, the worse performing tasks are unusual in their own way. In image generation, for instance, we are less able to extract the correct dataset entity, whereas in speech recognition, our model has more problems distinguishing paper models from competing models; see Figure 6 in the Appendix.

6.3 Linking

To evaluate linking performance in isolation of other steps we run it on tables with ground truth type and segmentation annotations. The annotations are available in the SEGMENTEDTABLES dataset for 24 Speech Recognition and 32 Semantic Segmentation papers with 287 annotated leaderboard records in total. For each cell with associated leaderboard annotation we generate cell contexts and use linking to retrieve the top-5 predictions. We test four approaches to generate evidence of mentions.

Table 3: Table segmentation results for 10-fold training with image classification papers fixed as a validation set and variable test set. Micro precision, recall and F_1 score are averaged over 5 runs.

	validation			test

curated	76	87	77	87	77	95	89	87
combined	67	87	68	78	72	95	86	85

Top-5 Accuracy [%]								
evidence	speech rec.				sem. segmentation			
	TDMS	T	D	M	TDMS	T	D	M
BoP	72	88	73	84	82	99	89	93
abbrs	76	89	76	84	93	100	94	99
curated	85	90	85	91	97	99	99	99
combined	81	89	81	89	97	99	99	99

Bag-of-Phrases The full name and any word (which is not an English stop-word) occurring in the name of a metric or dataset (as found in taxonomy) is evidence of mention. For example, for *Exact Match Ratio* metric we get *exact match ratio*, *exact*, *match* and *ratio*.

Abbreviations We run an abbreviation detector (Neumann et al., 2019) over the ArxivPapers dataset to extract pairs of common abbreviations and their full forms. The previous approach is extended with abbreviations of full forms occurring in the name of the metric or dataset. For example, with an extracted abbreviation–full form pair (*en-vi*, *English-Vietnamese*) and dataset name *IWSLT2015 English-Vietnamese*, *en-vi* is added as mention evidence for this dataset. For the *Exact Match Ratio* metric we extend the Bag-of-Phrases evidence with: *em* and *er* (extracted *Exact Match Ratio* abbreviations), *em* (extracted *Exact Match* abbreviation), *mr* (extracted *Match Ratio* abbreviation) and *r* (extracted *Ratio* abbreviation). To deal with the noise in abbreviations for a given full form we include only short forms that appear at least 20% of times as an abbreviation of that full form.

Manually Curated We extend the Bag-of-Phrases approach with list of manually curated mention evidence. Only mentions of datasets and metrics related to speech recognition and semantic segmentation are modified.

Combined The previous approach extended with abbreviations.

In Table 4 we show Top-1 and Top-5 accuracy of the predictions over all leaderboard records from each collection of papers. Using abbreviations significantly improves the performance over the Bag-of-Phrases approach. The worse performance caused by adding abbreviations to manually curated lists suggests that abbreviations could increase the rate of false-positive matches of mentions. Another explanation might be that manually curated lists of mentions are biased towards leaderboards related to speech recognition and semantic segmentation due to construction of the lists.

The overall performance of the linking step allows us to use it in production environment for efficient semi-automated extraction of results. Our solution proposes to users the Top-5 predictions associated with cells they indicated, thus eliminating the tedious and error-prone step of matching the results with existing leaderboards and ensuring that metric values are correctly normalized.

6.4 End-to-End Performance

We use annotations for Semantic Segmentation papers from SegmentedTables and LinkedResults datasets to analyse how AxCell performs in an end-to-end fashion. Figure 4 shows fractions of gold truth records incorrectly rejected in various steps of our pipeline. Both table type classification and segmentation steps were done using models trained with the Semantic Segmentation fold as a test set.

The most common reason for misprediction of datasets is confusion between validation and test sets. Additionally the linking model has difficulties in distinguishing between variants of Intersection over Union metrics (mean IoU, frequency weighted IoU, class and category IoU). The confus-

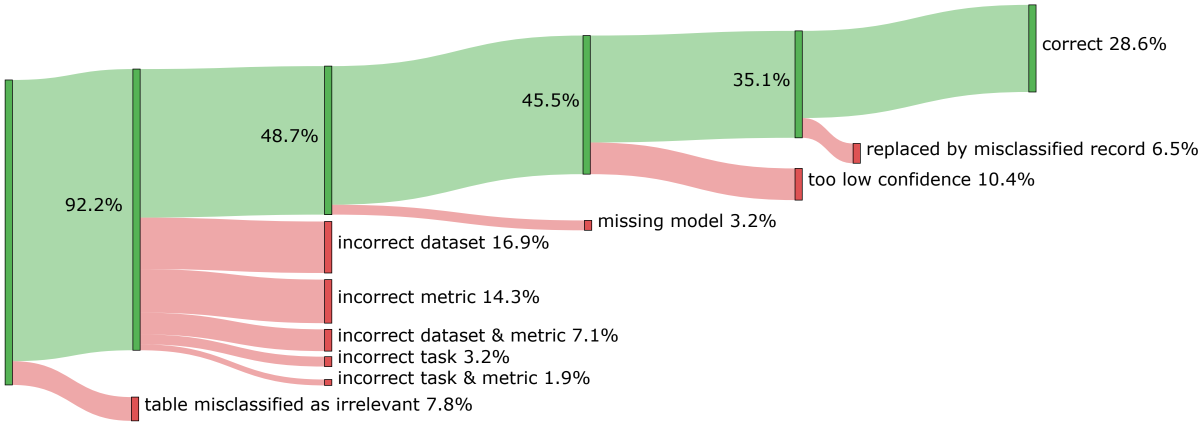

Figure 4: Analysis of end-to-end extraction on the Semantic Segmentation fold of LINKEDRESULTS dataset. Green blocks show percentage of gold truth tuples of (task, dataset, metric, score) that are correctly classified in various stages of our pipeline. Red blocks show reasons for which a given fraction of gold truth records is incorrectly rejected.

ing datasets and metrics names are also reasons for a low confidence of linked results, as the score is distributed over similar entities.

One should keep in mind that the above analysis might not fully generalise to other tasks. As shown in Table 3 and Figure 6, table segmentation performs differently on papers related to different machine learning tasks. Moreover, it is more common in case of Semantic Segmentation papers to report results on both validation and test sets due to test sets often being hidden. The difference between tasks is also apparent in linking performance on Speech Recognition and Semantic Segmentation papers, as presented in Table 4. While the Top-1 Accuracy is similar for both tasks, in terms of Top-5 Accuracy the linking step performs significantly better on Semantic Segmentation papers—most of the time the top 5 entries are sufficient to cover variants of Semantic Segmentation datasets and metrics.

7 Future Work

We cover three possible extensions to our work for future research.

First, we might want to consider methods that retrieve ***all*** results rather than just the principal results introduced in the paper. This includes extracting ablation studies to enable search over fine-grained comparison results.

Secondly, we could look more into automatic taxonomy discovery. Currently, we assume a closed-domain approach with a taxonomy of leaderboards known in advance. While manually extending the taxonomy requires only adding the task, dataset and metric names, it becomes problematic to cover a large fraction of papers due to publication rate and long tail of leaderboards.

Finally, to relax the necessity of AXCELL to have access to LaTeX source we consider using the ARXIVPAPERS dataset as a corpus to train extraction working directly with PDF files.

8 Conclusions

We presented a pipeline for extracting results from machine learning papers. Our method performs well across various tasks and leaderboards within machine learning, with a taxonomy that can be easily extended without retraining. Additionally we released a new collection of datasets for training and evaluating on the results extraction task. These datasets enable the training of more fine-grained feature extractors and detailed error analysis. We demonstrated that our approach achieves significant performance gains over the state-of-the-art. Future work may want to build on our approach for more comprehensive extraction tasks, focussing on more types of result, as well as other information contained in papers such as architectural details and hyperparameters.

A Training Details

A.1 Language Model Pre-training

Table Type Classifier and Table Semantic Segmentation models use ULMFiT architecture (Howard and Ruder, 2018) with a language model pretrained from scratch on the ARXIVPAPERS dataset. We trained a single language model with most of the hyperparameters set to the defaults from the fast.ai implementation (Howard and Gugger, 2020) (see Table 5).

All ULMFiT-based models were trained on a single NVIDIA Tesla V100 GPU instance with 16 GB of memory. See the corresponding Jupyter notebooks for the average training times.

A.2 Table Type Classifier

We use the pre-trained language model described above to train Table Type Classifier on the SEGMENTEDTABLES dataset. We used the Image Classification fold of the SEGMENTEDTABLES dataset as a validation set, Speech Recognition fold as a test set and the remaining 9 folds as a training set. We run grid search over configurations presented in Table 6. The model with the best binary accuracy (distinguishing leaderboard and ablation tables from irrelevant tables) on the validation set is used in AXCELL. All models are trained for 12 epochs in total with gradual unfreezing of encoder layers.

Table 6: ULMFiT table classifier hyperparameters. Multiple values were used for grid search, with the same 5 random seeds per configuration. The final configuration is in bold.

A.3 Table Semantic Segmentation

We use the pre-trained language model and folds of the SEGMENTEDTABLES dataset. We used the Image Classification fold as a validation set. For each of the remaining 10 folds we run grid search with a given fold used as a test set and the other 9 folds used as training data. The search was performed over the configurations showed in Table 7. The model with the best micro F_1 score on the validation set is used in AXCELL. Table 8 presents features input to the model. All models are trained for 10 epochs in total.

Table 8: Features For Table Segmentation

Feature	Description

B Datasets

B.1 ARXIVPAPERS Dataset

The ARXIVPAPERS dataset consists of 104,710 papers published on arXiv.org in the following categories: Artificial Intelligence (cs.AI), Computation and Language (cs.CL), Computer Vision and Pattern Recognition (cs.CV), Information Retrieval (cs.IR), Machine Learning (stat.ML, cs.LG), Neural and Evolutionary Computing (cs.NE).

When submitting a preprint to arXiv.org the submitter must either[7] grant arXiv.org a non-exclusive and irrevocable license to distribute the article[8] or select one of CC BY 4.0, CC BY-SA 4.0, CC BY-NC-SA 4.0 or CC0 1.0 public domain license. Currently the most common is the first, default option. Additionally, arXiv.org provided metadata of submitted papers is available in public domain.

Table 10: Statistics of the NLP-TDMS (Hou et al., 2019) Full and Exp datasets.

	Full	Exp
unique leaderboards	168	77
unique tasks	35	18
unique datasets	99	44
unique metrics	72	30
papers	332	332
results	848	606

As a consequence of legal requirements we are not able to fully publish the dataset of articles in a ready to use form, with extracted texts and tables. In order to make research in this area reproducible and results comparable, we publish our extraction pipeline and detailed information of extraction results. In particular, each paper contained in the ARXIVPAPERS dataset includes the following fields:

- arxiv_id: arXiv identifier with version,
- archive_size: the file size in bytes of the e-print archive,
- sha256: SHA-256 hash of the e-print archive,
- title: paper's title,
- status: the text and tables extraction status for this paper, one of: success, no-tex (LaTeX source is unavailable), processing-error (extraction issues), withdrawn (the paper is withdrawn from arXiv),
- sections: number of extracted sections and subsections,
- tables: number of extracted tables.

Extraction of texts and tables from papers was run on a single machine with 48 cores / 96 threads CPU with 2.5 GHz base clock. See the corresponding Jupyter notebooks for the average extraction time.

B.2 SEGMENTEDTABLES and LINKEDRESULTS datasets

The SEGMENTEDTABLES dataset contains annotations of 1,994 tables. Each paper contains the following fields:

---

[7] `https://arxiv.org/help/license`

[8] `http://arxiv.org/licenses/nonexclusive-distrib/1.0/license.html`

Table 11: Statistics for the SEGMENTEDTABLES and LINKEDRESULTS datasets.

ablation tables	468
LINKEDRESULTS	
unique leaderboards	470
unique tasks	56
unique datasets	245
unique metrics	88
papers	239
results	1591

- arxiv_id: arXiv identifier with version,
- sha256: SHA-256 hash of the e-print archive,
- fold: one of 11 folds (image classification, image generation, machine translation, miscellaneous, natural language inference, object detection, pose estimation, question answering, semantic segmentation, speech recognition, text classification), assigned automatically based on tasks names found in paper's abstract,
- tables: annotated tables with
  - index: 0-based index of tables extracted from paper,
  - leaderboard: a boolean denoting if this table is a leaderboard table,
  - ablation: a boolean denoting if this table is an ablation table,
  - dataset_text: datasets mentioned in table's caption, not normalized,
  - segmentation: for leaderboard tables, a 2D array (list of lists) with one label per cell.

Additionally we annotated a subset of the tables present in SEGMENTEDTABLES with performance results. Each table has an array of records with items containing the following fields:

- task, dataset, metric: task, dataset and metric names normalized across all papers from the dataset,
- value: normalized metric value,
- model: model name,
- row, column: 0-based cell location with this result.

Annotation Process Both datasets were annotated in our custom made web interface. For each paper the annotator is present with: title, abstract, tags (user editable), notes (user editable) and extracted tables. The interface allows annotators to quickly consult: PDF version of the paper, HTML version of the paper, Papers With Code and Semantic Scholar pages of the paper.

For each table extracted from the paper we show:

- caption (extracted),
- dataset text (user editable): caption fragment denoting datasets presented in the table,
- notes (user editable),
- tags (user editable),
- table content with color-coded segmentation.

Dataset text field denotes comma separated mentions of datasets found in table's caption. For example, for caption “Table 8: WER on SWB and CH with various LM configurations.” the annotators were instructed to put “SWB, CH”, i.e., to use exact form from the caption and not the full dataset name.

Table tags are defined as follows:

- leaderboard: table contains the principal results of the paper, including comparisons with other papers,
- ablation: table compares different variants of the paper's methodology,
- error: parsing error in the table extraction,
- datasets: table describing datasets used in the paper,
- architecture: table listing hyperparameters or architecture details,
- irrelevant: other type of tables, f.e., showing samples from a dataset.

The SEGMENTEDTABLES dataset contains tables not tagged with *error* label. Table tags are not exclusive.

For semantic segmentation, tables are present as a grid. An annotator can select a range of cells and assign them one of the following classes:

- best model: the best performing model introduced in the paper being annotated,
- paper model: model introduced in the paper that is not the best performing,
- competing model: model from another paper used for comparison or a baseline method used by authors,
- subdataset: subdataset (f.e., “dev”, “test” or “MS-COCO Trees”,
- dataset,
- paper dataset: dataset introduced in the paper
- metric,
- error: parsing issue, not required if the table is tagged with the *error* tag,
- parameters: model parameters used to distinguish various configurations (f.e., number of parameters, hidden state size, backbone network),
- meta: cell describing what is in other cells, f.e., “Model”, “Dataset”, “Task”, “Our models”.

Segmentation annotation was done for tables labelled with the *leaderboard* tag. In order to easy present the color-coded table structure the cell tags are exclusive. For cells for which more than one tag applies, the annotators were instructed to use most informative tag. For example, a cell containing “TIMIT PER” should be tagged as “dataset” and not “metric”, as metric is often implied by dataset.

By selecting cells an annotator can annotate what is in corresponding cells by editing a dynamically created spreadsheet-like grid. The grid allows one to specify: task name, dataset name, metric name, metric value and model name. The annotators were instructed to provide records only for cells corresponding to the best performing models introduced in a given paper.

The interface allows to link directly to a particular table to make it easy for annotators to consult ambiguous cases.

B.3 PWC LEADERBOARDS dataset

The PWC LEADERBOARDS dataset is based on open data published by Papers With Code and annotated by their community. We converted the data into format similar in structure to the LINKEDRESULTS dataset.

C Mention Probabilities

Using the methodology from Section 3.4, we can calculate $p\left(k \mid E\right)$ by combining probabilities of mentions, $p\left(m \mid \neg n, t, \text{property}(t,k)\right)$.

We compute all possible mentions directly from tasks, datasets and metrics names appearing in leaderboards. For a name of dataset or metric the mentions list consists of the whole name as well as each word, without duplicates and English stop words. As tasks names often consist of common words, to limit the number of false positives the mentions list for a given task contains only that task’s name. The mentions can be additionally extended with human curated lists or abbreviations extracted from papers, as described in Section 6.3.

Let $R(t) = \{\text{property}(t, k) : k \in \{1, \ldots, K\}\}$ be a set of all entities of type t and let $M(t, r)$ denote a set of all possible mentions for a given entity $r \in R(t)$. We compute the probability $p\,(m \mid \neg n, \text{property}(t, k))$ assuming all mentions (separately for tasks, datasets and metrics) for a given entity r are distributed uniformly, $p\,(r \mid \neg n, t, m) = 1/|M(t, r)|$. We then use Bayes rule to get $p\,(m \mid \neg n, \text{property}(t, k))$, assuming that all mentions of a given type are distributed uniformly. This results in the conditional probability of a mention being inversely proportional to the number of entities having that mention evidence in common:

$$p\,(m \mid \neg n, t, \text{property}(t, k)) \propto \frac{1}{|\{r' \in R(t) : m \in M(t, r')\}|}.$$

Abstract

Open attribute value extraction for emerging entities is an important but challenging task. A lot of previous works formulate the problem as a *question-answering* (QA) task. While the collections of articles from web corpus provide updated information about the emerging entities, the retrieved texts can be noisy, irrelevant, thus leading to inaccurate answers. Effectively filtering out noisy articles as well as bad answers is the key to improving extraction accuracy. Knowledge graph (KG), which contains rich, well organized information about entities, provides a good resource to address the challenge. In this work, we propose a knowledge-guided reinforcement learning (RL) framework for open attribute value extraction. Informed by relevant knowledge in KG, we trained a deep Q-network to sequentially compare extracted answers to improve extraction accuracy. The proposed framework is applicable to different information extraction system. Our experimental results show that our method outperforms the baselines by 16.5 - 27.8%.

1 Introduction

Numerous entities are emerging everyday. The attributes of the entities are often noisy or incomplete, even missing. In the field of electronic commerce, target attributes (e.g., brand, flavor, smell) of new products are often missing (Zheng et al., 2018). In medical analysis, attributes like transmission, genetics and origins of a novel virus are often unknown to people. Even in DBpedia, a well-constructed and large-scale knowledge base extracted from Wikipedia, half of the entities contain less than 5 relationships (Shi and Weninger, 2018). A method that is capable of supplementing reliable attribute values for emerging entities can be highly useful in many applications.

Although information extraction methods have been extensively studied, the task of open attribute value extraction remains challenging. First, the emerging entities may have new attribute values that are absent in the existing KG. Under such circumstances, the prediction methods under the closed-world assumption and the methods that cannot utilize external information are not well suited due to their limited recalls. Second, while web corpus can be used as a good resource to provide relatively updated and relevant articles for large varieties of emerging entities, the articles retrieved from web corpus can be noisy and/or irrelevant, which in turn leads to a limited precision. Finally, even when articles are relevant, the extracted answers might still be inaccurate due to the error-prone information extraction model.

To effectively filter out noisy answers that are obtained either due to the irreverent articles or the errors incurred by the information extraction system, we pose the following two questions: First, how many articles should we collect from the enormous web corpus? Second, how to select the most reliable value out of the pool of all the possible answers extracted from the articles?

There is no common answer to the first question that works for all triplets because of the inconsistent degrees of difficulties in finding the correct attribute values. The decision of when to stop querying more external articles needs to be made after successive evaluations of the candidate answers. Thus the decision making process is inherently sequential.

Reinforcement learning (RL) is a commonly adopted method to deal with sequential decision problems and has been widely studied in the field of robotic and game (Sutton et al., 1998). But

Figure 1: Illustration of overall process. The inputs are pairs of entities and attributes. Relevant articles are retrieved via search engines. The articles together with the KG are fed into the RL agent to inform the selection between candidate answers and the stopping decisions. When the RL agent decides to stop, it will output the best extracted answer.

there are not many researches on open attribute value extraction with RL. One existing literature of RL-based method for value extraction is proposed by (Narasimhan et al., 2016). In their work, a RL framework is designed to improve accuracy of event-related value extraction by acquiring and incorporating external evidences. However, their approach requires a great amount of context information about the specific event of interest during the training process. It is not trivial to extend their framework for open attribute value extraction, because we would need to collect context words and train a new model with annotated data for each emerging attribute. Therefore, their framework cannot be generalized to open attribute value extraction task when various entities and attributes are involved.

While using the context words to construct the states in RL is not suitable in our task, our solution is to leverage the rich, well-organized information in KG, which is not only informative but also generalizable. Such information can be leveraged in answer comparisons, which addresses our second question. For example, to fill the incomplete triplet $<$ *iPhone 11*, *display resolution*, ?$>$, from the KG we may find that the attribute values "display resolutions" of an entity that is under category "Phone" is commonly expressed in the format of "xxx by xxxx Pixels", where x stands for some digit. The typical instances of the attribute values for entities under the same category provide valuable background information.

In this paper, we propose a knowledge-guided RL framework to perform open attribute value extraction. The RL agent is trained to make good actions for answer selection and stopping time decision. Our experiments show that the proposed framework significantly boosts the extraction performance.

To the best of our knowledge, we are the first to integrate KG in a RL framework to perform open attribute value extraction In summary, our contribution are in three folds:

- We construct a novel knowledge-guided RL framework for open attribute value extraction task.
- We provide a benchmark data set for open attribute value extraction task.
- Our method achieves a significantly better performance than the state-of-the-art methods.

2 Overview

Problem Definition

We denote the entity-attribute-value triplet as $< e, r, v >$. The goal is to find the attribute value in an incomplete triplet $< e, r, ? >$. To achieve this purpose, we pose a question generated with a pre-defined template to search engine to obtain relevant articles. For example, to fill the incomplete triplet $<$ *GTX1080*, *Core code*, ?$>$, we retrieve articles with the query "What is the core code of GTX1080?".

An information extraction system, such as QANet (Yu et al., 2018), is used to extract a candidate answer with a certain confidence score from an article. However, due to the inconsistent qualities of the online articles and the inevitable errors caused by the information extraction system, the results of extracted from only one online article is not satisfactory in many cases. Another source of information that can be leveraged help to fulfill such a task is a KG. While it is hard to find out the attribute values for an emerging entity given the existing ones, the KG can serve as the background knowledge about the attributes. We approach the problem using a reinforcement learning framework that is illustrated in the next section.

System Overview

Our procedure is summarized in Figure 1. We use <*GTX1180*, *core code*, ?> as an example for illustration. The query "What is the core code of GTX1180?" is posed to the search engine to obtain a collection of relevant articles by downloading the top M headlines and bodies in the searching page. M is a pre-determined parameter that controls the maximum capacity of the retrieved articles. For each of the retrieved articles, we use an information extraction system to extract a candidate answer. In our example, *RTX2080* is extracted with a confidence score of 0.30 from the first queried article and *GV104* is extracted with a confidence score of 0.25 from the second article. Given the first two candidate answers, the RL decides on which answer to pick and whether more articles need to be retrieved.

To make such decisions, in addition to the confidence evidence from the information extraction system, the relevant facts in the KG will be fed into the RL agent to serve as the background knowledge about the attribute. For a triplet $< e, r, ? >$, we consider v^r as a reference value with respect to the attribute r if there is a triplet $< e', r, v^r >$ and e, e' belong to the same category[1] in the KG. In our example, since *GTX1180* belongs to the category *NVIDIA GPU*, and so does *GTX1080* and *GTX980*, the reference values are retrieved from the fact that the *core code* of *GTX1080* is *GP104* and the *core code* of *GTX980* is *GM204*. Guided by the KG, the RL agent makes successive evaluations and finally outputs the predicted candidate attribute value via a policy network such as DQN (Mnih et al., 2015).

3 Reinforcement Learning for Open Attribute Value Extraction

The attribute value extraction task is modeled as a *Markov decision process* (MDP), where the RL agent is actively engaged in the decision making process to maximize the reward, which measures the correctness of the extracted attribute values.

The MDP is modeled as a tuple (S, A, T, R), where $S = \{s\}$ is the space of all possible real-valued vector states; $A = \{a\}$ is the set of actions; $T(s'|s, a)$ refers to a transition function that maps the domain of state and action to a probability distribution of states; $R(s, a)$ is a reward function that maps the domain of state and action to a real number, which is encoded such that the higher value the better. We describe our RL methodology by illustrating these components as follows.

Action and transition At each decision stage, the agent will observe two candidate answers from two articles and make decisions to answer the two questions: (i) which answer is better out of the two? (ii) should the agent stop at *the current best answer* or continue querying more articles? At the initial decision point, two candidate answers are obtained from two articles simultaneously queried from the web, where we arbitrarily assign one of them to be the current best answer and the other the new candidate answer.

We define the following three actions in A:

1. *Retain*: (i) retain the current best answer and discard the new answer; (ii) query next.
2. *Replace*: (i) replace the current best answer with the new answer; (ii) query next.
3. *Stop*: (i) select the current best answer as the final answer; (ii) stop the query.

At all subsequent decision points, we will retain or replace the *current best answer* and continue comparing with the *new candidate answers* queried from the web until the action is *"Stop"*.

State At each decision point, the state is constructed by concatenating the following three components, where different sources of information are combined.

(1) State variables associated with the confidence scores. The first component is the confidence scores associated with the two candidate answers, which are defined by the information extraction system. We consider this part as the signal

---

[1] The category information is obtained from concept of CN-DBpedia. The knowledge base contains multi-level hierarchy of categories. We use the lowest-level (most specific) category in the hierarchy to derive the reference values.

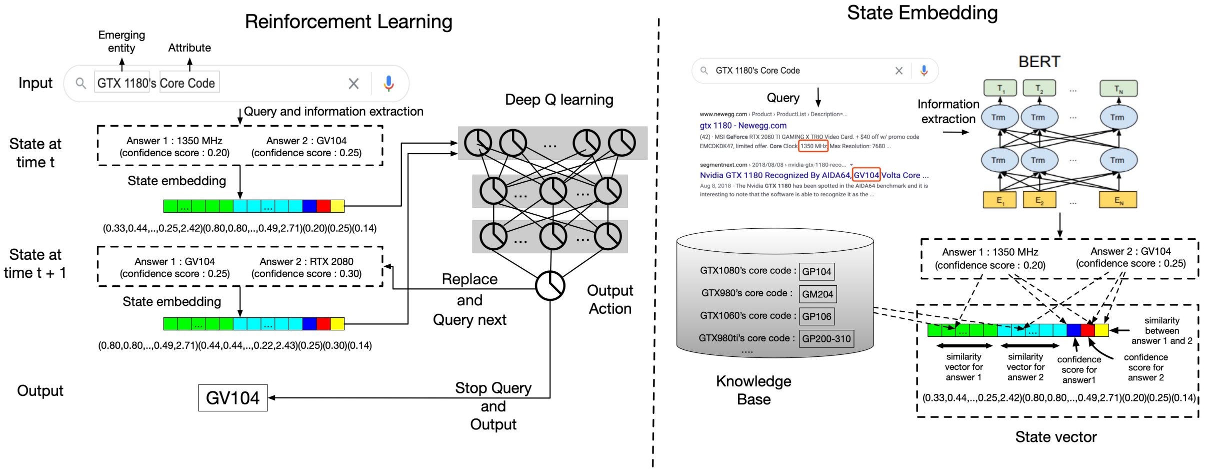

Figure 2: An example of reinforcement learning framework and state embedding. On the left panel, the inputs are the emerging entities and attributes. *The current best answer* and *the next candidate answer* are extracted from the retrieved articles with an information extraction system. The extracted answers are embedded into a state vector from the state embedding process. The state vector is fed into a policy network (DQN). The policy network selects the optimal actions and outputs the current best result. On the right panel, it presents the state embedding process. The extracted candidate answers are embedded into a state vector via similarity metrics and confidence scores.

of the goodness of the extracted answers related to the articles.

(2) State variables informed by the KG. The second component leverages knowledge from the reference values. For a given attribute, we expect the attribute values to be similar to each other in lexical sense. In order to capture such information, we first construct 7 features based on 2 string lexical similarity metrics. For each of the 7 features, we take the average and maximum of the features for each of the two candidate answers as state variables.

String similarity metrics The two string lexical similarity metrics as follows:

$$L\_Sim(s_1, s_2) = 1 - \frac{L(s_1, s_2)}{max(|s_1|, |s_2|)},$$

$$LCS\_Sim(s_1, s_2) = \frac{|LCS(s_1, s_2)|}{max(|s_1|, |s_2|)},$$

where $L(s_1, s_2)$ refers to Levenshtein distance (Levenshtein, 1966). It measures how different two strings are by counting the number of deletions, insertions or substitutions required to transform s_1 into s_2. $L\_Sim(s_1, s_2)$ is known as the Levenshtein similarity and $LCS(s_1,s_2)$ stands for the longest common sub-string of s_1 and s_2 (Gusfield, 1997).

Features based on similarity We define the following 7 features to capture the similarity between two strings from different aspects:

- f_1: *L_Sim* between s_1 and s_2;
- f_2: *LCS_Sim* between s_1 and s_2;
- f_3: *L_Sim* between s_1 and s_2 with numbers removed from s_1, s_2;
- f_4: *LCS_Sim* between s_1 and s_2 with numbers removed from s_1, s_2;
- f_5: *L_Sim* between s_1 and s_2 with s_1, s_2 wildcard masked[2];
- f_6: *LCS_Sim* between s_1 and s_2 with s_1, s_2 wildcard masked;
- f_7: The difference in the length of s_1 and s_2 in characters.

Construction of state variables by the KG For each of the 7 features, given the reference values in V^r and the two candidate answers, *answer*$_1$ and *answer*$_2$, we form the 28 state variables in this part by taking averages and maximums, which is specified as follows:

$$\begin{cases} \frac{1}{|V^r|}\sum_{\ell=1}^{|V^r|} f_i(answer_1, v_\ell^r), \\ \max_{\ell=1}^{|V^r|} f_i(answer_1, v_\ell^r), \\ \frac{1}{|V^r|}\sum_{\ell=1}^{|V^r|} f_i(answer_2, v_\ell^r), \\ \max_{\ell=1}^{|V^r|} f_i(answer_2, v_\ell^r), \end{cases}$$

for $i = 1, \dots, 7$. This is the part of the state where knowledge from KG is used to inform the decision of the RL agent.

---

[2] Wildcard mask means masking the numbers in the string. For example, a string "750 by 1334 Pixels" will be masked to "xxx by xxxx Pixels".

(3) State variables based on the candidate answers The third component contains the Levenshtein similarity between the two candidate answers. Intuitively, when the confidence scores of both candidate answers are high and they are very similar to each other, then it shows some positive signal for stopping.

The components (1) - (3) are concatenated together to construct the 31-dimensional state vector to carry information from different perspectives.

Reward The reward is set to 0 when the query process is ongoing; only at the final stage when the query is terminated, a nonzero reward is received, which measures the similarity between the final answer and the correct answer.

$$R(s,a) = \begin{cases} L\_Sim(\hat{v}, v) & a \text{ is } \textit{Stop}, \\ 0 & \text{otherwise}, \end{cases}$$

where $\hat{v}$ is the selected best attribute value and v is the true attribute value.

Method Since the state defined in our framework is from a continuous space, we adopt a deep Q-network (DQN) to approximate $Q(s,a)$ with a deep neural network denoted by $Q(s,a;\theta)$. Specifically, we parameterize an approximate value function $Q(s,a;\theta)$ using a three-layer deep neural network. The network takes the continuous 31-dimensional state vector s as input and predict $Q(s,a)$. We use the rectified linear unit (ReLU) activation functions in the hidden layers. The architecture is illustrated in Figure 2.

Algorithm 1 provides complete details of our MDP framework for the DQN training phase.

4 Experiments

In this section, we compare our proposed RL framework to the state-of-the-art extraction-based baselines, demonstrating its robustness and ability to obtain accurate answers for missing attribute values. Our codes are publicly available online.[3]

4.1 Data

The dataset is generated from existing triplets using the largest public Chinese knowledge base, CN-DBpedia (Xu et al., 2017), with a corresponding taxonomy CN-Probase. [4] Specially, the number of

```
Initialize a set of training triplets
    $x_i =< e_i, r_i, v_i >\in X$
Initialize parameters $\theta$ randomly
Initialize replay memory $\mathcal{D}$
for $x_i \in X$ do
    Download M articles by searching with query "$[e_i]'s[r_i]$"
    Queue the downloaded articles in $C_i$
    Identify reference values from the KG and save them in $V_i^r$
for epoch = 1, ...,E do
    for $i = 1, \ldots, |X|$ do
        Pop the first two articles in $C_i$ and obtain answer$_1$ with confidence$_1$ and answer$_2$ with confidence$_2$
        Form the state $s_1$ given answer$_1$, confidence$_1$, answer$_2$, confidence$_2$, $V_i^r$
        for $t = 1, \ldots, M-1$ do
            With probability $1-\epsilon$ select $a_t = \text{argmax}_a Q(s_t, a; \theta)$ otherwise select $a_t$ randomly
            if $a_t$ is not "Stop" then
                $r_t \leftarrow 0$
                Pop next article from $C_i$ and obtain answer$_{\text{new}}$ with confidence$_{\text{new}}$
                if $a_t$ is "Retain" then
                    answer$_2$ ← answer$_{\text{new}}$
                    confidence$_2$ ← confidence$_{\text{new}}$
                if $a_t$ is "Replace" then
                    answer$_1$ ← answer$_2$
                    confidence$_1$ ← confidence$_2$
                    answer$_2$ ← answer$_{\text{new}}$
                    confidence$_2$ ← confidence$_{\text{new}}$
                Form a new state $s_{t+1}$
            else
                $\hat{v}_i \leftarrow$ answer$_1$
                $r_t = L\_Sim(\hat{v}_i, v_i)$
                $s_{t+1} \leftarrow NULL$
            Store transition $(s_t, a_t, r_t, s_{t+1})$ in $\mathcal{D}$
            Sample random mini batch of transitions $(s_t, a_t, r_t, s_{t+1})$ from $\mathcal{D}$
            $y_t = r_t$ if $a_t$ is "Stop"
            else $r_t + \gamma max_{a'} Q(s_{t+1}, a'; \theta)$
            Update parameter $\theta$ on the loss $\mathcal{L}(\theta) = (y_t - Q(s_t, a_t; \theta))^2$
            if $a_t$ is "Stop" then break
```

---

[3] https://github.com/yeliu0930/Knowledge-guided-Open-Attribute-Value-Extraction-with-Reinforcement-Learning

[4] As far as we know, there is no public benchmark dataset suitable for our open attribute value extraction task with labeled values.

training triplets is 1022. The selected entities in the experiment are from four different fields, including GPU, game, movie and phone. The testing data contains 75 triplets for each field, hence the total number of triplets in the testing is 300. For each triplet in the training and testing data, we download articles from top $M = 10$ links obtained from the Baidu search engine. The CN-DBpedia is used as our external KG with the triplets in training and testing masked and to provide reference values.

4.2 Reinforcement Learning Implementation

In the RL setting, we use DQN to train the policy. Specifically, the DQN contains three layers of multilayer perceptron (MLP). The dimensions of hidden layers in MLP are chosen as 10 and 5 respectively. The dimension for the output is 3 which represents the three actions. In our experiments, the DQN model is trained 100 epochs where each epoch contains 1,000 transitions. We use a decreasing learning rate with epochs during the training process[5]. The ϵ in ϵ-greedy exploration is annealed from 1 to 0.02 over 10,000 transitions. The replay memory $\mathcal{D}$ is of size 10,000. We deploy our RL model in RLlib (Liang et al., 2017) for efficiently distributed computation.

4.3 Information Extraction System

Different information extraction methods are implemented during the experiment. Sequence labeling methods including Bi-LSTM labeling, Bi-LSTM-CRF labeling (Huang et al., 2015), CNN labeling (Collobert et al., 2011), CNN-att-CRF labeling (Tan et al., 2018), and OpenTag labeling (Zheng et al., 2018) are used. We also consider three *Machine Comprehension* (MC) models, including BiDAF (Seo et al., 2016), QANet and a Bert-based model(Devlin et al., 2018). The SQuAD-like Chinese open-domain MC datasets including WebQA (Li et al., 2016b) and CIPS-SOGOU factoid question-answering subtask dataset [6] are used to train the extraction systems with distant supervision.

4.4 Competitors

We experimented with three traditional aggregation methods and four variants of RL agents as the competitors during the experiment.

Traditional Aggregation Methods

1. Random choice (*Random*): We randomly select an article out of M articles and extract an answer from it with the information extraction system as the final answer.

2. First article (*First*): We use the answer extracted from the article that ranked first in the search engines.

3. Majority aggregation (*Majority*): We use a majority vote strategy over all the extracted answers.

4. Confidence aggregation (*Confidence*): The answer with the highest confidence score out is chosen as the final answer. This aggregation method is only feasible when each candidate answer is associated with a confidence score.

Variations of the RL framework

1. *RL-NK*: (No KG included) The RL agent do not leverage the information from KG. The KG-dependent part (i.e. the component (2) in state construction) is omitted from the state.

2. *RL-NR*: (No retain or replace actions) The only action in the RL framework is *Stop*. The final answer is the one with the highest confidence score among candidate answers seen before stop.

3. *RL-NS*: (No stop action) The RL agent do not make *Stop* decisions. All of the M extracted candidate answers are compared.

4. *RL-KG*: Our proposed RL framework.

Since the sequence labeling methods cannot provide valid confidence scores associated with the candidate answers, the answers extracted with these methods are aggregated using *Random* and *Majority* strategies. For the MC models, we implemented all the aggregation strategies including our RL-based methods.

4.5 Results

Our evaluating metric is the Levenshtein similarity between the final answer and the ground truth, which ranges from 0 to 1 and higher score represents better performance. The results are summarized in Table 1 when different information extraction systems are combined with different aggregation strategies. The results are evaluated separately under each field and the combined results are also reported in the tables. All results reported are averaged over 3 independent runs. The oracle performances are provided to differentiate the error incurred by imperfect decisions and the inherent errors caused by the information extraction system.

---

[5] The learning rate schedule is set to [[0, 0.05], [20, 0.01], [30, 0.005], [50, 0.001]].

Table 1: Accuracy of the baseline methods and our proposed methods. Bold indicates best baseline performances with a sequence labeling methods and best results achieved with BiDAF/QANet/BERT. The Oracle performance shows the best possible performance when perfect decisions are made. **Our proposed RL-KG improves the extraction performances substantially.**

From Table 1, we have the following observations. First, the RL based methods outperform all the competing baseline methods. By adopting the RL framework instead of traditional aggregation methods, the accuracies are boosted substantially. It demonstrate the effectiveness of the RL framework. Second, compared to the RL framework without the guide of KG (*RL-NK*), our proposed *RL-KG* framework achieves significantly better results. This suggests that the KG does provide valuable information in the task of the attribute value extraction. Third, the *RL-KG* framework outperforms all the other variants of the RL framework. It shows that considering answer selection and stopping decisions at the same time achieves the best performances.

We also conduct an experiment to see how our method performs when the KG is not able to provide information for some triplets, which is a common situation in reality. During the experiment, we randomly set the reference values for $0-100$ (incremented by 10) percent of triplets in the training and testing as empty. For those triplets that do not have reference values, the state variables associated with the KG (i.e. the component (2) in our state construction) are set to 0. Figure 3 displays how the performances change when information from KG is leveraged with different levels of frequency. It can be seen that for all the three information extraction models, the performances are getting better as the KG is used at higher frequencies.

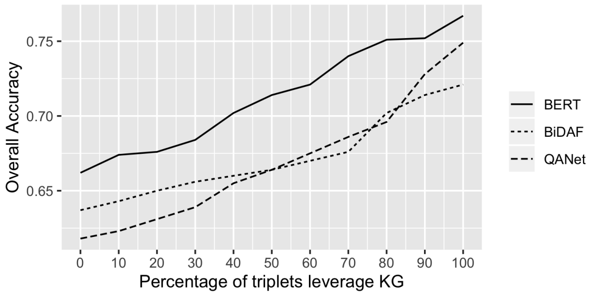

Figure 3: Extraction accuracy when KG is used with different levels of frequency. **Better extraction results are achieved when KG is used with higher frequencies.**

4.6 Case Study

By incorporating information from KG, RL agent is able to rule out some unreasonable answers and boost the extraction accuracy.

In Table 2, we present some cases where the trained RL agent helps to correct the information extraction errors. More details for the first two examples are included in Table 3. For the first example in Table 3, the emerging entity is *Founder r680-470* and the attribute of interest is *operating system*. The reference values retrieved from the KG include values like *IOS, DOS, Andriod, EMUI*. The trained RL agent stops after querying the six raw corpus and selects the answer *DOS* over the previous candidate values, which is exactly one of the reference values. In the second example in Table 3, we are interested in the *release date* for the emerging entity *super puzzles game*. The reference val-

Entity	Attribute	Truth	*RL-KG(BERT)*	*Confidence(BERT)*
Founder r680-470	Operating system	DOS	DOS	T2410

ues are dates like *02/24, 03/27/2018, 05/07/2016*, etc. The trained RL agent stops after one step, and outputs the candidate answer *12/25/2007*. By leveraging the reference values, our proposed method demonstrated its advantages in answer selection.

5 Related Work

5.1 Machine reading comprehension

Machine reading comprehension (MRC) and automated question (QA) answering are important and longstanding topic in NLP research due to its huge potentials in wide variety of applications. An end-to-end MRC QA models are expected to have the ability to read a piece of text and then answer questions about it. Significant progress has been made with the machine reading and QA task in recent years. Some notable works include BiDAF (Seo et al., 2016), SAN (Liu et al., 2017), QANet, ALBERT (Lan et al., 2019).

Our proposed framework can also be regarded an end-to-end MRC QA model that is built on top of an existing MRC QA model, which is used as the information extraction system in our extraction process. Different from most of the previous works, our focus is to enhance the performance of an existing model by utilizing external information from KG and by acquiring more articles when the agent does not feel confident about the extracted answer.

5.2 Open-world knowledge graph completion

Attribute value extraction under the open world assumption has received many attentions in NLP community recently. There has been quite a few works on open attribute value extraction. OpenTag (Zheng et al., 2018) formalized the extraction problem as a sequence tagging task and proposed an end-to-end framework for open attribute value extraction. The open-world KGC (Shi and Weninger, 2018) used a complex relationship dependent content masking architecture to mitigate the presence of noisy text descriptions and extract the attribute value from the denoised text. TXtract (Karamanolakis et al., 2020) incorporated the categorical structure into the value tagging system. However these methods suffer from irrelevant articles and is not able to filter out noisy answers.

5.3 NLP with reinforcement learning

RL (Sutton et al., 1998) is a framework that enables agents to reason about sequential decision making as an optimization process. It has been widely applied in NLP tasks, including article summarization (Paulus et al., 2017; Li et al., 2018; Celikyilmaz et al., 2018), dialogue generation (Li et al., 2016a; Serban et al., 2017; Li et al., 2019), and question answering (Xiong et al., 2017; Wang et al., 2018; Das et al., 2019) and so on. To the best of our knowledge, we are the first to integrate information from KG into a RL framework to fulfill the attribute extraction task.

6 Conclusion and discussion

This paper presents a novel RL framework to perform open attribute value extraction. Through a set of experiments, we observe that the most of the computation cost is incurred by training the information extraction system. The remaining computation cost from RL framework is comparably small during both the training and the prediction process. Specifically, during our experiments, we trained a three-layer deep neural network model, which has much fewer parameters compared to the information extraction system. The proposed RL method demonstrates promising performance, where the KG showed its ability to provide guidance in open attribute extraction task. Our framework also contributes to areas of knowledge graph completion and automatic question-answering for attribute values.

KG has huge potential to provide rich background information in many NLP applications. Our solution for attribute value extraction can be extended to other NLP tasks. A potential attempt might be to use KG to design the reward in the RL framework to provide weak supervision. We leave this as our future work.

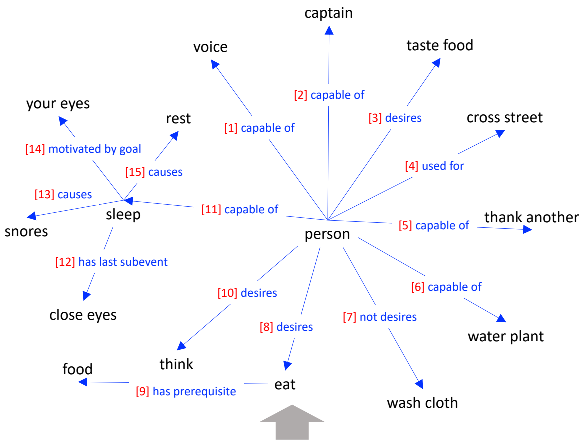
Abstract

In this work, we present a dual learning approach for unsupervised text to path and path to text transfers in Commonsense Knowledge Bases (KBs). We investigate the impact of weak supervision by creating a weakly supervised dataset and show that even a slight amount of supervision can significantly improve the model performance and enable better-quality transfers. We examine different model architectures, and evaluation metrics, proposing a novel Commonsense KB completion metric tailored for generative models. Extensive experimental results show that the proposed method compares very favorably to the existing baselines. This approach is a viable step towards a more advanced system for automatic KB construction/expansion and the reverse operation of KB conversion to coherent textual descriptions.

1 Introduction

The automatic construction of Knowledge Bases (KBs) from text and the reverse operation of sentence generation from KBs are dual tasks that are both active research topics.

The first task of automatic KB construction remains a significant challenge due to the difficulty of detecting parts of text representing meaningful facts and summarizing them in a systematic form. A simpler sub-task of KB completion, i.e., extending or filling-in missing nodes or edges, has also attracted the attention of the research community. For both tasks, the system needs to generate new or complete existing graph entities coherently, possibly matching to the already existing graph structure. The dual task of decoding the information from KB back to text is a valuable functionality. This enables knowledge transfer from potentially large complex graphs into a more descriptive, human-friendly output. This conditional generation is often seen as a step towards learning using KB as prior knowledge.



[1] a person can voice an opinion

[15] you sleep to rest.

Figure 1: Text to Path. Part of a larger graph generated from test sentences from our dataset. Sentences below the graph were a subset of inputs provided to the model.

In this work, we address the problem of KB construction/completion and the reverse task of KB decoding, but aim at a simpler objective: transferring a single sentence to a path, and generating text from a single KB path as its dual task. In terms of data, our focus will be on Commonsense KBs, derived from sets of commonsense facts expressed in natural language sentences (Lenat, 1995; Cambria et al., 2014; Speer et al., 2017; Sap et al., 2019). They are represented as graphs where each edge is expressed as a tuple (e_h, r, e_t) with head and tail nodes e_h and e_t composed of free-form text, connected with a relationship operator r; see

ConceptNet from Speer et al. (2017) or ATOMIC in Sap et al., 2019 for recent and commonly used examples of commonsense KBs.

We observe that to train such transfer model, an additional challenge comes from the lack of datasets with parallel text and KB facts, i.e., where text sentences and KBs edges are explicitly paired/labeled from one to another. However, there exist many datasets for each individual transfer domain. Therefore, successful approaches transferring text to KB and KB to text must be able to operate in unsupervised or (at best) weakly-supervised settings. We address this challenge by proposing a model trained under dual learning of translation/transfer from text to KB and from KB to text, we name *DualTKB*. This is similar in philosophy to dual learning in Neural Machine Translation (He et al., 2016), or unsupervised style transfer (Shen et al., 2017; Tian et al., 2018; Dai et al., 2019). We design our model to be trained in completely unsupervised settings. However, we observed that even a slight supervision significantly boosts model performance and enables better-quality transfers. Therefore, we also describe a simple heuristic methodology to create weakly-supervised datasets given a text corpus and a commonsense KB.

We must emphasize that our proposed dual learning method is not limited to commonsense KBs and can generalize to other domains/types of KBs such as biomedical KBs. Commonsense KBs, and particularly ConceptNet, are good starting points due to the nature of their composition. Since ConceptNet was partly extracted from free-form text originating from the Open Mind Common Sense (OMCS) list of commonsense fact sentences, its nodes are often composed of parts of sentences from OMCS. This allowed us to first explore whether the proposed method worked at all before evaluating a semi-supervised approach by creating a weak supervision from a mapping between ConceptNet triples and the original OMCS sentences. While KBs are often dense with short named entity descriptions for nodes, many nodes for commonsense KBs are parts of sentences, making them inherently sparse which impacts their performance as empirically studied by Malaviya et al. (2020).

The evaluation of this type of transfer models is a challenge in itself. For this purpose, we selected a set of metrics to examine different facets of the system using our created weakly-supervised dataset.

Figure 2: Path to Text. Sentences generated by our system from a subgrapth of the ConceptNet dataset. The paths shown in the graph are the inputs to the model.

For path generation, we rely on a *conventional* KB completion task where the goal is to maximize the validity score of a tail entity e_t given the pair (e_h, r). For example, Malaviya et al. (2020) addresses the challenges unique to commonsense KB completion due to sparsity and large numbers of nodes resulting from encoding commonsense facts. However, KB completion does not always equate generation of edges, with the exception of COMET from Bosselut et al. (2019) that generates tail node e_t given the pair (e_h, r).

Since repurposing generative models for conventional KB completion evaluation is difficult (Malaviya et al., 2020; Bosselut et al., 2019), we propose a new commonsense KB completion evaluation task for generative models. It is close in spirit to conventional KB completion, but comes with its own set of challenges. Moreover, we employ the Graph Edit Distance (GED) to examine the quality of the generated graph as a whole. For text generation, we rely on traditional NLP metrics such as BLEU and ROUGE.

Following is a list of highlights of our paper contributions: (1) Propose a dual learning bridge between text and commonsense KB. Implement approach as unsupervised text-to-path and path-to-text transfers; (2) Construct a weakly-supervised dataset, and explore weak-supervision training. (3) Define a novel Commonsense KB completion metric tailored for generative models. (4) Investigate successfully multiple model architectures.

Finally, in Fig. 1 and Fig. 2 we present a few examples generated by our proposed model. Fig. 1 is a text to KB translation. Each sentence below the graph is independently transferred to a path, consisting of one edge tuple (e_h, r, e_t). The whole path tuple is generated at once, with e_h, r, and e_t taking a free-form not restricted to any predefined sets of entities or relations. This contrasts with many existing works operating on a limited discrete set of already-defined edges in a dense conventional KB. Once all the sentences are transferred, we observe that this set of generated edges forms a connected structure, implicitly merging some nodes to form a prototype of a Knowledge Graph (KG).

Fig. 2 shows the transfer from KB to text. Each path in the graph is converted to a sentence. There is overall diversity in the generated sentences styles. Moreover, the samples show that the generation process is more sophisticated than just a trivial path flattening (i.e., merging text from all edge parts followed by minimal edits). Therefore, the proposed approach can eventually become a part of a more sophisticated system converting graphs to a coherent textual story and vice versa. Additional examples are presented in Appendix A.4.

2 Dual Learning

In this work we propose to use a dual learning approach to build a model performing two distinct but complementary generative tasks described in Fig. 3, and using notations from Tab. 1:

Task 1 (text→path): Given a sentence x_{A}, generate a path x_{AB} with well-formed entities and relation, that can either belong to an already constructed KB, or extend it in a factually meaningful way. This conditional generation is framed as a translation task referred to as T_{AB} where $x_{\text{AB}} = T_{\text{AB}}(x_{\text{A}})$.

Task 2 (path→text): Given a KB path x_{B}, generate a descriptive sentence x_{A}, coherently merging entities and relation from the path. This conditional generation is a translation task referred to as T_{BA}, where $x_{\text{BA}} = T_{\text{BA}}(x_{\text{B}})$.

From the above two tasks follows the definition of *back-translation* tasks T_{BAB} (path→text→path) and T_{ABA} (text→path→text). Reconstruction tasks T_{AA} and T_{BB} are trivially defined as generating the same text/path from itself.

In an unsupervised setting, where sentences x_{A} and paths x_{B} are not paired, the reconstruction tasks T_{AA}, T_{BB} and back-translation tasks T_{ABA}, T_{BAB} are the only ones available to define training losses. The back-translation tasks define the so-called cycle/consistency losses, which implicitly control the quality of the first transfers (T_{AB}, T_{BA}), by checking the reconstruction after the second transfers (T_{ABA}, T_{BAB}). By themselves, these cycle losses are effective in training good transfer model. However, as we show in Section 5, even a small weak supervision (by pairing some x_{A} to x_{B}) can significantly improve our model performance.

x_{S}	sentence, where type S can be	
	A, A^m	sentence, masked sentence
	AA	given A, reconstructed sentence
	BA	given B, generated sentence
	ABA	given AB, back-translated sentence
x_{P}	path, where type P can be	
	B, B^m	path, masked path
	BB	given B, reconstructed path
	B^{m}B	given B^m, reconstructed path
	AB	given A, generated path
	BAB	given BA, back-translated B
w	edge $w = (e_h, r, e_t)$ with (entity, rel. op., entity)	
w^m	masked edge/tuple, e.g., $(e_h, r, .)$, $(., r, e_t)$, etc.	
T_{D}	Translation task with direction D	
T_{AB}	Translation from A to B. $x_{\text{AB}} = T_{\text{AB}}(x_{\text{A}})$	
T_{BA}	Translation from B to A. $x_{\text{BA}} = T_{\text{BA}}(x_{\text{B}})$	
T_{ABA}	Back-Translation from AB, back to A where $x_{\text{ABA}} = T_{\text{BA}}(x_{\text{AB}}) = T_{\text{BA}}(T_{\text{AB}}(x_{\text{A}}))$	
T_{BAB}	Back-Translation from BA to B where $x_{\text{BAB}} = T_{\text{AB}}(x_{\text{BA}}) = T_{\text{AB}}(T_{\text{BA}}(x_{\text{B}}))$	
$T_{\text{B}^m\text{B}}$	Generation from masked path $x_{\text{P}} = T_{\text{B}^m\text{B}}(x_{\text{P}}^m)$	

Table 1: Notations used throughout the paper.

As shown in Fig. 3, our model uses an encoder-decoder architecture with a common encoder and two specialized decoders (A, generating sentences x_{A}, and B, generating paths x_{B}). The reason for a single encoder is to force the embeddings of path and text to lie in the same space, encoding a fact regardless of modality. It then becomes the job of each specific decoder to recover either one of the modalities. Note that the decoders share the same architecture, but not their parameters.

2.1 Un/Weakly-supervised Setups

For data source, we used the standard 600K set from Li et al. (2016) (CN-600K). It is a curated version of ConceptNet 5 (Speer et al., 2017), a well-known commonsense KB, which partly originated from the Open Mind Common Sense (OMCS) list of commonsense fact sentences. Despite no explicit pairing between sentences from OMCS and paths from CN-600K, both datasets cover a re-

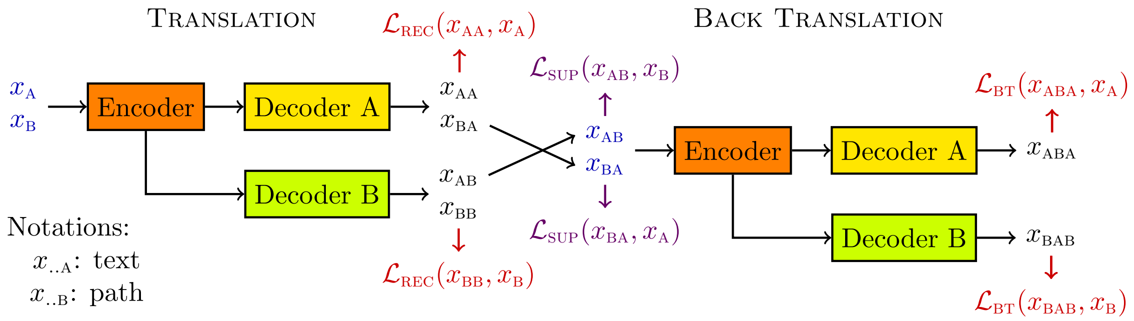

Figure 3: Our Encoder-Decoder model with translation and back-translation represented as a sequence of steps. Encoder and decoders are shared for both steps. The Encoder provides a representation of inputs x_{A} (text) and x_{B} (path) in a common embedding space. Decoders A and B are specialized to generate only sentences and paths (respectively) from these embeddings. Losses are indicated close to the generated values they require. Reconstruction loss $\mathscr{L}_{\text{REC}}$, back-translation loss $\mathscr{L}_{\text{BT}}$ are available in unsupervised learning, with $\mathscr{L}_{\text{SUP}}$ only available in supervised learning. Generation of x_{ABA} from x_{A} means two passes through our model: First pass, with x_{A} as input. Second pass, with $x_{\text{AB}} = T_{\text{AB}}(x_{\text{A}})$. The same model can accommodate path or text generation.

lated set of facts making them good candidates for our unsupervised and weakly-supervised training. ATOMIC (Sap et al., 2019) was created from many data sources (books, n-grams, etc.) not easily accessible, leaving us with no relevant text corpora to pair with. Therefore, we only use CN-600K.

The weakly-supervised dataset was obtained by doing fuzzy matching of sentences x_{A} to paths x_{B}. Each sentence is mapped to a list of paths, and each path to a list of sentences. Note that KB and text set do not align exactly; noise and mislabelling are inherently present. Despite these constraints, we can investigate the effects of weak supervision on model performance, and vary the amount of it by changing the fraction of available paired data. More details about how this weakly-supervised dataset[1] was created are in Section 5.1.

3 Model

Given a dataset X of paths and sentences, let x_t^k be its k-th random sample of type t, for $k = 1, \ldots, N$ and type $t \in \{\text{A}, \text{B}\}$, where x_{A} is a sentence and x_{B} is a path in the KG. Given the input x_t^k to the model, the corresponding generated output will be denoted as $x_{tt'}^k$, where tt' is the transfer direction, i.e., $tt' \in \{\text{AA}, \text{AB}, \text{BB}, \text{BA}\}$. For example, given path x_{B}^k, $x_{\text{BA}}^k = T_{\text{BA}}(x_{\text{B}}^k)$ denotes the corresponding generated sentence. Similarly, given $x_{tt'}^k$ as input, $x_{tt't''}^k$ denotes additional possible transfer directions, out of which we will be only interested in $tt't'' \in \{\text{ABA}, \text{BAB}\}$, as they represent the *back-translations* of a sample from a type t back to itself, since $t'' = t$. Given input sentence x_{BA}^k, x_{BAB}^k denotes its generated back-translation such that $x_{\text{BAB}}^k = T_{\text{AB}}(x_{\text{BA}}^k) = T_{\text{AB}}(T_{\text{BA}}(x_{\text{B}}^k))$. A model with perfect generation and back-translation would yield $x_{\text{BAB}}^k = x_{\text{B}}^k$ as $T_{\text{AB}}(T_{\text{BA}}(x))$ would be the identity function. Note that to reduce clutter, we drop the dataset index k from the notations.

3.1 Losses

There are three types of losses we employ in our training. The reconstruction loss is defined as

$$\mathscr{L}_{\text{REC}} = \mathop{\mathbb{E}}_{x_{\text{A}} \sim X} \left[-\log p_{\text{AA}}(x_{\text{A}}) \right] + \mathop{\mathbb{E}}_{x_{\text{B}} \sim X} \left[-\log p_{\text{BB}}(x_{\text{B}}) \right],$$

where $p_{\text{AA}}(x_{\text{A}})$ is the distribution for the reconstructed sentences $x_{\text{AA}} = T_{\text{AA}}(x_{\text{A}})$, and $p_{\text{BB}}(x_{\text{B}})$ for paths $x_{\text{BB}} = T_{\text{BB}}(x_{\text{B}})$. To enable model to perform transfers, we also employ the so-called back-translation, or cycle loss:

$$\begin{aligned} \mathscr{L}_{\text{BT}} = & \mathop{\mathbb{E}}_{x_{\text{A}} \sim X} \left[-\log p_{\text{ABA}}(x_{\text{A}} | x_{\text{AB}}) \right] \\ & + \mathop{\mathbb{E}}_{x_{\text{B}} \sim X} \left[-\log p_{\text{BAB}}(x_{\text{B}} | x_{\text{BA}}) \right]. \end{aligned} \quad (1)$$

Unsupervised training minimizes the combined loss $\mathscr{L}_{\text{REC}} + \mathscr{L}_{\text{BT}}$. When supervised data is available, we can additionally impose a supervision loss for the paired data:

$$\begin{aligned} \mathscr{L}_{\text{SUP}} = & \mathop{\mathbb{E}}_{x_{\text{A}}, x_{\text{B}} \sim X} \left[-\log p_{\text{AB}}(x_{\text{B}} | x_{\text{A}}) \right] \\ & + \mathop{\mathbb{E}}_{x_{\text{A}}, x_{\text{B}} \sim X} \left[-\log p_{\text{BA}}(x_{\text{A}} | x_{\text{B}}) \right]. \end{aligned} \quad (2)$$

---

[1] We plan on releasing this dataset publicly.

Supervised training minimizes the combined loss $\mathscr{L}_{\text{REC}} + \mathscr{L}_{\text{BT}} + \mathscr{L}_{\text{SUP}}$. We explore the impact of $\mathscr{L}_{\text{REC}}$, $\mathscr{L}_{\text{BT}}$, and $\mathscr{L}_{\text{SUP}}$ on training with an ablation study detailed in Section 5.3. Note that when the supervised data is limited, i.e., the sentence-path correspondence is only known for some pairs $(x_{\text{A}}, x_{\text{B}})$, the loss in (2) is adjusted accordingly and averaged only over the available pairs. As we show in Section 5.4, this modification enables us to examine the effect of the amount of supervision on the model performance.

4 Experimental Setup

In this Section, we provide details about model architecture, training procedure, and data processing.

Model Architectures. We explored several architectures for our encoder and decoder: GRU (Chung et al., 2014), Transformer (Vaswani et al., 2017), and BERT (Devlin et al., 2019).

All possible pairings of encoder and decoder, provide a total of nine different combinations. Some of them, such as Transformer-BERT, GRU-BERT, or BERT-BERT are not valid, since BERT can only serve as an encoder model. Other configurations were rejected based on their performance on our validation set. In particular, we found that GRU-Transformer and BERT-Transformer just did not perform well, setting them aside. In the end, we selected the following three combinations: (1) GRU-GRU, since GRU is a simple, well-known RNN architecture, relatively easy and fast to train; (2) BERT-GRU, selected to leverage potentially better encoding representation from BERT, a well-known encoder; (3) Transformer-Transformer (or Trans-Trans), chosen to explore another seq2seq architecture. All models parameters are trained, while for BERT we fine-tune the pre-trained model.

Teacher Forcing. During training, in the recurrent generation steps, we employ teacher forcing by feeding the ground truth tokens only 20% of the time, using the model output otherwise. We found this strategy very effective at preventing overfitting and increasing the overall generation quality.

Back-Translation. Traditionally, when using the back-translation loss in (1), gradients are back-propagated through the encoder-decoder structure twice to reflect the two transfers being done (e.g., $x_{\text{A}} \rightarrow x_{\text{AB}} \rightarrow x_{\text{ABA}}$). However, we observed better training behavior and model performance by detaching the gradients after the first pass through the system. The model still sees both back-propagations but the training becomes more stable.

Data processing. In our dataset, a path such as (e_h, r, e_t) = ("yeast", "is a", "ingredient in bread") will be encoded as "[SEP] yeast [SEP] is a [SEP] ingredient in bread [SEP]", including the special token [SEP], as done in Yao et al. (2019). Similar to Devlin et al. (2019), we mask a token by replacing it with a special token [MASK]. For a path, we replace either the head/tail by the mask token 50% of the time, e.g., $(\text{"[MASK]"}, r, e_t)$ for head masking. For text, we replace a randomly picked token with the mask token 10% of the time. For more robust training, we mask tokens in both text and paths input sequences and reconstruct the original. This is in the same spirit as recently proposed masked language modeling techniques (Devlin et al., 2019; Liu et al., 2019). While this technique helps learning robust encoder-decoder, it also inherently prepares the model for the link-predictions of KB completion evaluation.

5 Results and Discussions

In this Section we discuss in detail our dataset construction, evaluate the proposed models, and compare performances to existing baselines.

5.1 Datasets

We designed our own dataset due to the lack of available resources of paired text corpus and commonsense KBs. For KB, we started from CN-600K (Li et al., 2016) derived from ConceptNet (Speer et al., 2017). As mentioned earlier, we define a path as composed of two nodes and a directed edge connecting them. We only keep paths from CN-600K with confidence score greater than 1.6 for a total of 100K edges. Sentences in our dataset come directly from OMCS free-text sentences, removing those with detectable profanity.

Note that as is, this dataset can only be used for unsupervised training since its path-sentence pairs are not matched. To enable weak supervision, we map paths to sentences (and sentences to paths) using fuzzy matching directly on their sequence of tokens. Fuzzy matching uses term-frequency (tf) and inverse document frequency (idf) with n-grams to compute a cosine similarity score between two sets of strings (van den Berg, 2017).

Only the top matching pair is kept if its similarity score is greater than 0.6 to ensure a minimum quality for our matches. This score of 0.6 (from a range of -1 to 1) was chosen empirically after notic-

Table 3: BA text generation evaluation results for BLEU2 (B$_2$), BLEU3 (B$_3$), RougeL (R$_L$), and F1 BERT-score (B$_{F1}$). Models correspond to the ones in Tab. 2. Models with $*$ are selected by best B2 scores.

ing that the path-sentence pairs quality degraded quickly for lower scores, as some sentences did not have a good match. Indeed, *not all* OMCS sentences were used to create ConceptNet.

We create dataset splits *train* (240K) and *dev* (10K) under the strict policy that no path nor sentence in dev can exist in train, to ensure validation on text and path unseen in training.

During training, we can vary the amount of weak supervision available by applying the supervision loss $\mathscr{L}_{\text{SUP}}$ in (2) to a subset of the data. Note that for the pairs where $\mathscr{L}_{\text{SUP}}$ is not applied, the training becomes unsupervised since the remaining losses $\mathscr{L}_{\text{REC}} + \mathscr{L}_{\text{BT}}$ cannot exploit the presence of a match. Therefore, by changing the size of the subset to which $\mathscr{L}_{\text{SUP}}$ is applied we can go from full weak-supervision to unsupervised training.

Evaluations are reported on 1200 positive tuples of test set from the original split in Li et al. (2016) as done in prior works on commonsense KB (Malaviya et al., 2020). Irrespective of the choice of encoder, we tokenize the entire dataset (paths and sentences) using the BERT tokenizer.

5.2 Metrics and Results

The challenge in evaluating our models is that they accomplish different generation tasks, each with its own adequate metrics. Detecting an overall best model is therefore ambiguous and should be potentially application specific. Nevertheless, we present a set of metrics and results for all the important generation tasks for three model encoder-decoder architectures: GRU-GRU, BERT-GRU, and Trans-Trans, as well as discuss the model selection process. Results are obtained over 40 epochs of training. We present both the best results for each metric, and their averages over 4 models trained with distinct random seeds in Appendix in Tab. 6. Note that we refer to a generation task simply by its direction, i.e., use ABA for T_{ABA}.

AA, ABA: The performance on reconstruction task AA is indicative of the quality of autoencoding, while the back-translation task ABA, besides reconstruction also helps in evaluating implicitly the quality of transfer. We use the following metrics to evaluate generated sentence quality: BLEU2 (B2), BLEU3 (B3), ROUGEL (R$_L$), and F1 BERT-scoring metric (B$_{F1}$) (Zhang et al., 2019) in Tab. 5

Losses	DualTKB$_{\text{GRU-GRU}}$		DualTKB$_{\text{BERT-GRU}}$		DualTKB$_{\text{Trans-Trans}}$	
	MRR	BLEU2	MRR	BLEU2	MRR	BLEU2
$\mathscr{L}_{\text{REC}} + \mathscr{L}_{\text{BT}} + \mathscr{L}_{\text{SUP}}$	63.10	0.32	61.32	0.32	50.53	0.45
$\mathscr{L}_{\text{BT}} + \mathscr{L}_{\text{SUP}}$	17.09	0.48	0.14	0.07	45.42	0.46
$\mathscr{L}_{\text{BT}} + \mathscr{L}_{\text{REC}}$	20.08	0.25	52.52	0.03	23.56	0.26
$\mathscr{L}_{\text{REC}} + \mathscr{L}_{\text{SUP}}$	46.16	0.46	57.57	0.34	44.08	0.42

Table 4: Ablation study on different set of losses across various models

in Appendix. We observed that reconstruction AA is almost perfect in all metrics, while ABA is lagging as it must do first the translation and then recover back the sentence, a more challenging task. GRU-GRU is not as good for ABA as for AA, while Trans-Trans provides strong ABA results. BERT-GRU is ahead of the pack for ABA. Overall the models can handle AA and ABA reasonably well.

B$_m$B: KB Completion: KB completion is a common task for comparing models. Previous work established link prediction as the standard for evaluation relying on MRR (Mean Reciprocal Rank) and HITS as evaluation ranking metrics (Yang et al., 2015; Dettmers et al., 2018; Bordes et al., 2013). For tail prediction, e_t in all test tuples (e_h, r, e_t) are replaced by other nodes $\tilde{e}_t$ to produce corrupted tuples. A validity score is evaluated for all new corrupted tuples $(e_h, r, \tilde{e}_t)$, and a ranking is provided for the tuple with ground truth e_t. Head prediction is done similarly, often by reversing the relation r to r^- and ranking e_h given (e_t, r^-). As in Bordes et al. (2013), filtered versions of MRR and HITS are preferred as they filter out corrupted tuples present in training, dev, and test sets. We use filtered MRR and HITS for all results in this paper. We are aware of the recent critic of this KB completion evaluation by Akrami et al. (2020). However, since the community is yet to establish another methodology, and to be able to relate to previous work, we follow this procedure, albeit with a twist. For commonsense KB, Malaviya et al. (2020) mention the difficulty of repurposing generative models to ranking tuples for link-prediction. Our model is trained to generate a path tuple, not evaluate the quality score of its validity. Entities, relationship are all sequences of tokens that need to be generated properly, which does not fit well in the *conventional* KB completion evaluation framework. Therefore, we define a new meaningful commonsense KB completion task for generative models, and present the challenges that arise from it.

Since our models are trained from masked inputs, they can easily generate a new path $\hat{x}_{\text{B}} = T_{\text{B}^m\text{B}}(x^m_{\text{B}})$ from masked tuples $x^m_{\text{B}} = (e_h, r, .)$, or $x^m_{\text{B}} = (., r, e_t)$. This B^{m}B generation task can be done from any masked tuple, allowing for tail and head predictions without resorting to inverting the relationship r. For both predictions, the model generates a *complete* edge, not just e_h or e_t as for generative model COMET (Bosselut et al., 2019). However, the generated edge may not be a proper sequence of tokens for a (e_h, r, e_t) tuple, especially in early stages of training where the model is still learning the tuple structure. For improper generated tuples, tail and head predictions become impossible as the generated sequences of tokens cannot parse into correctly-formed tuples. For these cases, a worst case ranking score is given since no meaningful ranking is achievable, while their rankings are still required by MRR and HITS metrics. Our results are therefore *very* sensitive to the correct form of generated paths.

To summarize, for commonsense KB completion, we follow these steps: (1) Provide an input triple w/ masked entity (tail/head); (2) Generate a complete triple from our model (including a candidate for the missing/masked entity); (3) Score this predicted triple along with all corrupt triples (where the masked entity was replaced with all possible node candidates from our data) using fuzzy matching against the ground truth triple; (4) Remove corrupt triples before scoring if they already exist in train, test, or dev (filtering).

Defining a scoring function brings also another challenge. Indeed, even when producing proper tuples from masked entries, our generative model can still change some tokens in the unmasked part of the input tuple, i.e., for $x^m_{\text{B}} = (e_h, r, .)$, we could get a generated $\hat{x}_{\text{B}} = T_{\text{B}^m\text{B}}(x^m_{\text{B}})$ with $\hat{x}_{\text{B}} = (\hat{e}_h, \hat{r}, \hat{e}_t)$, where $e_h \neq \hat{e}_h$ and/or $r \neq \hat{r}$. There is no guarantee that the original pair (e_h, r) remains identical. The solution of using the original (e_h, r) for scoring, regardless of $(\hat{e}_h, \hat{r})$, is not fair as it will provide better performance than really achieved by the generative model. Therefore, for scoring function, we decided to compute the ranking scores using fuzzy matching of corrupted tuples, using the *whole* generated tuple sequence, taking into account any potential flawed generation of $(\hat{e}_h, \hat{r})$. MRR and HITS computation is exactly the same as in conventional KB completion.

We provide results for our KB completion in Tab. 2 where we added results from previous related work. During training, if models with the best MRR evaluation results are selected and used for testing, then GRU-GRU shows overall better performance. However, if BLEU2 metric is used for the selection, then BERT-GRU achieves higher scores. We observed that the overall performance of Trans-Trans was behind in these evaluation metrics. It is to be expected that not all metrics are strongly correlated and peak at the same time during training. It also confirms that for model selection, a weighted composite of all metrics would be a better approach.

BA: Sentence evaluation: The generation of sentence from path is another important task. For qualitative results, examples of such generation are shown in Fig. 2 and in Appendix A.4. For quantitative results, we evaluated the sentences using B2, B3, R$_L$, and B$_{F1}$ metrics, as reported in Tab. 3 for the same set of models as in Tab. 2. We compute these metrics against our weakly-supervised data, created using fuzzy matching. Selecting models solely on MRR has its shortcomings for other tasks. Models selected on MRR have relatively decent performances on KB completion metrics, but lag behind when compared to the models selected under text evaluation metrics. GRU-GRU and Trans-Trans are particularly good at this task, while BERT-GRU is in third place.

AB: Graph Edit Distance: In contrast to the single-instance evaluation, examining each generated path independently from others, we propose now to look at the generated graph as a whole and compare it to the ground truth one (based on our weakly-supervised dataset). In other words, given input sentences x_{A}, we generate the corresponding paths x_{AB} and compare them to the ground truth x_{B}. One of the metrics to compute graph similarity is Graph Edit Distance (GED) (Chen et al., 2019), which finds minimum cost path (consisting of node/edge substitutions, deletions, and insertions) transforming one graph into another. Since in general exact GED computation is NP-hard and practically infeasible for large graphs, we propose an approximation based on local subgraphs, as illustrated in Fig. 4. To define the cost of matching nodes (corresponding to heads and tails) and arcs (corresponding to relationship operators), we encode them into feature vectors using BERT and compare the value of their euclidean distance to a predefined threshold to identify matching nodes/edges. GED values are reported in Tab. 2 for all of our models. Trans-Trans has the lowest GED for all cases.

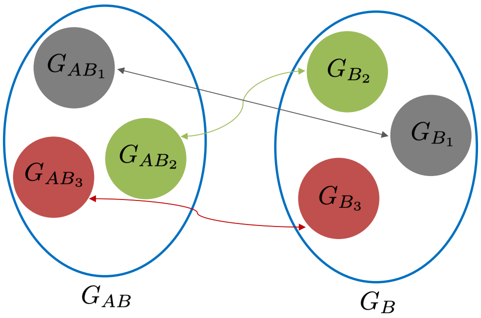

Figure 4: GED computation based on local subgraphs. GED is computed as an average of corresponding local graphs. As the size of local graph increases, the computed value better approximates the global GED. In our experiments we used subgraphs consisting of 10 paths due to computational cost. Larger numbers of paths result in prohibitive GED computation cost.

5.3 Ablation Study of Losses

In our ablation study, we evaluate the effect of each loss $\mathscr{L}_{\text{REC}}$, $\mathscr{L}_{\text{BT}}$, and $\mathscr{L}_{\text{SUP}}$ on the overall model performance. As seen in Tab. 4, by removing any of the losses, the MRR/HITS performance drops compared to the full loss case. At the same time, for different models, each loss has its own impact: e.g., $\mathscr{L}_{\text{BT}}$ has more value for GRU-GRU model, while the availability of weak supervision $\mathscr{L}_{\text{SUP}}$ is more important for Trans-Trans architecture. Another interesting conclusion is that although $\mathscr{L}_{\text{SUP}}$ explicitly and $\mathscr{L}_{\text{BT}}$ implicitly both control the quality of transfers (T_{AB} and T_{BA}), they remain complementary to each other, i.e., there is still a benefit of using both in the same loss.

5.4 Impact of Supervision Ratio

The impact of weak-supervision on model performance is illustrated in Fig. 5. For all the models, even a slight supervision amount leads to a

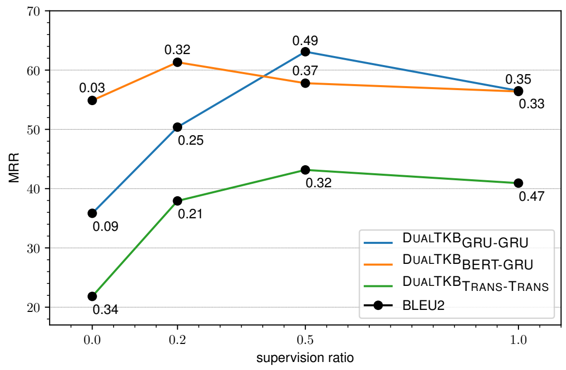

Figure 5: Models MRR and BLEU2 performance for supervision ratio 0, .2, .8 and 1.0. After gains from slight supervision, full supervision degrades performances, except for BLEU2 for Trans-Trans models.

rapid improvement for both MRR and BLEU2 metrics, which vindicates our decision to use weak-supervision. Importantly, model performance tends to peak before reaching full supervision: only our Trans-Trans model still sees an improvement for B2 scores at full supervision, while both GRU-GRU and BERT-GRU trained at 50% weak-supervision lead to better models. This can be explained by the nature of weak supervision itself. Fuzzy matching relies only on tf-idf and n-grams, which is not perfect when dealing with paths and sentences with different grammar structures. This procedure is inherently noisy and can pair sentences and paths with related but, nevertheless, not exact semantic matches. The full weak-supervision usually brings noise into the training, thus harming it more than helping. This conclusion is confirmed by the lower performance of our models at full supervision.

6 Conclusion

In this paper we proposed to use a dual learning bridge between text and commonsense KB. In this approach, a generative model is trained to transfer a sentence to a path and back. Assembling paths together results in a graph showing the presence of inherent structure, while generated sentences exhibit coherent and relevant semantics. For evaluation, we proposed a novel commonsense KB completion task tailored to generative models. Although our model is designed to work in unsupervised settings, we investigated the impact of weak-supervision by creating a weakly-supervised dataset and showed that even a slight amount of weak-supervision improves significantly model performance. The current work is one step towards the overarching goal of KB construction/completion *and* generation of human-readable text from KBs. Future work can focus on expanding the capabilities to generating whole paragraphs of text from graphs in KB, as well as converting large parts of text into coherent graph structures.

A Supplementary

A.1 Experimental Setup and Training

All our models were built using an NVIDIA V100 GPU, while validation was done with a CPU-only setup (using 2 cores). Each training epoch (240K samples) took between 1 hour for GRU-GRU (fastest), just over 1 hour for BERT-GRU, and 1.5h for Trans-Trans models (slowest). Our validation (10K samples) takes about 1.5 hours to evaluate as we need 2 passes for MRR and HITS (head and tail predictions), as well as a third pass for all NLP metrics for AA, ABA, and BA. Evaluation on our test set (1.2K samples) takes a matter of about 6 minutes for each head and tail prediction for MRR and HITS, with a third pass for NLP metrics, for a total of about 20 minutes. BLEU2 evaluation is relatively fast. GED evaluation can take up to 40 minutes. During training, we evaluate models at the end of each epoch, and use the best model over 40 epochs for testing.

All our models were built using PyTorch. They are trained with a batch size of 32 for a supervision ratio of 0.5. Masking for sentences is performed with a probability of 10% for each token while masking for paths tuples entities are set at 50% (when selected, all tokens of an entity are masked).

GRU models are trained with a learning rate of either 10^{-3} or 5×10^{-3} (10^{-4} yielded poor results) Transformer models were trained with a predefined learning rate schedule called ”NoamOpt” providing a warm-up phase up to 20K training mini-batches before a slow exponential decay. All our Transformer models had three sub-layers with three heads in the multi-head attention, while GRU models had a hidden size of 100 with a single recurrent layer.

All trainings had a seeded random number generator to ensure repeatability. For instance, results from Tab. 5 were obtained for one common seed for all models. For results in Tab. 6, 4 distinct seeds were used to show performance based on the average of the 4 individual model performances (standard deviation is also provided).

MRR and HITS metrics are defined in details in Dettmers et al. (2018) – code associated with the paper provides implementations in Python. We reimplemented them for better integration in our own codebase. BLEU metrics were used from NLTK implementations.

When running multiple supervision ratio for weak-supervision, hyper-parameters were all fixed to the values provided above, only the supervision ratio was changed.

A.2 AA, ABA: Reconstruction and Back-Translation Tasks

Tab. 5 show results for our models GRU-GRU, GRU-BERT, and Trans-Trans for BLEU2, BLEU3, ROUGE, and F1 BERT score for both AA and ABA tasks. AA is an easier task with excellent while ABA is more difficult. GRU-GRU and Trans-Trans excel at both AA and ABA.

A.3 Results for Multiple Random Generation Seeds

In Tab. 6, we present results for our three model architectures using MRR-HITS and BLEU metrics as averages over 4 models for each architecture built with distinct random generator seeds, trained with our default hyper-parameters described in Section A.1. We report average and standard deviation for every metrics.

A.4 AB: Graph Generation

In this Section we present additional examples of the text to path transfers, see Figures 6, 7 and 8, as well as the reverse transfer from path to text, see Figure 9.

Incremental Neural Coreference Resolution in Constant Memory

Patrick Xia[1] **João Sedoc**[2] **Benjamin Van Durme**[1]
paxia@cs.jhu.edu jsedoc@nyu.edu vandurme@cs.jhu.edu
[1]Johns Hopkins University [2]New York University

Abstract

We investigate modeling coreference resolution under a fixed memory constraint by extending an incremental clustering algorithm to utilize contextualized encoders and neural components. Given a new sentence, our end-to-end algorithm proposes and scores each mention span against explicit entity representations created from the earlier document context (if any). These spans are then used to update the entity's representations before being forgotten; we only retain a fixed set of salient *entities* throughout the document. In this work, we successfully convert a high-performing model (Joshi et al., 2020), asymptotically reducing its memory usage to constant space with only a 0.3% relative loss in F1 on OntoNotes 5.0.

1 Introduction

Coreference resolution is a core task in NLP for both model analysis and information extraction. At the sentence level, ambiguities in pronoun coreference can be used to probe a model for common sense (Levesque et al., 2012; Sakaguchi et al., 2020) or gender biases (Rudinger et al., 2018; Zhao et al., 2018). At the document level, coreference resolution is commonly used in information extraction pipelines, but can be applied to reading comprehension (Dasigi et al., 2019) or literature analysis (Bamman et al., 2014).

Models for this task typically encode the entire text before scoring and subsequently clustering candidate mention spans, either found by a parser (Clark and Manning, 2016b) or learned jointly (Lee et al., 2017). Prior work has primarily focused on improving pairwise span scoring functions (Raghunathan et al., 2010; Clark and Manning, 2016a; Wu et al., 2020) and methods for decoding into globally consistent clusters (Wiseman et al., 2016; Lee et al., 2018; Kantor and Globerson, 2019; Xu and Choi, 2020). Recent models have also benefited from pretrained encoders used to create high-dimensional input text (and span) representations, and improvements in contextualized encoders appear to translate directly to coreference resolution (Lee et al., 2018; Joshi et al., 2019, 2020).

These models typically rely on simultaneous access to all spans – $\Theta(n)$ for a document with length n – for *scoring* and all scores – up to $\Theta(n^2)$ – for *decoding*. As the dimensionality of contextualized encoders, and therefore the size of span representations, increases, this becomes computationally intractable for long documents or under limited memory. Given these constraints, expensive scoring functions are increasingly difficult to explore. Further, prior models depart from how humans incrementally read and reason about coreferent mentions; Webster and Curran (2014) argue in favor of a limited memory constraint as a more psycholinguistically plausible approach to reading and model coreference resolution via shift-reduce parsing.

Motivated by scalability and armed with advances in neural architectures, we revisit that intuition. Following prior work, our model begins with a SpanBERT encoding of a text segment to form a list of proposed mention spans (Joshi et al., 2019, 2020). Clustering is performed online: each span either attaches to an existing cluster or begins a new one. We substantially minimize memory usage during inference by storing only the embeddings of active entities in the document and a small set of candidate mention spans. Our two contributions of online clustering and storing a constant size set of active entities result in an end-to-end trainable model that uses $O(1)$ space with respect to document length while sacrificing little in performance (see Figure 1).[1]

2 Model

Our algorithm revisits the approach taken by Webster and Curran (2014) for incrementally making coreference resolution decisions (online clustering). The major differences lie in explicit entity representations, neural components, and learning.

Baseline First, we summarize the coreference resolution model described by Joshi et al. (2019), which itself extends from earlier work (Lee et al., 2017, 2018). For each document, this model enumerates and scores all spans up to a chosen width. The span representations are formed using BERT (Devlin et al., 2019) encodings of input text by concatenating the first, last, and an attention-weighted average of the token representations within the span. These spans are ranked and pruned to the top $\Theta(n)$ mentions. Both the maximum span width and fraction of remaining spans are hyperparameters. For each remaining span, the model learns a distribution over its possible antecedents (via a pairwise scorer) and the training objective maximizes the probability of its gold labeled antecedents. The entire model (including finetuning the encoder) is trained end-to-end over OntoNotes 5.0.

This model is further improved by Joshi et al. (2020), who introduces SpanBERT and uses it as the underlying encoder instead. The SpanBERT-large version of Joshi et al. (2019) is the baseline model used in this paper.

Inference Our method (Algorithm 1) stores a permanent list of entities (clusters), each with its own representation. For a given sentence or segment, the model proposes a candidate set of spans. For each span, a *scorer* scores the *span* representation against all the *cluster* representations. This is used to determine to which (if any) of the pre-existing clusters the current span should be added. Upon inclusion of the span in the cluster, the cluster's representation is subsequently updated via a (learned) function. Periodically, the model evicts less salient entities, writing them to disk. Under this algorithm, each clustering decision is permanent.[2]

Concretely, our model uses a contextualized encoder, SpanBERT (Joshi et al., 2020), to encode an entire segment. Given a segment, SPANS returns candidate spans, a result of enumerating all spans up to a fixed width, encoding spans as a combination of the embeddings within the span, and pruning using a learned scorer, following prior work (Lee et al., 2017; Joshi et al., 2019).

Algorithm 1 FindClusters(Document)

```
Create an empty Entity List, $E$
for segment $\in$ Document do
    $M \leftarrow$ SPANS(segment)
    for $m \in M$ do
        $scores \leftarrow$ PAIRSCORE$(m, E)$
        $top\_score \leftarrow \max(scores)$
        $top\_e \leftarrow \text{argmax}(scores)$
        if $top\_score > 0$ then
            UPDATE$(top\_e, m)$
        else
            ADD_NEW_ENTITY$(E, m)$
    EVICT$(E)$
return $E$
```

PAIRSCORE is a feedforward scorer which takes as input the concatenation of a mention span and entity representation along with additional embeddings for distance and genre. UPDATE updates the entity representation ($\mathbf{e}_{top\_e}$) with the newly linked span representation ($\mathbf{e}_m$). In this work, we use a learned weight, $\alpha = \sigma(\text{FF}([\mathbf{e}_{top\_e}, \mathbf{e}_m]))$ and update $\mathbf{e}_{top\_e} \leftarrow \alpha \mathbf{e}_{top\_e} + (1-\alpha)\mathbf{e}_m$.[3] Here, FF is a feedforward network and σ is the sigmoid function.

To ensure constant space, EVICT moves some entities from E to CPU. These entities are never revisited; the offsets are stored on CPU solely for evaluation purposes. We evict based on cluster size and distance from the end of the segment.

The algorithm is independent of these components, so long as they satisfy the correct interface. Specifically, our algorithm is compatible with the recent model by Wu et al. (2020). They use a query-based pairwise scorer, which could be adopted in place of the feedforward pairwise scorer. Our use of abstract components also allows for comparison of different encoders or update rules.

Training Similar to prior work (Lee et al., 2017), our training objective is to maximize the probability of the correct antecedent (cluster) for each mention span. However, rather than considering *all* correct antecedents, we are only interested in the cluster for the *most recent* one.[4] For each mention m, $scores$ is treated as an unnormalized probability distribution $P(e \mid m)$ for $e \in E$, where E is the entity list that includes an ε target label which represents the action of starting a new cluster. The exact objective is to maximize $P(e = e_{\text{gold}} \mid m)$;

---

[2] This uses greedy decoding; exploring decoding strategies is beyond the scope of this work, which is focused on memory.

[3] Using a simple moving average performs slightly worse.

[4] Scoring is between mention spans and entity clusters, so there needs to be a single correct cluster.

	MUC			B^3			$CEAF_{\phi_4}$			
	P	R	F1	P	R	F1	P	R	F1	Avg. F1
Baseline (Joshi et al., 2020)	85.8	84.8	85.3	78.3	77.9	78.1	76.4	74.2	75.3	79.6
Ours	85.7	84.8	85.3	78.1	77.5	77.8	76.3	74.1	75.2	79.4
Ours (without eviction)	85.7	84.9	85.3	78.1	77.5	77.8	76.2	74.2	75.2	79.4
CorefQA (Wu et al., 2020)	88.6	87.4	88.0	82.4	82.0	82.2	79.9	78.3	79.1	83.1

Table 1: Complete results of our model on the OntoNotes 5.0 test set with three coreference resolution metrics: MUC, B^3, and $CEAF_{\phi_4}$. For completeness, we also present the values for the current state-of-the-art. All models use an encoder derived from SpanBERT-large.

e_{gold} is the gold cluster of m (i.e., the cluster the most recent antecedent was assigned to).

However, the entirely sequential algorithm also introduces sample inefficiency, as most mentions have the same label (ε) and barely accrue loss. We speed up training by accumulating gradients periodically, trading computation time for space. This tradeoff is similar to that of batching by documents, which is impractical for our model from a memory perspective. Like prior work, we update parameters once per document (and not once per mention).

We lean on pretrained components: we reuse not only encoder weights that are already finetuned on this dataset, but also the mention and pairwise scorers from Joshi et al. (2020) as initialization for our encoder, SPANS and PAIRSCORE.[5]

3 Experiments

Since we reuse weights from Joshi et al. (2020) (our baseline), our primary experiment is to compare their model to our constant space adaptation in both task performance and memory usage. Additionally, we analyze document and segment length, conversational genre, and explicit clusters.

Data We use OntoNotes 5.0 (Weischedel et al., 2013; Pradhan et al., 2013), which consists of 2,802, 343, and 348 documents in the training, development and test splits respectively. These documents span several genres, including those with multiple speakers (broadcast and telephone conversations) and those without (broadcast news, newswire, magazines, weblogs, and the Bible).

Implementation We use the model dimensions and training hyperparameters from the baseline model, a publicly available coreference resolution model by Joshi et al. (2019, 2020). We also reuse their (trained) parameters for the encoder, span scorer, and span pair scorer as initialization. However, our model does not make use of speaker features, since it is not meaningful to assign a speaker to the cluster representation. At the end of each segment, we evict singleton (size 1) clusters more than 600 tokens away from the end of the segment. Additionally, we evict all clusters whose most recent member is more than 1200 tokens away. In this work, we also freeze the encoder—further finetuning the encoder provided little, if any, benefit likely because the encoder has already been finetuned on this dataset and task. Additional details, including our choice of eviction function, are described in Appendix A. All experiments are performed on either a single NVIDIA 1080 TI (11GB) or GTX Titan X (12GB).

4 Results

4.1 Performance

Table 1 presents the OntoNotes 5.0 test set scores for the metrics: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and $CEAF_{\phi_4}$ (Luo, 2005) using the official CoNLL-2012 scorer. We reevaluated the baseline, and we report the scores for CorefQA directly from Wu et al. (2020). We observe a small drop in performance compared to the baseline and apparently no drop with eviction.

4.2 Document Length

Our goal is a constant-memory model that is comparable to the baseline. We showed above that our model is competitive with and without eviction, the key to constant memory. In Table 2, we report the average F1 broken down based on the length (in subtokens)[6] of the document and number of speakers. Our model is competitive on most document sizes and in the single speaker setting. On longer documents, eviction has a minor effect.

---

[5] The implementation of Joshi et al. (2020, 2019) was the most amenable to extension and experimentation and therefore serves as our illustrative example.

[6] This split of the development set differs from that used by Joshi et al. (2019) which counts the number of 128-subtoken sized segments. We directly count subtokens.

Subset	#Docs	**JS-L**	Ours	Δ	-evict
All	343	80.1	79.5	-0.6	79.7
0-128	57	84.6	84.5	-0.1	84.5
129-256	73	83.7	83.6	-0.1	83.6
257-512	78	82.9	83.4	+0.5	83.4
513-768	71	80.1	79.3	-0.8	79.3
769-1152	52	79.1	78.6	-0.5	79.0
1153+	12	71.3	69.6	-1.7	69.8
1 Speaker	268	81.1	81.0	-0.1	81.2
2+ Speakers	75	76.7	75.0	-1.7	75.0
Test	348	79.6	79.4	-0.2	79.4

Table 2: Average F1 score on the development set broken down by document length and number of speakers. **JS-L** refers to the `spanbert_large` model from Joshi et al. (2020), which we treat as our baseline, and -evict refers to the model without eviction.

Model	GPU Memory (GB)	Dev. F1
Our model	2.0	79.5
No eviction	2.0	79.7
JS-B	6.4	77.7
JS-L	>11.9	80.1

Table 3: Space needed and performance over the development set. **JS-B** and **JS-L** refer to the `base` and `large` variants SpanBERT used in the baseline.

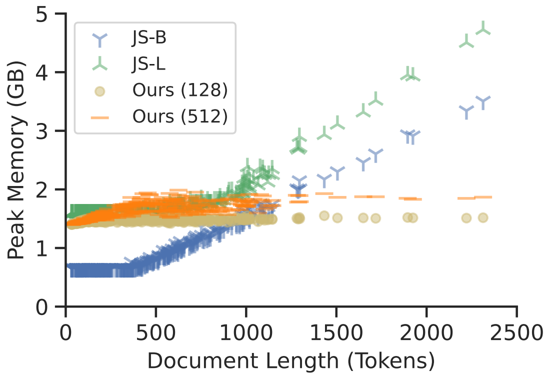

Figure 1: Total size of GPU-allocated tensors for each document in the development set. The base (**JS-B**) and large (**JS-L**) models of the baseline use apparently linear space, while ours with inference segment lengths of 128 and 512 use constant space.

Because our model does not make use of speaker embeddings, we perform worse on documents with multiple speakers. This drop due to speaker features matches previous findings (Lee et al., 2017). One way to include speakers and retain speaker-independent entity embeddings is by treating speakers as part of the input text (Wu et al., 2020).

4.3 Inference Memory

We now look towards space. In Table 3, we report the space needed to perform inference over the entire development set. Compared to the baseline and its smaller `base` version, our model uses substantially less memory. We also find that eviction has little effect on memory and F1 on this dataset.

Usage in practice is subject to the memory allocator, and our implementation (PyTorch) differs in framework from the baseline (TensorFlow). To fairly compare the two models, we compute the maximum *space used by the allocated tensors* for each document during inference.[7] Figure 1 compares this value of peak theoretical memory usage of several models against the dataset. It shows the baseline is dominated by a term that grows linearly with length, while that is not the case for our model, which has constant space usage.

Our model reduces the asymptotic memory usage to $O(1)$. In addition, these plots do not clearly show asymptotic memory usage: the baseline and other derivative models have a quadratic component for scoring span pairs (with a small coefficient). The encoder, SpanBERT, adds a significant constant term (with respect to document length) to all models. While there is some work in sparsifying Transformers (Child et al., 2019; Kitaev et al., 2020), there does not yet exist a sparse SpanBERT.

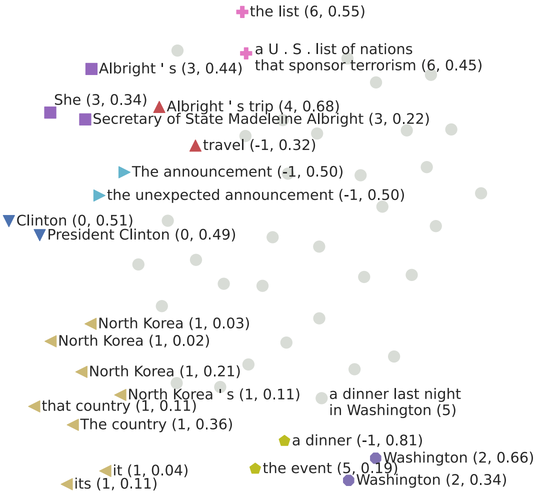
These plots show that models have relatively modest memory usage during inference. However, their usage grows in training, due to gradients and optimizer parameters. This additional memory usage would render training and finetuning the underlying encoder infeasible for the baseline but possible using our model with 12GB GPUs.

4.4 Segment Length

The memory usage at each step (and therefore of the algorithm) is also dependent on the segment length due to the encoder. Table 4 explores the effect of the length of each segment (split at sentence boundaries), which gives us further insight into the tradeoff between performance and memory reduction. We compare models without eviction to ensure fairness. Our observations follow those from Joshi et al. (2019) that larger context windows compatible with the encoder input size improve performance. We also observe that models trained on shorter sequences can be scaled, at infer-

---

[7] For profiling, we use `run_op_benchmark` for TensorFlow 1.15 and `pytorch_memlab` 0.0.4 and `torch.cuda` for PyTorch 1.5.



President Clinton may travel to North Korea in an attempt to improve relations with that country. The announcement comes after two days of talks between American and North Korean leaders in Washington. Secretary of State Madeleine Albright has accepted an invitation to visit North Korea and meet with leader Kim Jong-il. She made the unexpected announcement at a dinner last night in Washington. North Korea's top defense official hosted the event. The country is on a U.S. list of nations that sponsor terrorism. The Clinton administration is trying to persuade North Korea to halt its ballistic missile program as a way it can get off the list. There's no word yet when Albright's trip will take place.

Figure 2: t-SNE plot (left) of span representations of a single document (right) in the development set (cnn_0040_0). Each color/shape is a predicted cluster, while light gray circles indicate predicted singletons. For each span, the gold cluster label (-1, if not annotated) and its contribution to the entity embedding is noted in parentheses.

ence time, to longer sequences and obtain gains in performance. There is an unsurprising substantial drop using single sentences, owing to coreference being a cross-sentence phenomenon.

		Inference Length			
		Sentences		Tokens	
	Train↓	1 sent.	10 sent.	128 toks.	512 toks.
sents.	1	70.0	76.4	75.2	76.9
	5	70.0	77.4	76.4	78.6
	10	68.9	77.8	76.2	78.9
toks.	128	70.1	77.2	76.3	77.7
	256	69.1	77.9	76.5	78.8
	384	67.7	77.3	76.1	79.1
	512	67.1	77.7	75.6	79.7

Table 4: Average dev. F1 score for models trained and evaluated across a range of segment lengths (either fixed number of sentences or subtokens).

4.5 Span Representations

Figure 2 visualizes the proposed span representations for a single document in the development set. The colors/shapes represent our predictions, and each point is annotated with the text, the gold cluster label, and the (normalized) α for each span (recall α is used in the UPDATE function to determine a span's contribution to its entity embedding).

Given these embeddings, the figure supports the viability of clustering approaches: gold coreference clusters tend to be "close" in embedding space. Regarding α, some spans are weighted equally ("Clinton") while others are not ("North Korea"). This could be a result of online updates biasing more recent spans with higher weights. Alternatively, it may suggest that some spans (like names) are more informative than others (like pronouns).

5 Conclusion

We present an online algorithm for space efficient coreference resolution that incorporates contributions from recent neural end-to-end models. We show it is possible to transform a model which performs document-level inference into an incremental algorithm. In so doing, we greatly reduce the memory usage of the model during inference at virtually no cost to performance, thereby providing an option for researchers and practitioners interested in modern coreference resolution models for tasks constrained by memory, like the modeling of book-length texts.

A Hyperparameters

In this section, we describe several implementation details and other experiments that we tried. To improve memory usage, we use gradient accumulation. Ultimately, all training was performed on the NVIDIA 1080 TI (11GB), on which we accumulate gradients when the memory usage exceeds 7.5GB. In initial trials, we explored sampling losses for negative examples (spans that do not have an antecedent). While we found sampling at a rate of 0.2 (for example) would speed up training and inference, ultimately it contributed up to a one point deficit in F1.

We also explored teacher forcing, in which spans are added to the gold cluster during training instead of the predicted one. This would "correct" the training objective to match prior work. However, this did not have a noticeable effect on performance. Likewise, we were able to train a competitive model for which only the SpanBERT encoder from Joshi et al. (2019) was retained and the span scorer and pairwise scorer were randomly initialized. However, we opted not to use that for the full experiments because training was more expensive in time. Further, learning span detection is not guaranteed by this objective, leading to high variance across runs (most notably in the number of epochs). Thus, the effect of other hyperparameters would not be immediately apparent.

Additionally, we attempted further finetuning the encoder with a separate learning rate of [1e-5, 5e-6], but were unsuccessful in improving the performance. On our GPUs, training (without finetuning) roughly takes 70 min/epoch with negative sample rate 0.2, 100 min/epoch without sampling loss, and 160 min/epoch when finetuning. All runs are stopped after 5 to 15 epochs due to early stopping (patience = 5).

For eviction, a policy which evicts singletons distance > 600 and all clusters distance > 1200 would have a recall of 99.57% over the training set. This is a result of sweeping over [200, 300, 400, 500, 600, 900] for singletons and [400, 600, 800, 1000, 1200, 1800] for all clusters. We also try using a single fixed distance, as well as other non-constant schemes (e.g. size × distance as thresholds). Here, distance is between the current point in the document and the average of the start and end indices of the most recent span added to the cluster. We selected this policy from several other choices due to the recall it achieved.

Our model dimensions otherwise match up exactly with Joshi et al. (2019). Rather than omitting the speaker embedding and segment length embedding entirely (which would affect pairwise scorer dimensionality), we replace those embeddings with the zero vector.

Concretely, we performed grid searches over dropout ([0.3, 0.4, 0.5]), sample rate ([0.2, 0.5, 0.75, 1.0]), and update method ([alpha, mean]). We find that 0.4 dropout, 1.0 sample rate, and alpha weighting were the best after 2 epochs. Alpha weighting resulted in, on average, approximately 0.1 F1 improvement (after 2 epochs).

For alpha weighting, we used a two-layer MLP: the first layer has size 300 and ReLu nonlinearity, while the final layer then projected to a scalar with a sigmoid activation. After fixing those values, we explored learning rate ([5e-5, 1e-4, 2e-4, 5e-4]), eviction policy at training ([no eviction, eviction]), and gradient clipping value ([1, 5, 10]). Here, we found that 2e-4, no eviction, and gradient clipping at 10 performed slightly better, although there was little difference between them after these models were allowed to converge.

Given the final set of hyperparameters, we performed five training runs, resulting in average development set F1 of [79.4, 79.5, 79.5, 79.5, 79.7]. We selected the best performing model for the results in the paper. For Table 4, we trained each model only once.

For these experiments, our model contains 377M parameters, of which 340M is SpanBERT-large (Joshi et al., 2020).

Improving Low Compute Language Modeling with In-Domain Embedding Initialisation

Charles Welch, Rada Mihalcea and **Jonathan K. Kummerfeld**
Computer Science & Engineering
University of Michigan

Abstract

Many NLP applications, such as biomedical data and technical support, have 10-100 million tokens of in-domain data and limited computational resources for learning from it. How should we train a language model in this scenario? Most language modeling research considers either a small dataset with a closed vocabulary (like the standard 1 million token Penn Treebank), or the whole web with byte-pair encoding. We show that for our target setting in English, initialising and freezing input embeddings using in-domain data can improve language model performance by providing a useful representation of rare words, and this pattern holds across several different domains. In the process, we show that the standard convention of tying input and output embeddings does not improve perplexity when initializing with embeddings trained on in-domain data.

1 Introduction

Language modeling is an essential part of many NLP applications, including predictive keyboards, speech recognition, and translation. Recent work has focused on (1) small constrained datasets, such as the Penn Treebank (Marcus et al., 1993) and WikiText-103 (Merity et al., 2017b), and (2) vast resources with billions of words used to train enormous models with significant computational requirements (Radford et al., 2019). This leaves a gap: when a substantial amount of in-domain data is available, but computational power is limited.

We explore how initialising word embeddings using in-domain data can improve language modeling in English. Testing all valid configurations of weight tying, embedding freezing, and initialisation, we find that the standard configuration is not optimal when rare words are present. Instead, the best approach is to initialise with in-domain data, untie the input and output, and freeze the input.

To understand this difference, we run a series of experiments to measure the impact of changing (a) the threshold for replacing rare words with a special symbol; (b) the source of data for initialisation; (c) the amount of training data for the language model; and (d) the hyperparameters for both the baseline and our proposed approach. We find that the improvement comes from improved representation of rare words. These findings are confirmed through experiments on four additional domains, with similar trends.

We also compare our approach to an n-gram language model and a large-scale transformer model. We find that if a large-scale transformer is inappropriate either for computational or modeling reasons, it is best to train an LSTM-based language model with as much data as possible and initialise the embeddings on all available in-domain data.

2 Proposed Approach

We propose initialising the language model's word embeddings with vectors trained on additional in-domain data. To make this most effective, we make two other key changes to training. First, we prevent embeddings from shifting during training. Without this, the embedding space could become inconsistent as vectors for words seen in training shift while those for words seen only in the additional data stay the same. Second, we do not tie the weights of the input embeddings and final output layer. To understand the impact of these factors, we train models with every valid combination of weight tying, freezing, and pretraining.[1]

We experiment with Merity et al. (2017a)'s AWD-LSTM – a high-performing model that can be trained in under a day on a single GPU (without fine-tuning). We train embeddings using GloVe on Gigaword.[2] For evaluation, we consider two

---

[1] Note, for frozen output embeddings the bias is not frozen.

[2] Embedding size 400 and rare word cutoff 5, the same as in the original AWD-LSTM model and GloVe respectively. All other GloVe hyperparameters were set as specified in the original GloVe paper and trained using the released code.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8625–8634,
November 16–20, 2020.

versions of the Penn Treebank. *Std* is the standard version used in language modeling, with words of frequency less than five converted to UNK, all words lowercase, numbers replaced with a special symbol, and punctuation removed. *Rare* has the same pre-processing but without replacement of rare words.[3]

Table 1 shows the results, with icons to concisely describe the different configurations.[4] Looking first at the standard evaluation set, we can see the value of pretrained embeddings by considering pairs where the only difference is whether the embeddings are random or pretrained. Pretrained embeddings are better in all but one case (comparing the fourth last and second last rows), and there the difference is only 0.5. As for freezing the pretrained input embeddings, keeping all other aspects the same, it is always better to freeze them.

There are also four clear sections of performance in the table: (a) frozen random output embeddings; (b) frozen pretrained output embeddings; (c) frozen random input embeddings; (d) various configurations. These results have an asymmetry. Freezing the output embeddings consistently leads to poor performance, even with pretrained embeddings pretrained. In contrast, freezing with pretrained input embeddings leads to some of the best results. We expected freezing with random initialisation to perform poorly, but the drop is modest for input freezing and dramatic for output freezing. This suggests that the two embedding matrices are serving different purposes in the model. The results do support the practise of tying when the input embeddings are random, but the benefit is half as large when they are pretrained.

For the dataset with rare words we see mostly the same trends. The exception is the bottom six rows. Once rare words are present, random initialisation of the input embeddings is considerably worse than pretraining (third last row). Again, there is an asymmetry between input and output, with the top five models all using pretrained input embeddings, but only three of them using pretrained output embeddings. Tying is also no longer the best approach, with the top three models not tying. Our proposed approach, using pretrained untied embeddings and freezing the input, has the best results.

The only difference between Std and Rare is the lack of UNKs in Rare. This impacts 5.1% of tokens in the validation set (33% of types). While our pretrained embeddings do not cover all of these rare words, they do cover most. The vocabulary from Gigaword that we build vectors for covers 99.5% of the validation word tokens in Std (98% of word types), and 98.8% of the validation word tokens in Rare (84% of word types).

Table 1: Perplexity on the PTB for all valid combinations of weight tying, freezing, and pretraining. Results are sorted by perplexity on Std and shown to three significant figures.

3 When & Why Does Pretraining Help?

To understand the strengths and limitations of this new approach, we consider a series of experiments, each probing a specific variable. To simulate our target scenario, we use 44 million words of Wall Street Journal data from the North American

---

[3] The script to generate our *Rare* data from the LDC release is available at: `http://jkk.name/emnlp20lm/`.

[4] Dice Icon by Andrew Doane from the Noun Project. Fire and Snowflake Icons by Freepik from www.flaticon.com.

News Corpus (NANC, Graff, 1995). This provides enough data for pretraining, training, validation, and test sets all in the exact same domain (not even varying the newspaper). We apply similar preprocessing as in the previous section, but break the data down into articles rather than sentences and keep rare words.

We compare the six best configurations from Table 1. In all cases, output embeddings are not frozen, so we leave out the symbol. We use only one symbol for pretraining/random because both embeddings are the same in most cases. The exceptions have 🎲/🌐 to indicate pretrained input and random output.

■ 🔥 🎲	Standard approach.
⧉ 🔥 🎲/🌐	Our approach, but with random output embeddings and without freezing.
■ 🔥 🌐	Standard approach + pretraining.
⧉ 🔥 🌐	Our approach, but without freezing.
⧉ ❄ 🌐	Our approach.
⧉ ❄ 🎲/🌐	Our approach, but with random output embeddings.

Other Domains Show the Same Pattern. First we consider varying the domain to make sure this is not an artifact of news data. Table 2 shows results on Covid-19 research (Wang et al., 2020), Ubuntu IRC chat (Kummerfeld et al., 2019), Reddit, and Wikipedia, tokenised with either Scispacy (Neumann et al., 2019) or Stanza (Qi et al., 2020). Pretraining consistently helps, while freezing is best on all but Wikipedia. Our approach is consistently either the best or very close to the best.

The Improvement is Due to Rare Words. To probe the impact of rare words, we explore replacing them with UNK (using the same UNK symbol as used in embedding pretraining). We consider four variations, each constructed in two steps. First, we make a list of the words in the original training set and how many times each one occurs. Second, we make modified versions of the training and validation sets, replacing words with UNK if their count in our list is lower than K. For this step, any word that does not appear in our list is treated as if it has a count of zero. We consider K = 0, 1, 2 and 5. K is 0 for all other experiments in this section, which means that no words are replaced with UNK. When K is 1, 2, and 5, the introduction of UNKs means all words in the validation set are seen during language model training.

IRC	83	4.2	90	1.3	37	1.4
Reddit	81	6.1	86	0.69	15	0.71
Wiki	78	7.3	78	0.36	5.6	0.43

Table 4: Percentage of word types and tokens that occur five times or fewer in each dataset. The last two columns are the percentage of types/tokens in the training set that occur five or fewer times in the pretraining set. For PTB the pretraining set is Gigaword (as used in Table 1).

Table 3 shows a clear trend: the benefit of our approach grows as more rare words are present (i.e., K is smaller). Note, it may seem odd that perplexity is higher when K=1 than when K=0 since we have removed rare words. This is probably because when K is 1 there are UNKs in the validation set

Table 6: Expanding the language model training set.

but not in the language model training set.

Table 4 shows statistics about rare words in the datasets. 71-83% of word types in the training sets occur fewer than five times, but most of these appear frequently in the pretraining sets (compare the first column with the second last column). The same pattern occurs for word tokens. Comparing the statistics for the training set and the pretraining set, the percentage of rare word types is fairly consistent while the percentage of rare tokens consistently goes down.

Pretraining Data Needs to be from a Similar Domain. We would expect that the effectiveness of pretraining will depend on how similar the data is. Table 5 shows results with different embeddings, and indicates the number of words used in pretraining. We see that the value of additional data depends on the domain. Gigaword is also news text and is able to improve performance. The larger GloVe datasets use Wikipedia and CommonCrawl data, which is a poorer match and so does not improve performance. For GloVe we did have to change the embedding dimensions from 400 to 300, which may impact performance slightly.

The Effect Persists When Language Model Training Data is Increased. So far we have only used the additional in-domain data for pretraining. In this experiment, we expand the training set for the language model. We try two variations, one where the data is an exact domain match (NANC) and one where it is also news, but from different newspapers and from a different year (Gigaword). Table 6 shows that as we increase the amount of data our approach and the variant with random output embeddings continue to do best, but the margin shrinks between them and the standard approach. Note, however, that these results are with hyperparameters tuned for the baseline configuration. With tuning the 0.7 gap between our proposal and the baseline for 4xNANC widens to 6.6.

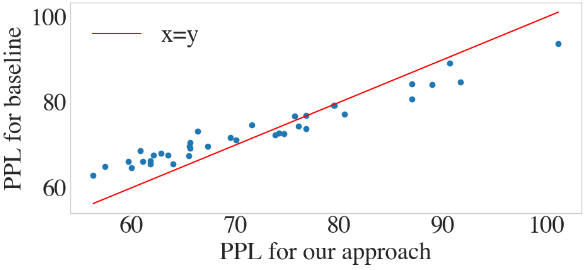

Figure 1: Hyperparameter search results with one point for each configuration. The line separates where our approach is better (left) or worse (right).

Hyperparameter Tuning Further Improves Results. All of the previous experiments were slightly tipped in favour of the baseline as we used the hyperparameters from Merity et al. (2017a). We do not have the resources to tune for every condition, so instead we focus on a final set of experiments with the 4xNANC condition from Table 6. We run 37 configurations with randomly sampled hyperparameters, using the same configurations for the baseline and our proposed approach (see the supplementary material for details). Figure 1 shows that our approach is even stronger after tuning, with a score that is 6.6 better than the baseline. Comparing the baseline and tuned hyperparameters, some shifted substantially more than others: the learning rate was halved; word dropout was halved; and the number of layers was increased from 3 to 4. The other parameters shifted by 15-30%.

Test Results Confirm Our Observations. Using the best configuration we train the baseline and our proposed approach using 8xNANC (the most our GPU could support). We compare to an n-gram language model trained on all of the NANC data (Heafield et al., 2013), and a transformer based model trained on a massive dataset, GPT-2 (Radford et al., 2019). While GPT-2 cannot be retrained in a low-compute scenario, it can be used. We compare to GPT-2 without fine-tuning. We evaluate byte-pair encoding (BPE) separately because with

	Words		BPE	
Model	Dev	Test	Dev	Test
N-Gram	92.3	95.0	56.7	55.3
GPT-2 (112m)	-	-	46.4	43.8
Baseline AWD-LSTM	52.8	53.5	37.8	36.7
Our approach	49.0	49.4	38.3	37.2
GPT-2 (774m)	-	-	32.5	33.7

Table 7: Final results, training with 8xNANC.

BPE tokenisation models have additional information when predicting the second or later piece of a token (Merity, 2019).

Table 7 shows that for word-level prediction, our approach improves over the baseline and an n-gram language model. BPE breaks up rare words, leading to no improvement over the baseline and while we do better than the 112m parameter GPT-2, we do not do as well as the 774m parameter one (both untuned). Overall, this indicates that for users who require word-level scores and have limited computational resources our approach is an effective way to use additional data when training LSTM language models.

4 Related Work

Embedding Tying. Tying input and output matrices has consistently increased performance while reducing the number of model parameters (Press and Wolf, 2017; Inan et al., 2017). The improvement is thought to be because otherwise only one input embedding is updated each step and the gradient has to propagate a long way through the model to reach it. Subsequent work has explored more advanced forms of tying, recognising that the role of the input and output matrices are not exactly the same (Pappas et al., 2018). This asymmetry has been found in the actual embedding spaces learned and shown to have a negative effect on performance (Gao et al., 2019; Demeter et al., 2020). These observations match the patterns we observe and provide theoretical justification for not tying when possible.

In-Domain Data Pretraining and Freezing. Word vectors are frequently used in downstream tasks and recent work has shown that their effectiveness depends on domain similarity (Peters et al., 2019; Arora et al., 2020) For language modeling, Kocmi and Bojar (2017) explored random and pretrained embeddings and found improvements, but did not consider tying and freezing. In-domain data is also useful for continuing to train contextual embedding models before fine-tuning (Gu et al., 2020; Gururangan et al., 2020), and for monolingual pretraining in machine translation (Neishi et al., 2017; Qi et al., 2018; Artetxe et al., 2018). This matches our observations, but does not cover the interactions between freezing and tying we consider.

Handling Rare Words. These remain challenging even for large transformer models (Schick and Schütze, 2020). Recent work has explored copying mechanisms and character based generation (Kawakami et al., 2017), with some success. These ideas are complementary to the results of our work, extending coverage to the open vocabulary case. Due to space and computational constraints we only consider English. For other languages, inflectional morphology and other factors may impact the effectiveness of our approach (Shareghi et al., 2019; Cotterell et al., 2018). Our work is also complementary to concurrent work on producing rare words as output (Pappas and Mulcaire, 2020).

Language Model Types. We focus on a single model type for computational budget reasons. We chose an LSTM because while transformer based models such as GPT-2 now dominate transfer learning, LSTMs continue to be competitive in language modeling (Du et al., 2020; Li et al., 2020; Melis et al., 2018; Merity et al., 2017a). Our ideas are orthogonal to this prior work and our findings may apply to transformers as well, but confirming that would require additional experiments.

5 Conclusion

Initialising embeddings with vectors trained on in-domain data can improve performance by providing better representations for rare words. This effect persists even as more in-domain data is used to train the language model. Our work also suggests that standard model components like embedding tying should be retested as we continue to explore the space of language modeling.

A Initialisation without additional data

This experiment considers a variation where we pretrain the embeddings only on the PTB (i.e., there is no additional pretraining data). LM uses the embeddings produced by training a baseline model (i.e., train an LM, then reset all parameters except the embeddings and train again).

Tie	Input	Pretraining Method	Val PPL
⧉	🔥	GloVe	64.5
⧉	❄	GloVe	66.2
⧉	🔥	LM	61.7
■	🔥	🎲	61.3
■	🔥	GloVe	60.5
⧉	❄	LM	60.3
■	🔥	LM	59.4

While pretraining on the training data improves performance here, the improvement does not persist through the finetuning stage.

B Note on model size

When we untie the embeddings it does increase the number of parameters. We ran experiments with 200 dimensional embeddings and found the same trends, but all results were slightly worse.

C Reproducibility Criteria

For each item in the list we have a section below with the relevant information.

C.1 Experimental Results

A clear description of the mathematical setting, algorithm, and/or model. The model we use is described in Merity et al. (2017a). We modify it to support weight freezing and initialisation.

For embeddings, we used GloVe with the same configuration as described in the original paper. For words in the LM training set that do not appear in the pretraining data, we used a random vector generated in the same way as Merity et al. (2017a).

A link to a downloadable source code, with specification of all dependencies, including external libraries The code for our work is attached as supplementary material and available at `http://jkk.name/emnlp20lm/`. For the main experiments we used CUDA 10.1 and PyTorch 0.1 to get results consistent with those reported in Merity et al. (2017a).[5]

Description of computing infrastructure used We used 7 GeForce GTX TITAN X GPUs with 12212 Mb of RAM each. For the GPT-2-large experiments we used a Tesla T4 via Google Colab based on the notebook from Callison-Burch and Ippolito (2020).

Average runtime for each approach Time per epoch varied from 60 to 2250 seconds depending on the amount of training data.

Number of parameters in each model For the language model this varied from 24,221,600 to 105,737,253, depending on the training data used. Those values do not count all of the pretrained vectors though, only the ones that occurred in either the training, development, or test sets. The pretrained vectors depended on the volume of data:

- Cord: 126,386,800
- IRC: 26,050,000
- NANC: 29,019,200
- Reddit: 77,719,200
- Wiki: 624,022,000
- Gigaword: 410,236,000

Corresponding validation performance for each reported test result Only the final table reports test results and it also contains the relevant validation results.

Explanation of evaluation metrics used, with links to code We use perplexity as implemented in (Merity et al., 2017a). The code is attached and available at `http://jkk.name/emnlp20lm/`.

C.2 Hyperparameter Search

We performed one hyperparameter search as described above.

Bounds for each hyperparameter These values are named as defined in the AWD-LSTM arguments:

- lr, [10, 25].
- dropouti, [0, 0.5].
- dropoute, [0, 0.5].
- nhid, [650, 1650].
- nlayers, [2, 5].
- dropout, [0.25, 0.55].
- dropouth, [0.1, 0.4].
- wdrop, [0.35, 0.65].

We fixed clipping, batch size, bptt, and wdecay based on observations in prior work. For hyperparameter tuning we reduced the number of epochs to 100 as improvements beyond that point were usually very small. We also stopped early if the loss at epoch N was not lower than in epochs [0: N-10], as proposed in Merity et al. (2018).

Hyperparameter configurations for best-performing models For most experiments we used the default hyperparameters from the AWD-LSTM, GPT-2 and kenlm. For the final experiments we used tuned hyperparameters as specified below.

Parameter	Tuned	Baseline
lr:	14.0	30

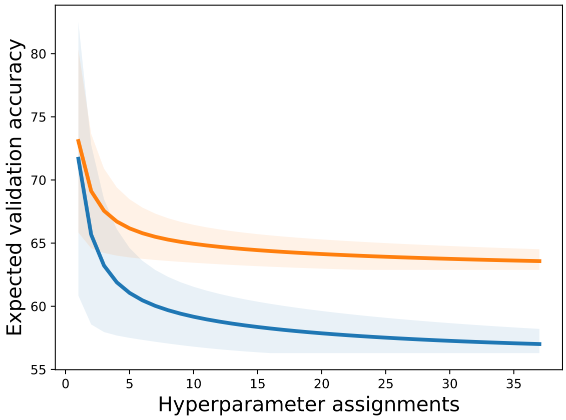
[5] Later versions of PyTorch and their code led to slightly worse performance.

Number of hyperparameter search trials See above.

The method of choosing hyperparameter values (e.g., uniform sampling, manual tuning, etc.) and the criterion used to select among them (e.g., accuracy) All of the hyperparameters were simultaneously varied, sampling all uniformly at random. We selected the final set based on validation perplexity.

Expected validation performance, as introduced in Section 3.1 in Dodge et al, 2019, or another measure of the mean and variance as a function of the number of hyperparameter trials. We use Dodge et al. (2019)'s approach to produce the following plot, where the orange line is the baseline and our approach is the blue line:



C.3 Datasets

We use several datasets:

- PTB: Mikolov's preprocessed version of the PTB (Marcus et al., 1993).
- PTB-Rare: Our version of the PTB.
- NANC: Wall Street Journal data from the North American News Corpus (Graff, 1995).
- Wiki: English Wikipedia.
- Reddit: A random sample of Reddit messages.
- CORD-19: Covid-19 research articles tokenised by Scispacy (Neumann et al., 2019).
- IRC: Ubuntu IRC dialogue disentangled by prior work (Kummerfeld et al., 2019).
- Gigaword: The Gigaword corpus (Parker et al., 2011).

Relevant statistics such as number of examples See below.

Details of train/validation/test splits

- PTB: We used the standard split: sections 00-20 for training, 21-22 for validation, 23-24 for test. These contain 88,7521, 70,390, and 78,669 tokens respectively.
- PTB-Rare: This is the same split as PTB.
- NANC: We randomly divide the data into splits the same size as PTB. For the additional LM data experiment we expand the training set first with the same amount of data again, then add another two times the data (adding the data each time, so smaller sets are subsets). The samples are not exactly the same size as the PTB training set as we add articles until we have just gone past the number of tokens. In all cases the pretraining, validation, and test set have 43,098,002, 72,356 and 79,408 tokens respectively. The 1x, 2x, and 4x training sets have 887,993, 1,776,407, and 3,551,496 tokens respectively. For the final experiment we use an 8x set (the 4x set plus another 4x) containing 7,101,988 tokens.
- Wiki: The same process as NANC. This gave pretraining, training, validation, and test sets of size 2,247,381,902, 887,933, 70,437, and 80,180 respectively.
- Reddit: The same process as NANC. This gave pretraining, training, validation, and test sets of size 219,940,812, 887,617, 70,439, and 78,796 respectively.
- CORD-19: The same process as NANC. This gave pretraining, training, validation, and test sets of size 194,840,142, 891,989, 73,014, and 81,648.
- IRC: The same process as NANC. This gave us pretraining, training, validation, and test sets of size 53,443,738, 887,716, 70,530, and 78,784.
- Gigaword: The same process as NANC for selecting 2x and 4x data. This gave us 4,790,293,007 tokens for pretraining, 888,869 extra tokens for 2x (added to the base NANC training data) and 2,664,487 extra tokens for 4x.

Explanation of any data that were excluded, and all pre-processing steps For all datasets aside from PTB and Reddit we used entire articles / conversations rather than breaking them into separate sentences. We applied preprocessing similar to the Mikolov PTB data, except that we do not remove rare words. Our scripts for preprocessing are in the attached code and at `http://jkk.name/emnlp20lm/`.

- PTB: We used the raw data directly.
- PTB-Rare: All data, preprocessed with the `make-non-unk-ptb.py` script.
- NANC: We used all articles from the Wall Street Journal, concatenating lines to form complete articles. For BPE evaluation we used the GPT-2 tokeniser to prepare the data.
- Wiki: Extracted using `https://github.com/attardi/wikiextractor`, then removed text that contained 'colspan' or 'rowspan', as wikiextractor sometimes extracts parts of tables. Also excluded titles.
- Reddit: Used the Stanford CoreNLP tokeniser.
- CORD-19: We use all of the articles with pmc json data that are shorter than 20,000 tokens (99% of the data).
- IRC: We use all of the automatically disentangled conversations.
- Gigaword: We use all of the articles, removing duplicates.

A link to a downloadable version of the data The raw data is available at the links below. The preprocessing we applied is described above.

- PTB: `http://www.fit.vutbr.cz/~imikolov/rnnlm/simple-examples.tgz`

KGPT: Knowledge-Grounded Pre-Training for Data-to-Text Generation

Wenhu Chen, Yu Su, Xifeng Yan, William Yang Wang
University of California, Santa Barbara, CA, USA
`{wenhuchen, xyan, william}@cs.ucsb.edu, su.809@osu.edu`

Abstract

Data-to-text generation has recently attracted substantial interests due to its wide applications. Existing methods have shown impressive performance on an array of tasks. However, they rely on a significant amount of labeled data for each task, which is costly to acquire and thus limits their application to new tasks and domains. In this paper, we propose to leverage pre-training and transfer learning to address this issue. We propose a knowledge-grounded pre-training (KGPT), which consists of two parts, 1) a general knowledge-grounded generation model to generate knowledge-enriched text. 2) a pre-training paradigm on a massive knowledge-grounded text corpus crawled from the web. The pre-trained model can be fine-tuned on various data-to-text generation tasks to generate task-specific text. We adopt three settings, namely fully-supervised, zero-shot, few-shot to evaluate its effectiveness. Under the fully-supervised setting, our model can achieve remarkable gains over the known baselines. Under zero-shot setting, our model without seeing any examples achieves over 30 ROUGE-L on WebNLG while all other baselines fail. Under the few-shot setting, our model only needs about one-fifteenth as many labeled examples to achieve the same level of performance as baseline models. These experiments consistently prove the strong generalization ability of our proposed framework[1].

1 Introduction

Data-to-text generation, i.e., generating textual description from structured data, is an important task with many real-world applications such as generating weather reports (Liang et al., 2009), sports news (Wiseman et al., 2017), dialog response (Wen et al., 2016; Dušek et al., 2019), etc. Neural generation models based on different strategies like soft-template (Wiseman et al., 2018; Ye et al., 2020), copy-mechanism (See et al., 2017), content planning (Reed et al., 2018; Moryossef et al., 2019), and structure awareness (Liu et al., 2018; Colin and Gardent, 2019) have achieved impressive results. However, existing studies are primarily focused on fully supervised setting requiring substantial labeled annotated data for each subtask, which restricts their adoption in real-world applications.

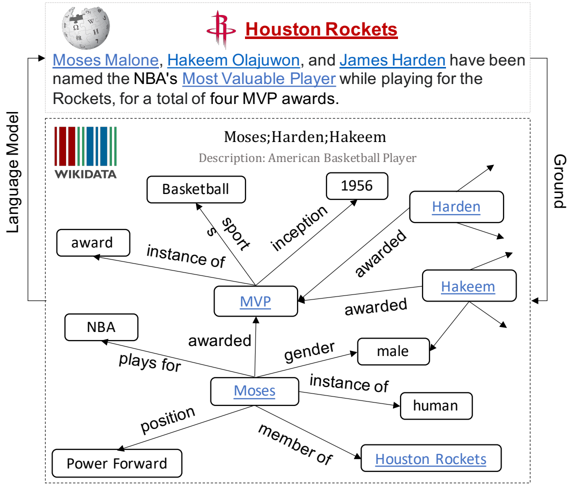

Figure 1: An example from the constructed KGText, which pairs a hyperlinked sentence from Wikipedia with a knowledge subgraph from WikiData.

In this paper, we are interested in developing a general-purpose model that can easily adapt to different domains/tasks and achieve strong performance with only a small amount or even zero annotated examples. Our model draws inspiration from the recent wave of pre-trained language model (Devlin et al., 2019; Radford et al., 2019; Dai et al., 2019) to exploit large-scale unlabeled data from the web for pre-training. The data pairs are constructed through the following procedure. We first crawl sentences with hyperlinks from Wikipedia, and then link the hyperlinked entities to Wiki-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8635–8648,
November 16–20, 2020.

Data (Vrandečić and Krötzsch, 2014) to find their 1-hop knowledge triples. Finally, we build a subgraph based on the linked triples. Such automatic alignment between knowledge graph and texts provides distant supervision (Mintz et al., 2009) for pre-training but it is bound to be noisy. Therefore, we design a selection strategy and only retain plausible alignments with high semantic overlap. The harvested knowledge-grounded corpus KGTEXT consists of over 1.8M (knowledge subgraph, text) pairs, as depicted in Figure 1.

We unify the input of KGTEXT and downstream data-to-text tasks into a generalized format and design a novel architecture KGPT to encode it. We use KGTEXT to first pre-train KGPT and then fine-tune it on downstream data-to-text tasks like WebNLG (Shimorina and Gardent, 2018), E2ENLG (Dušek et al., 2019) and WikiBio (Liu et al., 2018). Experimental results demonstrate KGPT's several advantages: 1) with full downstream dataset, KGPT can achieve remarkably better performance than known competitive baselines, 2) with zero training, KGPT can still achieve a reasonable score on WebNLG. 3) with a few training instances, KGPT can maintain a high BLEU score while the non-pre-trained baselines only generate gibberish text. A quantitative study shows that our pre-training scheme can reduce annotation costs by roughly 15x to achieve a decent BLEU score of 30. Our contribution is summarized as follows:

i). We design a distantly supervised learning algorithm to exploit large-scale unlabeled web text to pre-train data-to-text models.

ii). The proposed pre-training algorithm can bring significant performance under different settings, especially zero-shot and few-shot scenarios.

2 Related Work

Data-to-Text Generation Data-to-text is a long-standing problem (Kukich, 1983; Reiter and Dale, 1997), which involves generating natural language surface form from structured data. The traditional system is primarily built on a template-based algorithm. Recently, with the development of deep learning, attention has been gradually shifted to end-to-end neural generation models, which achieve significant performances on existing large-scale datasets like WebNLG (Shimorina and Gardent, 2018), E2ENLG (Dušek et al., 2019), WikiBio (Lebret et al., 2016), ROTOWIRE (Wiseman et al., 2017), TOTTO (Parikh et al., 2020), LogicNLG (Chen et al., 2020a), etc. However, these neural generation models are mainly focused on fully supervised learning requiring a huge amount of human annotation for the specific task. Our paper focuses on building a more generalized model architecture, which can adapt to specific tasks well with only a handful of training instances.

Knowledge-Grounded Language Modeling It is of primary importance to ground language models on existing knowledge of various forms. The neural language models (Bengio et al., 2003) have been shown to well capture the co-occurrences of n-grams in the sentences, but falls short to maintain the faithfulness or consistency to world facts. To combat such an issue, different knowledge-grounded language models (Ahn et al., 2016; Hayashi et al., 2020; Logan et al., 2019) have been proposed to infuse structured knowledge into the neural language model. These models are mainly focused on enhancing the factualness of unconditional generative models. Inspired by these pioneering studies, we explore the possibility to connect the unconditional generative model with downstream conditional generation tasks. The most straightforward knowledge-intensive conditional generative task is the data-to-text generation, which aims to verbatim given knowledge into lexical format. We demonstrate great potential of the knowledge-grounded pretraining in enhancing the model's factualness on these down-stream data-to-text tasks and believe such language models can be applied to broader range of NLP tasks requiring knowledge understanding.

Pre-trained Language Model Recently, the research community has witnessed the remarkable success of pre-training methods in a wide range of NLP tasks (Devlin et al., 2019; Radford et al., 2018, 2019; Dai et al., 2019; Yang et al., 2019; Liu et al., 2019b; Keskar et al., 2019; Lan et al., 2020; Lewis et al., 2019; Raffel et al., 2019). These models trained on millions or billions of data unlabeled data demonstrate unprecedented generalization ability to solve related down-stream tasks. However, the existing pre-trained text generation models (Radford et al., 2019; Keskar et al., 2019; Raffel et al., 2019) are initially designed to condition on text input, thus lacking the ability to encode structured inputs. The work closest to our concept is Switch-GPT-2 (Chen et al., 2020b), which fits the pre-trained GPT-2 model as the decoder part to perform table-to-text generation. However, their knowledge encoder is still trained from scratch, which compromises the performance. In this paper, we follow the existing paradigm to construct an unlabeled web data for LM pre-training.

3 Dataset Construction

The construction process has two stages, namely the crawling stage and the selection stage:

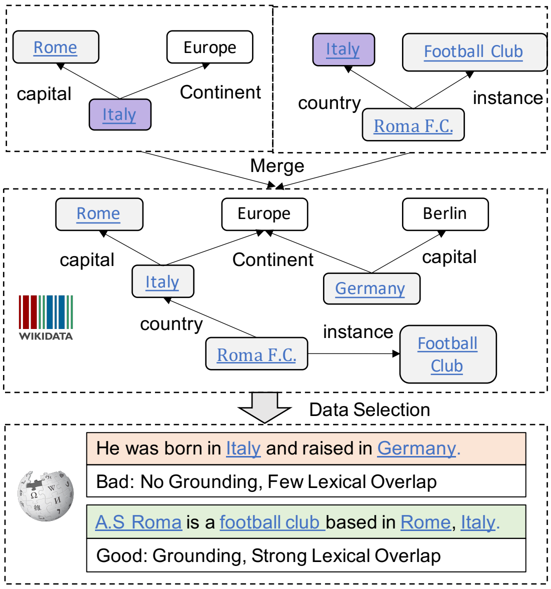
3.1 Hyperlinked Sentence Crawling

We use English Wikidump[2] as our data source. For each Wikipedia page, we split the whole paragraphs into an array of sentences and then tokenize with the nltk toolkit (Loper and Bird, 2002). We loop through each sentence to keep the sentences with more than 2 Wikipedia anchor links and within the length of 10 and 50. For each candidate sentence, we use its Wikipedia hyperlink to query WikiData (Vrandečić and Krötzsch, 2014) and obtain its corresponding entity page[3]. We retrieve the neighboring knowledge triples from these entity pages to construct a local 1-hop graph for each entity. The knowledge triples are divided into two types: 1) the object of the triple is also an entity like '(Roma F.C., country, Italy)', 2) the object of the triple is in plain text like '(Roma F.C., inception, 7 June 1927)'. In the first case, if the object entity also appears in the sentence, we use it as the bridge to build a multi-hop graph like Figure 2. After this step, we collected roughly 4 million pairs in the form of (subgraph, sentence) as the candidate for the following step.

3.2 Data Selection

We observe that the collected pairs are overly noisy with many sentences totally irrelevant to their paired subgraphs. Apparently, these pairs cannot serve our goal to build a knowledge-grounded language model. Therefore, we propose a data selection step to suppress the noise and filter out the data pairs of our interests. An example is depicted in Figure 2, the first sentence does not rely on any information provided by the knowledge graph, while the second sentence has a tight connection to the facts presented in the knowledge graph. Ideally, our proposed strategy should favor the second sentence over the first one.

To achieve this, we propose a simple lexical-based selection strategy to perform data selection. For example, the sentence 'He was born ...' in Figure 2 has two query words 'Italy' and 'Germany', we will conduct two rounds of lexical matching. In the first round, we use 'Italy' to query its surrounding neighbors in WikiData to the neighboring unigram, i.e. '(Rome, capital, Europe, Continent, Country, Roma F.C)'. We compute the unigram overlap with the original sentence '(He, was, ...)', which is still 0%. In the second round, we use 'Germany' to do the same computation and calculate the lexical overlap, which is still 0%. So the final averaged grounding score of two rounds is 0%. We can follow the same procedure to compute the grounding score for the second sentence in Figure 2 with four rounds '(AS Rome, FB, Rome, Italy)'. The grounding score is above 30%, which indicates that the sentence is highly grounded on WikiData subgraph. In this paper, we use a threshold of 0.13, which selects the top 7M 'good' sentences from the original 12M Wikipedia corpus.



He was born in Italy and raised in Germany.

Bad: No Grounding, Few Lexical Overlap

A.S Roma is a football club based in Rome, Italy.

Good: Grounding, Strong Lexical Overlap

Figure 2: Data denoising procedure for the KGTEXT.

After the selection step, we obtain a denoised knowledge-grounded corpus KGTEXT for pre-training. However, there still exist noisy false positives in the corpus, for example, a subgraph contains triple '(Roma F.C., country, Italy)', which is associated with the text 'An Italian player plays for A.S. Roma'. Though the two entities co-occur, they are not meant to describe the fact triple. By applying more strict rules, we can suppress such false positives, but the data capacity could significantly drop consequently. We experimented with differ-

---

[2] `https://dumps.wikimedia.org/`

[3] `https://www.wikidata.org`

ent thresholds to balance noise and data capacity and finally decide on a threshold with an acceptable noise degree. The detailed statistics of the KGTEXT is listed in Table 1. We held-out 10,000 sentences for both validation and testing to evaluate the pre-trained model.

#Sent	Length	#Ent	#Pred	#Triple	#Ent/Sent
7M	20.2	1.8M	1210	16M	3.0

Table 1: Statistics of collected KGText dataset

4 Model

We formally define the problem setting and KGPT's architectures in this section.

4.1 Problem Setting

In this paper, we consider inputs from structured data with diverse formats, like knowledge subgraph in KGTEXT, dialog act in E2E (Dušek et al., 2019), RDF triples in WebNLG (Shimorina and Gardent, 2018) and tables in WikiBio (Lebret et al., 2016). Here we unify them into a generalized dictionary format, which uses keys to represent subjects and values to denote the predicate-object pairs following the subject. We showcase the conversion criteria from structured inputs in different data-to-text datasets into our generalized format in Figure 3. The generalized input is denoted as X, and the output is denoted as y. Our model encodes X into a sequence of dense vectors, and then uses the decoder to attend and generate y.

4.2 Encoder

The encoder network is crucial to our model to capture the highly structured graph input. We mainly experiment with two types of encoders:

Graph Encoder This encoder is mainly based on graph attention network (Li et al., 2016; Kipf and Welling, 2017; Veličković et al., 2018) to explicitly encode the structure information. Specifically, we view each object, predicates, and subjects as the leaf nodes, and add `[ENT]`, `[TRIPLE]` as pseudo nodes for message passing purposes. The built graph is depicted in Figure 4.

First of all, we initialize the node representation with the averaged embedding of its subword units. For example, the node 'Moses Malone' has a representation of (E[Mos] + E[es] + E[Ma] + E[lone]) / 4 with E denoting the embedding. After we obtain the initial node representation, we use message propagation to update the node representations based on neighboring information.

In the first layer, we exchange the information between nodes inside a triple, e.g., 'Moses Malone' receives message from siblings 'Gender' and 'Male'. In the second layer, we aggregate information from sub/pred/obj nodes to the `[TRIPLE]` node, e.g., '[TRIPLE1]' receives message from children 'Moses, Gender, Male'. In the third layer, we aggregate the information from different `[TRIPLE]` to the `[ENT]` node. In the fourth layer, we exchange information between different `[ENT]` nodes to enhance cross-entity interactions. Formally, we propose to update the representation of the i-th node $g_i \in \mathbb{R}^D$ with the multi-head attention network, which aggregates information from neighboring nodes $g_j \in \mathcal{N}_i$ as follows:

$$\begin{aligned}\alpha_j^m &= \frac{e^{(W_Q^m g_i)^T (W_K^m g_j)}}{\sum_{j \in \mathcal{N}_i} e^{(W_Q^m g_i)^T (W_K^m g_j)}} \\ v &= concat[\sum_{j \in \mathcal{N}_i} \alpha_j^m W_v^m (g_j)] \\ \hat{g}_i &= LayerNorm(MLP(v + g_i))\end{aligned} \tag{1}$$

where m denotes the m-th head in the attention layer, $W_Q^m, W_K^m, W_V^m \in \mathbb{R}^{D\times D}$ are the matrices to output query, key, value vectors for m-th head. The attention output v and the residue connection from g_i are fed through the final MLP and LayerNorm to update i-th node representation as $\hat{g}_i$. The output of graph encoder is denoted as $G \in \mathbb{R}^{n\times D} = \{g_1, \cdots, g_n\}$ with n nodes.

Sequence Encoder This encoder is mainly based on transformer (Vaswani et al., 2017) with special embedding as an auxiliary input to infuse the structure information to the sequence model. The concept of special embedding was initially proposed by BERT (Devlin et al., 2019), more recently, it has been adopted by Herzig et al. (2020) to infuse structural information. We visualize the embedding layer in Figure 5, where we leverage additional entity embedding, triple embedding, and property embedding to softly encode the structure of the subgraph as a linearized sequence. For example, the entity embedding can inform the model which entity the current token belongs to, while the triple embedding can indicate which triple the current token belongs to and the property embedding indicates whether the token is a subject, predicate, or a subject. Such an encoding mechanism is designed to softly encode the graph structure into the embedding space for further self-attention. Compared

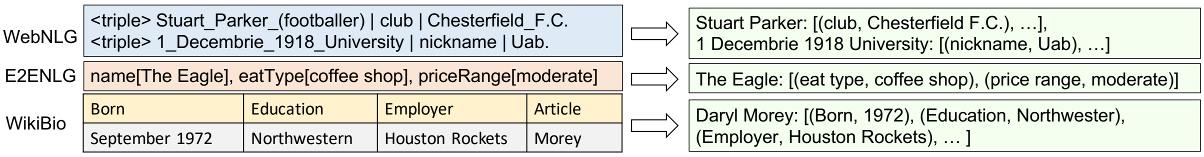


Figure 3: The conversion criterion to unify different structured data input into our generalized format.

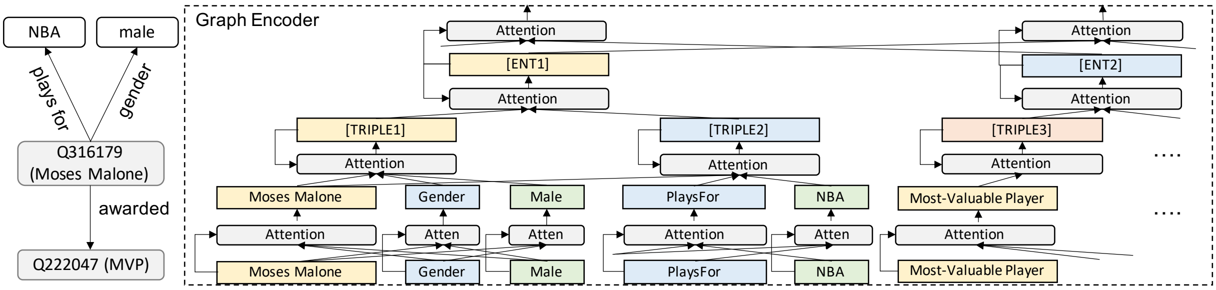

Figure 4: Graph Encoder with hierarchical propagation, where we propagate the information from bottom to top.

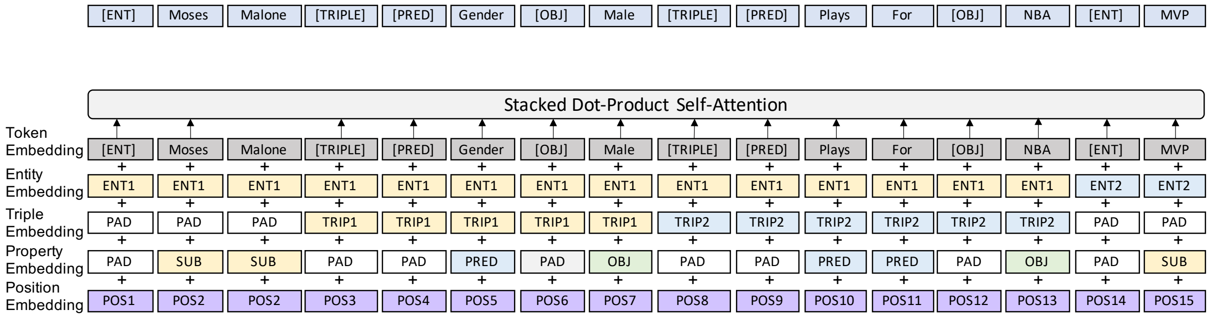

Token Embedding	[ENT]	Moses	Malone	[TRIPLE]	[PRED]	Gender	[OBJ]	Male	[TRIPLE]	[PRED]	Plays	For	[OBJ]	NBA	[ENT]	MVP
Entity Embedding	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT1	ENT2	ENT2
Triple Embedding	PAD	PAD	PAD	TRIP1	TRIP1	TRIP1	TRIP1	TRIP1	TRIP2	TRIP2	TRIP2	TRIP2	TRIP2	TRIP2	PAD	PAD
Property Embedding	PAD	SUB	SUB	PAD	PAD	PRED	PAD	OBJ	PAD	PAD	PRED	PRED	PAD	OBJ	PAD	SUB
Position Embedding	POS1	POS2	POS2	POS3	POS4	POS5	POS6	POS7	POS8	POS9	POS10	POS11	POS12	POS13	POS14	POS15

Figure 5: Encoding of the knowledge graph as a sequence using special embedding.

to the graph encoder, the sequence encoder does not enforce the structure as a hard constraint and allows more flexibility for the model to perform cross-triple and cross-entity interactions. Formally, the dot-product self-attention follows the definition of Transformer (Vaswani et al., 2017):

$$\begin{aligned} f_{att}(Q,K,V) &= softmax(\frac{QK^T}{\sqrt{D}}V) \\ G_m &= f_{att}(QW_Q^m, KW_K^m, VW_V^m) \\ G &= MLP(Concat(G_1,\cdots,Gm)) \end{aligned} \tag{2}$$

where Q, K, V are the computed from the input embedding, m represents m-th head and f_{att} is the core attention function, the final output is denoted as $G \in \mathbb{R}^{n\times D}$ with n denoting the sequence length.

4.3 Decoder

Our decoder architecture is mainly based on Transformer (Vaswani et al., 2017) and copy mechanism (See et al., 2017). At each decoding time step, the model has a copy gate p_{gen} to select y_i should be generated from the vocabulary $w \in \mathcal{V}$ or copied from the input tokens x:

$$\begin{aligned} \alpha_j = \frac{e^{o_i^T G_j}}{\sum_{j'} e^{o_i^T G_{j'}}}, \quad p_{gen} = \sigma(MLP(o_i)) \\ P(y_i = w) = p_{gen}P_{voc}(w) + (1 - p_{gen}) \sum_{j:x_j=w} \alpha_j \end{aligned} \tag{3}$$

where o_i is the last layer hidden state of the decoder at i-th time step, α_j is the copy probability over the whole input token sequences x.

4.4 Optimization

As we have defined our encoder-decoder model, we will simply represent it as $p_{encdec}(x)$ to output a distribution over word $y_i \in \mathcal{V}$ at the i-th time step. During pre-training, we optimize the log-likelihood function on D_{KGText}. After pre-training, we convert the downstream task's input into the defined dictionary format and denote the dataset as D_{down}, and then further optimize the log-likelihood objective with θ initialized from the pre-training stage.

The pre-train and fine-tuning procedure is displayed in Figure 6, where we first use KGTEXT to pre-train KGPT, and then fine-tune with different types of inputs using the standard auto-regressive log-likelihood objective.

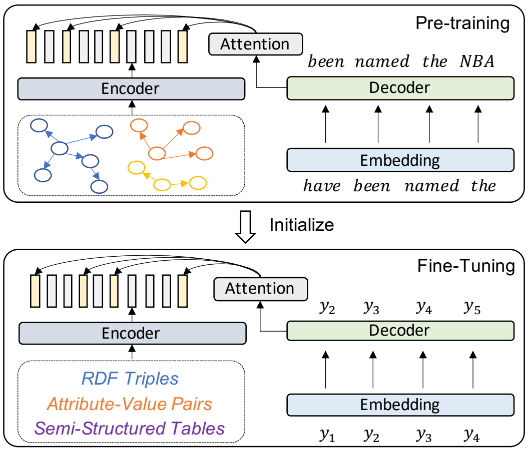

Figure 6: Overall pre-training and fine-tuning procedures for KGPT. The downstream knowledge data formats are converted into the generalized format.

5 Experiments

We experiment with three different down-stream tasks, which covers various table-to-text applications to verify the generalization capability of KGPT. Besides the fully supervised learning, we also evaluate zero-shot and few-shot learning.

5.1 Datasets

We use WebNLG (Shimorina and Gardent, 2018), E2ENLG (Dušek et al., 2019) and WikiBio (Lebret et al., 2016) to evaluate the performance of KGPT. Their basic statistics are listed in Table 2. WebNLG and E2ENLG are both crowd-sourced by human annotator while WikiBio is from the Web.

Dataset	Train	Val	Test	Input
WebNLG	34,338	4,313	4,222	RDF Triple
E2ENLG	42,061	4,672	4,693	Dialog Act
WikiBio	582,657	72,831	72,831	Table

Table 2: Statistics of different data-to-text datasets

WebNLG This dataset (Shimorina and Gardent, 2018) aims to convert RDF triples into a human annotated textual description. We use the recent release 2.0 from GitLab[4]. It contains sets with up to 7 triples each along with one or more references. The number of KB relations modeled in this scenario is potentially large and generation involves solving various subtasks (e.g. lexicalisation and aggregation). As the input RDF triples were modified from the original triples in DBPedia, we first need to check whether there are seen triples in pre-training dataset KGText. We verify that there is zero RDF triple seen during pre-training though 31% entities are seen. Therefore, we can confirm the comparison with other baselines is still fair given no information from test/dev is leaked.

E2ENLG This dataset (Dušek et al., 2019) aims to convert dialog act-based meaning representation into a spoken dialog response. It aims to provide higher-quality training data for end-to-end language generation systems to learn to produce more naturally sounding utterances. In this dataset, each meaning representation is associated with on average with 8.65 different reference utterances.

WikiBio This dataset (Lebret et al., 2016) aims to generate the first sentence of biography description based on a Wikipedia infoboxes table, with each table associated with only one reference. Unlike the previous two human-annotated datasets from different domains, WikiBio is also scraped from Wikipedia. Therefore, we filtered out the instances of KGText from the first paragraph of the biography domain to ensure no overlap or leakage about Wikibio's dev/test set.

5.2 Experimental Setup

We apply the standard GPT-2 (Radford et al., 2019) tokenizer from Hugginface Github[5] to tokenize the text input, which has a vocabulary of over 50K subword units. We test with both graph encoder and sequence encoder. We set their hidden size to 768 and stack 6 layers for both encoder and decoder with 8 attention heads. During pre-training, we run the model on KGText on 8 Titan RTX GPUs with a batch size of 512 for 15 epochs using Adam (Kingma and Ba, 2015) optimizer with a learning rate of 1e-4. The pre-training procedure takes roughly 8 days to finish. We use a held-out validation set to select the best checkpoint. During fine-tuning, we use a learning rate of 2e-5.

In our following experiments, we compare with the known best models from different datasets. As none of these models are pre-trained, we also add Template-GPT-2 (Chen et al., 2020a) and Switch-GPT-2 (Chen et al., 2020b) as our pre-trained baselines. Both models apply GPT-2 (Radford et al.,

---

[4] `https://gitlab.com/shimorina/webnlg-dataset`

[5] `https://github.com/huggingface/transformers`

2019) as the generator to decode description from a table. For the ablation purposes, we list the performance of all non-pre-trained KGPT to see the performance gain brought by pre-training alone. All the best models are selected based on the validation set score, and the numbers are reported in the following tables are for test split. For evaluation, we report the performance with BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE-L (Lin, 2004) using e2e-metric[6]. It's worth noting that we perform comprehensive data contamination studies in the following experiments to make sure the pre-training data contains very little overlap with the test split in downstream tasks. We filter out potentially information-leaking pages during the data crawling process.

5.3 Preliminary Study on KGTEXT

In the preliminary study, we evaluate our pre-trained model's performance on the held-out set of KGTEXT to conduct ablation study over KGPT. Specifically, we investigate 1) which encoding mechanism is better, 2) whether we need copy mechanism or copy supervision. As demonstrated in Table 3, we observe that the trivial difference between two encoder designs. With the copy mechanism, KGPT can greatly decrease the perplexity. However, supervising the copy attention does not have much influence on the performance. Therefore, in the following experiments, we will run experiments for both encoding schemes with a copy mechanism without copy loss.

Model	BLEU-4	Perplexity
KGPT-Graph	24.71	4.86
KGPT-Graph + Copy Loss	24.77	4.91
KGPT-Graph w/o Copy	22.69	7.23
KGPT-Seq	24.49	4.95
KGPT-Seq + Copy Loss	24.31	4.93
KGPT-Seq w/o Copy	22.92	7.11

Table 3: Ablation Study on held-out set of KGTEXT.

5.4 Fully-Supervised Results

We experiment with KGPT under the standard fully-supervised setting to compare its performance with other state-of-the-art algorithms.

WebNLG Challenge We list WebNLG's experimental results in Table 4, here we compare with the known models under the unconstrained setting. The baseline models (Shimorina and Gardent, 2018) uses sequence-to-sequence attention model (Luong et al., 2015) as the backbone and propose delexicalization and copy mechanism to enhance model's capability to handle rare items from the input. The GCN model (Marcheggiani and Perez-Beltrachini, 2018) uses graph convolutional neural encoder to encode the structured data input. Its implementation is from Github[7]. As can be seen, KGPT without pre-training already achieves better performance than the GCN baseline. With pre-training, the performance is further boosted by 1-2 BLEU-4, which reflects the effectiveness of our method.

Model	BLEU	METEOR	ROUGE
Seq2Seq†	54.0	37.0	64.0
Seq2Seq+Delex†	56.0	39.0	67.0
Seq2Seq+Copy†	61.0	42.0	71.0
GCN	60.80	42.76	71.13
KGPT-Graph w/o Pre	62.30	44.33	73.00
KGPT-Seq w/o Pre	61.79	44.39	72.97
KGPT-Graph w/ Pre	63.84	46.10	74.04
KGPT-Seq w/ Pre	**64.11**	**46.30**	**74.57**

Table 4: Experimental results on WebNLG's test set, w/ Pre refers to the model with pre-training, otherwise it refers to the model training from scratch. † results are copied from Shimorina and Gardent (2018).

E2E Challenge We list E2ENLG's experimental results in Table 5, here we compare with the state-of-the-art systems on the leaderboard of E2E challenge[8]. These baselines methods are based on neural template model (Wiseman et al., 2018), syntax-enhanced algorithms (Dušek and Jurcicek, 2016), slot alignment (Juraska et al., 2018) and controlling mechanism (Elder et al., 2018). As is seen from the table, KGPT can beat the SOTA systems by a remarkable margin. Overall, the improvement brought by pre-training is roughly 0.5-1.0 in terms of BLEU-4, which is less significant than WebNLG. Such a phenomena is understandable given that this dataset contains limited patterns and vocabulary in the input meaning representation, a full training set over 40K instances is more than enough for the generation model to memorize. In the following few-shot experiments, we will show the strength of KGPT to generate high-quality faithful descriptions with only 0.1% of training data.

KGPT-Graph w/ Pre	67.87	44.50	70.00
KGPT-Seq w/ Pre	**68.05**	**45.80**	**70.92**

Table 5: Experimental results on E2E's test set. NTemp is from Wiseman et al. (2018), TGen is from Dušek and Jurcicek (2016), SLUG2SLUG is from Juraska et al. (2018) and Adapt is from Elder et al. (2018).

WikiBio Dataset We list WikiBio's experimental results in Table 6 and compare with models like Table2Seq(Bao et al., 2018), Order Planning (Sha et al., 2018), Field Gating (Liu et al., 2018), Background-KB Attention (Chen et al., 2019), Hybrid Hierarchical Model (Liu et al., 2019a) trained with multiple auxiliary loss functions. We also train Template-GPT-2 on this dataset to observe pre-trained model's performance. As can be seen from the table, KGPT can achieve better results than the mentioned baseline models. Pre-training can yield an improvement of roughly 0.5 BLEU-4. As this dataset trainin/testing have similar table schema and the large number of training instances already teach the model to memorize the generation patterns, exploiting an external corpus of on par size (1.8M) does not bring a significant boost. So is the template-GPT-2 (Chen et al., 2020a), which performs on par with Field Gating (Liu et al., 2018). However, in the few-shot setting, we will show the 25+ BLEU gain brought by pre-training.

Model	BLEU

Table 6: Experimental results on WikiBio's test set.

5.5 Few-Shot Results

The few-shot learning setting aims to study the potential of the proposed pre-training to decrease annotation labor in data-to-text generation tasks. Under this setting, we not only compare with non-pre-trained baselines to observe how pre-training can benefit the model's few-shot learning capability but also compare with other pre-trained LM (Chen et al., 2020b,a) to see the benefit of KGPT over existing pre-trained LM.

Model	0.5%	1%	5%	10%
Seq2Seq	1.0	2.4	5.2	12.8
Seq2Seq+Delex	4.6	7.6	15.8	23.1
KGPT-Graph w/o Pre	0.6	2.1	5.9	14.4
KGPT-Seq w/o Pre	0.2	1.7	5.1	13.7
Template-GPT-2	8.5	12.1	35.3	41.6
KGPT-Graph w/ Pre	**22.3**	**25.6**	**41.2**	**47.9**
KGPT-Seq w/ Pre	21.1	24.7	40.2	46.5

Table 7: Few-shot results on WebNLG's test set.

Model	0.1%	0.5%	1%	5%
TGen	3.6	27.9	35.2	57.3
KGPT-Graph w/o Pre	2.5	26.8	34.1	57.8
KGPT-Seq w/o Pre	3.5	27.3	33.3	57.6
Template-GPT-2	22.5	47.8	53.3	59.9
KGPT-Graph w/ Pre	39.8	**53.3**	**55.1**	**61.5**
KGPT-Seq w/ Pre	**40.2**	53.0	54.1	61.1

Table 8: Few-shot results on E2ENLG's's test set.

WebNLG & E2ENLG Dataset In these two datasets, we use 0.1%, 0.5%, 1%, 5%, 10% of training instances to train the model and observe its performance curve in terms of BLEU-4.

For WebNLG challenge, the few-shot situation will pose a lot of unseen entities during test time. From Table 7, we can observe that the delexicalization mechanism can remarkably help with the few-shot situation. However, the improvement brought by delexicalization is much weaker than our proposed pre-training. Under the 5% setting, while the non-pre-trained baselines are only able to generate gibberish text, pre-trained KGPT can maintain a high BLEU score over 40.0 due to its strong generalization ability.

For E2E challenge, the task is comparatively simpler with rather limited items. From Table 8, we can observe that TGen (Dušek and Jurcicek, 2016) is achieving similar performance as our non-pre-trained KGPT, they both perform quite well even under 1% training instances. However, after we further reduce the training samples to roughly 0.1%, the baseline models fail while pre-trained KGPT still maintains a decent BLEU over 40.0.

WikiBio Dataset In this dataset, we adopt the same setting as Switch-GPT-2 (Chen et al., 2020b) and Pivot (Ma et al., 2019) to use 50, 100, 200 and 500 samples from the training set to train the generation model. From the results in Table 9, we observe that KGPT can achieve best scores and outperform both Template-GPT-2 and Switch-GPT-2 under most cases. Though Template-GPT-2 is getting slightly better score with 500 training samples, the overall performance on three datasets are remarkably lower than KGPT, especially under more extreme cases. It demonstrates the advantage of our knowledge-grounded pre-training objective over the naive LM pre-training objective.

Model	50	100	200	500
Field-Infusing	1.3	2.6	3.1	8.2
KGPT-Graph w/o Pre	0.2	1.1	3.8	9.7
KGPT-Seq w/o Pre	0.6	1.7	3.0	8.9
Pivot†	7.0	10.2	16.8	20.3
Switch-GPT-2†	17.2	23.8	25.4	28.6
Template-GPT-2	19.6	25.2	28.8	**30.8**
KGPT-Graph w/ Pre	**24.5**	27.5	28.9	30.1
KGPT-Seq w/ Pre	24.2	**27.6**	**29.1**	30.0

Table 9: Few-shot results on Wikibio's test set. † results are copied from Chen et al. (2020b).

Quantitative Study We further investigate how much sample complexity KGPT can reduce. Specifically, we specify a BLEU-4 score and vary the training data size to observe how much training samples are required to attain the performance. We specify BLEU=30 as our standard and display our results in Table 10. We compute the ratio of sample quantity to characterize the benefits from pre-training. Roughly speaking, pre-training can decrease the sample complexity for training by 15x, which suggests the great reduction rate the annotation cost with pre-trained KGPT to achieve the desired 'promising' performance.

Model	WebNLG	E2ENLG	WikiBio
KGPT w/o Pre	∼10000	∼300	∼8000
KGPT w/ Pre	∼700	∼20	∼500
Ratio	14x	15x	16x

Table 10: Required number of training samples to reach designated BLEU on different dataset.

5.6 Zero-Shot Results

We further evaluate KGPT's generalization capability under the extreme zero-shot setting and display our results for WebNLG in Table 11. As can be seen, all the non-pre-trained baselines and Template-GPT-2 fail under this setting, while KGPT can still manage to generate reasonable outputs and achieve a ROUGE-L score over 30. Given that no input knowledge triples in WebNLG were seen during pre-training, these results reflect KGPT's strong generalization ability to cope with out-of-domain unseen knowledge inputs.

Model	BLEU	METEOR	ROUGE
All Baselines	0	0	1.2
Template-GPT-2	0.3	0.5	3.4
KGPT-Graph w/ Pre	13.66	19.17	30.22
KGPT-Seq w/ Pre	13.86	20.15	30.23

Table 11: Zero-shot results on WebNLG's test set.

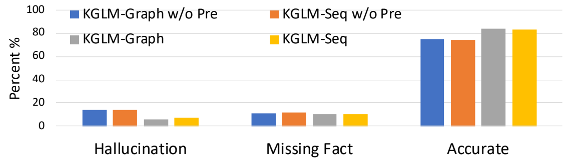

Figure 7: Human evaluation of the factual consistency of different models on WebNLG samples.

5.7 Human Evaluation

We conduct human evaluation to assess the factual accuracy of the generated sentences. Specifically, we sample 100 test samples from WebNLG and observe the model's factual consistency with given fact triples. We use AMT to distribute each generated sentence to four high-quality workers (95% approval rate, 500+ approved jobs) to choose from the three ratings. The majority voted rating is the final rating. We compare four different systems, i.e., non-pre-trained and pre-trained KGPT. Conditioned on the fact triples, we categorize the generated samples into the following categories: 1) hallucinating non-existing facts, 2) missing given facts without hallucination, 3) accurate description of given facts. We visualize the results in Figure 7, from which we observe that pre-trained KGPT are less prone to the known hallucination issue and generate more accurate text. The human evaluation suggests that pre-training can enhance the model's understanding over rare entities, thus reducing the over-generation of non-existent facts.

5.8 Conclusion

In this paper, we propose a pre-training recipe to exploit external unlabeled data for data-to-text generation tasks. Our proposed model has achieved significant performance under zero-shot and few-shot settings. Such a framework provides a plausible solution to greatly reduce human annotation costs in future NLG applications.

A Learning Curve

Here we observe the learning trend of both non-pre-trained and pre-trained models by evaluating the validation BLEU at each epoch end, here we show our findings in Figure 8. As can be seen from the figure, the pre-trained model converges much faster to the best score. More specifically, it only takes 20 epochs for the model to reach BLEU-4 over 60 while it takes 80-90 epochs for a non-pre-trained model to reach equivalent performance.

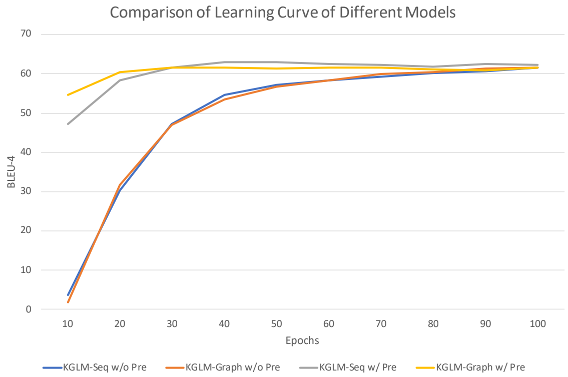

Figure 8: The learning curve of different models during training for the WebNLG dataset.

B Predicate Distribution

Here we demonstrate the most popular predicates in Figure 9. As can be seen, the most popular predicates are ‘instance of’, ‘occupation’, ‘country’, ‘located in’, etc. There are over 1000 predicates in our dataset, which covers the commonly seen categories in different domains like politics, athletics, music, news, etc.

C Case Study

Here we demonstrate some empirical study over the generated samples from our models in Figure 10. As can be seen, KGPT has developed a really strong generation capability to output fluent and coherent sentences. In the first line, the decoded sentence is mostly correct, just the name of ‘municipality’ should be ‘Belgrade’ rather than ‘Zemun’ itself according to `https://www.wikidata.org/wiki/’Q189419`. In the second line, the sentence is mostly correct, the error comes from the end date of Annibale. The third sentence is completely correct. The fourth sentence also suffers from a factual error, the relationship should be ‘married’ rather than ‘daughter’.

From these sentences, it’s understandable that the model can achieve reasonable zero-shot performance on the WebNLG dataset given that WebNLG also comes from a similar domain. The case study reveals that our generation model though generates fluent and relevant sentences from the given knowledge triples, the groundedness is still questionable with quite an amount of hallucination issues.

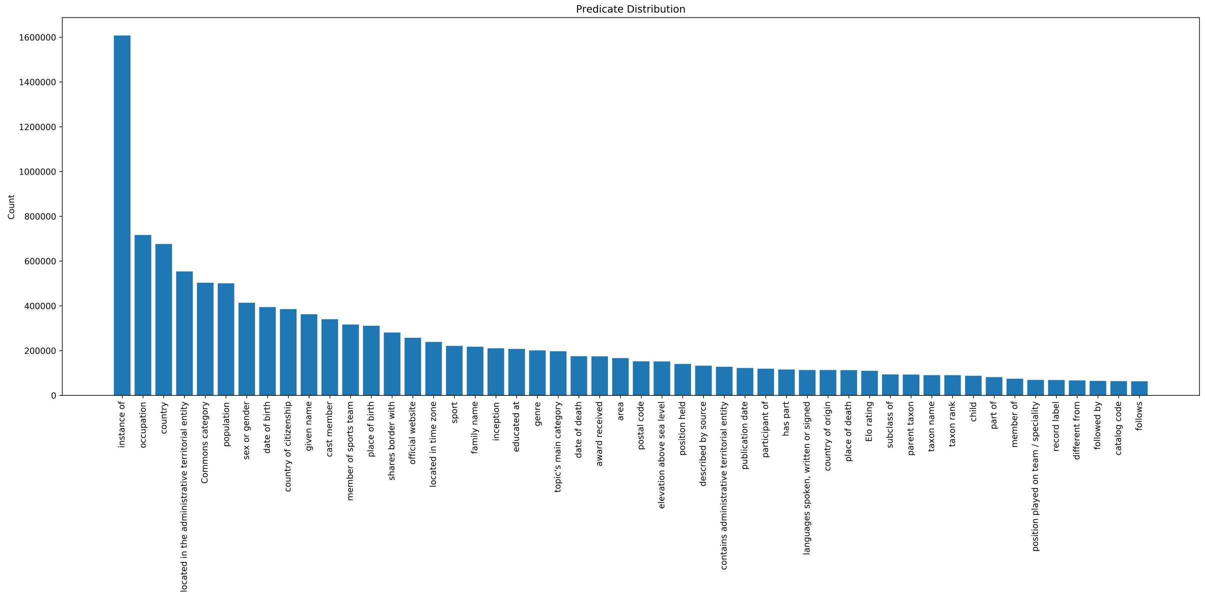

Figure 9: Predicate distribution over the knowledge triples in KGTEXT.

Abstract

Large-scale pre-trained language models, such as BERT and GPT-2, have achieved excellent performance in language representation learning and free-form text generation. However, these models cannot be directly employed to generate text under specified lexical constraints. To address this challenge, we present POINTER[1], a simple yet novel insertion-based approach for hard-constrained text generation. The proposed method operates by progressively inserting new tokens between existing tokens in a parallel manner. This procedure is recursively applied until a sequence is completed. The resulting coarse-to-fine hierarchy makes the generation process intuitive and interpretable. We pre-train our model with the proposed progressive insertion-based objective on a 12GB Wikipedia dataset, and fine-tune it on downstream hard-constrained generation tasks. Non-autoregressive decoding yields an empirically logarithmic time complexity during inference time. Experimental results on both News and Yelp datasets demonstrate that POINTER achieves state-of-the-art performance on constrained text generation. We released the pre-trained models and the source code to facilitate future research [2].

1 Introduction

Real-world editorial assistant applications must often generate text under specified lexical constraints, for example, convert a meeting note with key phrases into a concrete meeting summary, recast a user-input search query as a fluent sentence, generate a conversational response using grounding facts (Mou et al., 2016), or create a story using a pre-specified set of keywords (Fan et al., 2018; Yao et al., 2019; Donahue et al., 2020).

Generating text under specific lexical constraints is challenging. *Constrained* text generation broadly falls into two categories, depending on whether inclusion of specified keywords in the output is mandatory. In *soft-constrained* generation (Qin et al., 2019; Tang et al., 2019), keyword-text pairs are typically first constructed (sometimes along with other conditioning information), and a conditional text generation model is trained to capture their co-occurrence, so that the model learns to incorporate the constrained keywords into the generated text. While *soft-constrained* models are easy to design, even remedied by soft enforcing algorithms such as attention and copy mechanisms (Bahdanau et al., 2015; Gu et al., 2016; Chen et al., 2019a), keywords are still apt to be lost during generation, especially when multiple weakly correlated keywords must be included.

Hard-constrained generation (Hokamp and Liu, 2017; Post and Vilar, 2018; Hu et al., 2019; Miao et al., 2019; Welleck et al., 2019), on the other hand, requires that all the lexical constraints be present in the output sentence. This approach typically involves sophisticated design of network architectures. Hokamp and Liu (2017) construct a lexical-constrained grid beam search decoding algorithm to incorporate constraints. However, Hu et al. (2019) observe that a naive implementation of this algorithm has a high running time complexity. Miao et al. (2019) introduces a sampling-based conditional generation method, where the constraints are first placed in a template, then words in a random position are either inserted, deleted or updated under a Metropolis-Hastings-like scheme. However, individually sampling each token results in slow convergence, as the joint distribution of all the tokens in a sentence is highly correlated. Welleck et al. (2019) propose a tree-based text generation scheme, where a token is first generated in an arbitrary position, and then the model recursively

Table 1: Example of the progressive generation process with multiple stages from the POINTER model. Words in **blue** indicate newly generated words at the current stage. X^i denotes the generated partial sentence at Stage i. X^4 and X^3 are the same indicates the end of the generation process. Interestingly, our method allows informative words (*e.g.*, *company, change*) generated before the non-informative words (*e.g.*, *the, to*) generated at the end.

generates words to its left and right, yielding a binary tree. However, the constructed tree may not reflect the progressive hierarchy/granularity from high-level concepts to low-level details. Further, the time complexity of generating a sentence is $\mathcal{O}(n)$, like standard auto-regressive methods.

Motivated by the above, we propose a novel non-autoregressive model for hard-constrained text generation, called POINTER (**PrO**gressive **IN**sertion-based **T**ransform**ER**). As illustrated in Table 1, generation of words in POINTER is *progressive*, and *iterative*. Given lexical constraints, POINTER first generates high-level words (*e.g.*, nouns, verbs and adjectives) that bridge the keyword constraints, then these words are used as pivoting points at which to insert details of finer granularity. This process iterates until a sentence is finally completed by adding the least informative words (typically pronouns and prepositions).

Due to the resemblance to the masked language modeling (MLM) objective, BERT(Devlin et al., 2019) can be naturally utilized for initialization. Further, we perform large-scale pre-training on a large Wikipedia corpus to obtain a pre-trained POINTER model that which can be readily fine-tuned on specific downstream tasks.

The main contributions of this paper are summarized as follows. (i) We present POINTER, a novel insertion-based Transformer model for hard-constrained text generation. Compared with previous work, POINTER allows long-term control over generation due to the top-down progressive structure, and enjoys a significant reduction over emperical time complexity from $\mathcal{O}(n)$ to $\mathcal{O}(\log n)$ at best. (ii) Large-scale pre-training and novel beam search algorithms are proposed to further boost performance. (iii) We develop a novel beam search algorithm customized to our approach, further improving the generation quality. (iv) Experiments on several datasets across different domains (including News and Yelp) demonstrates the superiority of POINTER over strong baselines. Our approach is simple to understand and implement, yet powerful, and can be leveraged as a building block for future research.

2 Related Work

Language Model Pre-training Large-scale pre-trained language models, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), Text-to-text Transformer (Raffel et al., 2019) and ELECTRA (Clark et al., 2020), have achieved great success on natural language understanding benchmarks. GPT-2 (Radford et al., 2018) first demonstrates great potential for leveraging Transformer models in generating realistic text. MASS (Song et al., 2019) and BART (Lewis et al., 2019) propose methods for sequence-to-sequence pre-training. UniLM (Dong et al., 2019) unifies the generation and understanding tasks within a single pre-training scheme. DialoGPT (Zhang et al., 2020) and MEENA (Adiwardana et al., 2020) focus on open-domain conversations. CTRL (Keskar et al., 2019) and Grover (Zellers et al., 2019) guide text generation with pre-defined control codes. In addition, recent work has also investigated how to leverage BERT for conditional text generation (Chen et al., 2019b; Mansimov et al., 2019; Li et al., 2020). To the best of our knowledge, ours is the first large-scale pre-training work for hard-constrained text generation.

Non-autoregressive Generation Many attempts have been made to use non-autoregressive models for text generation tasks. For neural machine translation, the promise of such methods mostly lies in their decoding efficiency. For example, Gu et al. (2018) employs a non-autoregressive decoder that generates all the tokens simultaneously. Generation can be further refined with a post-processing step to remedy the conditional independence of the parallel decoding process (Lee et al., 2018; Ghazvininejad et al., 2019; Ma et al., 2019; Sun et al., 2019; Kasai et al., 2020). Deconvolutional decoders (Zhang et al., 2017; Wu et al., 2019) have also been studied for title generation and machine translation. The Insertion Transformer (Stern et al., 2019; Gu et al., 2019; Chan et al., 2019) is a partially autoregressive model that predicts both insertion positions and tokens, and is trained to maximize the entropy over all valid insertions, providing fast inference while maintaining good performance. Our POINTER model hybridizes the BERT and Insertion Transformer models, inheriting the advantages of both, and generates text in a progressive coarse-to-fine manner.

3 Method

3.1 Model Overview

Let $X = \{x_0, x_1, \cdots, x_T\}$ denote a sequence of discrete tokens, where each token $x_t \in V$, and V is a finite vocabulary set. For the hard-constrained text generation task, the goal is to generate a complete text sequence X, given a set of key words $\hat{X}$ as constraints, where the key words have to be exactly included in the final generated sequence with the same order.

Let us denote the lexical constraints as $X^0 = \hat{X}$. The generation procedure of our method can be formulated as a (progressive) sequence of K stages: $S = \{X^0, X^1, \cdots, X^{K-1}, X^K\}$, such that for each $k \in \{1, \ldots, K\}$, X^{k-1} is a sub-sequence of X^k. The following stage can be perceived as a finer-resolution text sequence compared to the preceding stage. X^K is the final generation, under the condition that the iterative procedure is converged (*i.e.*, $X^{K-1} = X^K$).

Table 1 shows an example of our progressive text generation process. Starting from the lexical constraints (X_0), at each stage, the algorithm inserts tokens progressively to formulate the target sequence. At each step, at most one new token can be generated between two existing tokens. Formally, we propose to factorize the distribution according to the *importance* (defined later) of each token:

$$p(X) = p(X^0) \prod_{k=1}^{K} p(X^k | X^{k-1}) \qquad (1)$$

where $p(X^k|X^{k-1}) = \prod_{x \in X^k - X^{k-1}} p(x|X^{k-1})$. The more important tokens that form the skeleton of the sentence, such as nouns and verbs, appear in earlier stages, and the auxiliary tokens, such as articles and prepositions, are generated at the later stages. In contrast, the autoregressive model factorizes the joint distribution of X in a standard left-to-right manner, *i.e.*, $p(X) = p(x_0) \prod_{t=1}^{T} p(x_t|x_{<t})$, ignoring the word importance. Though the Insertion Transformer (Stern et al., 2019) attempts to implement the progressive generation agenda in (1), it does not directly address how to train the model to generate important tokens first.

3.2 Data Preparation

Designing a loss function so that (i) generating an important token first and (ii) generating more tokens at each stage that would yield a lower loss would be complicated. Instead, we prepare data in a form that eases model training.

The construction of data-instance pairs reverses the generation process. We construct pairs of text sequences at adjacent stages, *i.e.*, (X^{k-1}, X^k), as the model input. Therefore, each training instance X is broken into a consecutive series of pairs: $(X^0, X^1), \cdots, (X^{K-1}, X^K)$, where K is the number of such pairs. At each iteration, the algorithm masks out a proportion of existing tokens X^k to yield a sub-sequence X^{k-1}, creating a training instance pair (X^{k-1}, X^k). This procedure is iterated until only less than c (c is small) tokens are left.

Two properties are desired when constructing data instances: (i) important tokens should appear in an earlier stage , so that the generation follows a progressive manner; (ii) the number of stages K is small, thus the generation is fast at inference time.

Token Importance Scoring We consider three different schemes to assess the importance score of a token: term frequency-inverse document frequency (TF-IDF), part-of-speech (POS) tagging, and Yet-Another-Keyword-Extractor (YAKE) (Campos et al., 2018, 2020). The TF-IDF score provides the uniqueness and local enrichment evaluation of a token at a corpus level. POS tagging indicates the role of a token at a sequence level. We explicitly assign noun or verb tokens a higher POS tagging score than tokens from other categories. YAKE is a commonly used unsupervised automatic keyword extraction method that relies on statistical features extracted from single documents to select the most important keywords (Campos et al., 2020). YAKE is good at extracting common key words, but relatively weak at extracting special nouns (*e.g.*, names), and does not provide any importance level for non-keyword tokens. Therefore, we combine the above three metrics for token importance scoring. Specifically, the overall score α_t of a token x_t is defined as $\alpha_t = \alpha_t^{\text{TF-IDF}} + \alpha_t^{\text{POS}} + \alpha_t^{\text{YAKE}}$, where $\alpha_t^{\text{TF-IDF}}$, α_t^{POS} and α_t^{YAKE} represent the TF-IDF, POS tagging and YAKE scores (each is rescaled to $[0, 1]$), respectively.

Additionally, stop words are manually assigned a low importance score. If a token appears several times in a sequence, the latter occurrences are assigned a decayed importance score to prevent the model from generating the same token multiple times in one step at inference time. We note that our choice of components of the importance score is heuristic. It would be better to obtain an unbiased/oracle assessment of importance, which we leave for future work.

DP-based Data Pair Construction Since we leverage the Insertion-based Transformer, which allows at most one new token to be generated between each two existing tokens, sentence length at most doubles at each iteration. Consequently, the optimal number of iterations K is $\log(T)$, where T is the length of the sequence. Therefore, generation efficiency can be optimized by encouraging more tokens to be discarded during each masking step when preparing the data. However, masking positional interleaving tokens ignores token importance, and thus loses the property of progressive planning from high-level concepts to low-level details at inference time. In practice, sequences generated by such an approach can be less semantically consistent as less important tokens occasionally steer generation towards random content.

We design an approach to mask the sequence by considering both token importance and efficiency using dynamic programming (DP). To accommodate the nature of insertion-based generation, the masking procedure is under the constraint that no consecutive tokens can be masked at the same stage. Under such a condition, we score each token and select a subset of tokens that add up to the highest score (all scores are positive). This allows the algorithm to adaptively choose as many high scored tokens as possible to mask.

Formally, as an integer linear programming problem (Richards and How, 2002), the objective is to find an optimal masking pattern $\Phi = \{\phi_1, \cdots, \phi_T\}$, where $\phi_t \in \{0, 1\}$, and $\phi_t = 1$ represents discarding the corresponding token x_t, and $\phi_t = 0$ indicates x_t remains. For a sequence X', the objective can be formulated as:

$$\max \sum_{t=1}^{T} \phi_t(\alpha_{\max} - \alpha_t), \\ \text{s.t.} \quad \phi_t \phi_{t+1} \neq 1\,, \forall t \tag{2}$$

where $\alpha_{\max} = \max_t\{\alpha_t\}$. Though solving Eq. (2) is computationally expensive, one can resort to an analogous problem for a solution, the so-called *House Robbery Problem*, a variant of *Maximum Subarray Problem* (Bentley, 1984), where a professional burglar plans to rob houses along a street and tries to maximize the outcome, but cannot break into two adjacent houses without triggering an alarm. This can be solved using dynamic programming (Bellman, 1954) (also known as *Kadane's algorithm* (Gries, 1982)) as shown in Algorithm 1.

Algorithm 1 DP-based Data Pair Construction.

```
Input: A sequence of discrete tokens $X = \{x_1 \cdots, x_T\}$ and its corresponding score list $\{\alpha_{\max} - \alpha_1, \cdots, \alpha_{\max} - \alpha_T\}$
Output: Masking pattern $\Phi = \{\phi_1, \cdots, \phi_T\}$
Initialization: Accumulating scores $s_1 \leftarrow \alpha_{\max} - \alpha_1$ and $s_2 \leftarrow \max(\alpha_{\max} - \alpha_1, \alpha_{\max} - \alpha_2)$; position tracker $p_1 \leftarrow -\inf$ and $p_2 \leftarrow -\inf$; $\Phi$ = 0
while $t \leq T$ do
    $s_t \leftarrow \max(s_{t-2} + \alpha_{\max} - \alpha_t, s_{t-1})$
    if $s_t = s_{t-1}$ then $p_t \leftarrow t - 1$
    else $p_t \leftarrow t - 2$
    end if
    $t \leftarrow t + 1$
end while
if $s_T = s_{T-1}$ then $t \leftarrow T - 1$
else $t \leftarrow T - 2$, $\phi_T \leftarrow 1$
end if
while $t \geq 1$ do
    $\phi_t \leftarrow 1$,$t \leftarrow p_t$
end while
```

3.3 Model Training

Stage-wise Insertion Prediction With all the data-instance pairs (X^{k-1}, X^k) created as described above as the model input, we optimize the following objective:

$$\begin{aligned} \mathcal{L} &= -\log p(X^k | X^{k-1}) \qquad (3) \\ &= -\sum_{x \in X^+} \log p(x|\Phi^{k-1}, X^{k-1}) p(\Phi^{k-1}|X^{k-1})\,, \end{aligned}$$

where $X^+ \triangleq X^k - X^{k-1}$, and Φ^{k-1} denotes an indicator vector in the k-th stage, representing whether an insertion operation is applied in a slot.

As illustrated in Figure 1, while the MLM objective in BERT only predicts the token of a masked

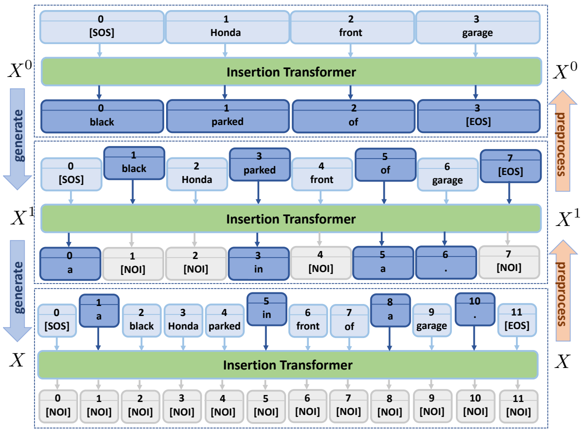

Figure 1: Illustration of the generation process ($X^0 \rightarrow X$) of the proposed POINTER model. At each stage, the Insertion Transformer module generates either a regular token or a special [NOI] token for each gap between two existing tokens. The generation stops when all the gaps predict [NOI]. The data preparation process reverses the above generative process.

placeholder, our objective comprises both (i) likelihood of an insertion indicator for each slot (between two existing tokens), and (ii) the likelihood of each new token conditioning on the activated slot. To handle this case, we expand the vocabulary with a special no-insertion token `[NOI]`. During inference time, the model can predict either a token from the vocabulary to insert, or an `[NOI]` token indicating no new token will be inserted at a certain slot at the current stage. By utilizing this special token, the two objectives are merged. Note that the same insertion transformer module is re-used at different stages. We empirically observed that the model can learn to insert different words at different stages; it presumably learns from the completion level (how discontinuous the context is) of the current context sequence to roughly estimate the progress up to that point.

During inference time, once in a stage (X^k), all the slots predict `[NOI]` for the next stage, the generation procedure is converged and X^k is the final output sequence. Note that to account for this final stage X^k, during data preparation we incorporate an (X, N) pair for each sentence in the training data, where N denotes a sequence of `[NOI]` with the same length of X. To enable the model to insert at the beginning and end of the sequence, an `[SOS]` token and an `[EOS]` token are added in the beginning and at the end of each sentence, respectively.

In light of the similarity with the MLM objective, we use BERT model to initialize the Insertion Transformer module.

Large-scale Pre-training In order to provide a general large-scale pretrained model that can benefit various downstream tasks with fine-tuning, we train a model on the massive publicly available English Wiki dataset, which covers a wide range of topics. The Wiki dataset is first preprocessed according to Sec. 3.2. We then initialize the model with BERT, and perform model training on the processed data using our training objective (3). After pre-training, the model can be used to generate an appropriate sentence with open-domain keyword constraints, in a tone that represents the Wiki style. In order to adapt the pre-trained model to a new domain (*e.g.*, News and Yelp reviews), the pre-trained model is further fine-tuned on new datasets, which empirically demonstrates better performance than training the model on the target domain alone.

3.4 Inference

During inference time, starting from the given lexical constraint X^0, the proposed model generates text stage-by-stage using greedy search or top-K sampling (Fan et al., 2018), by applying the Insertion Transformer module repeatedly until no additional token is generated. If a `[NOI]` token is generated, it is deleted at the next round.

Inner-Layer Beam Search According to (3), all new tokens are simultaneously generated based on the existing tokens at the previous stage. Despite of being fully parallel, like BERT (Yang et al., 2019) and NAT (Ghazvininejad et al., 2019; Kasai et al., 2020) this approach suffers from a conditional independence problem in which the predicted tokens are conditional-independently generated and are agnostic of each other. This can result in generating repeating or inconsistent new tokens at each generation round.[3]

To address this weak-dependency issue, we perform a modified beam search algorithm for decoding. Specifically, at stage k, suppose the existing tokens from last stage are $X^{k-1} = \{x_1^{k-1}, \cdots, x_{T_{k-1}}^{k-1}\}$, where T_{k-1} is the length of X^{k-1}. For predicting next stage X^k, there will be T_{k-1} available slots. A naive approach to perform beam search would be to maintain a priority queue of top B candidate token series predictions when moving from the leftmost slot to the rightmost slot. At the t-th move, the priority queue contains top B sequences

---

[3] For example, from an existing token "*and*", the model generates "*clean and clean*".

for existing predicted tokens: $(s_1^{(b)}, \cdots, s_{t-1}^{(b)})$, where $s_i^{(b)}$ denotes the predicted token for the i-th slot in the b-th ($b \in \{1, \cdots, B\}$) sequence. The model then evaluates the likelihood of each item (including [NOI]) in the vocabulary for the slot s_t, by computing the likelihood of $(s_1^{(b)}, x_1^{k-1}, \cdots, s_{t-1}^{(b)}, x_{t-1}^{k-1}, s_t, x_t^{k-1}, \texttt{[NOI]}, \cdots, \texttt{[NOI]}, x_{T_{k-1}}^{k-1})$. This is followed by a ranking step to select the top B most likely series among the VB series to grow. However, such a naive approach is expensive, as the runtime complexity takes $\mathcal{O}(TBV)$ evaluations.

Instead, we approximate the search by constraining it in a narrow band. We design a customized beam search algorithm for our model, called *inner-layer beam search* (ILBS). This method applies an approximate local beam search at each iteration to find the optimal stage-wise decoding. At the t-th slot, ILBS first generates top B token candidates by applying one evaluation step based on existing generation. Prediction is limited to these top B token candidates, and thus the beam search procedure as described above is applied on the narrow band of B instead of the full vocabulary V. This reduces the computation to $\mathcal{O}(TB^2)$.

4 Experiments

We evaluate the POINTER model on constrained text generation over News and Yelp datasets. Details of the datasets and experimental results are provided in the following sub-sections. The pre-trained models and the source code are available at Github [4].

4.1 Experimental Setup

Datasets and Pre-processing We evaluate our model on two datasets. The *EMNLP2017 WMT News dataset*[5] contains 268,586 sentences, and we randomly pick 10k sentences as the validation set, and 1k sentences as the test set. The *Yelp English review dataset* is from Cho et al. (2018), which contains 160k training examples, 10k validation examples and 1k test examples. These two datasets vary in sentence length and domain, enabling the assessment of our model in different scenarios.

The English Wikipedia dataset we used for pre-training is first pre-processed into a set of natural sentences, with maximum sequence length of 64 tokens, which results in 1.99 million sentences for model training in total (12.6 GB raw text). On average, each sentence contains 27.4 tokens.

For inference, we extract the testing lexical constraints for all the compared methods using the 3rd party extracting tool YAKE[6]. The maximum length of the lexical constraints we used for News and Yelp is set to 4 and 7, respectively, to account the average length for News ($27.9 \approx 4 \times 2^3$) and Yelp ($50.3 \approx 7 \times 2^3$), as we would hope the generation can be done within 4 stages.

Baselines We compare our model with two state-of-the-art methods for hard-constrained text generation: (i) Non-Monotonic Sequential Text Generation (NMSTG) (Welleck et al., 2019), and (ii) Constrained Sentence Generation by Metropolis-Hastings Sampling (CGMH) (Miao et al., 2019). We also compared with an autoregressive soft-constraint baseline(Gao et al., 2020). Note that the Insertion Transformer (Stern et al., 2019) focuses on machine translation rather than hard-constrained generation task, and therefore is not considered for comparison. Other methods based on grid beam search typically have long inference time, and they only operate on the inference stage; these are also excluded from comparison. For all compared system, we use the default settings suggested by the authors, the models are trained until the evaluation loss does not decrease. More details are provided in the Appendix.

Experiment Setups We employ the tokenizer and model architecture from BERT-base and BERT-large models for all the tasks. BERT models are used as our model initialization. Each model is trained until the validation loss is no longer decreasing. We use a learning rate of 3e-5 without any warming-up schedule for all the training procedures. The optimization algorithm is Adam (Kingma and Ba, 2015). We pre-train our model on the Wiki dataset for 2-4 epochs, and fine-tune on the News and Yelp datasets for around 10 epochs.

Evaluation Metrics Following Zhang et al. (2020), we perform automatic evaluation using commonly adopted text generation metrics, including BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007), and NIST (Doddington, 2002). Following (Kann et al., 2018), to assess the coherence of generated sentences, we also report the perplexity over the test set using pre-trained GPT-2

Table 2: Automatic evaluation results on the News (upper) and Yelp (lower) dataset. ILBS denotes beam search. "+Wiki" denotes fine-tuning on the Wiki-pretrained model. "base/large" represents the greedy generation from a based(110M)/large(340M) model. "Human" represents the held-out human reference.

medium (large) model[7]. We use Entropy (Zhang et al., 2018) and Dist-n (Li et al., 2016) to evaluate lexical diversity.

Keywords	**estate pay stay policy**
CGMH	an economic **estate** developer that could **pay** for it is that a **stay policy** .
NMSTG	as **estate** owners , they cannot **pay** for households for hundreds of middle - income property , buyers **stay** in retail **policy** .
POINTER (Greedy, base)	if you buy new buildings from real **estate** company, you may have to **pay** down a mortgage and **stay** with the **policy** for financial reasons .
POINTER (ILBS, base)	but no matter what foreign buyers do , real **estate** agents will have to **pay** a small fee to **stay** consistent with the **policy** .
POINTER (Greedy, Large)	but it would also be required for **estate** agents , who must **pay** a larger amount of cash but **stay** with the same **policy** for all other assets .

Table 3: Generated examples from the News dataset.

Keywords	**joint great food great drinks greater staff**
CGMH	very cool **joint** with **great food** , **great drinks** and even **greater staff** . ! .
NMSTG	awesome **joint** . **great** service. **great food** great **drinks**. good to **greater** and great **staff**!
POINTER (Greedy, base)	my favorite local **joint** around old town. **great** atmosphere, amazing **food**, delicious and delicious coffee, **great** wine selection and delicious cold **drinks**, oh and maybe even a **greater** patio space and energetic front desk **staff**.
POINTER (ILBS, base)	the best breakfast **joint** in charlotte . **great** service and amazing **food** . they have **great** selection of **drinks** that suits the **greater** aesthetic of the **staff** .
POINTER (Greedy, Large)	this is the new modern breakfast **joint** to be found around the area . **great** atmosphere , central location and excellent **food** . nice variety of selections . **great** selection of local craft beers , good **drinks** . quite cheap unless you ask for **greater** price . very friendly patio and fun **staff** . love it !

Table 4: Generated examples from the Yelp dataset.

4.2 Experimental Results

News Generation We first conduct experiments on the News dataset to generate sentences from 4 lexical constraints. Quantitative results are summarized in Table 2 (upper). Some qualitative examples including the progressive generations at each stage are provided in Table 3 and Appendix B. POINTER is able to take full advantage of BERT initialization and Wiki pre-training to improve relevance scores (NIST, BLEU and METEOR). Leveraging the ILBS or using a larger model further improves most automatic metrics we evaluated [8]. For diversity scores, as CGMH is a sampling-based method in nature, it achieves the highest Dist-n scores (even surpasses human score). We observed that the length of generated sentences, the diversity scores and the GPT-2 perplexity from POINTER are close to human oracle.

Yelp Generation We further evaluate our method

---

[7] `https://github.com/openai/gpt-2`

[8] The ILBS for larger models performs similarly to greedy decoding, and thus is omitted from comparison

Semantics: *A and B, which is more semantically meaningful and consistent?*

Table 5: **Human Evaluation** on two datasets for semantic consistency, fluency and informativeness, showing preferences (%) for our POINTER(base) model vis-à-vis baselines and real human responses. Numbers in bold indicate the most preferred systems. Differences in mean preferences are statistically significant at $p \leq 0.00001$.

on the Yelp dataset, where the goal is to generate a long-form text from more constraints. Generating a longer piece of text with more lexical constraints is generally more challenging, since the model needs to capture the long-term dependency structure from the text, and effectively conjure up with a plan to realize the generation. Results of automatic evaluation are provided in Table 2 (lower). Generated examples are shown in Table 4 and Appendix C. Generally, the generation from our model effectively considers all the lexical constraints, and is semantically more coherent and grammatically more fluent, compared with the baseline methods. The automatic evaluation results is generally consistent with the observations from News dataset, with an exception that Dist-n scores is much lower than the human Dist-n scores. Compared with greedy approach, at a cost of efficiency, ILBS is typically more concise and contains less repeated information, a defect the greedy approach occasionally suffers (e.g., Table 4, "delicious and delicious").

For both datasets, most of the generations converges with in 4 stages. We perform additional experiments on zero-shot generation from the pre-trained model on both datasets, to test the versatility of pre-training. The generated sentences, albeit Wiki-like, are relatively fluent and coherent (see examples in Appendix B and C), and yield relatively high relevance scores (see Appendix E for details). Interestingly, less informative constraints are able to be expanded to coherent sentences. Given the constraint is to from, our model generates "it is oriented to its east, but from the west".

The autoregressive soft-constraint baseline(Gao et al., 2020) has no guarantee that it will cover all keywords in the given order, thus we omit it in the Table 2. For this baseline, the percentage of keywords that appear in the outputs are 57% and 43% for News and Yelp datasets, respectively. With the similar model size (117M), this baselines performance is worse than ours approach in automatic metrics for News dataset (BLEU4: 2.99 → 1.74; NIST4: 3.22 → 1.10; METEOR: 16% → 9%; DIST2: 61% → 58%; PPL: 66 → 84). The performance gap in Yelp dataset is even larger due to more lexical constraints.

Human Evaluation Using a public crowd-sourcing platform (UHRS), we conducted a human evaluation of 400 randomly sampled outputs (out of 1k test set) of CGMH, NMSTG and our base and large models with greedy decoding. Systems were paired and each pair of system outputs was randomly presented (in random order) to 5 crowd-sourced judges , who ranked the outputs pairwise for coherence, informativeness and fluency using

Model	Training	Inference
CGMH	4382 toks/s	33h
NMSTG	357 toks/s	487s
POINTER	5096 toks/s	94s

Table 6: Speed comparison. "toks/s" represents tokens per second. Inference time is computed on 1000 test examples. POINTER uses (greedy, base)

a 5-point Likert-like scale. The human evaluation template is provided in Appendix G. The overall judge preferences for fluency, informativeness and semantic coherence are presented as percentages of the total "vote" in Table 5. P-values are all p¡0.00001 (line 721), computed using 10000 bootstrap replications. For inter-annotator agreement, Krippendorff's alpha is 0.23 on the News dataset and 0.18 on the Yelp dataset. Despite the noise, the judgments show a strong across-the-board preference for POINTER(base) over the two baseline systems on all categories. A clear preference for the human ground truth over our method is also observed. The base and large models show comparable human judge preferences on the News dataset, while human judges clearly prefer the large model on Yelp data (see Appendix D for more details).

Running-time Comparison One of the motivations of this work is that at each stage the generation can be parallel, leading to a significant reduction in training and inference. We compare the model training time and the inference decoding time of all the methods on the Yelp dataset, and summarize the results in Table 6. The evaluation is based on a single Nvidia V100 GPU. Training time for CGMH and POINTER is relatively fast, while NMSTG processes fewer tokens per second since it needs to generate a tree-like structure for each sentence. With respect to inference time, CGMH is slow, as it typically needs hundreds of sampling iterations to decode one sentence.

We note there is no theoretical guarantee of $\mathcal{O}(\log N)$ time complexity for our method. However, our approach encourages filling as many slots as possible at each stage, which permits enables the model to achieve an empirical $\mathcal{O}(\log N)$ speed. In our experiment 98% of generations end within 4 stages.

Note that our method in Table 6 uses greedy decoding. ILBS is around 20 times slower than greedy. The large model is around 3 times slower than the base model.

5 Conclusion

We have presented POINTER, a simple yet powerful approach to generating text from a given set of lexical constraints in a non-autoregressive manner. The proposed method leverages a large-scale pre-trained model (such as BERT initialization and our insertion-based pre-training on Wikipedia) to generate text in a progressive manner using an insertion-based Transformer. Both automatic and human evaluation demonstrate the effectiveness of POINTER. In future work, we hope to leverage sentence structure, such as the use of constituency parsing, to further enhance the design of the progressive hierarchy. Our model can be also extended to allow inflected/variant forms and arbitrary ordering of given lexical constraints.

Appendix

A Baseline and Experimental Details

For NMSTG, we first convert the lexical constraints into a prefix sub-tree, and then sample a sentence to complete the sub-tree. We use the default settings suggested by the authors, and use an LSTM with hidden size of 1024 as the text generator, and select the best performed variants (*annealed*) as our baseline. For CGMH, we use their default setting, which uses an LSTM with hidden size of 300, and set the vocabulary size as 50k. Both models are trained until the evaluation loss does not decrease. During inference, we run CGMH for 500 iterations with default hyperparameters.

For experiment setup, we employ the tokenizer from BERT, and use WordPiece Embeddings (Wu et al., 2016) with a 30k token vocabulary for all the tasks. A special no-insertion token `[NOI]` is added to the vocabulary. We utilize the BERT-base and BERT-large models with 12 self-attention layers and 768 hidden dimensions as our model initialization. Each model is trained until there is no progress on the validation loss. We use a learning rate of 3e-5 without any warming-up schedule for all the training procedures. The optimization algorithm is Adam (Kingma and Ba, 2015). We pretrain our model on the Wiki dataset for 2 epochs, and fine-tune on the News and Yelp datasets for around 10 epochs.

B Additional Generated Examples for News Dataset

We provide two examples on News dataset for how the model progressively generates the sentences in Table 7. All the generations are from the Pointer large model using greedy decoding.

In this section, we also provide some additional examples from the 1k news test data.

Stage	Generated text sequence
0 (X^0)	aware negative immediately sites
1 (X^1)	**if** aware **posts** negative **should** immediately **any** sites **posts**
2 (X^2)	**would** if **user** aware **that** posts **have** negative **impact** should immediately **related** any **these** sites **remove** posts
3 (X^3)	**this** would **prefer** if **the** user **is** aware that **the** posts have **a** negative impact **and** should **be** immediately related **to** any **of** these sites **and** remove **those** posts .

Stage	Generated text sequence
0 (X^0)	estate pay stay policy
1 (X^1)	**also** estate **agents** pay **amount** stay **same** policy assets
2 (X^2)	**it** also **required** estate agents **who** pay **same** amount **cash** stay **with** same policy **all** assets
3 (X^3)	**but** it **would** also **be** required **for** estate agents **,** who **must** pay **the** same amount **of** cash **but** stay with **the** same policy **for** all **other** assets .

Table 7: Example of the progressive generation process with multiple stages from the Pointer model. New additions at each stage are marked as **blue**.

Keywords	aware negative immediately sites
Oracle	where we become **aware** of any accounts that may be **negative** , we **immediately** contact companies such as Instagram , although we have no control over what they allow on their **sites** .
CGMH	not even **aware** of **negative** events including video events **immediately** at stations , Facebook **sites**.
NMSTG	health providers in a country for England are **aware** of small health systems - and not non - health care but all **negative** is **immediately** treated by heads of businesses and departments in the **sites** .
Pointer (Greedy, base)	‘ if users are **aware** of the **negative** impact of blocking , how can they so **immediately** ban these **sites** ? ’ the researchers wrote .
Pointer (ILBS, base)	if the users are **aware** of or the **negative** messages , they can **immediately** be transferred to other **sites** .
Pointer (Greedy, Large)	this would prefer if the user is **aware** that the posts have a **negative** impact and should be **immediately** related to any of these **sites** and remove those posts .
Wiki zero-shot	he is not **aware** of the **negative** , and will **immediately** go to the positive **sites** .

Keywords	children fault left charge
ORACLE	my relationship with my **children** was seriously affected as they were told time and again that everything was my **fault** , they were even **left** ‘ in **charge** ’ of me if my wife went out of the house .
CGMH	his two **children** are the rare **fault** that **left** the police **charge**
NMSTG	but despite **children** from hospitals to last one by **fault** backing this month , there have arrived as Mr Hunt has been **left charge** .
POINTER (Greedy, base)	but i found that these **children** were not at school however this was not their **fault** , and if so they were **left** without a parent in **charge** .
POINTER (ILBS, base)	but my lovely wife and **children** consider that it is not our own **fault** and we should not be **left** alone in **charge** .
POINTER (Greedy, Large)	i said to my **children** : it ’ s not his **fault** the parents **left** him ; the parents should be in **charge** of him .
Wiki zero-shot	but for the **children** who are not at a **fault** , they are **left** behind on the **charge** .

Keywords	estate pay stay policy
ORACLE	how many people on the **estate** does he think will be affected by the new **pay** - to - **stay policy** ?
CGMH	an economic **estate** developer that could **pay** for it is that a **stay policy**
NMSTG	as **estate** owners , they cannot **pay** for households for hundreds of middle - income property , buyers **stay** in retail **policy** .
POINTER (Greedy, base)	if you buy new buildings from real **estate** company, you may have to **pay** down a mortgage and **stay** with the **policy** for financial reasons .
POINTER (ILBS, base)	but no matter what foreign buyers do , real **estate** agents will have to **pay** a small fee to **stay** consistent with the **policy** .
POINTER (Greedy, Large)	but it would also be required for **estate** agents , who must **pay** a larger amount of cash but **stay** with the same **policy** for all other assets .
Wiki zero-shot	however , his real **estate** agent agreed to **pay** him for the **stay** under the same **policy** .

Keywords	managers cut costs million
ORACLE	he was the third of four **managers** sent in to **cut costs** and deal with the city ’ s $ 13 **million** deficit .
CGMH	the **managers** , who tried to **cut** off their **costs** , added 20 **million** euros
NMSTG	business **managers cut** demand for more expensive **costs** in 2017 - by October - is around 5 **million** 8 per cent , and has fallen by 0 . 3 per cent in January and 2017 .
POINTER (Greedy, base)	under one of its general **managers** , the firm had already **cut** its annual operating **costs** from $ 13 . 5 **million** to six million euros .
POINTER (ILBS, base)	and last month , the **managers** announced that it had **cut** its operating **costs** by $ 30 **million** .
POINTER (Greedy, Large)	the biggest expense is for the **managers** , where it plans to **cut** their annual management **costs** from $ 18 . 5 **million** to $ 12 million .
Wiki zero-shot	but then he and all of his **managers** agreed to **cut** off all of the operating **costs** by about 1 **million** .

Keywords	looked report realized wife
ORACLE	i **looked** at the **report** and saw her name , and that’s when I **realized** it was my ex-**wife** .
CGMH	he **looked** at the **report** and said he **realized** that if his **wife** Jane
NMSTG	i **looked** at my **report** about before I **realized** I return to travel holidays but - it doesn ’ t haven ’ t made anything like my **wife** .
POINTER (Greedy, base)	when i turned and **looked** at a file **report** from the airport and **realized** it was not my **wife** and daughter .
POINTER (ILBS, base)	when i turned around and **looked** down at the pictures from the **report** , i **realized** that it was my **wife** .
POINTER (Greedy, Large)	however , when they **looked** at the details of the **report** about this murder , they quickly **realized** that the suspect was not with his **wife** or his partner .
Wiki zero-shot	but when he **looked** up at the **report** , he **realized** that it was not his **wife** .

Keywords	time claim tax year
ORACLE	walker says there is still **time** to **claim** this higher protection if you haven ’ t already as the deadline is the end of the 2016 / 2017 **tax** **year** .
CGMH	” two states , one - **time** voters can **claim** a federal **tax** **year**
NMSTG	this **time** they had three to **claim** of an equal **tax** and 34 women at which indicated they should leave that over the **year** of 16 .
POINTER (Greedy, base)	it is the very first **time** in history that trump will ever **claim** over $ 400 million in federal income **tax** that he had held last **year** , the same report says .
POINTER (ILBS, base)	is this the very first **time** someone has to **claim** federal income **tax** twice in a single **year** ?
POINTER (Greedy, Large)	this is not for the first **time** that the scottish government was able to **claim** **tax** cuts of thousands of pounds a **year** to pay .
Wiki zero-shot	but at the **time** , the **claim** was that the same sales **tax** that was from the previous fiscal **year** .

Keywords	model years big drama
ORACLE	the former **model** said : “ I haven ’ t seen him in so many **years** , I can ’ t make a **big** **drama** out of it . ”
CGMH	the “ **model** ” continues , like many **years** of sexual and **big** **drama** going
NMSTG	after **model** two **years** and did it like , could we already get bigger than others in a **big** **drama** ?
POINTER (Greedy, base)	but i am a good role **model** , who has been around for 10 **years** now , and that is a **big** example of what i can do in **drama** on screen .
POINTER (ILBS, base)	but the young actress and **model** , for 15 **years** , made a very **big** impact on the **drama** .
POINTER (Greedy, Large)	i have seen the different **model** she recommends of over **years** , but it ’ s no **big** change in the **drama** after all .
Wiki zero-shot	she was a **model** actress for many **years** and was a **big** star in the **drama** .

Keywords	made year resolution managed
ORACLE	i once **made** this my new **year** ’ s **resolution** , and it is the only one that I ’ ve actually ever **managed** to keep .
CGMH	indeed , as he **made** up the previous **year** , the GOP **resolution** was **managed**
NMSTG	while additional sanctions had been issued last week **made** a **year** from the latest **resolution** , Russia ’ s Russian ministers have but have **managed** .
POINTER (Greedy, base)	no progress has been **made** in syria since the security council started a **year** ago , when a **resolution** expressed confidence that moscow **managed** to save aleppo .
POINTER (ILBS, base)	and the enormous progress we have **made** over the last **year** is to bring about a **resolution** that has not been **managed** .
POINTER (Greedy, Large)	the obama administration , which **made** a similar call earlier this **year** and has also voted against a **resolution** to crack down on the funding , **managed** to recover it .
Wiki zero-shot	but despite all the same changes **made** both in both the previous fiscal **year** , and by the un **resolution** itself , only the federal government **managed** ...

Keywords	club believed centre window
ORACLE	the **club** are **believed** to be keen on bringing in cover at **centre** - back during the current transfer **window** , with a loan move most likely .
CGMH	the **club** has also been **believed** that more than a new **centre** - up **window**
NMSTG	one **club** **believed** it was not clear that the **centre** would hold place on the **window** until there were no cases that they had heard or had the decision disappeared .
POINTER (Greedy, base)	he had been talking to the **club** since he is **believed** to have reached the **centre** spot in the queue before the january transfer **window** was suspended .
POINTER (ILBS, base)	when he left his old **club** , chelsea , he was **believed** to be at the **centre** of the transfer **window** .
POINTER (Greedy, Large)	the striker has remained at the **club** at the weekend and is increasingly **believed** to be available as a **centre** of the club during the summer transfer **window** until january 2016 .
Wiki zero-shot	during his first **club** as manager he was widely **believed** to be at the **centre** forward in the january transfer **window** .

Keywords	great past decade city
ORACLE	it ' s been a **great** time , the **past decade** or so , to be the mayor of a major capital **city** .
CGMH	the great past decade is that so much of a new home city
NMSTG	i like to thank you for me and I ' ve wanted it to grow in every **great past decade** over the **city** , a very amazing time .
POINTER (Greedy, base)	this is one of the **great** cities that he have visited in the **past** two **decade** , the kansas **city** , missouri , he says .
POINTER (ILBS, base)	you don ' t feel as **great** as you ' ve been in the **past decade** in a major **city** .
POINTER (Greedy, Large)	there has been a lot of **great** work here in the **past** few years within more than a **decade** , done for the **city** , he says .
Wiki zero-shot	there was a **great** success in the **past** during the last **decade** for the **city** .

C Additional Generated Examples for Yelp Dataset

We provide two examples on Yelp dataset for how the model progressively generates the sentences in Table 8. All the generations are from the POINTER large model using greedy decoding.

We also provide some additional examples from the Yelp test set. The results includes keywords, human oracle, CGMH, NMSTG and our models. For our models, we include POINTER base and large models with greedy decoding and base model with ILBS. The large model with ILBS is time consuming so we omit them from the comparison.

Stage	Generated text sequence
0 (X^0)	delicious love mole rice back

Keywords	service perfect delicious service awesome good place
ORACLE	yummy excellent **service** . ordered the carne asada medium rare . it was **perfect** . and **delicious** . their customer **service** was **awesome** . they were so friendly and made sure all was **good** . i definitely recommend this **place** .
CGMH	great **service** **perfect** food and **delicious** **service** . **awesome** place and **good** **place** !.
NMSTG	**service** was **perfect** , **delicious** and great **service** **awesome** service **good** food . this **place** will go back .
POINTER (Greedy, base)	excellent food , great **service** , really nice atmosphere , **perfect** amount of spring rolls , **delicious** especially the chicken and eel . the **service** was very friendly and the prices are **awesome** too . for a female who loves **good** japanese restaurant , this is definitely your **place** !
POINTER (ILBS, base)	from the food to **service** . the foods are **perfect** , they were **delicious** . and **service** is beyond expectation . christina was **awesome** , so many **good** things about this **place** .
POINTER (Greedy, Large)	absolutely loved the food and very friendly **service** . i had the chicken , it was cooked **perfect** and the seafood pasta was thick and **delicious** and not too heavy though . our **service** guy at the front bar was so **awesome** , he made sure we had a **good** time . would definitely recommend to try this **place** to anyone !
Wiki zero-shot	he said the **service** was **perfect** , and **delicious** , and the **service** that is **awesome** , and very **good** in its **place** .

Keywords	good drinks love clients tighter great service
ORACLE	**great** atmosphere , good food and **drinks** . i **love** coming here in the fall to spring to meet with **clients** . their inside is a little small and makes summer a bit **tighter** , but still a **great** staff with excellent **service** .
CGMH	**good** **drinks** . i **love** how out **clients** are **tighter** . **great** customer **service** .
NMSTG	such **good** place with i love the mushroom **drinks** . the menu they **love** the **clients** . and **tighter** out the menu are **great** **service** .
POINTER (Greedy, base)	this place is **good** . they have a wide variety of **drinks** . this really fits your taste . **love** the cozy bar that allows **clients** to be able to fit very tightly and **tighter** , better blending with the crowd . **great** coffee , reasonable prices , and friendly **service** !
POINTER (ILBS, base)	nice place , with **good** vibe . nice mix of **drinks** and intimate space . what i really **love** about was there were so more mature **clients** , and they can fit in a **tighter** timeline . overall , **great** atmosphere and excellent **service** .
POINTER (Greedy, Large)	really like this place . has a **good** dj , good atmosphere and cool **drinks** and quite nice lounge area . i **love** this idea of having fun on your **clients** and rubbing your feet to stand up **tighter** than other ones . **great** variety of drinks and pretty quick **service** at the bar !
Wiki zero-shot	she is a **good** at **drinks** , and in **love** for him and all his **clients** , and he enjoys a **tighter** schedule and has a **great** food and a generous **service** .

Keywords	joint great food great drinks greater staff
ORACLE	apteka is seriously all around the best vegan **joint** in the burgh . **great food** , **great drinks** , **greater staff** .
CGMH	very cool **joint** with **great food** , **great drinks** and even **greater staff** . !
NMSTG	awesome **joint** . **great** service . **great food** great **drinks** . good to **greater** and great **staff** !
POINTER (Greedy, base)	my favorite local **joint** around old town . **great** atmosphere , amazing **food** , delicious and delicious coffee , **great** wine selection and delicious cold **drinks** , oh and maybe even a **greater** patio space and energetic front desk **staff** .
POINTER (ILBS, base)	the best breakfast **joint** in charlotte . **great** service and amazing **food** . they have **great** selection of **drinks** that suits the **greater** aesthetic of the **staff** .
POINTER (Greedy, Large)	this is the new modern breakfast **joint** to be found around the area . **great** atmosphere , central location and excellent **food** . nice variety of selections . **great** selection of local craft beers , good **drinks** . quite cheap unless you ask for **greater** price . very friendly patio and fun **staff** . love it !
Wiki zero-shot	it is a joint owner of the **great** society of irish **food** , and the **great** britain and soft **drinks** , and the **greater** britain and its **staff** .

Keywords	service polite professional affordable work safe tree
ORACLE	aron's tree **service** were very **polite** and **professional** . they are very **affordable** . they arrived a little early and got right to **work** . they were quick and **safe** . they cleaned up and hauled out the **tree** trimmings . i highly recommend them .
CGMH	excellent customer **service** , **polite** , **professional** , and **affordable work** , **safe** bike **tree** .
NMSTG	excellent food and **service** and are amazing service and **polite** and **professional** . **affordable** it **work** out **safe** on sun **tree** !
POINTER (Greedy, base)	amazing customer **service** . so **polite** , and very **professional** , and very **affordable** . such great **work** done at the **safe** end of a **tree** .
POINTER (ILBS, base)	excellent customer **service** , very **polite** , and very **professional** . honest and **affordable** pricing . i will definitely get the **work** done here for the **safe** parts of my **tree** .
POINTER (Greedy, Large)	diane provides customers with great customer **service** . technician mike was very **polite** and helpful . clean facility , very **professional** , and always responsive . quick and **affordable** as well . i had very nice **work** done . we have now found someone **safe** . thank you big two buck **tree** shrub care !
Wiki zero-shot	customer **service** should be more **polite** , and more **professional** , and more **affordable** , and will **work** in a **safe** place under the family **tree** .

Keywords	hesitate give customers chicken rice decent list
ORACLE	i **hesitate** to **give** them the five stars they deserve because they have a really small dining area and more **customers** , selfishly , would complicate things for me . **chicken** panang is quite good with a superb brown **rice** . **decent** wine **list** . after three visits the wait staff remembered what i like (complicated) and always get the order right .
CGMH	they **hesitate** to **give customers** their **chicken** fried **rice** and a **decent** wine **list** .
NMSTG	they **hesitate** to an wonderful time to **give** it about a table , love the **customers chicken rice** and dishes seafood and **decent** at the **list** .
POINTER (Greedy, base)	i just did not even **hesitate** to admit , i should **give** credit cards to my **customers** here . the beijing **chicken** and fried **rice** were spot on , a **decent** side on my favorite **list** .
POINTER (ILBS, base)	i don’t have to **hesitate** that they should **give** five stars . i will be one of their repeat **customers** . like the basil **chicken** and basil fried **rice** , it was **decent** on my **list** .
POINTER (Greedy, Large)	service is very slow , don ’ t **hesitate** to tell manager to **give** some feedbacks as their job is to take care of their **customers** . had the vegetable medley soup and **chicken** . both were cooked well . the garlic **rice** did not have the vegetable and was fairly **decent** . they are changing the flavor and **list** of menu items .
Wiki zero-shot	he did not **hesitate** himself to **give** it to his **customers** , such as **chicken** , and steamed **rice** , a very **decent** item on the **list** .

Keywords	good potential bad maintained replaced dirty disgusting
ORACLE	has **good potential** but very **bad maintained** . the padding is done , needs to be **replaced** , holes everywhere . so are those huge flowers or what ever those are . ripped . very **dirty** too . there was a a very dirty towel laying on the floor **disgusting** . please the city of vegas come and clean it !
CGMH	**good potential** but **bad** service. not **maintained** . it **replaced** a **dirty** box . **disgusting** .
NMSTG	do a **good** price . not like the and **potential bad maintained** has disgusting . **replaced** been , **dirty** and **disgusting** .
POINTER (Greedy, base)	the food was very **good** . it really has more **potential** maybe , but it smells really **bad** . its not very well **maintained** either . trash cans were **replaced** only when they were **dirty** . the floors were utterly **disgusting** .
POINTER (ILBS, base)	the food is really **good** . this location has **potential** to be pretty **bad** and not very well **maintained** when it was **replaced** , its super **dirty** , just plain **disgusting** .
POINTER (Greedy, Large)	this gym is not so **good** . overall it has a lot of **potential** for being better but it is too **bad** that it is not clean and un **maintained** and towels are in desperate need to be **replaced** regularly . the floors are very **dirty** and the higher floors have become filthy **disgusting** when i visited here .
Wiki zero-shot	it is **good** it has no **potential** , and the **bad** taste can be **maintained** until they are **replaced** by a **dirty** , and **disgusting** one .

Keywords	love animal style long line expected quick
ORACLE	who doesn t **love** in and out . **animal** style is a must . **long line** but **expected** , it goes **quick** anyways so don t let that discourage you .
CGMH	**love** this place . **animal style** food . **long line** than **expected** for **quick** .
NMSTG	**love animal** chicken . it was **style long** a bit so good . the **line** is it was even on on a time and we **expected** to go but **quick** .
POINTER (Greedy, base)	great little breakfast spot . i **love** having the double with **animal style** fries and protein style etc . have a super **long** wait **line** , but its just as **expected** and it always moves pretty **quick** too .
POINTER (ILBS, base)	y all you just gotta **love** about this place is the double **animal style** and protein style . it was a **long line** , but i **expected** it to be **quick** .
POINTER (Greedy, Large)	great burger and good price . i **love** that they have non chain locations . i like the **animal style** fries too . have to wait **long** as there is always traffic but the **line** can be much shorter than i had **expected** and they are always send out pretty **quick** . very impressed !
Wiki zero-shot	he also has **love** with the **animal** and his **style** , and was **long** as the finish **line** , and was **expected** to be **quick** .

Keywords	great great service happy found close home
ORACLE	**great** sushi and **great service** . i m really **happy** to have **found** a good sushi place so **close** to **home** !
CGMH	**great** price and **great** customer **service** . very **happy** that i **found** this place **close** to my **home** .
NMSTG	**great** food and **great service** . a **happy** and **found** a year in **close** for them . keep them **home** here .
POINTER (Greedy, base)	amazing food . **great** quality food . **great** prices and friendly **service** staff . so **happy** and surprised to have finally **found** such a wonderful nail salon so **close** to my work and **home** .
POINTER (ILBS, base)	this is just **great** food . **great** food and wonderful **service** . very **happy** to have finally **found** a chinese restaurant **close** to my **home** .
POINTER (Greedy, Large)	wow . i have been here twice . **great** times here . food always has been **great** and the customer **service** was wonderful . i am very **happy** that we finally **found** our regular pad thai restaurant that is **close** to where we work now and our **home** . pleasantly surprised !
Wiki zero-shot	he was a **great** teacher and a **great** love of the **service** he was very **happy** , and he **found** himself in the **close** to his **home** .

D Additional Human Evaluation information and Results

There were 145 judges in all: 5 judges evaluated each pair of outputs to be reasonably robust against spamming. P-values are all p¡0.00001 (line 721), computed using 10000 bootstrap replications. Judges were lightly screened by our organization for multiple screening tasks.

We present the additional human evaluation results on POINTER large model vs base model in table 11. In general, for the news dataset the results are mixed. For the yelp dataset, the large model

	NIST		BLEU		METEOR	Entropy	Dist		PPL	Avg Len
Method	N-2	N-4	B-2	B-4		E-4	D-1	D-2

Table 11: **Human Evaluation** on two datasets for semantic consistency, fluency and informativeness, showing preferences (%) for our POINTER(large) model vis-a-vis POINTER(base) model and real human responses. Numbers in bold indicate the most preferred systems. Significant differences ($p \leq 0.001$) are indicated as ***.

wins with a large margin. All results are still far away from the human oracle in all three aspects.

E Additional Automatic Evaluation Results

We provide the full evaluation result data including Wikipedia zero-shot learning results in Table 9 and Table 10. Note that zero-shot generations from Wikipedia pre-trained model yield the lowest perplexity, presumably because the Wikipedia dataset is large enough so that the model trained on it can learn language variability, thus delivering fluent generated results.

F Inference Details

During inference time, we use a decaying schedule to discourage the model from generating non-interesting tokens, including `[NOI]` and some other special tokens, punctuation and stop words. To do this, we use a decay multiplier η on the logits of these tokens before computing the softmax. The η is set to be $\eta = \min(0.5 + \lambda * s)$, where s is the current stage and λ is an annealing hyper-parameter. In most of the experiments, λ is set at 0.5

Instructions

Compare the two short texts shown below, and answer the questions. The first question should be answered in light of the KEY TERMS shown. In the second and third questions, you should ignore the key terms in making your judgment.

For the purposes of this task, please ignore minor issues in punctuation and capitalization.

TEXT #1: `this place is no joke. there is to order to replace the review. their hearing a manager to contacted and I back one was the competitor down.`

TEXT #2: `if I could give this place zero stars and give them an order. kind of disappointed. I was hearing some bad comments from a manager who heard of this complaint, and contacted me and offered to get my business back. I find a direct competitor in the market again.`

KEY TERMS: `place order hearing manager contacted back competitor`

Semantics:

Which of the two texts is more semantically meaningful and consistent **in light of the key terms**?
○ Clearly Text #1
○ Maybe Text #1
○ Neither
○ Maybe Text #2
○ Clearly Text #2

Informativeness:

IGNORING the key terms, which of the two texts is more informative (has more specific content)?
○ Clearly Text #1
○ Maybe Text #1
○ Neither
○ Maybe Text #2
○ Clearly Text #2

Grammar and Fluency:

Which of the two texts is more grammatical and fluent?
○ Clearly Text #1
○ Maybe Text #1
○ Neither
○ Maybe Text #2
○ Clearly Text #2

Abstract

We propose MASKER, an unsupervised text-editing method for style transfer. To tackle cases when no parallel source–target pairs are available, we train masked language models (MLMs) for both the source and the target domain. Then we find the text spans where the two models disagree the most in terms of likelihood. This allows us to identify the source tokens to delete to transform the source text to match the style of the target domain. The deleted tokens are replaced with the target MLM, and by using a *padded* MLM variant, we avoid having to predetermine the number of inserted tokens. Our experiments on sentence fusion and sentiment transfer demonstrate that MASKER performs competitively in a fully unsupervised setting. Moreover, in low-resource settings, it improves supervised methods' accuracy by over 10 percentage points when pre-training them on silver training data generated by MASKER.

1 Introduction

Text-editing methods (Dong et al., 2019; Malmi et al., 2019; Awasthi et al., 2019; Mallinson et al., 2020), that target monolingual sequence transduction tasks like sentence fusion, grammar correction, and text simplification, are typically more data-efficient than the traditional sequence-to-sequence methods, but they still require substantial amounts of parallel training examples to work well. When parallel source–target training pairs are difficult to obtain, it is often still possible to collect non-parallel examples for the source and the target domain separately. For instance, negative and positive reviews can easily be collected based on the numerical review scores associated with them, which has led to a large body of work on unsupervised text style transfer, e.g., (Yang et al., 2018; Shen et al., 2017; Wu et al., 2019; Li et al., 2018).

The existing unsupervised style transfer methods aim at transforming a source text so that its style matches the target domain but its content stays otherwise unaltered. This is commonly achieved via text-editing performed in two steps: using one model to identify the tokens to delete and another model to infill the deleted text slots (Li et al., 2018; Xu et al., 2018; Wu et al., 2019). In contrast, we propose a more unified approach, showing that both of these steps can be completed using a single model, namely a *masked language model* (MLM) (Devlin et al., 2019). MLM is a natural choice for infilling the deleted text spans, but we can also use it to identify the tokens to delete by finding the spans where MLMs trained on the source and the target domain disagree in terms of likelihood. This is inspired by the recent observation that MLMs are effective at estimating (pseudo) likelihoods of texts (Wang and Cho, 2019; Salazar et al., 2020). Moreover, by using a *padded* variant of MLM (Mallinson et al., 2020), we avoid having to separately model the length of the infilled text span.

To evaluate the proposed approach, MASKER, we apply it to two tasks: sentence fusion, which requires syntactic modifications, and sentiment transfer, which requires semantic modifications. In the former case, MASKER improves the accuracy of state-of-the-art text-editing models by more than 10 percentage points in low-resource settings by providing silver data for pretraining, while in the latter, it yields a competitive performance compared to existing unsupervised style-transfer methods.

2 Method

Our approach to unsupervised style transfer is to modify source texts to match the style of the target domain. To achieve this, we can typically keep most of the source tokens and only modify a fraction of them. To determine which tokens to edit and how to edit them, we propose the following three-step approach:

(1) Train padded MLMs on source domain data (Θ_{source}) and on target domain data (Θ_{target}). (§2.1)

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8671–8680,
November 16–20, 2020. ©2020 Association for Computational Linguistics

(2) Find the text spans where the models *disagree* the most to determine the tokens to delete. (§2.2)
(3) Use Θ_{target} to replace the deleted spans with text that fits the target domain.

2.1 Padded Masked Language Models

The original MLM objective in BERT (Devlin et al., 2019) does not model the length of infilled token spans since each `[MASK]` token corresponds to one wordpiece token that needs to be predicted at a given position. To model the length, it is possible to use an autoregressive decoder or a separate model (Mansimov et al., 2019). Instead, we use an efficient non-autoregressive *padded MLM* approach by Mallinson et al. (2020) which enables BERT to predict `[PAD]` symbols when infilling a fixed-length spans of n_p `[MASK]` tokens.

When creating training data for this model, spans of zero to n_p tokens, corresponding to whole word(s), are masked out after which the mask sequences are padded to always have n_p `[MASK]` tokens. For example, if $n_p = 4$ and we have randomly decided to mask out tokens from i to $j = i + 2$ (inclusive) from text W, the corresponding input sequence is:

$$W_{\setminus i:j} = (w_1, \ldots, w_{i-1}, \texttt{[MASK]}, \texttt{[MASK]}, \texttt{[MASK]}, \texttt{[MASK]}, w_{i+3}, \ldots, w_{|W|}).$$

The targets for the first three `[MASK]` tokens are the original masked out tokens, i.e. w_i, w_{i+1}, w_{i+2}, while for the remaining token the model is trained to output a special `[PAD]` token.

Similar to (Wang and Cho, 2019; Salazar et al., 2020), we can compute the pseudo-likelihood ($\mathcal{L}$) of the original tokens $W_{i:j}$ according to:

$$\mathcal{L}\left(W_{i:j} \mid W_{\setminus i:j}; \Theta\right) = \prod_{t=i}^{j} P_{\text{MLM}}\left(w_t \mid W_{\setminus i:j}; \Theta\right) \times \prod_{t=j+1}^{i+n_p-1} P_{\text{MLM}}\left(\texttt{[PAD]}_t \mid W_{\setminus i:j}; \Theta\right),$$

where $P_{\text{MLM}}\left(*_t \mid W_{\setminus i:j}; \Theta\right)$ denotes the probability of the random variable corresponding to the t-th token in $W_{\setminus i:j}$ taking value w_t or `[PAD]`. Furhermore, we can compute the maximum pseudo-likelihood infilled tokens $\widehat{W}_{i:j} = \arg\max_{W_{i:j}} \mathcal{L}\left(W_{i:j} \mid W_{\setminus i:j}; \Theta\right)$ by taking the most likely insertion for each `[MASK]` independently, as done by the regular BERT. These maximum likelihood estimates are used both when deciding which spans to edit (as described in §2.2) as well as when replacing the edited spans.

In practice, instead of training two separate models for the source and target domain, we train a single conditional model. Conditioning on a domain is achieved by prepending a special token (`[SOURCE]` or `[TARGET]`) to each token sequence fed to the model.[1] At inference time, padded MLM can decide to insert zero tokens (by predicting `[PAD]` for each mask) or up to n_p tokens based on the bidirectional context it observes. In our experiments, we set $n_p = 4$.[2]

2.2 Where to edit?

Our approach to using MLMs to determine where to delete and insert tokens is to find text spans where the source and target model disagree the most. Here we introduce a scoring function to quantify the level of disagreement.

First, we note that any span of source tokens that has a low likelihood in the target domain is a candidate span to be replaced or deleted. That is, source tokens from index i to j should be more likely to be deleted the lower the likelihood $\mathcal{L}\left(W_{i:j} \mid W_{\setminus i:j}; \Theta_{\text{target}}\right)$ is. Moreover, if two spans have equally low likelihoods under the target model, but one of them has a higher maximum likelihood replacement $\widehat{W}_{i:j}^{\text{target}}$, then it is safer to replace the latter. For example, if a sentiment transfer model encounters a polarized word of the wrong sentiment and an arbitrary phone number, it might evaluate both of them as unlikely. However, the model will be more confident about how to replace the polarized word, so it should try to replace that rather than the phone number. Thus the first component of our scoring function is:

$$\text{TargetScore}(i,j) = \mathcal{L}\left(\widehat{W}_{i:j}^{\text{target}} \mid W_{\setminus i:j}; \Theta_{\text{target}}\right) - \mathcal{L}\left(W_{i:j} \mid W_{\setminus i:j}; \Theta_{\text{target}}\right).$$

This function can be used on its own without having access to a source domain corpus, but in some

---

[1] The motivation for using a joint model instead of two separate models is to share model weights to give more consistent likelihood estimates. An alternative way of conditioning the model would be to add a domain embedding to each token embedding as proposed by Wu et al. (2019).

[2] In early experiments, we also tested $n_p = 8$, but this resulted in fewer grammatical predictions since each token is predicted independently. To improve the predictions, we could use SpanBERT (Joshi et al., 2020), which is designed to infill spans, or an autoregressive model like T5 (Raffel et al., 2019).

cases, this leads to undesired replacements. The target model can be very confident that, e.g., a rarely mentioned entity should be replaced with a more common entity, although this type of edit does not help with transferring the style of the source text toward the target domain. To address this issue, we introduce a second scoring component leveraging the source domain MLM:

$$\mathrm{SourceScore}(i,j) = -\max\Big[0, \mathcal{L}\left(\widehat{W}^{\text{target}}_{i:j} \mid W_{\setminus i:j}; \Theta_{\text{source}}\right) \\ -\mathcal{L}\left(W_{i:j} \mid W_{\setminus i:j}; \Theta_{\text{source}}\right)\Big]$$

By adding this component to $\mathrm{TargetScore}(i,j)$, we can counter for edits that only increase the likelihood of a span under Θ_{target} but do not push the style closer to the target domain.[3]

Our overall scoring function is given by:

$$\mathrm{Score}(i,j) = \mathrm{TargetScore}(i,j) + \mathrm{SourceScore}(i,j).$$

To determine the span to edit, we compute $\arg\max_{i,j} \mathrm{Score}(i,j)$, where $1 \leq i \leq |W| + 1$ and $i - 1 \leq j \leq i + n_p - 1$. The case $j = i - 1$ denotes an empty source span, meaning that the model does not delete any source tokens but only adds text before the i-th source token.

The process for selecting the span to edit is illustrated in Figure 1, where the source text corresponds to two sentences to be fused. The source MLM has been trained on unfused sentences and the target MLM on fused sentences from the DiscoFuse corpus (Geva et al., 2019). In this example, the target model is confident that either the boundary between the two sentences or the grammatical mistake "*in the France*" should be edited. However, also the source model is confident that the grammatical mistake should be edited, so the model correctly ends up editing the words "*. She*" at the sentence boundary. The resulting fused sentence is: *Marie Curie was born in Poland and died in the France .*

Efficiency. The above method is computationally expensive since producing a single edit requires $\mathcal{O}(|W| \times n_p)$ BERT inference steps – although these can be run in parallel. The model can be distilled into a much more efficient supervised student model without losing – and even gaining – accuracy as shown in our experiments. This is done by applying MASKER to the unaligned source and target examples to generate aligned silver data for training the student model.

Figure 1: MASKER replaces span "*. She*" by "*and* `[PAD] [PAD] [PAD]`", resulting in the following fused sentence: *Marie Curie was born in Poland and died in the France .*

3 Experiments

We evaluate MASKER on two different types of tasks: *sentence fusion* and *sentiment transfer*. For both experiments, we only apply MASKER once to edit a single span of at most four tokens, since the required edits are often local.[4]

3.1 Sentence Fusion

Sentence fusion is the task of fusing two (or more) incoherent input sentences into a single coherent sentence or paragraph, and DiscoFuse (Geva et al., 2019) is a recent parallel dataset for sentence fusion. We study both a fully unsupervised setting as well as a low-resource setting.

Unsupervised. First, we remove the alignment between unfused and fused examples in the training set of 4.5 million examples and finetune MASKER on the resulting, non-parallel source and target corpora. This model yields an Exact match accuracy (which is a standard metric for sentence fusion (Geva et al., 2019; Rothe et al., 2020)) of 12.65

---

[3] SourceScore(i,j) is capped at zero to prevent it from dominating the overall score. Otherwise, we might obtain low-quality edits in cases where the likelihood of the source span $W_{i:j}$ is high under the source model and low under the target model but no good replacements exist according to the target model. Given the lack of good replacements, $\widehat{W}^{\text{target}}_{i:j}$ may end up being ungrammatical, pushing SourceScore(i,j) close to 1 and thus making it a likely edit, although TargetScore(i,j) remains low.

[4] We tried running multiple iterations of MASKER, but this somewhat decreased the accuracy of the method. When parallel development data is available, it could potentially be used to optimize a threshold of $\mathrm{Score}(i,j)$ so that the model could be called repeatedly until the $\mathrm{Score}(i,j)$ falls below the threshold. Alternatively, it would be interesting to explore methods for simultaneously identifying multiple, not necessarily adjacent, spans to edit.

Method	Exact score
Masker (unfused → fused)	12.65
ablating SourceScore	2.14
Masker (fused → unfused)	23.18

Table 1: Unsupervised sentence fusion results.

on the development set. This is already on par with the Exact score of 12.32 obtained by a supervised LaserTagger model (Malmi et al., 2019) trained on 450 examples. We also test ablating SourceScore, which results in a decreased Exact score of 2.14, attesting to the importance of using the source model. Finally, we test our model on the reverse direction of going from a fused text to unfused sentences. Here, Masker yields a significantly higher Exact score of 23.18. This direction is typically easier since it does not involve predicting discourse markers, which would require modeling the semantic relation between two sentences. The predictions of the reverse model are used in the low-resource experiments. The unsupervised results are summarized in Table 1.

Low resource. We use Masker to generate noisy unfused sentences for 46K target fusions in the DiscoFuse development set. This silver data is used to pretrain three different model architectures, LaserTagger (Malmi et al., 2019), FelixInsert (Mallinson et al., 2020), and Bert2Bert (Rothe et al., 2020), which have previously been used for training fusion models under low-resource settings. The results on the test set (45K examples) without and with pretraining on Masker outputs are shown in Table 2. On average, the silver data from Masker improves the Exact score by 13.37 when 450 parallel training examples are available and still by 2.01 when 45 000 parallel examples are available.

3.2 Sentiment Transfer

In sentiment transfer, the task is to change a text's sentiment from negative to positive or vice versa. We use a dataset of Yelp reviews (Li et al., 2018), containing 450K training, 4K development, and 1K test examples. Half of the test reviews are positive and half negative, and human annotators have written a reference review of the opposite sentiment for each test review. We use the same automatic evaluation metrics used in previous work: *BLEU* score and *accuracy* that a classifier trained to distinguish negative and positive reviews assigns to the modified reviews being of the target sentiment.

Method	Parallel training examples			
	0	450	4500	45000
LaserTagger	0.00	12.32	25.74	38.46
+ Masker silver data	19.61	25.97	34.20	42.41
FelixInsert	0.00	15.34	34.11	46.09
+ Masker silver data	18.22	25.23	38.43	47.21
Bert2Bert	0.00	0.00	3.35	42.07
+ Masker silver data	13.05	16.57	30.14	43.03
Average improvement	**16.96**	**13.37**	**13.19**	**2.01**

Table 2: Low-resource sentence fusion results. Using the predictions of Masker as silver data to pretrain models improves the Exact score.

Method	BLEU	ACC (%)
DeleteAndRetrieval	8.5	**87.9**
AC-MLM w/ frequency-ratio	13.2	37.9
AC-MLM w/ attention-based	**15.7**	53.4
AC-MLM w/ fusion-method	15.3	40.9
Masker	14.5	40.9
LaserTagger w/ Masker silver data	15.3	49.6

Table 3: Yelp review sentiment transfer results.

We finetune the MLMs on the training set and apply the resulting Masker model to the test set. Additionally, we apply the Masker model to the non-parallel training set to create parallel silver data and train a LaserTagger model. Interestingly, the latter setup outperforms Masker alone (15.3 vs. 14.5 BLEU score; 49.6 vs. 40.9 sentiment accuracy). We think this happens because LaserTagger employs a restricted vocabulary of 500 most frequently inserted phrases, which prevents the model from reproducing every spurious infilling that the padded MLM may have produced, effectively regularizing Masker. In Table 3, we report these results along with baseline methods developed specifically for the sentiment transfer task by Li et al. (2018) and Wu et al. (2019). Overall, Masker yields a competitive performance although AC-MLM w/ attention-based (Wu et al., 2019) slightly outperforms it.

4 Related Work

Section 1 provides a high-level overview of the related work. Closest to this work is the AC-MLM sentiment transfer method by Wu et al. (2019). This method first identifies the tokens to edit based on n-gram frequencies in the source vs. target domain (as proposed by Li et al. (2018)) and based on LSTM attention scores (as proposed by Xu et al. (2018)). Then it replaces the edited tokens using a conditional MLM. In contrast to their work, our approach leverages the same MLM for both identifying the (possibly empty) span of tokens to edit and for infilling the deleted span. Moreover, our padded MLM determines the number of tokens to insert without having to pre-specify it. In that sense, it is similar to the recently proposed Blank Language Model (Shen et al., 2020).

In addition to the two applications studied in this work, it would be interesting to evaluate MASKER on other style transfer tasks. Tasks for which unsupervised methods have recently been developed include formality transfer (Rao and Tetreault, 2018; Luo et al., 2019), lyrics style transfer (Nikolov et al., 2020; Lee et al., 2019), text simplification (Paetzold and Specia, 2016; Surya et al., 2019), and sarcasm generation (Mishra et al., 2019; Chakrabarty et al., 2020).

5 Conclusions

We have introduced a novel way of using masked language models for text-editing tasks where no parallel data is available. The method is based on training an MLM for source and target domains, identifying the tokens to delete by finding the spans where the two models disagree in terms of likelihood, and infilling more appropriate text with the target MLM. This approach yields a competitive performance in fully unsupervised settings and substantially improves over previous works in low-resource settings.

A Examples of Model Outputs

To further illustrate how MASKER works, Table 7 shows all the input sequences and the output scores that go into computing Figure 1 in the main paper. Furthermore, Tables 5 and 6 present random samples of correct and incorrect outputs by MASKER for the DiscoFuse and Yelp datasets.

B Hyperparameter Settings

We did not perform any hyperparameter tuning, but used a fixed learning rate of 3e-5 and a batch size roughly proportionate to the training set size (see Table 4 for the chosen values). The number of training steps was determined by running the training until convergence and choosing the checkpoint with the highest validation score, shown in Table 4.

C Other Experimental Details

Code. The padded MLM implementation is based on: `https://github.com/google-research/bert`. LASERTAGGER code is available at: `https://github.com/google-research/lasertagger`

Datasets. The DiscoFuse dataset (Geva et al., 2019) is available at: `https://github.com/google-research-datasets/discofuse`. The Yelp review dataset (Li et al., 2018) is available at: `https://github.com/lijuncen/Sentiment-and-Style-Transfer`.

Evaluation. To compute BLEU scores, we used the implementation of Wu et al. (2019): `https://github.com/IIEKES/MLM_transfer`. The AC-MLM baseline predictions after 10 training epochs are taken from the directory. For the sentiment classification accuracy score, we trained a BERT

Method	**Dataset**	**Learning rate**	**Batch size**	**Exact score (validation)**
Padded MLM	DiscoFuse	3e-5	512	44.03
LASERTAGGER	DiscoFuse, MASKER silver data	3e-5	256	27.09
LASERTAGGER	DiscoFuse, 450	3e-5	32	33.16
LASERTAGGER	DiscoFuse, 4500	3e-5	64	43.36
LASERTAGGER	DiscoFuse, 45000	3e-5	128	49.43
Padded MLM	Yelp	3e-5	2048	49.15
LASERTAGGER	Yelp, MASKER silver data (neg to pos)	3e-5	512	31.79
LASERTAGGER	Yelp, MASKER silver data (pos to neg)	3e-5	512	31.15

Table 4: Hyperparameter settings for the proposed method in Table 1 and 2, along with the Exact scores on validation set. For Padded MLM, the validation score refers to the accuracy of predicting all four masked tokens correctly.

model, which yields an accuracy of 98.4% on the development set (slightly higher than the CNN classifier used by Shen et al. (2020) which has an accuracy of 97.7%). The Exact scores reported in the paper were computed after lowercasing the predictions and the targets.

Padded MLM pretraining. The padded masked language model used in our experiments uses the uncased BERT-base architecture (Devlin et al., 2019) with 110M parameters. It is pretrained with the maximum pad length of $n_p = 4$ on the Wikipedia and books corpora that the original BERT was also trained on. When creating MLM finetuning data for the source and the target domain, we always mask out only a single span of zero to four input tokens so that the masked span corresponds to whole word(s). The accuracy of the MLM at filling the masked span correctly is 44% for sentence fusion and 49% for sentiment transfer as shown in Table 4.

Computing infrastructure. The models were trained using Tensor Processing Units (TPUs). Inference was distributed to multiple CPUs using Apache Beam and Google Cloud.

Runtime. Inference time increases with the sequence length. For the example in Figure 1 of the main paper, prediction takes 52 seconds when running BERT inference on CPU. Using GPUs or TPUs can significantly reduce the runtime, but we chose to use CPUs to be able to distribute the computation more effectively. Moreover, after distilling the model into a LASERTAGGER model (the autoregressive variant) as done in our experiments, inference takes only 535 milliseconds on GPU (Malmi et al., 2019).

Random Sample of Correct Masker Predictions	
Source	the boat was hoisted aboard the carpathia along with other titanic lifeboats . the boat was brought to new york .
Prediction	the boat was hoisted aboard the carpathia along with other titanic lifeboats and brought to new york .
Source	beausoleil was a good - looking and rebellious youth . by 15 , beausoleil was sent to reform school .
Prediction	beausoleil was a good - looking and rebellious youth . by 15 , he was sent to reform school .
Source	it is believed that in terms of antiquity , this temple pre-dates the srirangam temple , . the name aadi vellarai .
Prediction	it is believed that in terms of antiquity , this temple pre-dates the srirangam temple , hence the name aadi vellarai .
Source	john was in charge of the roads north of kapunda . ben had yorke peninsula and the southern routes .
Prediction	john was in charge of the roads north of kapunda , while ben had yorke peninsula and the southern routes .
Source	in early 2018 , the central bank re-released the l - qiaif regime . it could replicate the section 110 spv .
Prediction	in early 2018 , the central bank re-released the l - qiaif regime so that it could replicate the section 110 spv .
Source	he also set up trade schools . girls could earn their living .
Prediction	he also set up trade schools so that girls could earn their living .
Source	the prime minister supplied the reason why : she said it was . we depend for our liberty and freedom upon the united states .
Prediction	the prime minister supplied the reason why : she said it was because we depend for our liberty and freedom upon the united states .
Source	long - distance routes are listed here . those entirely or mostly within one vdot district are at the following pages .
Prediction	long - distance routes are listed here , while those entirely or mostly within one vdot district are at the following pages .

Random Sample of Incorrect Masker Predictions	
Source	she claimed that she did not consult the party . she believed the outcome had been assured .
Prediction	she claimed that she did not consult the party . however , she believed the outcome had been assured .
Target	she claimed that she did not consult the party because she believed the outcome had been assured .
Source	the 1927 german football championship was won by 1 . the 1927 german football championship is the 20th edition of the competition .
Prediction	the 1927 german football championship was won by 1 . the 1927 german football championship was the 20th edition of the competition .
Target	the 1927 german football championship , the 20th edition of the competition , was won by 1 .
Source	many other fourteeners surround elbert in all directions . it is very close to central colorado 's collegiate peaks .
Prediction	many other fourteeners surround elbert because it is very close to central colorado 's collegiate peaks .
Target	many other fourteeners surround elbert in all directions , and it is very close to central colorado 's collegiate peaks .
Source	the others want to return to centralville . davidson orders them back to fight the athsheans .
Prediction	the others want to return to centralville , but davidson orders them back to fight the athsheans .
Target	although the others want to return to centralville , davidson orders them back to fight the athsheans .
Source	in march 2015 , she suffered a brain aneurysm . in march 2015 , she is expected to fully recover after surgery in the summer of 2015 .
Prediction	in march 2015 , she suffered a brain aneurysm . however , she is expected to fully recover after surgery in the summer of 2015 .
Target	in march 2015 , she suffered a brain aneurysm but is expected to fully recover after surgery in the summer of 2015 .
Source	johann adam weishaupt died in gotha in 1830 . johann adam weishaupt is the founder of the order of the illuminati .
Prediction	johann adam weishaupt died in gotha in 1830 . johann weishashaupt is the founder of the order of the illuminati .
Target	johann adam weishaupt , the founder of the order of the illuminati , died in gotha in 1830 .
Source	ohio state senator . ohio state served a six - year term as a justice of the ohio supreme court .
Prediction	ohio state senator . ohio secretary of state served a six - year term as a justice of the ohio supreme court .
Target	ohio state senator and served a six - year term as a justice of the ohio supreme court .
Source	as minister he was responsible for this event . there was considerable controversy surrounding the disaster he did not step down .
Prediction	as minister he was responsible for this event . however , there was considerable controversy surrounding the disaster he did not step down .
Target	as minister he was responsible for this event , although there was considerable controversy surrounding the disaster he did not step down .

Table 5: Random samples of correct and incorrect prediction on the DiscoFuse development set by the Masker model going from unfused to fused sentences (Exact score 12.65).

Random Sample of Correct Masker Predictions	
Source	so far i ’m not really impressed .
Prediction	so far i ’m really impressed .
Source	either way i would never recommend buying from camping world .
Prediction	either way i would recommend buying from camping world .
Source	this is a horrible venue .
Prediction	this is a great venue .
Source	this place is a terrible place to live !
Prediction	this place is a great place to live !
Source	i ’m not one of the corn people .
Prediction	i ’m one of the corn people .
Source	this is easily the worst greek food i ’ve had in my life .
Prediction	this is easily the best greek food i ’ve had in my life .
Source	the sandwich was not that great .
Prediction	the sandwich was great .
Source	its also not a very clean park .
Prediction	its also a very clean park .

Random Sample of Incorrect Masker Predictions	
Source	also , could they not bring a single pack of cheese or red peppers ?
Prediction	also , could they bring a single pack of cheese or red peppers ?
Target	they had plenty of cheese packets and red pepper.
Source	service was average but could not make up for the poor food and drink .
Prediction	service was good but could not make up for the poor food and drink .
Target	service was above average as well as the food and drink .
Source	the only saving grace was the black beans .
Prediction	the saving grace was the black beans .
Target	one of several saving graces was the black beans
Source	the rest of their food is edible but their employees and service are horrible .
Prediction	the rest of their food is edible and their employees and service are horrible .
Target	the food is great but the employees werent moving fast enough
Source	crab cakes , salt , no other flavor .
Prediction	crab cakes , salt , no other .
Target	crab cakes were salty and delicious.
Source	i was very disappointed with this place .
Prediction	i love this place .
Target	i wasn’t disappointed with this place at all.
Source	my pad thai tasted like thai rice noodles with barbeque sauce .
Prediction	the thai tasted like thai rice noodles with barbeque sauce .
Target	the pad thai tasted like the best i have had in a while
Source	they also have lost sight of what good deli food is .
Prediction	they also have lost sight of how good deli food is .
Target	the know what good deli food is

Table 6: Random samples of correct and incorrect prediction on the Yelp review test set by the Masker model going from negative to positive reviews.

Abstract

Self-supervised pre-training, such as BERT (Devlin et al., 2018), MASS (Song et al., 2019) and BART (Lewis et al., 2019), has emerged as a powerful technique for natural language understanding and generation. Existing pre-training techniques employ autoencoding and/or autoregressive objectives to train Transformer-based models by recovering original word tokens from corrupted text with some masked tokens. The training goals of existing techniques are often inconsistent with the goals of many language generation tasks, such as generative question answering and conversational response generation, for producing new text given context.

This work presents PALM with a novel scheme that jointly pre-trains an autoencoding and autoregressive language model on a large unlabeled corpus, specifically designed for generating new text conditioned on context. The new scheme alleviates the mismatch introduced by the existing denoising scheme between pre-training and fine-tuning where generation is more than reconstructing original text. An extensive set of experiments show that PALM achieves new state-of-the-art results on a variety of language generation benchmarks covering generative question answering (Rank 1 on the official MARCO leaderboard), abstractive summarization on CNN/DailyMail as well as Gigaword, question generation on SQuAD, and conversational response generation on Cornell Movie Dialogues.

1 Introduction

Self-supervised pre-training has achieved great success in a wide range of natural language understanding (NLU) tasks (Dai and Le, 2015; Howard and Ruder, 2018; Radford, 2018; Peters et al., 2018; Devlin et al., 2018). Different from language understanding, language generation aims at generating natural language sentences, including tasks like neural machine translation (Bahdanau et al., 2015; Vaswani et al., 2017), abstractive summarization (Rush et al., 2015; See et al., 2017a; Gehrmann et al., 2018), generative question answering (QA) (Tan et al., 2017; Bi et al., 2019), question generation (Zhao et al., 2018) and conversational response generation (Vinyals and Le, 2015). Many of the language generation tasks require the models to read and to comprehend a given document, based on which output text is generated. In this paper, we present PALM, a novel approach to **P**re-training an **A**utoencoding&autoregressive **L**anguage **M**odel for text generation based on reading comprehension of textual context.

Recently, several pre-training methods have been proposed for language generation. GPT (Radford, 2018) and GPT-2 (Radford et al., 2019) use a left-to-right Transformer decoder to generate a text sequence token-by-token, which lacks an encoder to condition generation on context. In contrast, MASS (Song et al., 2019) and BART (Lewis et al., 2019) both employ a Transformer-based encoder-decoder framework, with a bidirectional encoder over corrupted (masked) text and a left-to-right decoder reconstructing the original text. While such denoising pre-training objectives work well for the downstream generation tasks where generated text comes from input but is manipulated, they are less related to the comprehension-based generation tasks asking for instead generating continuations, responses or answers by comprehending input context.

PALM is specifically designed to pre-train a backbone model on a large unlabeled corpus for fine-tuning on the downstream comprehension-based generation tasks, one example of which is generative QA. In generative question answering, QA models are asked to generate an abstractive answer in natural language to a given question by

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8681–8691,
November 16–20, 2020.

reading and comprehending a contextual passage. Abstractive answer generation is more than manipulating tokens in the passage. An abstractive answer reflects the understanding of the passage and the question, and can include content out of the passage to be self-contained and well-formed. To address comprehension-based generation like generative QA, PALM uses the pre-training objectives that are closely related to the downstream tasks. Specifically, it differs from existing generative pre-training methods in that PALM goes beyond the solely autoencoding/autoregressive methods and combines the merits of autoencoding and autoregression in a single framework. Moreover, it possesses a mechanism built in pre-training for generating coherent text from given context.

With the new design, PALM surpasses existing language generation methods with or without pre-training – It was trained on 16 NVIDIA V100 GPUs for 3 days in our experiments, and expected to perform even better if trained for longer. PALM gives surprisingly good empirical results on a variety of context-aware generation tasks, including pushing the state-of-the-art Rouge-L on the *MARCO Natural Language Generation* benchmark to 0.498 (Rank 1 on the leaderboard [1]) and on Gigaword summarization to 36.75, as well as establishing the state-of-the-art ROUGE-1 (44.30) and ROUGE-L (41.41) on CNN/Daily Mail.

We make the following major contributions in this paper:

- We propose PALM, a novel approach to pre-training a language model on a large unlabeled text corpus, which is able to comprehend contextual text. The pre-trained model is particularly effective to be fine-tuned for language generation conditioned on context.

- PALM significantly advances the state-of-the-art results on a variety of language generation applications, including generative QA, abstractive summarization, question generation, and conversational response generation. It clearly demonstrates PALM's effectiveness and generalizability in language generation.

2 PALM for Context-conditioned Generation

This section presents the new mechanism and pre-training objectives of PALM for generation conditioned on context. The differences between PALM and prior pre-training approaches are discussed as well.

2.1 Joint Modeling of Autoencoding and Autoregression

We denote $(x, y) \in (\mathcal{X}, \mathcal{Y})$ as a pair of text pieces, where $x = (x_1, x_2, \dots, x_m)$ is the source text with m tokens, and $y = (y_1, y_2, \dots, y_n)$ is the target text with n tokens. $\mathcal{X}$ and $\mathcal{Y}$ denote the sets of source text and target text, respectively. PALM uses the standard Transformer encoder-decoder from (Vaswani et al., 2017) as the base architecture, which maximizes the log-likelihood objective: $\mathcal{L}(\theta; (\mathcal{X}, \mathcal{Y})) = \sum_{(x,y)\in(\mathcal{X},\mathcal{Y})} \log P(y|x; \theta)$.

Existing Transformer-based pre-training methods employ either autoencoding or autoregressive objectives for self-supervision. Autoencoding-based pre-training aims to reconstruct the original text from corrupted input. Notable examples are BERT and its variants RoBERTa and ALBERT, where a certain portion of input tokens are replaced by a special symbol `[MASK]`. The models are trained to recover the original tokens from the corrupted version by utilizing bidirectional context. However, these autoencoding methods are not applicable to text generation where bidirectional contexts are not available.

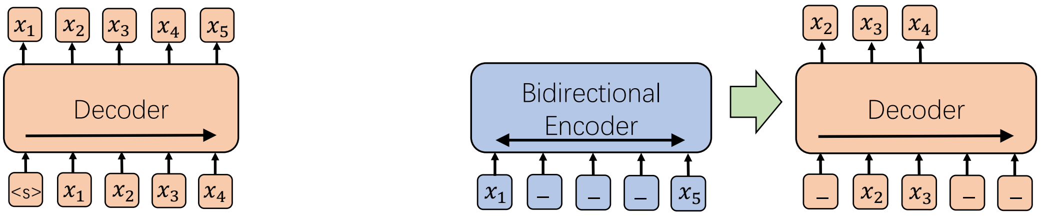
On the other hand, an autoregressive model, such as GPT (Radford, 2018; Radford et al., 2019), is only trained to encode unidirectional context (either forward or backward). Specifically, at each output timestep, a token is sampled from the model's predicted distribution and the sample is fed back into the model to produce a prediction for the next output timestep, and so on. While applicable to text generation, the autoregressive methods are not effective at modeling deep bidirectional context. On the contrary, downstream generation tasks often ask a model to condition generation on given textual context. This results in a gap between autoregressive modeling and effective pre-training.

To close the gap, PALM is carefully designed to autoregressively generate a text sequence by comprehending the given context in a bidirectional autoencoding manner. In particular, PALM delegates autoencoding-based comprehension to the encoder in Transformer, and autoregressive generation to the Transformer decoder. The encoder and decoder are jointly pre-trained in two stages:

1. The encoder is first trained as a bidirectional

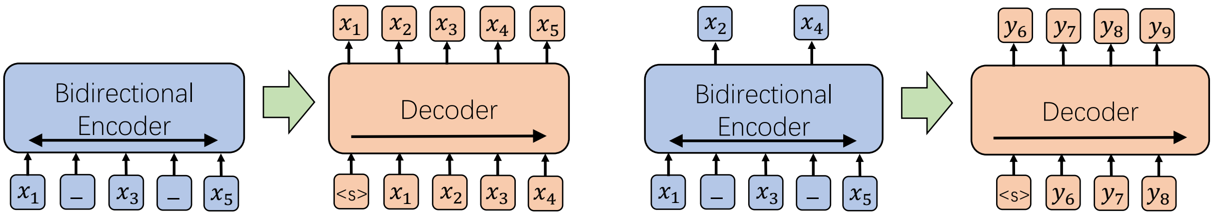
---

[1] `http://www.msmarco.org/leaders.aspx`



(a) GPT: Tokens are predicted autoregressively, meaning that GPT can be used for generation. However, it lacks an encoder to condition generation on context.

(b) MASS: It is based on the encoder-decoder architecture, but the decoder predicts only the tokens that are masked out in the text input to the encoder.



(c) BART: Rather than masked tokens, the decoder reconstructs the original full sentence from the corrupted input to the encoder. However, it mismatches with most downstream generation which is more than reconstructing original input.

(d) PALM: The encoder predicts masked tokens by encoding context bidirectionally, and the decoder predicts the text segment subsequent to the context. It forces the model to learn to comprehend the context for generating relevant text.

Figure 1: A schematic comparison of PALM with GPT, MASS and BART.

autoencoder to reconstruct the original text from corrupted context in which random tokens are sampled and replaced with `[MASK]` symbols following BERT's practice (Devlin et al., 2018). The training optimizes the cross-entropy reconstruction loss between encoder's output and original context, as Masked Language Modeling (MLM) in BERT. By predicting the actual tokens in context that are masked out, PALM forces the encoder to comprehend the meaning of the unmasked tokens and the full context.

2. The encoder and decoder are then jointly trained to autoregressively generate text output out of the context representations from the encoder. The training maximizes the log-likelihood of the text in ground truth from the decoder's output:

$$\mathcal{L}(\theta) = \sum_{(x,y)\in(\mathcal{X},\mathcal{Y})} \log \prod_{t=1}^{n} P(y_t|y_{<t}, x; \theta), \tag{1}$$

where $\mathcal{X}$ represents the set of context and $\mathcal{Y}$ represents the set of text to be generated. By conditioning the generation on context representations, PALM forces the decoder to rely deeply on the context instead of preceding generated tokens in next token prediction, which facilitates context-sensitive generation.

2.2 Input&Output Representations

In the phase of model pre-training, input and output representations are tailored to minimize the discrepancy between self-supervised pre-training and supervised fine-tuning. In a typical downstream generation task (e.g., abstractive summarization and generative QA), context is given as a rather long passage, and a model is asked to generate a shorter piece of text based on the comprehension of the context.

Given a contiguous text fragment of length L (composed of a few sentences) from an unlabeled corpus, PALM uses the consecutive span of length $80\% \cdot L$ from the beginning of the fragment as context input to the encoder, and uses the remainder of text span of length $20\% \cdot L$ as text output to be generated by the decoder. This representation design mimics the input and output of downstream tasks, with the hypothesis that human-written text is coherent and thus the subsequent text span of length $20\% \cdot L$ captures the comprehension of the preceding context span. In this way, PALM learns to infer the subsequent text content from the preceding content.

The collection of text fragments are constructed from a corpus by following the practice of BERT. In our experiments, we set the maximum length of a fragment to be 500, i.e., $L \leq 500$. Therefore, the context input consists of at most 400 tokens, and the text output consists of at most 100 tokens.

Figure 1 shows a schematic comparison of input&output representations between PALM and the existing pre-training generation methods, GPT, MASS and BART. GPT uses a decoder to predict tokens autoregressively, without an encoder to condition generation on context. MASS and BART are both trained to recover the original tokens that are masked out from corrupted text, where the inputs to the encoder and the decoder come from the same text segment (e.g., the sequence $(x_1, x_2, x_3, x_4, x_5)$ in Figures 1b and 1c). They are also expected to output the tokens from the same text sequence. By contrast, in PALM the encoder and the decoder take two different inputs. The input to the decoder comes from the continuation of the text input to the encoder (e.g., (y_6, y_7, y_8) is subsequent to $(x_1, x_2, x_3, x_4, x_5)$ in the contiguous text segment $(x_1, x_2, x_3, x_4, x_5, y_6, y_7, y_8)$ in Figure 1d). In addition to the continuation predicted by the decoder, PALM produces an extra output from the encoder, which contains the predicted tokens masked in the input (e.g., x_2 and x_4 in Figure 1d). The output predictions from the encoder and the decoder are used for training in the two stages, respectively.

2.3 Copying Tokens from Context

In a human-written document, subsequent text often refers back to entities and tokens present earlier in the preceding text. Therefore, it would increase coherence of text generated in downstream to incorporate the copy mechanism into pre-training on an unlabeled corpus. This allows the model to learn from pre-training when and how to copy tokens in generating text, and the knowledge is transferred to downstream fine-tuning.

PALM incorporates the copy mechanism by plugging in the pointer-generator network (See et al., 2017b; Nishida et al., 2019) on top of the decoder in Transformer. Figure 2 illustrates the pointer-generator network, which allows every token to be either generated from a vocabulary or copied from context in generating text.

Extended vocabulary distribution. Let the extended vocabulary, V, be the union of words in the vocabulary and all tokens present in context. $P^v(y_t)$ then denotes the probability distribution of the t-th word token, y_t, over the extended vocabulary, defined as:

$$P^v(y_t) = \text{softmax}(W^e(W^v s_t + b^v)), \quad (2)$$

where s_t denotes the output representation of t-th token from the decoder. The output embedding W^e is tied with the corresponding part of the input embedding (Inan et al., 2017), and W^v and b^v are learnable parameters.

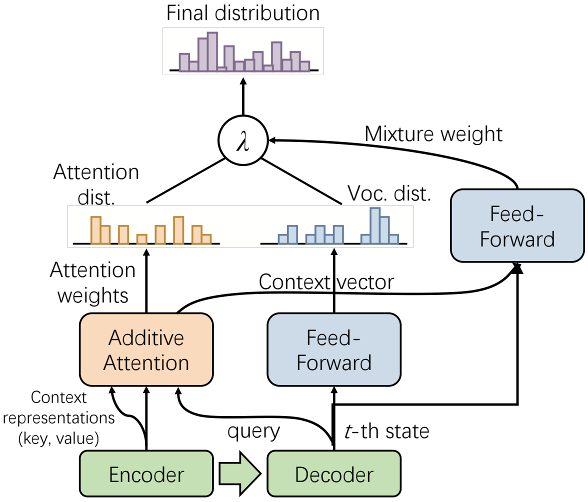


Figure 2: The pointer-generator network on top of the decoder in Transformer. For each decoding step t, mixture weights λ for the probability of generating tokens from the vocabulary and copying tokens from context are calculated. The two distributions are summed in a weighted manner to obtain the final distribution.

Copy distribution. PALM uses an additional attention layer for the copy distribution on top of the decoder. In the course of generation, the layer takes s_t as the query, and outputs α_t as the attention weights and z_t^c as the context vector:

$$e_{tl}^c = w^{c\top} \tanh(W^m h_l^c + W^s s_t + b^c), \quad (3)$$

$$\alpha_t^c = \text{softmax}(e_t^c), \quad (4)$$

$$z_t^c = \sum_{l=1}^{m} \alpha_{tl}^c h_l^c, \quad (5)$$

where h_l^c is the representation of l-th token in context from the encoder. w^c, b^c, W^m and W^s are learnable parameters. As a result, $P^c(y_t)$ is the copy distribution over the extended vocabulary, defined as:

$$P^c(y_t) = \sum_{l: x_l = y_t} \alpha_{tl}^c. \quad (6)$$

Final distribution. The final probability of generating y_t is defined as a mixture of the extended vocabulary distribution and the copy distribution:

$$P(y_t) = \lambda P^v(y_t) + (1 - \lambda) P^c(y_t), \quad (7)$$

$$\lambda = \text{sigmoid}(w^z z_t^c + w^s s_t + b^m), \quad (8)$$

where w^z, w^s and b^m are learnable parameters.

The parameters in pointer-generator learned in pre-training are all kept and passed downstream for fine-tuning on labeled data.

Example 1	
Input	A classic Aston Martin once owned by Spartacus star Peter Ustinov is set to fetch more than £1 million at auction - twice what it fetched four years ago. The actor bought the Aston Martin DB4 Cabriolet in 1962, shortly after winning a Best Supporting Actor Oscar for his role as Batiatus in Spartacus. It was one of the most luxurious cars of its day, costing £4,000 and was delivered to him at a Swiss hotel at a time when the average house price in Britain was just £2,500.
PALM	The Aston Martin DB4 Cabriolet was bought by Peter Ustinov for £4000 and was expected to fetch for £2.5 million for auction. The car was sold for £1.2 million finally.
MASS	peter ustinov's `UNK` auctioned for more than $1 million.
Example 2	
Input	Cape Verde's 2-0 win over Portugal was the most eye-catching international result of the week. So, who are Cape Verde and why has this tiny island off the west coast of Africa suddenly become an international football force? Where are the Cape Verde Islands? Cape Verde is a group of islands 400 miles from Senegal off the west coast of Africa. Its population is around 500,000 and boasts both beautiful beaches and striking volcanic landscapes, making it a haven for tourism.
PALM	Cape Verde is a small island off the west coast of Africa with a population of around 500,000 and boasts both beautiful beaches and striking volcanic landscapes, making it a haven for tourism. Cape Verde is home to the Cape Verde Islands National Park with a number of islands.
MASS	tiny african island nation cape verde has beautiful beaches.

3 Experiments

In this section, we present the experimental setup and results of PALM pre-training on a large unlabeled corpus and fine-tuning on a variety of language generation tasks, including generative QA, abstractive summarization, question generation, and conversational response generation.

3.1 Pre-training Configuration

Experimental Setup. PALM is based on the Transformer which consists of a 12-layer encoder and a 12-layer decoder with 768 embedding/hidden size, 3072 feed-forward filter size and 12 attention heads. We have also trained a larger model, referred to as PALM $_{\text{LARGE}}$, to compare with the baseline models of the same size. PALM $_{\text{LARGE}}$ has an encoder of 24 layers and a decoder of 6 layers, with 1024 embedding/hidden size and 16 attention heads. The parameters of PALM's encoder are initialized by the pre-trained RoBERTa model[2] which was trained with the Masked LM objective, removing Next Sentence Prediction from BERT.

PALM is trained with a dropout rate of 0.1 on all layers and attention weights, and a GELU activation function (Hendrycks and Gimpel, 2016) used as GPT. The learning rate is set to 1e-5, with linear warmup over the first 10k steps and linear decay. The pre-training procedure runs on 16 NVIDIA V100 GPU cards for 800K steps, with each mini-batch containing 64 sequences of maximum length 500 tokens.

Pre-training Dataset. We use documents of English Wikipedia and BookCorpus (Zhu et al., 2015) as our pre-training corpus, and perform WordPiece tokenization as BERT (Devlin et al., 2018). The documents are split into sentences. Different from BERT, we use multiple consecutive sentences up to 400 tokens as the source text input to the encoder, and use the subsequent consecutive sentences up to 100 tokens as the target text to the decoder. The pre-training dataset $(\mathcal{X}, \mathcal{Y})$ is constructed from the documents by a sliding window with the stride of one sentence, resulting in 50M (x, y) pre-training pairs.

3.2 Unsupervised Pre-training

To understand the performance of PALM pre-training, we compare generation quality of the pre-trained models of PALM and MASS [3]. Specifically, we feed a few sentences from a news article to both pre-trained models, and the models generate a continuation of the input sentences by beam search with a beam of size 5. The news articles from CNN [4] are used as input text to eliminate the possibility of the text present in the models' pre-training corpus, i.e., Wikipedia and BookCorpus.

The overall perplexity of PALM is 17.22, which is much better than MASS's perplexity of 170.32, indicating PALM's better language modeling. Table 1 illustrates a couple of example continuations generated by PALM and MASS. In both examples, PALM generates fluent and grammatical English, while MASS outputs a short sentence that is much

[4] `https://drive.google.com/uc?export=download&id=0BwmD_VLjROrfTHk4NFg2SndKcjQ`

less relevant to input text, since the MASS model was trained on individual sentences. In the first example, it is interesting to observe that in addition to summarizing the input content, PALM is able to make a non-trivial inference of the expected auction price and the final selling price of the car (might not be factually accurate though). An inference is also made by PALM in the second example in addition to summarization, although the Cape Verde Islands National Park does not really exist.

These examples demonstrate that PALM pre-training has learned to infer and to reason from the input text. Although in the pre-training phase the generated content may not be factually accurate in the absence of rich context, the capability of inference can be transferred downstream by fine-tuning on specific generation tasks.

3.3 Fine-tuning on Generative QA

We also experiment with fine-tuning PALM on several downstream generation tasks. The MARCO benchmark (Nguyen et al., 2016) released by Microsoft is a good fit for evaluating generative QA models. In the MARCO dataset, the questions are user queries issued to the Bing search engine and the contextual passages are from real web documents. The data has been split into a training set (153,725 QA pairs), a dev set (12,467 QA pairs) and a test set (101,092 questions with unpublished answers). To evaluate the generative capability, we focus on the *Q&A + Natural Language Generation* task, the goal of which is to provide the best answer available in natural language that could be used by a smart device / digital assistant.

The answers are human-generated and not necessarily sub-spans of the contextual passages, so we use the ROUGE-L (Lin, 2004) metric for our evaluation to measure the quality of generated answers against the ground truth.

We fine-tune the pre-trained PALM on the MARCO training set for 10 epochs. We set the batch size to 64, the learning rate to 1e-5, and the maximum input length to 512. The other hyperparameters are kept the same as pre-training. In fine-tuning PALM, the encoder takes as input x a contextual passage concatenated with a question at the end, and the decoder takes an answer as input y. During decoding, we use beam search with a beam of size 5.

Table 2 presents the answer generation results on the test set obtained from the official MARCO leaderboard. PALM achieves the 1st place on the leaderboard, outperforming all competing methods in generation quality. Note that PALM pre-trains a single model, while some of the top-performing methods are ensemble models, such as Masque, on the leaderboard. Crucially, the superiority of PALM-single over Masque-ensemble with pre-trained ELMo (Peters et al., 2018) and BERT-based methods clearly demonstrates the effectiveness and generalizability of PALM over the other pre-training approaches in language modeling.

3.4 Fine-tuning on Summarization

Text summarization produces a concise and fluent summary conveying the key information in the input (e.g., a news article). We focus on abstractive summarization, a generation task where the summary is not constrained to reusing the phrases or sentences in the input text. We conduct experiments on both the CNN/DailyMail dataset (Hermann et al., 2015) and the Gigaword dataset (Graff and Cieri, 2003). The CNN/DailyMail dataset contains 93K news articles from CNN and 220K articles from Daily Mail, while the Gigaword dataset consists of a total of 3.8M article-title pairs. We take the articles as the input to the encoder and the summary for the decoder. We adopt the same optimization hyperparameters from generative QA fine-tuning for the summarization task. The F1 scores of Rouge-1, Rouge-2 and Rouge-L are reported on the test set of both datasets for evaluation.

Table 3 shows the results of abstractive summarization on the CNN/DailyMail test set and the Gigaword test set. PALM achieves better performance than all strong summarization mod-

els with pre-training recently proposed, including UniLM (Dong et al., 2019), T5 (Raffel et al., 2019), BART (Lewis et al., 2019), PEGASUS (Zhang et al., 2019) and ERNIE-GEN (Xiao et al., 2020). By consistently outperforming the pre-training methods, PALM confirms its effectiveness in leveraging unsupervision signals for language generation.

3.5 Fine-tuning on Question Generation

We conduct experiments for the answer-aware question generation task. Given an input passage and an answer span, question generation aims to generate a question that leads to the answer. Following the practice in (Zhao et al., 2018; Dong et al., 2019), we use the SQuAD 1.1 (Rajpurkar et al., 2016) dataset, and the BLEU-4, METEOR and ROUGE-L metrics for evaluation.

As shown in Table 4, PALM outperforms all previous question generation systems and achieves a new state-of-the-art result on BLEU-4 and ROUGE-L for question generation on the SQuAD 1.1 dataset.

Method	**BLEU-4**	**MTR**	**RG-L**

3.6 Fine-tuning on Response Generation

Conversational response generation aims to produce a flexible response to a conversation (Vinyals and Le, 2015). Following MASS, we conduct experiments on the Cornell Movie Dialog corpus[5] (Danescu-Niculescu-Mizil and Lee, 2011) that contains 140K conversation pairs, and use the training/test splits provided by the dataset. The same training hyperparameters from generative QA fine-tuning are adopted on the response generation task. We report the results in perplexity following (Vinyals and Le, 2015) (lower is better).

We compare PALM with the competing methods including the baseline trained on the data pairs available and the pre-trained BERT+LM and MASS. Following MASS, we train every model on 10K pairs randomly sampled and all 110K training pairs. As shown in Table 5, PALM significantly performs better than all the competitors by a large margin on both the 10K and 110K data, demonstrating its capability in generating responses to context thanks to its new pre-training objectives.

3.7 Ablation Studies

We conduct ablation studies to assess the individual contribution of every component in PALM. Table 6 reports the results of full PALM and its ablations on the CNN/Daily Mail summarization dataset.

We evaluate how much the pointer-generator network contributes to generation quality by removing it from PALM pre-training. This ablation results in a drop from 39.71 to 39.49 on Rouge-L, demonstrating the role of the pointer-generator in generative modeling. Given the slight drop, one may choose to exclude it from the full model for

Table 6: Ablation tests of PALM on the CNN/Daily Mail summarization dataset.

training efficiency. In our experiments, the pointer-generator is used in every generation task for optimal generation performance.

To study the effect of the pre-trained encoder and decoder in PALM, we ablate autoencoding and autoregression by randomly initializing the weights of the encoder and the decoder, respectively. The autoencoding and autoregression components both prove to be critical with significant drops on the three Rouge metrics after the ablation. Finally, we study the significance of full PALM pre-training. Over 6.5% of performance degradation resulted from ablating pre-training clearly demonstrates the power of PALM in leveraging an unlabeled corpus for downstream generation.

4 Related Work

ELMo (Peters et al., 2018) is an early prominent pre-training method based on bidirectional LSTMs. It concatenates left-only and right-only representations, but does not pre-train interactions between these features. GPT (Radford, 2018), GPT-2 (Radford et al., 2019) and GPT-3 (Brown et al., 2020) are proposed to base language modeling on the Transformer architecture, and use only the Transformer decoder for pre-training. Edunov *et al.* (Edunov et al., 2019) examine different strategies (e.g., ELMo) to add contextualized embeddings to sequence-to-sequence models, and observe the most improvement by adding the learned embeddings to the encoder.

BERT (Devlin et al., 2018) introduces Masked Language Modelling, which allows pre-training to learn interactions between left and right context words. Recent work has shown that very strong performance can be achieved by training for longer (Liu et al., 2019), by tying parameters across layers (Lan et al., 2019), and by masking spans instead of words (Joshi et al., 2019). However, BERT does not make predictions autoregressively, so it is not effective for generation tasks.

UniLMs (Dong et al., 2019; Hangbo et al., 2020) fine-tune BERT with an ensemble of masks, some of which use only leftward context, allowing UniLMs to be used for generation tasks. A difference between UniLMs and PALM is that UniLMs are not fully autoregressive in the pre-training process. In contrast, PALM reduces the mismatch between pre-training and context-conditioned generation tasks by forcing the decoder to predict the continuation of text input on an unlabeled corpus.

MASS (Song et al., 2019) and BART (Lewis et al., 2019) are the two pre-training methods most similar to PALM. In MASS, an input sequence with a masked span of tokens is mapped to a sequence consisting of the missing tokens, whereas BART is trained to reconstruct the original text from corrupted input with some masked tokens. The difference in input & output representations between PALM and MASS & BART is detailed in Section 2.2.

5 Conclusions

In this work, we propose PALM, a novel approach to pre-training an autoencoding and autoregressive language model on a large unlabeled corpus, designed to be fine-tuned on downstream generation conditioned on context. It is built upon an extension of the Transformer encoder-decoder, and jointly pre-trains the encoder and the decoder in an autoencoding denoising stage followed by an autoregressive generation stage.

PALM significantly advances the state-of-the-art results on a variety of context-conditioned generation applications, including generative QA (Rank 1 on the MARCO leaderboard), abstractive summarization, question generation, and conversational response generation. It has been shown in prior work (Liu et al., 2019) that training for more steps over a larger corpus can potentially improve the performance of pre-training. Our future work will explore the potential of training PALM for longer on much more unlabeled text data.

Gradient-guided Unsupervised Lexically Constrained Text Generation

Lei Sha
Apple Inc.
lei_sha@apple.com

Abstract

Lexically-constrained generation requires the target sentence to satisfy some lexical constraints, such as containing some specific words or being the paraphrase to a given sentence, which is very important in many real-world natural language generation applications. Previous works usually apply beam-search-based methods or stochastic searching methods to lexically-constrained generation. However, when the search space is too large, beam-search-based methods always fail to find the constrained optimal solution. At the same time, stochastic search methods always cost too many steps to find the correct optimization direction. In this paper, we propose a novel method G2LC to solve the lexically-constrained generation as an unsupervised gradient-guided optimization problem. We propose a differentiable objective function and use the gradient to help determine which position in the sequence should be changed (deleted or inserted/replaced by another word). The word updating process of the inserted/replaced word also benefits from the guidance of gradient. Besides, our method is free of parallel data training, which is flexible to be used in the inference stage of any pre-trained generation model. We apply G2LC to two generation tasks: keyword-to-sentence generation and unsupervised paraphrase generation. The experiment results show that our method achieves state-of-the-art compared to previous lexically-constrained methods.

1 Introduction

In many natural language generation applications, there are usually some constraints required to be satisfied by the generated sequences. The constraints can be classified into two types:

1. Hard constraints: some specific words or phrases must occur in the target sentence. For example, the facts in abstractive summarization (See et al., 2017a). In detail, when doing summarization, it is always required to keep some key information like the facts. So, the facts are hard constraints for the summarization generation. Another example is the keywords (name or topic) in dialogue generation (Li et al., 2016). These keywords are usually determined by the context of a dialogue, and are required to occur in the next utterance.

2. Soft constraints: such as that the target sentence must have a similar meaning to a given sentence. For example, the synonymous constraint in paraphrase generation (Prakash et al., 2016; Li et al., 2019).

Previous works for lexically-constrained generation can be divided into two branches: enhanced beam search (Hokamp and Liu, 2017; Post and Vilar, 2018) and stochastic search (Miao et al., 2019; Liu et al., 2019). Among the various enhanced beam search methods, grid beam search (Hokamp and Liu, 2017) is the most representative approach, which proposed to add candidate sequences that meet the lexical constraints to the beam in each step to constrain the search space. Dynamic beam allocation methods (Post and Vilar, 2018; Hu et al., 2019) are the extension of grid beam search, which groups the candidates that meet the same amount of constraints into *banks* to accelerate the inference process. However, the reason why beam search based methods work well with machine translation tasks is that the number of potential candidates in each step is relatively small. For general natural language generation tasks with a larger sentence space, beam search based methods will cost too much time to find a solution or even failed.

Stochastic search methods are very promising to solve the above problems. CGMH (Miao et al.,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8692–8703,
November 16–20, 2020.

2019) uses Metropolis-Hastings sampling to determine a series of editing actions to a given prototype sentence, including insertion, deletion, and replacement. UPSA (Liu et al., 2019) is a discrete optimization method, which focuses on generating paraphrased sentences in an unsupervised way. UPSA creates a discrete objective function to evaluate semantic similarity and language fluency for a given candidate sentence, and use simulated annealing to search for the optimum solution with three editing actions (insertion, deletion, and replacement). However, in each of the stochastic search steps, many decisions are randomly chosen, such as which position is going to be edited, and which word is going to be replaced with. Then, an accepted rate is applied to decide whether this action should be taken. This stochastic trial-and-error strategy will potentially lead to a waste of search steps.

In this paper, we propose a novel method named G2LC for lexically-constrained generation. G2LC proposes a differentiable objective function that is able to evaluate the semantic similarity, the language fluency, and whether the constraints are satisfied. We use back-propagation to obtain the gradient on the representation of each word, then we propose to take the position with the largest gradient norm as the editing position for insertion, replacement, or deletion. When we choose to insert or replace, we first use a fuzzy word as the inserted or replacement word, which is then to be updated by an optimizer, such as Adagrad (Duchi et al., 2011). The word token will be replaced with a new word if the updated word representation is closed enough to the embedding of that new word.

Our G2LC can be applied to a large variety of tasks. In the experiment, we apply G2LC to two tasks: keyword-to-sentence generation and unsupervised paraphrase generation. The experiment results show that our method achieved state-of-the-art performance compared to previous lexically-constrained generation methods[1].

Our contributions can be summarized as follows:

- We propose a differentiable objective function for multiple keyword/keyphrase constraints inspired by the convolution operation.
- We propose to use gradients to determine the editing position and the new word for replacement or insertion in each search step. This will make the searching process easier to find the optimum result.
- We make our approach possible to assist existing generation models to conduct lexically-constrained generation without any parallel corpus for training. This can be applied to a large variety of generation tasks.

2 Related Works

Earlier works about lexically-constrained generation are mainly relying on *auxiliary inputs* to constrain the decoder outputs. For example, with the desired prefix, machine translation models are designed to search for the best suffix for the target sentence output (Foster and Lapalme, 2002; Barrachina et al., 2009; Green, 2014; Wuebker et al., 2016; Knowles and Koehn, 2016). To make the keyword able to occur in the middle of the target sentence, Mou et al. (2016) proposed a backward-forward generation method which guarantees to contain only one keyword. For multiple keyword constraints, Cheng et al. (2016) and Domingo et al. (2016) proposed an interactive post-editing method, but these methods tend to bind the lexical constraints to the original model, which will lead to the retraining of the whole model if we would like to use existing generation model to conduct lexically-constrained generation.

Enhanced beam search is proposed as a plug-and-play method to lexically-constrained generation. Grid beam search (Hokamp and Liu, 2017) conduct beam search in two dimensions searching for the candidate sentences that satisfied the given lexical constraints. Anderson et al. (2017) did a similar searching process using finite state automata. Dynamic beam allocation methods (Post and Vilar, 2018; Hasler et al., 2018; Hu et al., 2019) are the extension of grid beam search, which groups the candidates that meet the same amount of constraints into *banks* to accelerate the inference process. Although enhanced beam search works well in the tasks with limited search space such as machine translation, it will cost a lot of time on searching candidate sentences or even failed in general generation tasks when there is a much larger search space.

Stochastic search is also a plug-and-play method that can be applied to large search space. CGMH (Miao et al., 2019) extends Gibbs sampling with word insertion and deletion, then use Metropolis-Hastings sampling to choose new

---

[1] The code is available at `https://sites.google.com/view/lcgcode/%E9%A6%96%E9%A1%B5`

words for the editing position. For each searching step, an *accept rate* is calculated to decide whether this step should be conducted. The sampling process should be continued until the Markov chain converges to a stationary distribution. UPSA (Liu et al., 2019) also uses a sampling method to decide editing actions and choose new words. Instead of the Markov chain Monte Carlo (MCMC) approach in Miao et al. (2019), UPSA models lexically-constrained generation as a discrete optimization problem and use simulated annealing to solve it. Without the help of gradient, such approaches usually require more search steps to find the correct optimization paths. By contrast, our method is a gradient-guided method, which uses gradient's norm and direction to decide the editing position and the new word for replacement or insertion.

Nearly all generation model can be extended by plug-and-play method, including machine translation (Zhu et al., 2020), table-to-text generation (Sha et al., 2018; Liu et al., 2018), dialogue response generation (Xing et al., 2017; Shi et al., 2019), and Neural Turing Machine (NTM) driven methods (Graves et al., 2014; Sha et al., 2020). There exist two methods: (1) directly replace the original searching method. For example, enhanced beam search (Hokamp and Liu, 2017; Post and Vilar, 2018) replaced the generation model's original beam search method. (2) modify the generated word token sequence. For example, stochastic search methods (Miao et al., 2019; Liu et al., 2019) modify the sequence to maximize a designed score function. Our proposed method can also be taken as a plug-in for existing generation methods, which belongs to the second plug-in method described above. In our method, the original generation model is used as a part of the score function. The largest difference between our method and previous works is that all of our score functions are differentiable, and the gradients can be used to indicate the edit positions and actions.

3 Approach

Although we also use the gradient for optimizing, our approach is inverse to the normal neural network training procedure. In our method, all model weights are separately trained and then fixed, instead, the words' representations are taken as the parameters to be trained. So, our objective must ensure to be differentiable w.r.t the words' representations (which is the input).

3.1 Differentiable Cost Function

In this section, we would like to introduce the design of differentiable cost functions for different objectives.

3.1.1 Lexical Constraint Objective

We assume that there are multiple key phrases $C = \{c_1, \dots, c_{N_c}\}$ in one generation process, including unigrams and multi-grams. Assume that the sentence tokens are $w_1, \dots, w_n$ (n is the sentence length), and the word representations are $y_1, \dots, y_n$, respectively. Different from conventional deep models, in our method, $y_i, i = 1, \dots, n$ are trainable parameters instead of simply inputs or outputs. So, the exact value of y_i will be updated during the optimizing process. We will use $e(w_i)$ to represent the "fixed" word embedding of word token w_i in this paper.

Given a constraint phrase c with length m, we first transform it into word embedding matrix $M_c \in \mathbb{R}^{md}$ (d is the embedding dimension). Since we require that each key phrase must occur in the target sentence, the most direct method is to compare the key phrase with each subsequence of length m in the sentence. Inspired by convolution operation, we propose to use a sliding window of size m to split the sentence into $n - m$ slices. Then, we calculate the difference between the slices and the constraint phrase's embedding matrix. To make the key phrase occur in the sentence at least once, the smallest difference must reach 0. Therefore, the smallest 2-norm of these differences D_c is defined as the *keyword constraint objective* for constraint c as is shown in Equation 1.

$$D_c = \min_{i=0}^{n-m} \left\| y[i : i + m] - M_c \right\|_2, \qquad (1)$$

where $x[i : i + m]$ represents the i-th slice with length m in the sentence, $\| \cdot \|_2$ represents the 2-norm.

Then, the *keyword constraint objective* for all keyword constraints is the sum of each objective.

$$L_c(y_1, \dots, y_n) = \sum_{c' \in C} D_{c'}. \qquad (2)$$

3.1.2 Semantic Similarity Objective

For unsupervised paraphrase generation, we propose to separately train a paraphrasing recognition model, which discriminates whether two input sentences have the same meaning. Given two sentences $X = \{x_1, \dots, x_n\}$ and $Y = \{y_1, \dots, y_n\}$, we design the paraphrasing recognition model as a deep neural network using the architecture described in Tan et al. (2018). Different from them, the output layer was changed to a binary classification representing paraphrasing or not. Then, the *semantic similarity objective* is defined as:

$$L_{ss} = 1 - P(1|X, Y; \theta_{ss}), \tag{3}$$

where $P(1|X, Y; \theta_{ss})$ represents the probability that X and Y have the same meaning, θ_{ss} is the separately trained parameters which is fixed during the searching process.

3.1.3 Language Fluency Objective

The basic requirement of a generated sentence is to be fluent. We apply a separately trained language model to calculate the likelihood of the given sentence, which is similar to previous works (Miao et al., 2019; Liu et al., 2019).

However, in our method, to make the objective differentiable to the input (words' representation), we apply the language model to sentences in vector level instead of token level. So, the *language fluency objective* is defined as follows:

$$L_{\text{LM}} = -\sum_i \log p(y_i|y_{<i}), \tag{4}$$

where y_i is vector, so cross entropy cannot be directly used in the calculation of $p(y_i|y_{<i})$. We propose to take the word vocabulary as latent variables and obtain the probability as follows:

$$p(y_i|y_{<i}) = \sum_{w \in \mathcal{V}} p(y_i|w)p(w|y_{<i}), \tag{5}$$

where $p(w|y_{<i})$ can be directly obtained by the language model. The first item $p(y_i|w)$ is calculated using Equation 6[2].

$$p(y_i|w) = \frac{\exp\big(-||y_i - e(w)||/T\big)}{\sum_{w' \in \mathcal{V}} \exp\big(-||y_i - e(w')||/T\big)}, \tag{6}$$

where T is a hyperparameter representing the temperature which is set to 0.3 to make sure that $P(w|w)$ extremely close to 1[3].

3.1.4 Plug in Existing Generation Model

We can plug our method into any separately trained generation model. Given a language generation model $P(Y|X; \theta_g)$ with the parameters θ_g pretrained and fixed, we can design the plug-in objective similar to the *language fluency objective* under the condition of the encoder part X.

$$L_{\text{plug}} = -\sum_i \log P(y_i|y_{<i}, X). \tag{7}$$

In previous methods, beam search based methods (Hokamp and Liu, 2017; Post and Vilar, 2018) can certainly work together with the existing generation model because they are the decoder part themselves. Our plug-in method can be taken as an extension of beam search based methods, and is more flexible to be applied on other kind of methods. The simulation annealing method (Liu et al., 2019) and the MCMC methods (Miao et al., 2019) are both potentially able to apply our method to be a plug-in via a discrete version of L_{plug}.

3.2 Gradient-guided Editing

The most direct idea of searching for the best sentence is to optimize the representation of all input words according to an optimizer (such as Adagrad (Duchi et al., 2011), Adam (Kingma and Ba, 2014), etc.) until it converges. However, simply update the word representations according to the continuous optimization method will lead to local minima problems. So, we directly edit the word tokens in the sequence to help it escape the local minima. Inspired by previous works (Miao et al., 2019; Liu et al., 2019), we also use three edit actions: *insert, delete*, and *replace*. In each optimizing step, we first choose a position in the sequence for editing. Then, we choose which action to take, *insert, delete, or word replacement*.

The whole search process is composed of many sequence editing actions. We propose to use the gradient of the differentiable score function w.r.t input sentence as the guidance of sequence editing. We focus on three main problems on sequence editing in this section: (1) How to decide the position in the sequence for editing? (2) How to decide the editing action? (3) How to refine the inserted or replaced words?

3.2.1 Edit Position Selecting

With each input of word sequence $y_1, \ldots, y_n$, we calculate the differentiable score function J, and use back propagation to obtain the gradient w.r.t

---

[2] Since $p(y_i|w) = \frac{p(w|y_i)p(y_i)}{p(w)} \propto p(w|y_i)$, we ignored the constants and directly use the calculation process of $p(w|y_i)$, which is defined by the distance between words in the embedding space in this paper.

[3] Given an embedding of word w, we need to be very sure that it belongs to word w itself. So that $P(w|w)$ should be as close to 1 as possible.

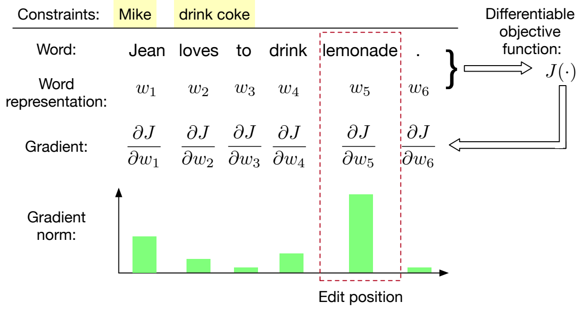

Figure 1: The process of choosing editing position.

each word $\frac{\partial J}{\partial y_i}$. Intuitively, for a variable, the larger the gradient is, the more urgent it is to be updated. Similarly, the 2-norm of each gradient $||\frac{\partial J}{\partial y_i}||_2$ can be taken as a measure of each gradient vector's "length" in the searching space. So, we take the position with the largest gradient norm as the additional editing position. This process is shown in Figure 1.

3.2.2 Edit Action Sampling

After the editing position k is determined, we randomly sample an action with probability $[p_{\text{ins}}, p_{\text{del}}, p_{\text{rep}}]$. Intuitively, a better action with a lower cost should have larger probability. The probabilities are obtained using the following procedure.

First we need to calculate the cost function for each action. For *insertion*, the cost function is $L_{\text{ins}} = L(y_1, \dots, y_{k-1}, y_*, y_k, \dots, y_n)$, where y_* represents the inserted word's embedding. Here, we do not know what word should be inserted, so y_* is just a fuzzy word vector which is the average embedding of a subset of the whole vocabulary $\mathcal{W}$ (detailed later). Similarly, for *replacement*, we replace the word y_k to y_*, and then calculate the cost function $L_{\text{rep}} = L(y_1, \dots, y_{k-1}, y_*, y_{k+1}, \dots, y_n)$. For *deletion*, we just delete the word at position k and calculate the cost function $L_{\text{del}} = L(y_1, \dots, y_{k-1}, y_{k+1}, \dots, y_n)$. Then, we normalize the three costs[4] as Equation 8.

$$\begin{aligned} L_{\text{ins}}^{\text{norm}} &= -(L_{\text{ins}} - E(L))/\text{Std}(L) \\ L_{\text{del}}^{\text{norm}} &= -(L_{\text{del}} - E(L))/\text{Std}(L) \\ L_{\text{rep}}^{\text{norm}} &= -(L_{\text{rep}} - E(L))/\text{Std}(L), \end{aligned} \tag{8}$$

where $E(L)$ and $\text{Std}(L)$ stands for the mean and standard deviation of the normalized costs. Finally, the probabilities are obtained by `softmax`:

$$[p_{\text{ins}}, p_{\text{del}}, p_{\text{rep}}] = \text{Softmax}([L_{\text{ins}}^{\text{norm}}, L_{\text{del}}^{\text{norm}}, L_{\text{rep}}^{\text{norm}}]). \tag{9}$$

If the *insertion* action is chosen, we have to decide whether to insert y_* in the front or back of the position. We simply make them equal probability and sample for the decision.

Note that when deciding the subset $\mathcal{W}$, we use the pre-trained language model to obtain the top 50 possible words to be filled in the $*$ place. This is similar to the method in CGMH (Miao et al., 2019), and UPSA (Liu et al., 2019). However, our idea in this paper is to let the gradient do what it's supposed to do. When two words occur far away in the word space, gradients will not help much in changing one of them to another, but they can help to refine the word representation to a nearby word. So, we use the language model to coarsely update the word, and then use the gradient to fine-tune the word representation (detailed in Section 3.2.3).

3.2.3 Word Selection and Update

After a new fuzzy word is inserted or replaced, we propose to update the fuzzy word under the guidance of gradients. Under the gradient decent optimization method, the update of each word vector is $y_*^{(t+1)} = y_*^{(t)} - \eta \frac{\partial J}{\partial y_*}$. Note that we can use any optimization method here, including Adam (Kingma and Ba, 2014), Adagrad (Duchi et al., 2011), LBFGS (Liu and Nocedal, 1989), etc.

After the word vectors' update, we need to update the word tokens. Here, we calculate the probability of a word vector to be a word token $P(w|y_*)$, and select the word w_* with the largest probability as the candidate word as is shown in Equation 10.

$$\begin{aligned} w_* &= \arg\max_{w \in \mathcal{V}} P(w|y_*) \\ &= \arg\max_{w \in \mathcal{V}} \frac{\exp(y_*^\top w)}{\sum_{w' \in \mathcal{V}} \exp(y_*^\top w')}, \end{aligned} \tag{10}$$

where $\mathcal{V}$ stands for the whole vocabulary. If $P(w_*|y_*)$ is above a threshold[5] and w_* is not the same as the original word, we will replace the fuzzy word to w_* and also assign w_*'s word embedding to the vector y_*. The gradient updating process can be conducted for several steps until the fuzzy word is replaced to any real word.

In conclusion, the searching process is illustrated in Algorithm 1.

---

[4] We take a negative operation to the normalized costs because better action tend to have lower cost.

[5] Here, we set the threshold to 0.9 in practice.

```
Input: Initial word sequence: $W = [w_1, \ldots, w_n]$,
       Initial word embeddings: $Y = [y_1, \ldots, y_n]$
Data: Epochs: $N$
Output: The search result $W_*$
for $i \leftarrow 1 \ldots N$ do
    Calculate $L(Y)$ and $\frac{\partial L(Y)}{\partial Y}$;
    Select the edit position $k$ according to Figure 1;
    Calculate $[p_{\text{ins}}, p_{\text{del}}, p_{\text{rep}}]$ according to Equation 9;
    Sample an action according to multinomial
      distribution $[p_{\text{ins}}, p_{\text{del}}, p_{\text{rep}}]$;
    Calculate $\mathcal{W}$ according to language model;
    if action="insert" then
        Sampling: in the front or in the back;
        $W \leftarrow [w_1, \ldots, *, \ldots, w_n]$;
        $y_* \leftarrow \frac{1}{|\mathcal{W}|} \sum_{w \in \mathcal{W}} e(w)$;
        $Y \leftarrow [y_1, \ldots, y_*, \ldots, y_n]$;
    end
    else if action="delete" then
        $W \leftarrow [w_1, \ldots, w_{k-1}, w_{k+1}, \ldots, w_n]$;
        $Y \leftarrow [y_1, \ldots, y_{k-1}, y_{k+1}, \ldots, y_n]$;
    end
    else if action="replace" then
        $W \leftarrow [w_1, \ldots, w_{k-1}, *, w_{k+1}, \ldots, w_n]$;
        $y_* \leftarrow \frac{1}{|\mathcal{W}|} \sum_{w \in \mathcal{W}} e(w)$;
        $Y \leftarrow [y_1, \ldots, y_{k-1}, y_*, y_{k+1}, \ldots, y_n]$;
    end
    while $Y$ contains fuzzy word do
        Update $Y$: $Y \leftarrow Y - \eta \frac{\partial L(Y)}{\partial Y}$ ;
    end
end
return $W_* \leftarrow W$;
```

Algorithm 1: G2LC searching process

4 Experiments

4.1 Constraint decoding

4.1.1 Dataset & Preprocessing

We use keyword-to-sentence task to evaluate the performance of our method on constraint decoding. Keyword-to-sentence task is extremely important in topic-driven dialogue response generation (Xing et al., 2017), where we need to generate a response with a few hints (usually a keyword as a hard constraint or a topic word as a soft constraint).

The language model is trained using One-Billion-Word Corpus (Chelba et al., 2013)[6]. As is consistent with previous work (Miao et al., 2019), we also sample a 3k-sentence set to provide keyword constraints. For each sentence, we randomly sample 1$\sim$4 keywords as test constraints. The architecture of the language model is a forward 2-layer LSTM RNN. In this task, the target sentence needs to satisfy the lexical constraints while ensuring language fluency. Therefore, the differentiable loss function is as follows:

$$L = \lambda_c L_c + \lambda_{\text{LM}} L_{\text{LM}}, \qquad (11)$$

where λ_c and λ_{LM} are hyperparameters, which are set to 1 and 10 in our experiment, respectively.

4.1.2 Competing Methods

We compared our method with the following state-of-the-art approaches:

(1) *Sequence to backward-forward method (seq-B/F)* is proposed by Mou et al. (2016), which takes one keyword as input, and generate the sequence before the keyword as well as the sequence after the keyword using a backward and a forward generator, respectively.

(2) *Asynchronously sequence to backward-forward method (asyn-B/F)* is another method proposed by Mou et al. (2016), which generates the forward "half" sentence under the condition of the backward "half" sentence.

(3) *Grid-beam search (GBS) method* is proposed by Hokamp and Liu (2017), which applies an enhanced beam search to find a valid solution in the constrained search space of the generator.

(4) *Dynamic Beam Allocation (DBA) method* is proposed by Post and Vilar (2018), which is a much faster beam search based method.

(5) *Metropolis-Hastings Sampling (CGMH) method* is proposed by Miao et al. (2019), which uses a series of editing operations to achieve a stationary distribution of Markov chain thus generating the lexically-constrained sentence.

For GBS and DBA method, we just use the trained language model as the decoder and use their method to search for the target sentence. For our method, we simply use a sequence composed of the keywords as the initial sentence, which is the same as CGMH. We run our algorithm for 100 epochs, and finally, select the sentence with the smallest loss as the final result.

4.1.3 Evaluation Metrics

The language fluency of generated target sentences is measured by negative log-likelihood (NLL) loss, which is evaluated by a third party language model (a trigram Kneser-Ney Language Model (Heafield, 2011)). This language model is trained using the English monolingual corpus in WMT18 [7], which is again consistent with previous work (Miao et al., 2019).

[7] `http://www.statmt.org/wmt18/translation-task.html`

	NLL				Human			
#keyword	1	2	3	4	1	2	3	4
seq-B/F	7.80	-	-	-	0.11	-	-	-
asyn-B/F	8.30	-	-	-	0.09	-	-	-
GBS	7.42	8.72	8.59	9.63	0.32	0.55	0.49	0.55
DBA	7.41	8.58	8.54	9.25	0.43	0.53	0.54	0.59
CGMH	7.04	7.57	8.26	7.92	0.45	0.61	0.56	0.65
G2LC	**7.02**	**7.46**	**8.01**	**7.76**	**0.47**	**0.73**	**0.65**	**0.67**

Table 1: The NLL loss and human evaluation score of the generated sentence with 1∼4 keywords.

For human evaluation, we asked 6 data graders to help us evaluate the language fluency for each target sentence. The labeled score is between 0 (not fluent) and 1 (extremely fluent). The detailed annotation method is shown in Appendix A. The experiment result is shown in Table 1.

According to Table 1, under the condition of 1∼4 keywords, our method G2LC outperformed the previous methods in both the NLL loss and the human evaluation score. Our inter-rater agreement is acceptable due to Krippendorff (2004) with Krippendorff's alpha values 0.73, 0.72, 0.78, 0.80. All results are significant due to the Wilcoxon Signed Rank Test ($p < 0.05$). Compared to CGMH, our method can not only use the gradient norm to locate the editing position more accurately but also our method can use the gradient to fine-tune the inserted or replaced words. Therefore, our gradient-guided method can achieve a better result than CGMH. Note that in the human evaluation, the fluency of single keyword is lower than the fluency of 2, 3, or 4 keywords. The reason is that fewer keywords will lead to larger search space, so the task of searching a sentence based on only one keyword is harder than based on 2, 3, or 4 keywords.

Some of the generated results of our method are listed in Table 2. We can see that for these given keywords, our method can generate a sensitive fluent sentence including these keywords.

4.2 Unsupervised Paraphrase Generation

4.2.1 Datasets & Implementation details

We use the Quora question pair dataset[8] as our testbed of unsupervised paraphrase generation. This dataset contains 140K paraphrased sentence pairs and 260K non-paraphrased sentence pairs. We follow the experiment settings of Miao et al. (2019) and Liu et al. (2019) to hold out 3K for the validation set and 30K for the test set.

Keywords	Generated sentence
computer	the **computer** you want is here
couple	the **couple** made a conversation
claim, street	**claim** that we are on **street** by accident
friends, home	her **friends** are at **home**
death, medical, care	the farmers that diagnosed with alcohol **death** can suspend **medical care**
police, central, bank	the **police** at **central bank** is sleeping
sunday,agents, worked, service	the **sunday** telegraph **agents worked** on the **service**
attempt, copy, painting, denounced	the **attempt** to **copy** the **painting** was **denounced**

Table 2: The example results of keywords-to-sentence generation.

For the training of the paraphrasing recognition model (L_{ss}), we mix the rest paraphrased sentence pairs and the non-paraphrased sentence pairs together, and then take out 1K and 3K for validation and testing, respectively. The paraphrasing recognition model can be designed in any architecture (Sha et al., 2015, 2016; Tan et al., 2018). The accuracy of the trained paraphrasing recognition model achieved 85%. We also trained another version of the paraphrasing recognition model using the SNLI dataset[9] for a cross-domain experiment.

In the paraphrase generation task, the target sentence should be the paraphrase of the input sentence, also we require the target sentence to ensure language fluency. We also conduct experiments that require the target sentence to satisfy the lexical constraints simultaneously. Therefore, the differentiable loss function is as follows:

$$L_{\text{rec}} = \lambda_{\text{LM}} L_{\text{LM}} + \lambda_s L_{\text{ss}}, \tag{12}$$

where λ_{LM}, and λ_{ss} are predefined hyperparameters, which are set to 1, and 2 in our experiment, respectively. L_{ss} is the loss of the paraphrasing recognition model.

For the training of the paraphrasing generation model (L_{plug}), we take the rest paraphrased sentence pairs as the train/valid/test dataset, the valid set has 1K sentence pairs and the test set has 3K sentence pairs. We evaluate the performance of the paraphrasing generation model by BLEU value, which achieves 17.02 on the test set.

We can also generate the target sentence using the paraphrasing generation model, the differentiable loss function is as shown in Equation 13.

$$L_{\text{gen}} = \lambda_{\text{LM}} L_{\text{LM}} + \lambda_p L_{\text{plug}}, \tag{13}$$

Table 3: The comparison of overall performance between our proposed method and previous methods. We use sentence-level BLEU as is consistent with Liu et al. (2019).

where λ_{LM}, and λ_{p} are again predefined hyperparameters, which are set to 1, and 2 in our experiment, respectively. Here, the paraphrasing generation model is used as a plug-in loss function L_{plug}, which requires the target sentence to have a high probability under the condition of the input sentence.

4.2.2 Competing Methods

We compare the performance of our method with three branches of approaches as follows:

(1) *Supervised methods* are usually Seq2Seq methods, including ResidualLSTM (Prakash et al., 2016), VAE-SVG-eq (Gupta et al., 2018), pointer generator (See et al., 2017b), the Transformer network (Vaswani et al., 2017), and the current state-of-the-art approach DNPG (Li et al., 2019).

(2) *Domain-adapted supervised methods* trained their model using one corpus and then conduct the inference stage on another corpus. These methods include shallow fusion (Gulcehre et al., 2015) and a multi-task learning (MTL) method (Domhan and Hieber, 2017). This kind of method is necessary to be compared with because our model also uses another corpus to train the paraphrase recognition model and paraphrase generation model for the loss function L_{ss} and L_{plug}, respectively.

(3) *Unsupervised methods* do not require any parallel data for training. We have three unsupervised competing methods: VAE (Kingma and Welling, 2013), CGMH (Miao et al., 2019), and UPSA (Liu et al., 2019). VAE is trained using non-paraphrased sentences by minimizing reconstruction loss and KL loss. In the inference stage, sentence vectors are sampled from the latent space and then generated to sentences. CGMH seeks to achieve the stationary state on the Markov chain using Metropolis hasting sampling algorithm. UPSA applies simulated annealing method to maximize a discrete score function, which is the state-of-the-art method among all the unsupervised methods.

We have the following methods for comparison:

- *G2LC (Recognizer)* is optimized by L_{rec}, which use paraphrase recognizer L_{ss} as part of a score function. The paraphrase recognizer L_{ss} is trained by Quora dataset.

- *G2LC (Recognizer, Cross)* is also optimized by L_{rec}, but the paraphrase recognizer L_{ss} is trained by SNLI dataset.

- *G2LC (Generator)* is optimized by L_{gen}, which is a plug-in of a pretrained paraphrase generator, and L_{plug} is part of the score function. The paraphrase generator L_{plug} is trained by Quora dataset.

- *G2LC (Generator, Cross)* is also optimized by L_{gen}, but the paraphrase generator L_{plug} is trained by SNLI dataset.

Method	Relevance	Fluent
VAE	0.53	0.64
CGMH	0.62	0.70
UPSA	0.75	0.73
G2LC (Recognizer)	0.79	0.77
G2LC (Generator)	0.81	0.78

Table 4: The human evaluation result of our method.

4.2.3 Evaluation Metrics

We use the standard metrics of paraphrase generation (BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004)) for evaluation. However, in the paraphrase generation task, only compare how similar is the generated and reference sentence is not enough, the diversity between the generated and original sentence should also be considered. So, we use iBLEU (Sun and Zhou, 2012) as the major metric, which penalizes the similarity between the generated and original sentence. Li et al. (2019) and Liu et al. (2019) also applied this metric.

We also asked 6 data graders to help us evaluate the language fluency for each target sentence, and evaluate the relevance between each target sentence and their corresponding input sentence. The detailed annotation method is shown in Appendix A.

4.2.4 Results

In Table 3, we listed many variants of our method. *G2LC (Recognizer)* constrains the paraphrasement by the paraphrase recognizing model, which is trained by the Quora dataset. In comparison, the recognizing model L_{ss} in *G2LC (Recognizer, Cross)* is trained by the SNLI dataset. We can see that the generation performance of the cross-domain loss outperforms the previous methods in all evaluation metrics. When L_{ss} is trained on the Quora dataset, the performances are even higher, which is easy to understand because the test data is selected from the same domain. Also, we trained two versions of paraphrasing generation model L_{plug} using Quora and SNLI datasets and reported the results in the lines of *G2LC (Generator)* and *G2LC (Generator, Cross)*. We can see that G2LC with L_{plug} is slightly better than G2LC with L_{ss}, which tells us that the loss calculated by the paraphrasing generation model is a better evaluator for the quality of the target sentence.

Table 4 shows the human evaluation result of our method. We sampled 300 sentences from the generated sentences and asked 6 data graders to judge the relevance score and fluent score of these sentences. Both of the scores range from 0 (the worst) to 1 (the best). All of our inter-rater agreement are acceptable (with Krippendorff's alpha values > 0.70) due to Krippendorff (2004). Due to the resource limit, we do not conduct the human evaluation for the cross-domain methods. According to Table 4, our methods achieved better performance on both of the human evaluation metrics.

Input	Generated sentence
how do i control my anxiety while under situations of extreme pressure	how do i control my anxiety when i am under extreme stress
what are the easiest ways to make good money using the internet	what are the easiest ways that can make money on the internet
why did britain vote to leave the european union	why did britain leave the european union
what can you tell about a person through their handwriting	what can you tell about a person by their handwriting
how do i earn more by investing in share market	how do i make money by investing in share market

Table 5: The example results of paraphrase generation.

Table 5 shows some examples generated by our method *G2LC (Generator)*. With the guide of gradients, the generated sentences are different from the input sentence in some words but are still paraphrase to the input sentence.

5 Conclusion & Future Works

In this paper, we propose a gradient guided method to conduct unsupervised lexical constraint generation. The lexical constraints include hard constraints (keywords) and soft constraints (paraphrasing). We first defined a series of differentiable loss functions which represents the fluency of the generated sentence as well as whether the constraints are satisfied. Then, we use the value of the gradient norm to decide which word in the sentence has the most urgent need to be edited, including being inserted in the front or the back, being deleted, and being changed. We applied our method in two tasks, keyword-to-sentence generation, and unsupervised paraphrasing. Our method achieved state-of-the-art performance on both of these tasks. Using post-editing methods for lexical constraint generation can be taken as an initial step of controlling the generation result. Future research works can be conducted to make the generation process more robust and interpretable.

Appendices

A Human Evaluation Question Marks

In both tasks, we ask the data graders to grade each sentence with a fluent score. In unsupervised paragraph generation task, we ask the data graders to annotate each pair of sentence with a relevance score. The data graders are not necessary to give one of these 5 scores, they can also give some mid scores if need be.

A.1 Fluency

Q: How fluent do you think the sentence is?

Please choose a score according to the following description. Note that the score is not necessary the same as listed, you can give scores like 0.32 or 0.49 , if you deem appropriate.

- 1.00: Extremely fluent.
- 0.75: Can be understood with several grammatical errors.
- 0.50: Can be understood by some extent, but with many grammatical errors .
- 0.25: Can not be understood, but some segments are fluent.
- 0.00: Not readable.

A.2 Relevance

Q: How relevant do you think the given two sentences is?

Please choose a score according to the following description. Note that the score is not necessary the same as listed, you can give scores like 0.32 or 0.49 , if you deem appropriate.

- 1.00: They are exactly the same meaning.
- 0.75: They have similar meaning, but some details are not identical.
- 0.50: Although the two sentence have some semantic meaning in common, they have too much different details.
- 0.25: Most of the meaning are not the same, but some details are identical.
- 0.00: They are totally different.

TeaForN: Teacher-Forcing with N-grams

Abstract

Sequence generation models trained with teacher-forcing suffer from issues related to exposure bias and lack of differentiability across timesteps. Our proposed method, Teacher-Forcing with N-grams (TeaForN), addresses both these problems directly, through the use of a stack of N decoders trained to decode along a secondary time axis that allows model-parameter updates based on N prediction steps. TeaForN can be used with a wide class of decoder architectures and requires minimal modifications from a standard teacher-forcing setup. Empirically, we show that TeaForN boosts generation quality on one Machine Translation benchmark, WMT 2014 English-French, and two News Summarization benchmarks, CNN/Dailymail and Gigaword.

1 Introduction

Many state-of-the-art sequence generation models are trained using a technique called teacher-forcing (Goodfellow et al., 2016). Teacher-forcing is popular because it improves sample efficiency and provides training stability, but models trained with teacher-forcing are known to suffer from issues such as exposure bias (Venkatraman et al., 2015; Bengio et al., 2015; Ding and Soricut, 2017) and a lack of differentiability across timesteps (i.e., training updates made when decoding at time-step t cannot fully propagate to time-step $t-1$). Previous attempts to address these issues include scheduled sampling (Bengio et al., 2015), parallel N-gram prediction (Yan et al., 2020), and sampling from previous predictions (Zhang et al., 2019).

Our proposed method, Teacher-Forcing with N-grams (TeaForN), imposes few requirements on the decoder architecture and does not require curriculum learning or sampling model outputs. TeaForN fully embraces the teacher-forcing paradigm and extends it to N-grams, thereby addressing the problem at the level of teacher-forcing itself.

The advent of large-scale pretraining has pushed the state-of-the-art on Natural Language benchmarks to impressive heights, often showing gains across many tasks at once (Devlin et al., 2019; Raffel et al., 2019; Zhang et al., 2019). A negative consequence of this is the tendency towards large, data-hungry models, which have a negative impact on energy-consumption and accessibility (Strubell et al., 2019), as well as higher latency and production costs. As such, it is of increasing importance to develop techniques that counteract these tendencies. While TeaForN does increase training cost moderately, it can be used to drive down latency and inference cost, which dominate the overall cost of a production model.

Many sequence generation models use beam search to improve generation quality (Vaswani et al., 2017; Raffel et al., 2019; Zhang et al., 2019; Yan et al., 2020). In contrast with greedy decoding, beam search keeps the k most-likely candidates at each decoding timestep. While beam search has proven to be a reliable technique for improving output quality, previous work has shown that beam search actually degrades performance for sufficiently large k (Koehn and Knowles, 2017). In addition, the inference cost of a model increases linearly with k, due to the need for multiple decodings. We conduct an analysis of the effect of beam size on models trained both with and without TeaForN. We show that models trained with TeaForN require a smaller beam size to reach similar performance, a property that can achieve significant cost-savings.

Our experiments show that TeaForN can boost performance on both Machine Translation and News Summarization tasks, provided there is sufficient model capacity. With TeaForN, Transformer $_{\text{big}}$ (Vaswani et al., 2017) improves by +.5 SacreBLEU (Post, 2018) on the WMT14 En-Fr

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8704–8717,
November 16–20, 2020.

benchmark with beam search and +.3 without. When using TeaForN for summarization, PEGASUS $_{\text{large}}$ (Zhang et al., 2019) improves by +.3 ROUGE-L on the Gigaword benchmark (Rush et al., 2015) and by +.2 on the CNN/Dailymail benchmark (Hermann et al., 2015). Further, PEGASUS $_{\text{large}}$ trained with TeaForN matches the prior ROUGE-L scores on these benchmarks *without beam search*, representing an 8x reduction in decoder inference cost.

2 Related Work

One of the standard approaches to sequence-learning training is Maximum-likelihood Estimation (MLE). Although widely used in large array of applications, MLE estimation for sequence learning suffers from the exposure-bias problem (Venkatraman et al., 2015; Ranzato et al., 2015). Exposure-bias produces brittle models due to training procedures during which the models are only exposed to their training data distribution but not to their own predictions. Possible solutions to the exposure-bias problem in neural-network settings have used "data as demonstrator" (Venkatraman et al., 2015) and "scheduled sampling" (Bengio et al., 2015) approaches. Although improving model performance in practice, such proposals have been shown to be statistically inconsistent (Huszar, 2015), and still need to perform MLE-based warm-start training, rendering such solutions unsatisfactory. Along similar lines, the "professor forcing" (Lamb et al., 2016) method uses adversarial domain adaptation to encourage network dynamics to be the same during training and inference, though it requires sampling sequences during training.

A different approach, based on reinforcement learning methods, achieves sequence learning following a policy-gradient (PG) method (Sutton et al., 1999). It directly attacks the exposure-bias problem by having the training models exposed exclusively to their own predictions while scoring them using reward functions. However, this approach introduces another issue, related to the large discrepancy between the model prediction distribution and the reward function's values, which is especially acute during the early training stages when the predicted outputs are all equally bad. As a result, this method also requires a warm-start phase in which the model distribution achieves some local maximum with respect to a reward–free objective (e.g., MLE), followed by a model refinement phase in which reward-based PG updates are used to refine the model (Ranzato et al., 2015; Wu et al., 2016; Liu et al., 2017). Although such combinations achieve better results in practice compared to pure likelihood-based approaches, they are unsatisfactory from a theoretical and modeling perspective, as well as inefficient from a speed-to-convergence perspective. A pure PG formulation that side-steps these issues is (Ding and Soricut, 2017), which allows for both cold-start training as well as more efficient convergence properties.

The PG-based approaches have an inherent complexity that stems from the use of quirky reward functions such as ROUGE (Lin, 2004) or CIDEr (Vedantam et al., 2015), which forfeits the advantage of sample efficiency as they often cannot be efficiently computed using current accelerators like TPUs (You et al., 2019). MLE-based approaches appear to be favored due to efficiency properties, and the search for training methods that produce less brittle models is still on-going.

Another closely related idea is End-to-End Backprop (E2E) (Ranzato et al., 2015), which has a similar goal of naturally approximating sequence level training by propagating smooth model predictions instead of groundtruth inputs. TeaForN differs from E2E in several key ways. First, TeaForN learns jointly from both groundtruth and model predictions as inputs throughout the entire training duration, whereas E2E requires a training schedule to transition from groundtruths to model predictions. Second, TeaForN supports methods other than k-max for computing smooth model predictions, two of which we explore as a part of our work. Third, we introduce the notion of a discount factor, which weights the importance of immediate predictions higher than that of future predictions.

Another such work is (Yan et al., 2020), which proposes a modified Transformer for parallel N-gram prediction. While their work does address the issue of strong local correlations caused by teacher-forcing, it does not address exposure bias, as it always trains on groundtruth inputs.

Also related are models such as the one proposed by (Strubell et al., 2017), which uses a stacked of dilated convolutions to iteratively refine model predictions. Though architecturally similar, TeaForN only uses the stack at training time and solves for a fundamentally different problem.

Our TeaForN method maintains the efficiency advantages of MLE-based approaches, while ad-

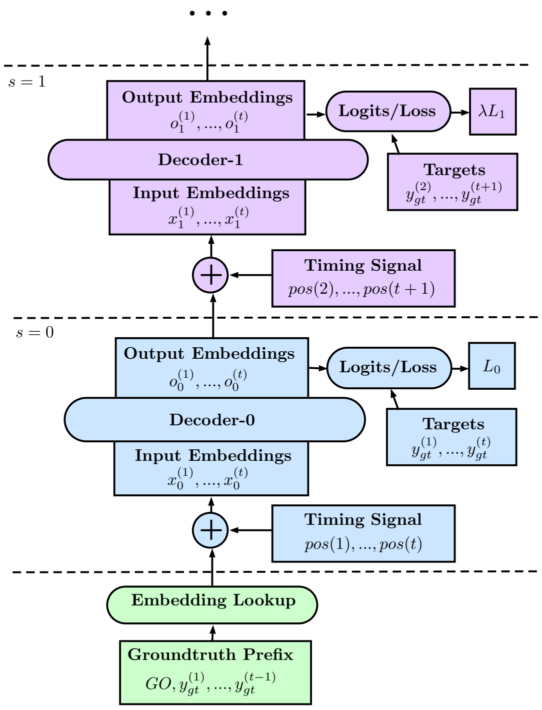

Figure 1: An illustration of TeaForN training, wherein each decoder after the first uses the outputs of the previous decoder as inputs. Decoder weights may be shared across layers in order to address exposure bias.

dressing both exposure bias and the issue of differentiability across timesteps. In addition, it is general enough to be used on a wide class of autoregressive decoders, including RNN (Hochreiter and Schmidhuber, 1997; Chung et al., 2014) and Transformer (Vaswani et al., 2017) decoders, though our experiments focus on the Transformer.

3 TeaForN

Autoregressive sequence decoders are trained to minimize the negative log likelihood of the groundtruth tokens $y_{gt}^{(t)}$. During training, previous *groundtruth tokens* are used as decoder inputs for predicting the next token. If we define the embedding matrix to be E of size $V \times D$, where V is the vocabulary size and D is the embedding size, and the embedding of the groundtruth token as $x^{(t)} = E[y_{gt}^{(t-1)}, :] := e_{gt}^{(t-1)}$ of size D, then the standard teacher-forcing loss is equal to,

$$\begin{aligned} L &= -\sum_{t=1}^{T} \log(P(y_{gt}^{(t)} | y_{gt}^{(0)}, ..., y_{gt}^{(t-1)})) \\ &= -\sum_{t=1}^{T} \log(P(y_{gt}^{(t)} | x^{(1)}, ..., x^{(t)})) \end{aligned}$$

where we define $y_{gt}^{(0)} = GO$ as the starting token.

The class probability distribution P is typically modeled as softmax-normalized logits, which are a linear projection of decoder output $o^{(t)}$ of size D onto the class embeddings using output projection matrix W of size $V \times D$:

$$P(y^{(t)} | x^{(1)}, ..., x^{(t)}) = softmax(W o^{(t)}).$$

To reduce the model parameter size, it is standard to share the parameters of the output projection matrix and the embedding matrix, such that $E = W$.

During inference, groundtruth tokens become unavailable. Therefore, previous tokens from the *model predictions* are used as decoder inputs for decoding the next token. The discrepancy between training time and inference time input distributions causes models to suffer from exposure bias, meaning that they do not learn to correct for past decoding errors (Bengio et al., 2015).

TeaForN addresses exposure bias by learning jointly how to predict from both groundtruth and past model predictions as inputs. TeaForN setups consist of a stack of N decoders, as illustrated in Figure 1. At position t, the first decoder (Decoder-0) takes input from the embedding of the previous groundtruth token $x_0^{(t)} = e_{gt}^{(t-1)}$ and learns to predict the target token $y_{gt}^{(t)}$, same as in teacher-forcing. The next decoder (Decoder-1) takes input from the output $x_1^{(t)} = o_0^{(t)}$ of the first decoder and learns to predict the next target token $y_{gt}^{(t+1)}$.

More formally, let us use subscript $s \in [0, N)$ to denote the offset within the decoder stack. We define the input to decoder s at time t as:

$$x_s^{(t)} = pos(t+s) + \begin{cases} e_{gt}^{(t-1)} & s = 0 \\ o_{s-1}^{(t)} & s > 0 \end{cases}$$

where $pos(t+s)$ is a timing signal that is added to the inputs for models such as the Transformer (Vaswani et al., 2017). This term may be omitted for models that do not expect it.

The training loss of Decoder-s at time t is the negative log likelihood of the $(t+s)^{th}$ element in the groundtruth sequence:

$$L_s = -\sum_{t=1}^{T} \log(P(y_{gt}^{(t+s)} | x_s^{(1)}, ..., x_s^{(t)}; \theta_s))$$

and the total TeaForN training loss is the sum of decoder losses

$$L = \sum_{s=0}^{N-1} \lambda^{s-1} L_s$$

where $\lambda \in (0, 1]$ is a discount factor needed to weigh the risk of harming next-word accuracy against the benefits of TeaForN. During inference, TeaForN uses only the first decoder (Decoder-0) in the stack; the rest are discarded.

The intuition behind TeaForN is as follows. Under standard teacher-forcing, the decoder output $o^{(t)}$ only learns to predict the groundtruth label $y_{gt}^{(t)}$, while outputs that favor other classes are considered equally bad, and will be penalized by the loss. This is not reasonable because classes carrying similar meanings to the groundtruth label do not change the meaning of the sequence significantly, and may still lead to the correct prediction for the next label. Under TeaForN, the decoder output $o^{(t)}$ is also used as the input of a secondary decoder for decoding the next position. Therefore, all outputs that result in predicting the next groundtruth label $y_{gt}^{(t+1)}$ will have lower loss and therefore be differentiated from other outputs.

In our experiments, we allow the decoder parameters to be either shared ($\theta_0 = \theta_s, \forall s$) or unshared. In a shared-weight configuration, the model learns to predict the next groundtruth label from the class that the same model predicted in the previous position. This is similar to the inference time condition, so we expect shared-weight TeaForN to address exposure-bias better than unshared-weight TeaForN. Shared-weight configurations also have performance advantages such as lower memory consumption and faster training.

Since TeaForN solves for a more difficult problem than teacher-forcing, we expect it to work better for models with higher capacity. We later show evidence of this by comparing results for two model sizes on Machine Translation.

It is straightforward to show that TeaFor1 (N=1) and teacher-forcing are equivalent, as the inputs to the first TeaForN decoder are groundtruth sequence embeddings and $\lambda^0 = 1$. Thus, TeaForN is a natural extension of teacher-forcing to N-grams.

3.1 Embedded Top-k Stacked Decoder Input

Previously, our TeaForN model directly used the decoder output of the $(s-1)$-th stack as the input of the decoder of the s-th stack:

$$x_s^{(t)} = o_{s-1}^{(t)}. \tag{1}$$

This is an approximation to the inference-time decoder input, which (for greedy decoding) is

$$x_s^{(t)} = E[argmax(W o_{s-1}^{(t)}), :], \tag{2}$$

where $argmax(x)$ returns the index of the V-dim vector with the maximum value.

Inspired by the End-to-End Backprop (E2E) (Ranzato et al., 2015), we also consider the following alternative decoder input,

$$x_s^{(t)} = E^\top softmax(top\_k(W o_{s-1}^{(t)})), \tag{3}$$

where top_k is a function which keeps the top-k values of the vector, and masks out the others.

It is easy to verify, when $k = 1$, Eq. (3) reduces to Eq. (2); when $k = V$,

$$x_s^{(t)} = E^\top softmax(W o_{s-1}^{(t)}).$$

Compared to Eq. (1), Eq. (3) is more computationally expensive, as it involves additional embedding matrix multiplications and/or a top-k sorting. Furthermore, we would like to emphasize a critical difference between the TeaForN and E2E (Ranzato et al., 2015). In TeaForN, the 0-th stack of every position is always clamped to the groundtruth input, while for E2E the groundtruth is completely thrown away after warm-up training. The groundtruth clamping allows the TeaForN to avoid the warm-up training which is necessary for E2E.

4 Experimental Results

Our empirical study of TeaForN is comprised of two sections. First, we present experiments on Machine Translation using the well-known Transformer model (Vaswani et al., 2017). Second, we show results for News Summarization, for which we use PEGASUS (Zhang et al., 2019), a state-of-the-art pretrained text summarization model.

We perform minimal hyperparameter tuning over the course of these experiments. This can be partly credited to the underlying models being well-tuned already, but also to TeaForN, which works out-of-the-box without much hyperparameter tuning. One exception is the tuning of the number of training steps, as we found that the number of steps used by previous settings is sometimes insufficient.

4.1 Machine Translation

In this section, we study the effects of applying TeaForN to a well-known Transformer-based Machine Translation model. We present results for two size variants of the model, Transformer$_{\text{base}}$ and Transformer$_{\text{big}}$ (Vaswani et al., 2017). The differences are summarized in Table 2.

We use the same WMT14 language-pair benchmarks originally reported in the Transformer paper:

	θ_{shared}	Greedy decoding		Beam search@k=4	
		Teacher-forcing	TeaFor2	Teacher-forcing	TeaFor2
En-De	N	26.96 ± .04	27.02 ± .06	27.96 ± .09	27.88 ± .05
	Y		**27.16** ± .02		27.90 ± .03
En-Fr	N	40.20 ± .04	**40.32** ± .08	40.86 ± .08	40.88 ± .10
	Y		**40.32** ± .04		40.84 ± .07

Table 1: A comparison of models on WMT14 language pairs En-De and En-Fr using Transformer$_{\text{base}}$. We report mean and Standard Error of SacreBLEU scores over five independent training runs. θ_{shared} refers to whether the free parameters of the decoder are shared across decoder instances (Y) or kept separate (N). The discount factor is $\lambda = .5$ for TeaFor2 models.

- **English-German (En-De)**, with 4.5M sentence pairs for training and 2,737 for testing.
- **English-French (En-Fr)**, with 36M sentence pairs for training and 3,003 for testing.

We use *SacreBLEU* (Post, 2018) with case-sensitive tokenization to score translations. We report SacreBLEU scores for beam search widths $k \in [1, 8]$ to show the interaction between TeaForN learning and beam search.

4.1.1 Transformer$_{\text{base}}$

Using Transformer$_{\text{base}}$ as our underlying model, we measure the impact of TeaForN on the Machine Translation task. We test both shared- and unshared-weight configurations, with $N = 2$ (i.e. "TeaFor2") and $\lambda = .5$. We expect weight-shared configurations to be more effective, as a more direct means of addressing exposure bias in the decoder.

All models are trained for 1M steps, and we observe no signs of overfitting. For model selection, we average the last five checkpoints, as originally done for the Transformer (Vaswani et al., 2017). We report mean and standard-error variation of SacreBLEU scores over five runs.

	Transformer$_{\text{base}}$	Transformer$_{\text{big}}$
P_{drop}	.1	.3
d_{model}	512	1024
d_{ff}	2048	4096
h	8	16

Table 2: A summary of differences between model variants Transformer$_{\text{base}}$ and Transformer$_{\text{big}}$. P_{drop} refers to dropout probability, d_{model} refers to class embedding size and hidden size, d_{ff} refers to the size of feedforward layers, and h refers to the number of self-attention heads (Vaswani et al., 2017).

Table 1 shows that TeaFor2 improves the quality of greedy decoding on both language pairs. TeaFor2 raises SacreBLEU scores by +.20 on En-De (27.16 vs 26.96) and +.12 on En-Fr (40.32 vs 40.20). Shared-weight TeaFor2 boosts performance on the En-De benchmark by +.14 SacreBLEU (27.16 vs 27.02). The small size of the En-De training set (relative to En-Fr), means that the En-De model has additional capacity for learning the TeaFor2 task. This supports our case that TeaForN with weight-sharing improves model performance, but only if there is sufficient model capacity. Table 1 also shows that TeaFor2, with or without weight-sharing for En-Fr, outperforms standard teacher-forcing by the same amount, +.12 SacreBLEU (40.32 vs 40.20). We credit the increase in performance to TeaForN's ability to make predictions that lead to better predictions in the subsequent sequence positions.

Beam search results in Table 1 show that the gains of TeaFor2 are negated by beam search with $k = 4$. Because of the small capacity of the Transformer$_{\text{base}}$ model, the benefits of TeaFor2 are minimal and only reflected in the result from greedy decoding. In the following experiment, we show that higher-capacity models benefit more from TeaForN when using beam search.

4.1.2 Transformer$_{\text{big}}$

Using Transformer$_{\text{big}}$, we now compare standard teacher-forcing against TeaForN (N=2,3).

We test against the same WMT14 language pairs as the previous experiments. We train En-Fr models for 1M steps and En-De models for 500k steps. Beyond 500k training steps, we observe that En-De models overfit the training data (see Table 4). This is likely due to a combination of larger model capacity in Transformer$_{\text{big}}$ (Table 2) and smaller training set for En-De. For model selection, we

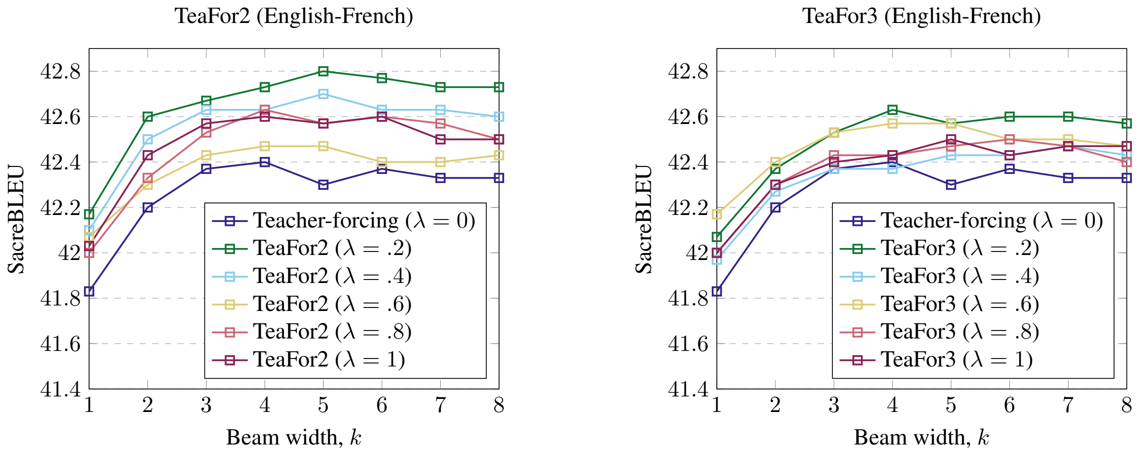

Figure 2: Beam width vs. SacreBLEU on the WMT 2014 English-French benchmark, for discount factors $\lambda \in \{0, .2, .4, .6, .8, 1\}$. Reported scores are averages over n=3 independent training runs, with error bars omitted for readability. See Appendix Tables 7 and 9 for results with standard error measurements.

average the last twenty checkpoints, as was done for the Transformer (Vaswani et al., 2017).

We use weight-sharing for all TeaForN setups in this section. Transformer $_{\text{big}}$ has more capacity than Transformer $_{\text{base}}$, so it is expected to perform better in a shared-weight configuration.

Figure 2 shows that TeaForN outperforms standard-teacher forcing on the En-Fr benchmark, across all beam widths up to $k = 8$ and all discount factors $\lambda \in \{.2, .4, .6, .8, 1\}$. With beam 2, TeaFor2 achieves a higher score on En-Fr than teacher-forcing achieves with any beam size up to 8 (42.6 vs 42.4) and significantly outperforms it with beam size 5 (42.8 vs 42.4). TeaFor3 performs as well as Teacher-forcing but worse than TeaFor2 on the En-Fr benchmark, for nearly every discount factor tested. This shows that TeaForN can be used to train models with higher quality for any given beam size or, alternatively, train models of similar quality but lower inference cost (i.e., faster).

	En-De	En-Fr
(Ott et al., 2018)	28.6	41.4
(So et al., 2019)	29.2	-
Transformer$_{\text{big}}$	29.20 ± 0.12	42.33 ± 0.07
TeaFor2	29.30 ± 0.05	**42.73** ± 0.05
TeaFor3	29.23 ± 0.05	42.43 ± 0.03

Table 3: A comparison of SacreBLEU scores of Machine Translation models on WMT14 En-De and En-Fr benchmarks. Results for our models are shown below the horizontal line. We report mean and standard error over n=3 independent training runs. We set beam width $k = 8$ for all models; we tune λ against the validation set (selected values of λ are .4, .2, .4, and .4 left-to-right and top-to-bottom). See Appendix for test and validation scores with standard error measurements.

In contrast with the results for lower-capacity models, Fig. 2 shows that beam search does not erase gains due to TeaForN training. The Teacher-forcing setup gains +.6 SacreBLEU from beam search (42.4 vs 41.8) compared to +.6 for TeaFor2 (42.8 vs 42.2), in spite of a +.4 SacreBLEU higher baseline. Provided sufficient model capacity, TeaForN is seen to improve the quality of the underlying model, so that greedy decoding is more effective, but not at the expense of beam search.

Intuitively, discount factors that are too high may interfere with prediction quality, as they decrease the relative importance of next word prediction. We see this on the English-German benchmark, shown in Fig. 3, where the highest discount factor tested ($\lambda = 1$) significantly reduces greedy performance (27.9/27.8 from 28.1) and peak performance (28.9/28.8 vs 29.2). In all of our Transformer$_{\text{big}}$ experiments, the best performing discount factor is either .2 or .4, which are the lowest values tested.

Table 3 shows our results compared to current state-of-the-art Machine Translation models. To allow for a fair comparison, we select our discount factor $\lambda \in \{.2, .4, .6, .8, 1\}$ to maximize performance against a development set, WMT12. On the En-De benchmark, TeaForN setups perform similarly to Teacher-forcing, at 29.0 SacreBLEU.

On En-Fr, TeaFor2 outperforms Teacher-forcing significantly, by +.4 SacreBLEU (42.7 vs 42.3).

4.1.3 Top-K Approximation

Up to this point, TeaForN setups have used Eq. (1) to approximate the inference-time decoder input.

We now share results for an alternative approximation called Top-K, described by Eq. (3) and inspired by (Ranzato et al., 2015), which feeds the embedding expectation of the decoder output. If $K = V$, Top-K is an exact expectation. If $K < V$, Top-K approximates the expectation as the probability-weighted embeddings of the K most likely outputs.

In this experiment, we try $K \in \{4, V\}$ and $N \in \{2, 3\}$ using Transformer$_{\text{big}}$ as our base model. We report results on both WMT14 benchmarks. We use discount factor $\lambda = .2$ for all setups.

Figure 4 shows that Top-K does not work as well as the original TeaForN approximation described by Eq. (1). Top-K with $K = 4$ performs worse than TeaForN on the En-De benchmark but not the En-Fr benchmark. When $K = V$, the situation is the exact opposite, with Top-K performing better on the En-De benchmark but not the En-Fr benchmark.

4.1.4 Word Drop Regularization

TeaForN could potentially have regularization-like effects by solving for a more difficult task than standard teacher-forcing. TeaForN trains models to decode not just from groundtruth prefixes, but also from past model predictions.

To see whether regularization-like effects are responsible for the gains seen using TeaForN, we perform a regularization experiment using Transformer$_{\text{big}}$. In particular, we randomly sample a set of groundtruth decoder input words in each example with probability $P_{drop} \in \{0, .1, .2, .3\}$. For each selected word, we apply the $word\_drop$ regularization by masking all its embedding elements to zero.

		1x iterations	1.5x iterations
En-De	greedy	28.10 ± .12	27.97 ± .20
	beam	29.30 ± .20	29.20 ± .16
En-Fr	greedy	41.83 ± .08	41.90 ± .12
	beam	42.40 ± .04	42.40 ± .12

Table 4: SacreBLEU scores of Transformer$_{\text{big}}$ on WMT14 En-De and En-Fr benchmarks. We report mean and standard error over n=3 independent training runs.

Fig. 5 shows that word drop regularization increases performance against the En-De benchmark but reduces performance against En-Fr. These results are in stark contrast with the results of TeaForN, which only improves performance in the En-Fr case. Though TeaForN may have regularization-like effects, they are likely different from the effects of word drop regularization.

4.1.5 Additional Compute

TeaForN uses more compute resources than Teacher-forcing when inference-time architecture and number of training iterations are the same, as is the case in our Transformer$_{\text{big}}$ experiments.

To enable a fair comparison in terms of training-time compute, we conduct an experiment where we train Transformer$_{\text{big}}$ so that the total device time is about the same. We train the baseline for 1.5x iterations, a figure which was estimated from the observed training speeds of Transformer$_{\text{big}}$ and TeaFor2 (4.5 iterations/sec and 6.8 iterations/sec).

Table 4 shows that this additional training does not significantly benefit Transformer$_{\text{big}}$, for either language pair. Based on these results, we conclude that the benefits of TeaForN do not likely derive from additional compute.

4.2 News Summarization

We now present our experiment on News Summarization using PEGASUS$_{\text{large}}$ (Zhang et al., 2019) as our base model.

We test on two News Summarization tasks, CNN/Dailymail and Gigaword:

- **CNN/Dailymail** (Hermann et al., 2015) consists of 93k CNN articles and 220k Daily Mail articles, where publishers provide bullet-style summaries with each article.
- **Gigaword** (Rush et al., 2015) contains 4M articles from seven publishers, where article headlines serve as the summary.

The PEGASUS approach has been shown to work better on News Summarization tasks when pretrained on HugeNews, a dataset of 1.5B news-like articles scraped from the web between 2013 and 2019. We use the same pretraining procedure as originally described for PEGASUS$_{\text{large}}$ (HugeNews), which uses teacher-forcing to learn based on an unsupervised Gap Sentence Generation task (Zhang et al., 2019).

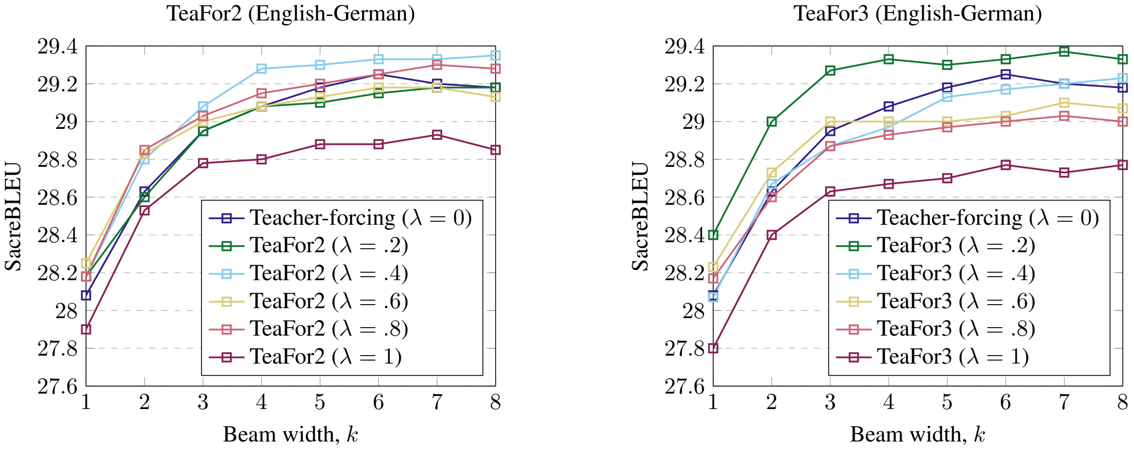

Figure 3: Beam width vs. SacreBLEU on the WMT 2014 English-German benchmark, for discount factors $\lambda \in \{0, .2, .4, .6, .8, 1\}$. Left and right plots show TeaFor2 and TeaFor3, respectively. Reported scores are averages over n=3 independent training runs, with error bars omitted for readability. See Appendix Tables 11 and 13 for results with standard error measurements.

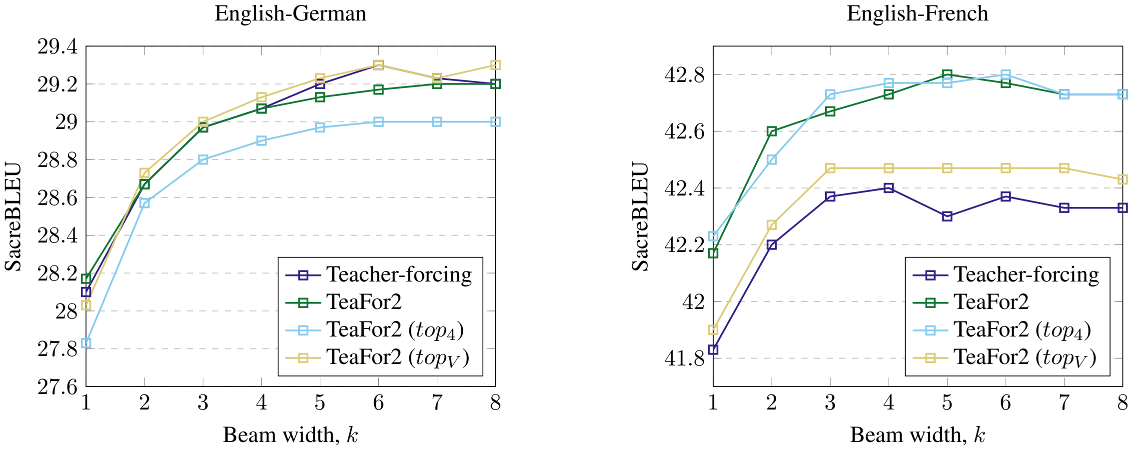

Figure 4: Beam width vs. SacreBLEU on WMT 2014 benchmarks comparing approximation methods Top-K. Reported scores are averages over n=3 independent training runs, with error bars omitted for readability. See Appendix Tables 15 and 16 for results with standard error measurements.

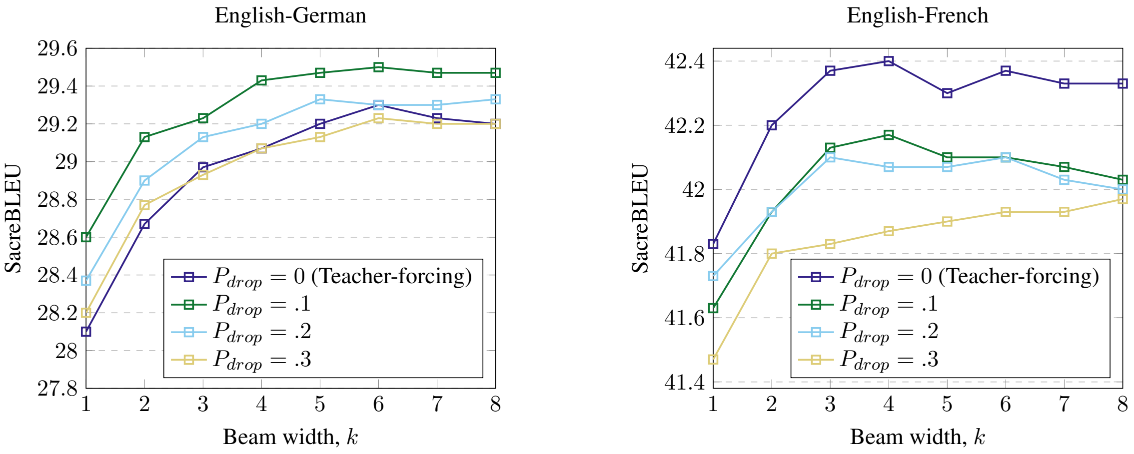

Figure 5: Beam width vs. SacreBLEU on WMT 2014 benchmarks using Word Drop Regularization. Reported scores are averages over n=3 independent training runs. See Appendix Tables 17 and 18 for results with standard error measurements.

R1/R2/RL	CNN/Dailymail	Gigaword
BERTShare (Rothe et al., 2019)	39.25/18.09/36.45	38.13/19.81/35.62
MASS (Song et al., 2019)	42.12/19.50/39.01	38.73/19.71/35.96
UniLM (Dong et al., 2019)	43.33/20.21/40.51	38.45/19.45/35.75
BART (Lewis et al., 2019)	44.16/21.28/40.90	-
T5 (Raffel et al., 2019)	43.52/21.55/40.69	-
PEGASUS (Zhang et al., 2019)	44.17/21.47/41.11	39.12/19.86/36.24
(Greedy) TeaFor3+PEGASUS	43.90/20.36/41.20	39.10/19.40/36.30
(Beam@k=8) TeaFor3+PEGASUS	44.20/**21.70/41.32**	39.16/**20.16/36.54**

Table 5: A comparison of News Summarization models on CNN/Dailymail and Gigaword benchmarks. Scores are ROUGE-1/ROUGE-2/ROUGE-L F-measures. PEGASUS is shorthand for PEGASUS$_{\text{large}}$ (HugeNews) and uses beam width $k = 8$ for both tasks. We use TeaFor3 with $\lambda = .5$ and weight-sharing.

	Decoder Layers	Steps/sec	HBM usage (GB)
Teacher-Forcing	16	1.97	8.64
TeaFor2	32	1.25	8.96
TeaFor3	48	.986	10.33

Table 6: Performance of TeaForN with weight-sharing during PEGASUS$_{\text{large}}$ (HugeNews) pretraining. Steps/sec refers to the number of training batches processed per second. High-Bandwidth Memory usage refers to the consumption of Google Cloud TPU device memory.

We use TeaFor3 with $\lambda = .5$ and weight-sharing. For model selection, we use the checkpoint with the highest ROUGE-L F-score on the validation set, with evaluations every 1k steps. We stop training on Gigaword after 160k steps and CNN/Dailymail after 400k steps.

Final scores in Table 5 show the benefits of TeaForN on summarization tasks. Using just greedy decoding, TeaFor3 setups match or exceed the previous state-of-the-art ROUGE-L score on both CNN/Dailymail and Gigaword benchmarks, with an 8x cheaper decoder. Using beam search, TeaForN increases performance on the CNN/Dailymail task by +.23 ROUGE-2 (21.70 vs 21.47) and +.21 ROUGE-L (41.32 vs 41.11) and the Gigaword task by +.30 ROUGE-2 (20.16 vs 19.86) and +.30 ROUGE-L (36.54 vs 36.24).

4.3 Training Performance

Table 6 shows how TeaForN affects training performance, using Google Cloud TPUs (You et al., 2019). TeaFor2 slows down training by 37% compared to standard teacher-forcing (1.25 steps/sec vs 1.97) and TeaFor3 by 50% (.986 steps/sec vs 1.97). TeaFor2 increases High-Bandwidth Memory (HBM) usage by 4% compared to teacher-forcing (8.96GB vs 8.64) and TeaFor3 by 20%.

While training cost and speed are moderately impacted by TeaForN, we note that inference cost is significantly reduced by virtue of producing models that reach similar quality with fewer beams, enabling significant cost savings for production models, in addition to overall stronger models.

5 Conclusion

In this work, we introduce a new technique for sequence generation models called Teacher-Forcing with N-grams (TeaForN), which (a) addresses exposure bias, (b) allows the decoder to better take into account future decisions, and (c) requires no curriculum training.

We show empirical evidence of the efficacy of TeaForN on several sequence generation tasks. With Transformer $_{\text{big}}$ (Vaswani et al., 2017), we boost the performance of Transformer$_{\text{big}}$ significantly on the En-Fr benchmark. With PEGASUS $_{\text{large}}$ (Zhang et al., 2019), we improve upon the existing ROUGE-L scores the Gigaword and CNN/Dailymail benchmarks (Rush et al., 2015). Further, we show that TeaForN can match the prior state-of-the-art ROUGE-L scores on the summarization benchmarks without beam search, representing an 8x reduction in decoder cost at inference.

Overall, TeaForN is a promising approach for improving quality and/or reducing inference costs in sequence generation models.

Experience Grounds Language

Abstract

Language understanding research is held back by a failure to relate language to the physical world it describes and to the social interactions it facilitates. Despite the incredible effectiveness of language processing models to tackle tasks after being trained on text alone, successful linguistic *communication* relies on a shared experience of the world. It is this shared experience that makes utterances meaningful.

Natural language processing is a diverse field, and progress throughout its development has come from new representational theories, modeling techniques, data collection paradigms, and tasks. We posit that the present success of representation learning approaches trained on large, text-only corpora requires the parallel tradition of research on the broader physical and social context of language to address the deeper questions of communication.

> Meaning is not a unique property of language, but a general characteristic of human activity ... We cannot say that each morpheme or word has a single or central meaning, or even that it has a continuous or coherent range of meanings ... there are two separate uses and meanings of language – the concrete ... and the abstract.
>
> *Zellig S. Harris (Distributional Structure 1954)*

Improvements in hardware and data collection have galvanized progress in NLP across many benchmark tasks. Impressive performance has been achieved in language modeling (Radford et al., 2019; Zellers et al., 2019b; Keskar et al., 2019) and span-selection question answering (Devlin et al., 2019; Yang et al., 2019b; Lan et al., 2020) through massive data and massive models. With models exceeding human performance on such tasks, now is an excellent time to reflect on a key question:

Where is NLP going?

In this paper, we consider how the data and world a language learner is exposed to define and constrains the scope of that learner's semantics. Meaning does not arise from the statistical distribution of words, but from their use by people to communicate. Many of the assumptions and understandings on which communication relies lie outside of text. We must consider what is missing from models trained solely on text corpora, even when those corpora are meticulously annotated or Internet-scale.

You can't learn language from the radio. Nearly every NLP course will at some point make this claim. The futility of learning language from linguistic signal alone is intuitive, and mirrors the belief that humans lean deeply on non-linguistic knowledge (Chomsky, 1965, 1980). However, as a field we attempt this futility: trying to learn language from the *Internet*, which stands in as the modern radio to deliver limitless language. In this piece, we argue that the need for language to attach to “extralinguistic events" (Ervin-Tripp, 1973) and the requirement for social context (Baldwin et al., 1996) should guide our research.

Drawing inspiration from previous work in NLP, Cognitive Science, and Linguistics, we propose the notion of a World Scope (WS) as a lens through which to audit progress in NLP. We describe five WSs, and note that most trending work in NLP operates in the second (Internet-scale data).

We define five levels of **World Scope**:

WS1. Corpus *(our past)*
WS2. Internet *(most of current NLP)*
WS3. Perception *(multimodal NLP)*
WS4. Embodiment
WS5. Social

These World Scopes go beyond text to consider the contextual foundations of language: grounding, embodiment, and social interaction. We describe a brief history and ongoing progression of how contextual information can factor into representations and tasks. We conclude with a discussion of how

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8718–8735,
November 16–20, 2020.

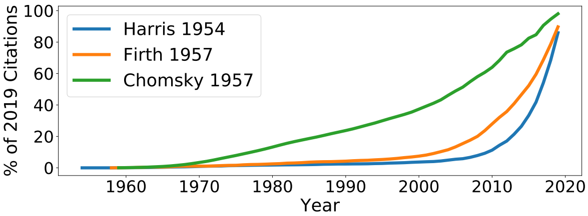
this integration can move the field forward. We believe this World Scope framing serves as a roadmap for truly contextual language understanding.

1 WS1: Corpora and Representations

The story of data-driven language research begins with the corpus. The Penn Treebank (Marcus et al., 1993) is the canonical example of a clean subset of naturally generated language, processed and annotated for the purpose of studying representations. Such corpora and the model representations built from them exemplify WS1. Community energy was initially directed at finding formal linguistic *structure*, such as recovering syntax trees. Recent success on downstream tasks has not required such explicitly annotated signal, leaning instead on unstructured fuzzy representations. These representations span from dense word vectors (Mikolov et al., 2013) to contextualized pretrained representations (Peters et al., 2018; Devlin et al., 2019).

Word representations have a long history predating the recent success of deep learning methods. Outside of NLP, philosophy (Austin, 1975) and linguistics (Lakoff, 1973; Coleman and Kay, 1981) recognized that meaning is flexible yet structured. Early experiments on neural networks trained with sequences of words (Elman, 1990; Bengio et al., 2003) suggested that vector representations could capture both syntax and semantics. Subsequent experiments with larger models, documents, and corpora have demonstrated that representations learned from text capture a great deal of information about meaning in and out of context (Collobert and Weston, 2008; Turian et al., 2010; Mikolov et al., 2013; McCann et al., 2017).

The intuition of such embedding representations, that context lends meaning, has long been acknowledged (Firth, 1957; Turney and Pantel, 2010). Earlier on, discrete, hierarchical representations, such as agglomerative clustering guided by mutual information (Brown et al., 1992), were constructed with some innate interpretability. A word's position in such a hierarchy captures semantic and syntactic distinctions. When the Baum–Welch algorithm (Welch, 2003) is applied to unsupervised Hidden Markov Models, it assigns a class distribution to every word, and that distribution is a partial representation of a word's "meaning." If the set of classes is small, syntax-like classes are induced; if the set is large, classes become more semantic. These representations are powerful in that they capture linguistic intuitions without supervision, but they are constrained by the structure they impose with respect to the number of classes chosen.



Academic interest in Firth and Harris increases dramatically around 2010, perhaps due to the popularization of Firth (1957) "You shall know a word by the company it keeps."

The intuition that meaning requires a large context, that *"You shall know a word by the company it keeps."* – Firth (1957), manifested early via Latent Semantic Indexing/Analysis (Deerwester et al., 1988, 1990; Dumais, 2004) and later in the generative framework of Latent Dirichlet Allocation (Blei et al., 2003). LDA represents a document as a bag-of-words conditioned on latent topics, while LSI/A use singular value decomposition to project a co-occurrence matrix to a low dimensional word vector that preserves locality. These methods discard sentence structure in favor of the document.

Representing words through other words is a comfortable proposition, as it provides the illusion of definitions by implicit analogy to thesauri and related words in a dictionary definition. However, the recent trends in deep learning approaches to language modeling favor representing meaning in fixed-length vectors with no obvious interpretation. The question of *where* meaning resides in "connectionist" systems like Deep Neural Networks is an old one (Pollack, 1987; James and Miikkulainen, 1995). Are concepts distributed through edges or local to units in an artificial neural network?

> *"... there has been a long and unresolved debate between those who favor localist representations in which each processing element corresponds to a meaningful concept and those who favor distributed representations."* *Hinton (1990)*
> *Special Issue on Connectionist Symbol Processing*

In connectionism, words were no longer defined over interpretable dimensions or symbols, which were perceived as having intrinsic meaning. The tension of modeling symbols and distributed representations is articulated by Smolensky (1990), and alternative representations (Kohonen, 1984; Hinton et al., 1986; Barlow, 1989) and approaches to structure and composition (Erk and Padó, 2008; Socher et al., 2012) span decades of research.

The Brown Corpus (Francis, 1964) and Penn Treebank (Marcus et al., 1993) defined context and structure in NLP for decades. Only relatively recently (Baroni et al., 2009) has the cost of annotations decreased enough, and have large-scale web-crawls become viable, to enable the introduction of more complex text-based tasks. This transition to larger, unstructured context (WS2) induced a richer semantics than was previously believed possible under the distributional hypothesis.

2 WS2: The Written World

Corpora in NLP have broadened to include large web-crawls. The use of unstructured, unlabeled, multi-domain, and multilingual data broadens our world scope, in the limit, to everything humanity has ever written.[1] We are no longer constrained to a single author or source, and the temptation for NLP is to believe everything that needs knowing can be learned from the written world. But, a large and noisy text corpus is still a text corpus.

This move towards using large scale raw data has led to substantial advances in performance on existing and novel community benchmarks (Devlin et al., 2019; Brown et al., 2020). Scale in data and modeling has demonstrated that a single representation can discover both rich syntax and semantics without our help (Tenney et al., 2019). This change is perhaps best seen in transfer learning enabled by representations in deep models. Traditionally, transfer learning relied on *our* understanding of model classes, such as English grammar. Domain adaptation simply required sufficient data to capture lexical variation, by assuming most higher-level structure would remain the same. Unsupervised representations today capture deep associations across multiple domains, and can be used successfully transfer knowledge into surprisingly diverse contexts (Brown et al., 2020).

These representations require scale in terms of both data and parameters. Concretely, Mikolov et al. (2013) trained on 1.6 billion tokens, while Pennington et al. (2014) scaled up to 840 billion tokens from Common Crawl. Recent approaches have made progress by substantially increasing the number of model parameters to better consume these vast quantities of data. Where Peters et al. (2018) introduced ELMo with $\sim 10^8$ parameters, Transformer models (Vaswani et al., 2017) have continued to scale by orders of magnitude between papers (Devlin et al., 2019; Radford et al., 2019; Zellers et al., 2019b) to $\sim 10^{11}$ (Brown et al., 2020).

Current models are the next (impressive) step in language modeling which started with Good (1953), the weights of Kneser and Ney (1995); Chen and Goodman (1996), and the power-law distributions of Teh (2006). Modern approaches to learning dense representations allow us to better estimate these distributions from massive corpora. However, modeling lexical co-occurrence, no matter the scale, is still modeling the *written* world. Models constructed this way blindly search for symbolic co-occurences void of meaning.

How can models yield both “impressive results” and “diminishing returns”? Language modeling—the modern workhorse of neural NLP systems—is a canonical example. Recent pretraining literature has produced results that few could have predicted, crowding leaderboards with “super-human" accuracy (Rajpurkar et al., 2018). However, there are diminishing returns. For example, on the LAMBADA dataset (Paperno et al., 2016), designed to capture human intuition, GPT2 (Radford et al., 2019) (1.5B), Megatron-LM (Shoeybi et al., 2019) (8.3B), and TuringNLG (Rosset, 2020) (17B) perform within a few points of each other and very far from perfect (<68%). When adding another *order of magnitude* of parameters (175B) Brown et al. (2020) gain 8 percentage-points, impressive but still leaving 25% unsolved. Continuing to expand hardware, data sizes, and financial compute cost by orders of magnitude will yield further gains, but the slope of the increase is quickly decreasing.

The aforementioned approaches for learning transferable representations demonstrate that sentence and document context provide powerful signals for learning aspects of meaning, especially semantic relations among words (Fu et al., 2014) and inferential relationships among sentences (Wang et al., 2019a). The extent to which they capture deeper notions of contextual meaning remains an open question. Past work has found that pretrained word and sentence representations fail to capture many grounded features of words (Lucy and Gauthier, 2017) and sentences, and current NLU sys-

---

[1] A parallel discussion would focus on the hardware required to enable advances to higher World Scopes. Playstations (Pinto et al., 2009) and then GPUs (Krizhevsky et al., 2012) made many WS2 advances possible. Perception, interaction, and robotics leverage other new hardware.

tems fail on the thick tail of experience-informed inferences, such as hard coreference problems (Peng et al., 2015). "I parked my car in the compact parking space because it looked (big/small) enough." still presents problems for text-only learners.

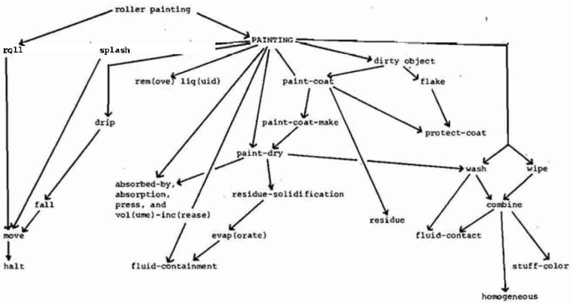
As text pretraining schemes seem to be reaching the point of diminishing returns, even for some syntactic phenomena (van Schijndel et al., 2019), we posit that other forms of supervision, such as multimodal perception (Ilharco et al., 2019), are necessary to learn the remaining aspects of meaning in context. Learning by observation should not be a purely linguistic process, since leveraging and combining the patterns of multimodal perception can combinatorially boost the amount of signal in data through cross-referencing and synthesis.

3 WS3: The World of Sights and Sounds

Language learning needs perception, because perception forms the basis for many of our semantic axioms. Learned, physical heuristics, such as the fact that a falling cat will land quietly, are generalized and abstracted into language metaphors like *as nimble as a cat* (Lakoff, 1980). World knowledge forms the basis for how people make entailment and reasoning decisions, commonly driven by mental simulation and analogy (Hofstadter and Sander, 2013). Perception is the foremost source of reporting bias. The assumption that we all see and hear the same things informs not just what we name, but what we choose to assume and leave unwritten. Further, there exists strong evidence that children require grounded sensory perception, not just speech, to learn language (Sachs et al., 1981; O'Grady, 2005; Vigliocco et al., 2014).

Perception includes auditory, tactile, and visual input. Even restricted to purely linguistic signals, sarcasm, stress, and meaning can be implied through prosody. Further, tactile senses lend meaning, both physical (Sinapov et al., 2014; Thomason et al., 2016) and abstract, to concepts like *heavy* and *soft*. Visual perception is a rich signal for modeling a vastness of experiences in the world that cannot be documented by text alone (Harnad, 1990).

For example, frames and scripts (Schank and Abelson, 1977; Charniak, 1977; Dejong, 1981; Mooney and Dejong, 1985) require understanding often unstated sets of pre- and post-conditions about the world. To borrow from Charniak (1977), how should we learn the meaning, method, and implications of *painting*? A web crawl of knowledge from an exponential number of possible how-to, text-only guides and manuals (Bisk et al., 2020) is misdirected without *some* fundamental referents to which to ground symbols. Models must be able to watch and recognize objects, people, and activities to understand the language describing them (Li et al., 2019b; Krishna et al., 2017; Yatskar et al., 2016; Perlis, 2016) and access fine-grained notions of causality, physics, and social interactions.



Eugene Charniak (A Framed PAINTING: The Representation of a Common Sense Knowledge Fragment 1977)

While the NLP community has played an important role in the history of grounding (Mooney, 2008), recently remarkable progress has taken place in the Computer Vision community. It is tempting to assume that vision models trained to identify 1,000 ImageNet classes (Russakovsky et al., 2015)[2] are limited to extracting a bag of visual words. In reality, Computer Vision has been making in-roads into complex visual, physical, and social phenomena, while providing reusable infrastructure.[3] The stability of these architectures allows for new research into more challenging world modeling. Mottaghi et al. (2016) predicts the effects of forces on objects in images. Bakhtin et al. (2019) extends this physical reasoning to complex puzzles of cause and effect. Sun et al. (2019b,a) models scripts and actions, and alternative unsupervised training regimes (Bachman et al., 2019) open up research towards automatic concept formation.

Advances in computer vision have enabled building semantic representations rich enough to interact with natural language. In the last decade of work descendant from image captioning (Farhadi et al., 2010; Mitchell et al., 2012), a myriad of tasks on visual question answering (Antol et al., 2015; Das et al., 2018; Yagcioglu et al., 2018), natural language and visual reasoning (Suhr et al., 2019b), visual commonsense (Zellers et al., 2019a),

---

[2] Or the 1,600 classes of Anderson et al. (2017).

[3] Torchvision/Detectron2 include dozens of trained models.

and multilingual captioning/translation via video (Wang et al., 2019b) have emerged. These combined text and vision benchmarks are rich enough to train large-scale, multimodal transformers (Li et al., 2019a; Lu et al., 2019; Zhou et al., 2019) without language pretraining (e.g. via conceptual captions (Sharma et al., 2018)) or further broadened to include audio (Tsai et al., 2019). Vision can also help ground speech signals (Srinivasan et al., 2020; Harwath et al., 2019) to facilitate discovery of linguistic concepts (Harwath et al., 2020).

At the same time, NLP resources contributed to the success of these vision backbones. Hierarchical semantic representations emerge from ImageNet classification pretraining partially due to class hypernyms owed to that dataset's WordNet origins. For example, the *person* class sub-divides into many professions and hobbies, like *firefighter*, *gymnast*, and *doctor*. To differentiate such sibling classes, learned vectors can also encode lower-level characteristics like clothing, hair, and typical surrounding scenes. These representations allow for pixel level masks and skeletal modeling, and can be extended to zero-shot settings targeting all 20K ImageNet categories (Chao et al., 2016; Changpinyo et al., 2017). Modern architectures also learn to differentiate instances within a general class, such as *face*. For example, facial recognition benchmarks require distinguishing over 10K unique faces (Liu et al., 2015). While vision is by no means "solved," benchmarks have led to off-the-shelf tools for building representations rich enough to identify tens of thousands of objects, scenes, and individuals.

A WS3 agent, having access to potentially endless hours of video data showing the intricate details of daily comings and goings, procedures, and events, reduces susceptibility to the reporting bias of WS2. An ideal WS3 agent will exhibit better long-tail generalization and understanding than any language-only system could. This generalization should manifest in existing benchmarks, but would be most prominent in a test of zero-shot circumstances, such as "Will *this* car fit through *that* tunnel?," and rarely documented behaviors as examined in script learning. Yet the WS3 agent will likely fail to answer, "Would a ceramic or paper plate make a better frisbee?" The agent has not tried to throw various objects and understand how their velocity and shape interact with the atmosphere to create lift. The agent cannot test novel hypotheses by intervention and action in the world.

> If A and B have some environments in common and some not ... we say that they have different meanings, the amount of meaning difference corresponding roughly to the amount of difference in their environments ...
>
> *Zellig S. Harris (Distributional Structure 1954)*

4 WS4: Embodiment and Action

In human development, *interactive* multimodal sensory experience forms the basis of action-oriented categories (Thelen and Smith, 1996) as children learn how to manipulate their perception by manipulating their environment. Language grounding enables an agent to connect words to these action-oriented categories for communication (Smith and Gasser, 2005), but requires action to fully discover such connections. Embodiment—situated action taking—is therefore a natural next broader context.

An embodied agent, whether in a virtual world, such as a 2D Maze (MacMahon et al., 2006), a grid world (Chevalier-Boisvert et al., 2019), a simulated house (Anderson et al., 2018; Thomason et al., 2019b; Shridhar et al., 2020), or the real world (Tellex et al., 2011; Matuszek, 2018; Thomason et al., 2020; Tellex et al., 2020) must translate from language to action. Control and action taking open several new dimensions to understanding and actively learning about the world. Queries can be resolved via dialog-based exploration with a human interlocutor (Liu and Chai, 2015), even as new object properties, like texture and weight (Thomason et al., 2017), or feedback, like muscle activations (Moro and Kennington, 2018), become available. We see the need for embodied language with complex meaning when thinking deeply about even the most innocuous of questions:

> *Is an orange more like a baseball or more like a banana?*

WS1 is likely not to have an answer beyond that the objects are common nouns that can both be held. WS2 may capture that oranges and baseballs both roll, but is not the deformation strength, surface texture, or relative sizes of these objects (Elazar et al., 2019). WS3 may realize the relative deformability of these objects, but is likely to confuse how much force is necessary given that baseballs are used much more roughly than oranges. WS4 can appreciate the nuances of the question—the orange and baseball afford similar manipulation *because* they have similar texture and weight, while the orange and banana both contain peels, deform, and are edible. People can reason over rich representations of common objects that these words evoke.

Planning is where people first learn abstraction and simple examples of post-conditions through trial and error. The most basic scripts humans learn start with moving our own bodies and achieving simple goals as children, such as stacking blocks. In this space, we have unlimited supervision from the environment and can learn to generalize across plans and actions. In general, simple worlds do not entail simple concepts: even in a block world concepts like "mirroring" appear (Bisk et al., 2018). Humans generalize and apply physical phenomena to abstract concepts with ease.

In addition to learning basic physical properties of the world from interaction, WS4 also allows the agent to construct rich pre-linguistic representations from which to generalize. Hespos and Spelke (2004) show pre-linguistic category formation within children that are then later codified by social constructs. Mounting evidence seems to indicate that children have trouble transferring knowledge from the 2D world of books (Barr, 2013) and iPads (Lin et al., 2017) to the physical 3D world. So while we might choose to believe that we can encode parameters (Chomsky, 1981) more effectively and efficiently than evolution provided us, developmental experiments indicate doing so without 3D interaction may prove difficult.

Part of the problem is that much of the knowledge humans hold about the world is intuitive, possibly incommunicable by language, but still required to understand language. Much of this knowledge revolves around physical realities that real-world agents will encounter. Consider how many explicit and implicit metaphors are based on the idea that far-away things have little influence on manipulating local space: "a distant concern" and "we'll cross that bridge when we come to it."

Robotics and embodiment are not available in the same off-the-shelf manner as computer vision models. However, there is rapid progress in simulators and commercial robotics, and as language researchers we should match these advances at every step. As action spaces grow, we can study complex language instructions in simulated homes (Shridhar et al., 2020) or map language to physical robot control (Blukis et al., 2019; Chai et al., 2018). The last few years have seen massive advances in both high fidelity simulators for robotics (Todorov et al., 2012; Coumans and Bai, 2016–2019; NVIDIA, 2019; Xiang et al., 2020) and the cost and availability of commodity hardware (Fitzgerald, 2013; Campeau-Lecours et al., 2019; Murali et al., 2019).

As computers transition from desktops to pervasive mobile and edge devices, we must make and meet the expectation that NLP can be deployed in any of these contexts. Current representations have very limited utility in even the most basic robotic settings (Scalise et al., 2019), making collaborative robotics (Rosenthal et al., 2010) largely a domain of custom engineering rather than science.

> In order to talk about concepts, we must understand the importance of mental models... we set up a model of the world which serves as a framework in which to organize our thoughts. We abstract the presence of particular objects, having properties, and entering into events and relationships.
>
> *Terry Winograd - 1971*

5 WS5: The Social World

Interpersonal communication is the foundational use case of natural language (Dunbar, 1993). The physical world gives meaning to metaphors and instructions, but utterances come from a source with a purpose. Take J.L. Austin's classic example of "BULL" being written on the side of a fence in a large field (Austin, 1975). It is a fundamentally *social* inference to realize that this word indicates the presence of a dangerous creature, and that the word is written on the *opposite side* of the fence from where that creature lives.

Interpersonal dialogue as a grand test for AI is older than the term "artificial intelligence," beginning at least with Turing (1950)'s Imitation Game. Turing was careful to show how easily a naïve tester could be tricked. Framing, such as suggesting that a chatbot speaks English as a second language (Sample and Hern, 2014), can create the appearance of genuine content where there is none (Weizenbaum, 1966). This phenomenon has been noted countless times, from criticisms of Speech Recognition as "deceit and glamour" (Pierce, 1969) to complaints of humanity's "gullibility gap" (Marcus and Davis, 2019). We instead focus on why the social world is vital to *language learning*.

Language that Does Something Work in the philosophy of language has long suggested that *function* is the source of meaning, as famously illustrated through Wittgenstein's "language games" (Wittgenstein, 1953, 1958). In linguistics, the usage-based theory of language acquisition suggests that constructions that are useful are the building blocks for everything else (Langacker, 1987, 1991). The *economy* of this notion of use has been the subject of much inquiry and debate (Grice, 1975). In recent years, these threads have begun to shed light on what use-cases language presents in both acquisition and its initial origins in our species (Tomasello, 2009; Barsalou, 2008), indicating the fundamental role of the social world.

WS1, WS2, WS3, and WS4 expand the factorizations of information available to linguistic meaning. allows language to be a *cause* instead of just a source of data. This is the ultimate goal for a language learner: to generate language that *does* something to the world.

Passive creation and evaluation of generated language separates generated utterances from their effects on other people, and while the latter is a rich learning signal it is inherently difficult to annotate. In order to learn the effects language has on the world, an agent must *participate* in linguistic activity, such as negotiation (Yang et al., 2019a; He et al., 2018; Lewis et al., 2017), collaboration (Chai et al., 2017), visual disambiguation (Anderson et al., 2018; Lazaridou et al., 2017; Liu and Chai, 2015), or providing emotional support (Rashkin et al., 2019). These activities require inferring mental states and social outcomes—a key area of interest in itself (Zadeh et al., 2019).

What "lame" means in terms of discriminative information is always at question: it can be defined as "undesirable," but what it tells one about the processes operating in the environment requires social context to determine (Bloom, 2002). It is the toddler's social experimentation with "You're so lame!" that gives the word weight and definite intent (Ornaghi et al., 2011). In other words, the discriminative signal for the most foundational part of a word's meaning can only be observed by its effect on the world, and active experimentation is key to learning that effect. Active experimentation with language starkly contrasts with the disembodied chat bots that are the focus of the current dialogue community (Roller et al., 2020; Adiwardana et al., 2020; Zhou et al., 2020; Chen et al., 2018; Serban et al., 2017), which often do not learn from individual experiences and whose environments are not persistent enough to learn the effects of actions.

Theory of Mind When attempting to get what we want, we confront people who have their own desires and identities. The ability to consider the feelings and knowledge of others is now commonly referred to as the "Theory of Mind" (Nematzadeh et al., 2018). This paradigm has also been described under the "Speaker-Listener" model (Stephens et al., 2010), and a rich theory to describe this computationally is being actively developed under the Rational Speech Act Model (Frank and Goodman, 2012; Bergen et al., 2016).

A series of challenges that attempt to address this fundamental aspect of communication have been introduced (Nematzadeh et al., 2018; Sap et al., 2019). These works are a great start towards deeper understanding, but static datasets can be problematic due to the risk of embedding spurious patterns and bias (de Vries et al., 2020; Le et al., 2019; Gururangan et al., 2018; Glockner et al., 2018), especially because examples where annotators cannot agree (which are usually thrown out before the dataset is released) still occur in real use cases. More flexible, dynamic evaluation (Zellers et al., 2020; Dinan et al., 2019) are a partial solution, but true persistence of identity and adaption to change are both necessary and still a long way off.

Training data in WS1-4, complex and large as it can be, does not offer the discriminatory signals that make the hypothesizing of consistent identity or mental states an efficient path towards lowering perplexity or raising accuracy (Liu et al., 2016; DeVault et al., 2006). First, there is a lack of inductive bias (Martin et al., 2018). Models learn what they need to discriminate between potential labels, and it is unlikely that universal function approximators such as neural networks would ever reliably posit that people, events, and causality exist without being biased towards such solutions (Mitchell, 1980). Second, current cross entropy training losses actively discourage learning the tail of the distribution properly, as statistically infrequent events are drowned out (Pennington et al., 2014; Holtzman et al., 2020). Meanwhile, it is precisely human's ability to draw on past experience and make zero-shot decisions that AI aims to emulate.

Language in a Social Context Whenever language is used between people, it exists in a concrete social context: status, role, intention, and countless other variables intersect at a specific point (Wardhaugh, 2011). These complexities are overlooked through selecting labels on which crowd workers agree. Current notions of ground truth in dataset construction are based on crowd consensus bereft of social context. We posit that ecologically valid evaluation of generative models will require the construction of situations where artificial agents are considered to have enough identity to be granted *social standing* for these interactions.

Social interaction is a precious signal, but initial studies have been strained by the training-validation-test set scenario and reference-backed evaluations. Collecting data about rich natural situations is often impossible. To address this gap, learning by participation, where users can freely interact with an agent, is a necessary step to the ultimately *social* venture of communication. By exhibiting different attributes and sending varying signals, the sociolinguistic construction of identity (Ochs, 1993) could be examined more deeply. Such experimentation in social intelligence is simply not possible with a fixed corpus. Once models are expected to be interacted with when tested, probing their decision boundaries for simplifications of reality and a lack of commonsense knowledge as in Gardner et al.; Kaushik et al. will become natural.

6 Self-Evaluation

We use the notion of World Scopes to make the following concrete claims:

You can't learn language ...

... from the radio (Internet). **WS2 ⊂ WS3**

> *A task learner cannot be said to be in* WS*3 if it can succeed without perception (e.g., visual, auditory).*

... from a television. **WS3 ⊂ WS4**

> *A task learner cannot be said to be in* WS*4 if the space of its world actions and consequences can be enumerated.*

... by yourself. **WS4 ⊂ WS5**

> *A task learner cannot be said to be in* WS*5 unless achieving its goals requires cooperating with a human in the loop.*

By these definitions, most of NLP research still resides in WS2. This fact does not invalidate the utility or need for any of the research within NLP, but it is to say that much of that existing research targets a different goal than *language learning*.

> These problems include the need to bring meaning and reasoning into systems that perform natural language processing, the need to infer and represent causality, the need to develop computationally-tractable representations of uncertainty and the need to develop systems that formulate and pursue long-term goals.
>
> *Michael Jordan (Artificial intelligence – the revolution hasn't happened yet, 2019)*

Where Should We Start? Many in our community are already examining phenomena in WSs 3-5. Note that research can explore higher WS phenomena without a resultant learner being in a higher WS. For example, a chatbot can investigate principles of the social world, but still lack the underlying social standing required for WS5. Next we describe four language use contexts which we believe are both research questions to be tackled and help illustrate the need to move beyond WS2.

Second language acquisition when visiting a foreign country leverages a shared, social world model that allows pointing to referent objects and miming internal states like hunger. The interlingua is physical and experiential. Such a rich internal world model should also be the goal for MT models: starting with images (Huang et al., 2020), moving through simulation, and then to the real world.

Coreference and WSD leverage a shared scene and theory of mind. To what extent are current coreference resolution issues resolved if an agent models the listener's desires and experiences explicitly rather than looking solely for adjacent lexical items? This setting is easiest to explore in embodied environments, but is not exclusive to them (e.g., TextWorld (Côté et al., 2018)).

Novel word learning from tactile knowledge and use: What is the instrument that you wear like a guitar but play like a piano? Objects can be described with both gestures and words about appearance and function. Such knowledge could begin to tackle physical metaphors that current NLP systems struggle with.

Personally charged language: How should a dialogue agent learn what is hurtful to a specific person? To someone who is sensitive about their grades because they had a period of struggle in school, the sentiment of "Don't be a fool!" can be hurtful, while for others it may seem playful. Social knowledge is requisite for realistic understanding of sentiment in situated human contexts.

Relevant recent work The move from WS2 to WS3 requires rethinking existing tasks and investigating where their semantics can be expanded and grounded. This idea is not new (Chen and Mooney, 2008; Feng and Lapata, 2010; Bruni et al., 2014; Lazaridou et al., 2016) and has accelerated in the last few years. Elliott et al. (2016) reframes machine translation with visual observations, a trend extended into videos (Wang et al., 2019b). Regneri et al. (2013) introduce a foundational dataset aligning text descriptions and semantic annotations of actions with videos. Vision can even inform core tasks like syntax (Shi et al., 2019) and language modeling (Ororbia et al., 2019). Careful design is key, as visually augmented tasks can fail to require sensory perception (Thomason et al., 2019a).

Language-guided, embodied agents invoke many of the challenges of WS4. Language-based navigation (Anderson et al., 2018) and task completion (Shridhar et al., 2020) in simulation environments ground language to actions, but even complex simulation action spaces can be discretized and enumerated. By contrast, language-guided robots that perform task completion (Tellex et al., 2014) and learning (She et al., 2014) in the real world face challenging, continuous perception and control (Tellex et al., 2020). Consequently, research in this space effectively restricts understanding to small grammars (Paul et al., 2018; Walter et al., 2013) or controlled dialog responses (Thomason et al., 2020). These efforts to translate language instructions to actions build towards using language for end-to-end, continuous control (WS4).

Collaborative games have long served as a testbed for studying language (Werner and Dyer, 1991) and emergent communication (Schlangen, 2019a; Lazaridou et al., 2018; Chaabouni et al., 2020). Suhr et al. (2019a) introduced an environment for evaluating language understanding in the service of a shared goal, and Andreas and Klein (2016) use a visual paradigm for studying pragmatics. Such efforts help us examine how inductive biases and environmental pressures build towards socialization (WS5), even if full social context is still too difficult and expensive to be practical.

Most of this research provides resources such as data, code, simulators and methodology for evaluating the multimodal content of linguistic representations (Schlangen, 2019b; Silberer and Lapata, 2014; Bruni et al., 2012). Moving forward, we encourage a broad re-examination of how NLP frames the relationship between meaning and context (Bender and Koller, 2020) and how pretraining obfuscates our ability to measure generalization (Linzen, 2020).

7 Conclusions

Our World Scopes are steep steps. WS5 implies a persistent agent experiencing time and a personalized set of experiences. confined to IID datasets that lack the structure in time from which humans draw correlations about long-range causal dependencies. What happens if a machine is allowed to participate consistently? This is difficult to test under current evaluation paradigms for generalization. Yet, this is the structure of generalization in human development: drawing analogies to episodic memories and gathering new data through non-independent experiments.

As with many who have analyzed the history of NLP, its trends (Church, 2007), its maturation toward a science (Steedman, 2008), and its major challenges (Hirschberg and Manning, 2015; McClelland et al., 2019), we hope to provide momentum for a direction many are already heading. We call for and embrace the incremental, but purposeful, contextualization of language in human experience. With all that we have learned about what words can tell us and what they keep implicit, now is the time to ask: *What tasks, representations, and inductive-biases will fill the gaps?*

Computer vision and speech recognition are mature enough for investigation of broader linguistic contexts (WS3). The robotics industry is rapidly developing commodity hardware and sophisticated software that both facilitate new research and expect to incorporate language technologies (WS4). Simulators and videogames provide potential environments for social language learners (WS5). Our call to action is to encourage the community to lean in to trends prioritizing grounding and agency, and explicitly aim to broaden the corresponding World Scopes available to our models.

Abstract

Text-based games present a unique challenge for autonomous agents to operate in natural language and handle enormous action spaces. In this paper, we propose the Contextual Action Language Model (CALM) to generate a compact set of action candidates at each game state. Our key insight is to train language models on human gameplay, where people demonstrate linguistic priors and a general *game sense* for promising actions conditioned on game history. We combine CALM with a reinforcement learning agent which re-ranks the generated action candidates to maximize in-game rewards. We evaluate our approach using the Jericho benchmark (Hausknecht et al., 2019a), on games *unseen* by CALM during training. Our method obtains a 69% relative improvement in average game score over the previous state-of-the-art model. Surprisingly, on half of these games, CALM is competitive with or better than other models that have access to ground truth admissible actions.[*]

1 Introduction

Text-based games have proven to be useful testbeds for developing agents that operate in language. As interactions in these games (input observations, action commands) are through text, they require solid language understanding for successful gameplay. While several reinforcement learning (RL) models have been proposed recently (Narasimhan et al., 2015; He et al., 2015; Hausknecht et al., 2019a; Ammanabrolu and Riedl, 2019), combinatorially large action spaces continue to make these games challenging for these approaches.

> *Observation:* You are in the living room. There is a doorway to the east, a wooden door with strange gothic lettering to the west, which appears to be nailed shut, a trophy case, and a large oriental rug in the center of the room. You are carrying: A brass lantern . . .
>
> **Random Actions**:
> close door, north a, eat troll with egg, . . .
> **CALM (n-gram) Actions**:
> enter room, leave room, lock room,
> open door, close door, knock on door, . . .
> **CALM (GPT-2) Actions**:
> east, open case, get rug, turn on lantern,
> move rug, unlock case with key, . . .
>
> *Next Observation*: With a great effort, the rug is moved to one side of the room, revealing the dusty cover of a closed trap door...

Figure 1: Sample gameplay from ZORK1 along with action sets generated by two variants of CALM. The game recognizes a vocabulary size of 697, resulting in more than $697^4 \approx 200$ billion potential 4-word actions. '*move rug*' is the optimal action to take here and is generated by our method as a candidate.

The action space problem is exacerbated by the fact that only a tiny fraction of action commands are admissible in any given game state. An admissible action is one that is parseable by the game engine and changes the underlying game state. For example, in Figure 1, one can observe that randomly sampling actions from the game vocabulary leads to several inadmissible ones like '*north a*' or '*eat troll with egg*'. Thus, narrowing down the action space to admissible actions requires both syntactic and semantic knowledge, making it challenging for current systems.

Further, even within the space of admissible actions, it is imperative for an autonomous agent to know which actions are most promising to advance the game forward, and explore them first. Human players innately display such game-related common sense. For instance in Figure 1, players

November 16–20, 2020.

might prefer the command "move rug" over "knock on door" since the door is nailed shut. However, even the state-of-the-art game-playing agents do not incorporate such priors, and instead rely on rule-based heuristics (Hausknecht et al., 2019a) or handicaps provided by the learning environment (Hausknecht et al., 2019a; Ammanabrolu and Hausknecht, 2020) to circumvent these issues.

In this work, we propose the Contextual Action Language Model (CALM) to alleviate this challenge. Specifically, at each game step we use CALM to generate action candidates, which are fed into a Deep Reinforcement Relevance Network (DRRN) (He et al., 2015) that uses game rewards to learn a value function over these actions. This allows our model to combine generic linguistic priors for action generation with the ability to adaptively choose actions that are best suited for the game.

To train CALM, we introduce a novel dataset of 426 human gameplay transcripts for 590 different text-based games. While these transcripts are noisy and actions are not always optimal, they contain a substantial amount of linguistic priors and game sense. Using this dataset, we train a single instance of CALM and deploy it to generate actions across many different downstream games. Importantly, in order to demonstrate the generalization of our approach, we do not use any transcripts from our evaluation games to train the language model.

We investigate both n-gram and state-of-the-art GPT-2 (Radford et al., 2019) language models and first evaluate the quality of generated actions in isolation by comparing against ground-truth sets of admissible actions. Subsequently, we evaluate the quality of CALM in conjunction with RL over 28 games from the Jericho benchmark (Hausknecht et al., 2019a). Our method outperforms the previous state-of-the-art method by 69% in terms of average normalized score. Surprisingly, on 8 games our method even outperforms competing methods that use the admissible action handicap – for example, in the game of INHUMANE, we achieve a score of 25.7 while the state-of-the-art KG-A2C agent (Ammanabrolu and Hausknecht, 2020) achieved 3.

In summary, our contributions are two-fold. First, we propose a novel learning-based approach for reducing enormous action spaces in text-based games using linguistic knowledge. Second, we introduce a new dataset of human gameplay transcripts, along with an evaluation scheme to measure the quality of action generation in these games.

2 Related Work

Reinforcement Learning for Text-based Games Early work on text-based games (Narasimhan et al., 2015; He et al., 2015) developed RL agents on synthetic environments with small, pre-defined text action spaces. Even with small actions spaces (e.g. < 200 actions), approaches to filter inadmissible actions (Zahavy et al., 2018; Jain et al., 2019) led to faster learning convergence. Recently, Hausknecht et al. (2019a) introduced Jericho – a benchmark of challenging man-made text games. These games contain significantly greater linguistic variation and larger action spaces compared to frameworks like TextWorld (Côté et al., 2018).

To assist RL agents, Jericho provides a handicap that identifies admissible actions at each game state. This has been used by approaches like DRRN (He et al., 2015) as a reduced action space. Other RL agents like TDQN (Hausknecht et al., 2019a) and KGA2C (Ammanabrolu and Hausknecht, 2020) rely on the handicap for an auxiliary training loss. In general, as these RL approaches lack linguistic priors and only learn through in-game rewards, they are reliant on the admissible-action handicap to make the action space tractable to explore.

Linguistic Priors for Text-based Games A different line of work has explored various linguistic priors for generating action commands. Fulda et al. (2017) used Word2vec (Mikolov et al., 2013) embeddings to infer affordance properties (i.e. verbs suitable for an object). Other approaches (Kostka et al., 2017; Hausknecht et al., 2019b) trained simple n-gram language models to learn affordances for action generation. Perhaps most similar to our work is that of Tao et al. (2018), who trained seq2seq (Sutskever et al., 2014) models to produce admissible actions in synthetic TextWorld (Côté et al., 2018) games. In a slightly different setting, Urbanek et al. (2019) trained BERT (Devlin et al., 2018) to generate contextually relevant dialogue utterances and actions in fantasy settings. However, these approaches are game-specific and do not use any reinforcement learning to optimize gameplay. In contrast, we combine strong linguistic priors with reinforcement learning, and use a modern language model that can generate complex actions and flexibly model the dependency between actions and contexts. We also train on multiple games and generalize to unseen games.

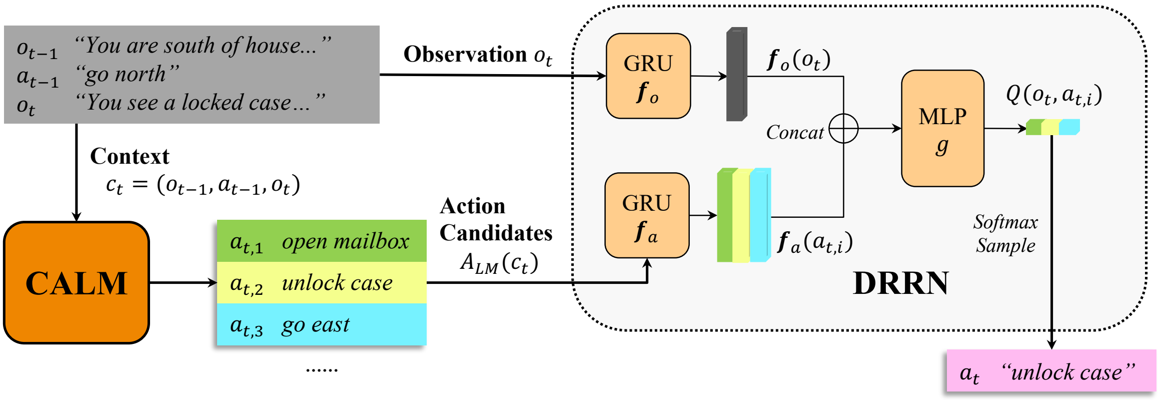

Figure 2: CALM combined with an RL agent – DRRN (He et al., 2015) – for gameplay. CALM is trained on transcripts of human gameplay for action generation. At each state, CALM generates action candidates conditioned on the game context, and the DRRN calculates the Q-values over them to select an action. Once trained, a single instance of CALM can be used to generate actions for any text-based game.

Generation in Text-based Games and Interactive Dialog Besides solving games, researchers have also used language models to *create* text-based games. Ammanabrolu et al. (2019) used Markov chains and neural language models to procedurally generate quests for TextWorld-like games. AI Dungeon 2 (Walton, 2019) used GPT-2 to generate narrative text in response to arbitrary text actions, but lacked temporal consistency over many steps.

More broadly, the concept of generating candidates and re-ranking has been studied in other interactive lanugage tasks such as dialogue (Zhao and Eskenazi, 2016; Williams et al., 2017; Song et al., 2016; Chen et al., 2017) and communication games (Lazaridou et al., 2020). These approaches often focus on improving aspects like fluency and accuracy of the generated utterances, whereas our re-ranking approach only aims to maximize future rewards in the task. Also, our CALM pre-trained model generalizes to new environments without requiring any re-training.

3 Method

3.1 Background

A text-based game can be formally specified as a partially observable Markov decision process (POMDP) (S, T, A, O, R, γ), where a player issues text actions $a \in A$ and receives text observations $o \in O$ and scalar rewards $r = R(s, a)$ at each step. Different games have different reward designs, but typically provide sparse positive rewards for solving key puzzles and advancing the story, and negative rewards for dying. $\gamma \in [0, 1]$ is the reward discount factor. Latent state $s \in S$ contains the current game information (e.g. locations of the player and items, the player's inventory), which is only partially reflected in o. The transition function $s' = T(s, a)$ specifies how action a is applied on state s, and a is **admissible** at state s if $T(s, a) \neq s$ (i.e. if it is parseable by the game and changes the state). S, T and R are not provided to the player.

Reinforcement Learning One approach to developing text-based game agents is reinforcement learning (RL). The Deep Reinforcement Relevance Network (DRRN) (He et al., 2015) is an RL algorithm that learns a Q-network $Q_\phi(o, a)$ parametrized by ϕ. The model encodes the observation o and each action candidate a using two separate encoders f_o and f_a (usually recurrent neural networks such as GRU (Cho et al., 2014)), and then aggregates the representations to derive the Q-value through a decoder g:

$$Q_\phi(o, a) = g(f_o(o), f_a(a)) \tag{1}$$

For learning ϕ, tuples (o, a, r, o') of observation, action, reward and the next observation are sampled from an experience replay buffer and the following temporal difference (TD) loss is minimized:

$$\mathcal{L}_{\text{TD}}(\phi) = (r + \gamma \max_{a' \in A} Q_\phi(o', a') - Q_\phi(o, a))^2 \tag{2}$$

During gameplay, a softmax exploration policy is used to sample an action:

$$\pi_\phi(a|o) = \frac{\exp(Q_\phi(o, a))}{\sum_{a' \in A} \exp(Q_\phi(o, a'))} \tag{3}$$

While the above equation contains only a single observation, this can also be extended to a policy $\pi(a|c)$ conditioned on a longer context $c = (o_1, a_1, ..., o_t)$ of previous observations and actions till current time step t. Note that when the action space A is large, (2) and (3) become intractable.

3.2 Contextual Action Language Model (CALM)

To reduce large action spaces and make learning tractable, we train language models to generate compact sets of actions candidates. Consider a dataset $\mathcal{D}$ of N trajectories of human gameplay across different games, where each trajectory of length l consists of interleaved observations and actions $(o_1, a_1, o_2, a_2, \cdots, o_l, a_l)$. The *context* c_t at timestep t is defined as the history of observations and actions, i.e. $c_t = (o_1, a_1, ..., a_{t-1}, o_t)$. In practice, we find that a window size of 2 works well, i.e. $c_t = (o_{t-1}, a_{t-1}, o_t)$. We train parametrized language models p_θ to generate actions a conditioned on contexts c. Specifically, we use all N trajectories and minimize the following cross-entropy loss:

$$\mathcal{L}_{\text{LM}}(\theta) = -\mathbb{E}_{(a,c)\sim D} \log p_\theta(a|c) \quad (4)$$

Since each action a is typically a multi-word phrase consisting of m tokens $a^1, a^2, \cdots, a^m$, we can further factorize the right hand side of (4) as:

$$p_\theta(a|c) = \prod_{i=1}^{m} p_\theta(a^i|a^{<i}, c) \quad (5)$$

Thus, we can simply use the cross-entropy loss over each token a^i in action a during training. We investigate two types of language models:

1. n-gram: This model simply uses n-gram counts from actions in $\mathcal{D}$ to model the following probability:

$$p_{(n,\alpha)}(a^i|a^{<i}) = \frac{cnt(a^{i-n+1}, \cdots, a^i) + \alpha}{cnt(a^{i-n+1}, \cdots, a^{i-1}) + \alpha|V|} \quad (6)$$

where $cnt(a^i, \cdots, a^j)$ counts the number of occurrences of the action sub-sequence $(a^i, \cdots, a^j)$ in the training set, α is a smoothing constant, and V is the token vocabulary. Note that this model is trained in a *context-independent* way and only captures basic linguistic structure and common affordance relations observed in human actions. We optimize the parameters (n, α) to minimize the perplexity on a held-out validation set of actions.

To generate top actions given context c, we construct a restricted action space $\mathcal{A}_c = \mathcal{V} \times \mathcal{B}_c$, where $\mathcal{V}$ is the set of verb phrases (e.g. *open*, *knock on*) collected from training actions, and $\mathcal{B}_c$ is the set of nouns (e.g. *door*) detected in c using spaCy's[†] noun-phrase detection. Then we calculate $p_{(n,\alpha)}(a)$ for each $a \in \mathcal{A}_c$ and choose the top ones.

2. GPT-2 (Radford et al., 2019): We use a pretrained GPT-2 and train it on $\mathcal{D}$ according to (4) and (5). Unlike the previous n-gram model, GPT-2 helps model dependencies between the context and the action in a flexible way, relying on minimal assumptions about the structure of actions. We use beam search to generate most likely actions.

3.3 Reinforcement Learning with CALM

Though language models learn to generate useful actions, they are not optimized for gameplay performance. Therefore, we use CALM to generate top-k action candidates $A_{\text{LM}}(c, k) \subset A$ given context c, and train a DRRN to learn a Q-function over this action space. This can be done by simply replacing A with $A_{\text{LM}}(c, k)$ in equations (2) and (3). In this way, we combine the CALM's generic action priors with the ability of RL to learn policies optimized for the gameplay. We choose not to fine-tune CALM in RL so as to avoid overfitting to a specific game and invalidate the general priors present in CALM.

To summarize, we employ CALM for providing a reduced action space for text adventure agents to explore efficiently. Even though we choose a specific RL agent (DRRN) in our experiments, CALM is simple and generic, and can be combined with any RL agent.

4 Experimental Setup

We perform empirical studies to 1) evaluate the quality of actions generated by CALM in isolation from the complexities of RL, 2) evaluate CALM combined with an RL agent for gameplay, and 3) analyze what factors contribute to the effectiveness of our method. We describe our setup in this section and provide results in Section 5.

4.1 Data and Environment

ClubFloyd Dataset We collect data from ClubFloyd[‡], which archives transcripts of humans cooperatively playing text-based games. We

---

[†] https://spacy.io/

[‡] http://www.allthingsjacq.com/interactive_fiction.html#clubfloyd

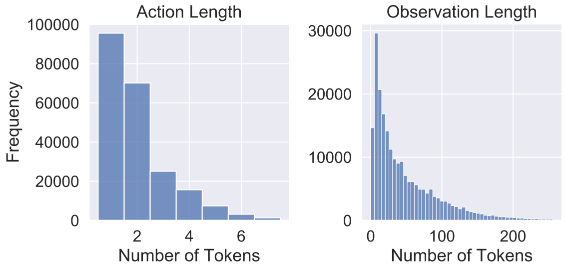

Figure 3: Distributions of actions and observations in the ClubFloyd Dataset, in terms of the number of tokens. Actions more than 7 tokens (<0.5%) and observations more than 256 tokens (<2%) are trimmed.

crawl 426 transcripts covering 590 games (in some transcripts people play more than one game), and build a dataset of 223,527 context-action pairs $\{((o_{t-1}, a_{t-1}, o_t), a_t)\}$. We pre-process the data by removing samples with meta-actions (e.g. '*save*','*restore*') or observations with over 256 tokens. Figure 3 visualizes the action and observation length distributions. We also note that a few common actions (e.g. '*north*', '*take all*', '*examine*') make up a large portion of the data. More details on the dataset are in the supplementary material.

Game Environment To test our RL agents, we use 28 man-made text games from the Jericho framework (Hausknecht et al., 2019a). We augment state observations with location and inventory descriptions by issuing the '*look*' and '*inventory*' commands, following the standard practice described in Hausknecht et al. (2019a).

The Jericho framework implements an *admissible action handicap* by enumerating all combinations of game verbs and objects at each state, and testing each action's admissibility by accessing the underlying simulator states and load-and-save functions. As a result, the handicap runs no faster than a GPT-2 inference pass, and could in fact be unavailable for games outside Jericho. Jericho also provides an optimal *walkthrough* trajectory to win each game. Table 1 provides statistics of the ClubFloyd Dataset and the Jericho walkthroughs. We observe that ClubFloyd has a much larger vocabulary and a diverse set of games, which makes it ideal for training CALM. We utilize Jericho walkthroughs in our standalone evaluation of CALM in § 5.1.

4.2 CALM Setup

Training For training CALM (n-gram), we condition only on the current observation, i.e. $c_t = o_t$ instead of $c_t = (o_{t-1}, a_{t-1}, o_t)$, since o_{t-1} and a_{t-1} may contain irrelevant objects to the current state. We split the dataset into 90% training set and 10% validation set, and choose n and α based on the validation set perplexity. We find a bi-gram model $n = 2, \alpha = 0.00073$ works best, achieving a per-action perplexity of $863,808$ on the validation set and $17,181$ on the training set.

	ClubFloyd Dataset	**Jericho Walkthroughs**
# unique games	590	28
Vocab size	39,670	9,623
Vocab size (game avg.)	2,363	1,037
Avg. trajectory length	360	98
Action Quality	Non-optimal	Optimal

Table 1: Statistics of the ClubFloyd Dataset and Jericho walkthrough trajectories.

For CALM (GPT-2), we start with a 12-layer, 768-hidden, 12-head, 117M parameter GPT-2 model pre-trained on the WebText corpus (Radford et al., 2019). The implementation and pretrained weights of this model are obtained from Wolf et al. (2019). We then train it on the ClubFloyd transcripts for 3 epochs to minimize (4). We split the dataset into 90% training set and 10% validation set and we obtain a training loss of 0.25 and a validation loss of 1.98. Importantly, *both models are trained only on transcripts that do not overlap with the 28 Jericho games we evaluate on.*

Generating Top Actions For every unique state of each game, we generate the top $k = 30$ actions. For CALM (n-gram), we enumerate all actions in $\mathcal{A}_c$ plus 13 one-word directional actions (e.g. '*north*', '*up*', '*exit*'). To encourage action diversity, at most 4 actions are generated for each object $b \in \mathcal{B}_c$. For CALM (GPT-2), we use beam search with a beam size of 40, and then choose the top 30 actions.

4.3 RL Agent Setup

Training We use DRRN (He et al., 2015) to estimate Q-Values over action candidates generated by CALM. Following Hausknecht et al. (2019a), we use a FastText model (Joulin et al., 2017) to predict the admissibility of an action based on the game's textual response and filter out candidate actions that are found to be inadmissible. We train the DRRN asynchronously on 8 parallel instances of the game environment for 10^6 steps in total. Following Narasimhan et al. (2015), we use a separate

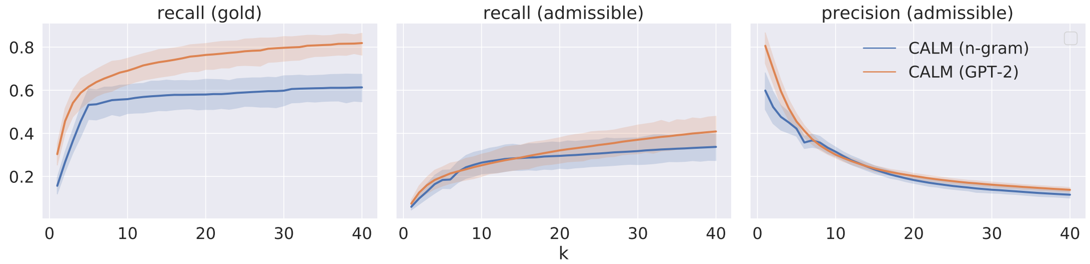

Figure 4: Precision and recall of gold and admissible actions generated by CALM, evaluated on walkthrough trajectories of 28 games provided by Jericho. k is the number of actions generated by CALM. Shaded areas represent standard deviation.

experience replay buffer to store trajectories with the best score at any point of time. The final score of a training run is taken to be the average score of the final 100 episodes during training. For each game, we train five independent agents with different random seeds and report the average score. For model variants in § 5.3 we only run one trail.

Baselines We compare with three baselines:

1. *NAIL* (Hausknecht et al., 2019b): Uses hand-written rules to act and explore, therefore requires no reinforcement learning or oracle access to admissible actions.
2. *DRRN* (He et al., 2015): This RL agent described in § 3.1 uses ground-truth admissible actions provided by the Jericho handicap.
3. *KG-A2C* (Ammanabrolu and Hausknecht, 2020): This RL agent constructs a game knowledge graph to augment the state space as well as constrain the types of actions generated. During learning, it requires the admissible action handicap to guide its exploration of the action space.

Of these methods, DRRN and KG-A2C require ground-truth admissible actions, which our model does not use, but we add them as reference comparisons for completeness.

5 Results

5.1 Evaluating CALM on walkthroughs

Metrics like validation loss or accuracy on validation set of our ClubFloyd data are not sufficient to evaluate CALM (see supplementary material for details on these metrics). This is because: 1) there can be multiple admissible actions in each state, and 2) the human actions in the trajectories are not guaranteed to be optimal or even admissible. Therefore, we use the walkthroughs provided in Jericho to provide an additional assessment on the quality of actions generated by CALM.

Consider a walkthrough to be an optimal trajectory $(o_1, a_1, \cdots, o_l, a_l)$ leading to the maximum score achievable in the game. At step t ($1 \leq t \leq l$), the context c_t is (o_{t-1}, a_{t-1}, o_t), the *gold* action is a_t and the full set of admissible actions A_t is obtained from the Jericho handicap. Suppose the generated set of top-k actions at step t is $A_{\text{LM}}(c_t, k)$. We then calculate the average precision of admissible actions ($prec_a$), recall of admissible actions (rec_a), and recall of gold actions (rec_g) as follows:

$$prec_a(k) = \frac{1}{l} \sum_{t=1}^{l} \frac{|A_t \cap A_{\text{LM}}(c_t, k)|}{k} \tag{7}$$

$$rec_a(k) = \frac{1}{l} \sum_{t=1}^{l} \frac{|A_t \cap A_{\text{LM}}(c_t, k)|}{|A_t|} \tag{8}$$

$$rec_g(k) = \frac{1}{l} \sum_{t=1}^{l} |\{a_t\} \cap A_{\text{LM}}(c_t, k)| \tag{9}$$

We calculate these metrics on each of the 28 games and present the averaged metrics as a function of k in Figure 4. The rec_a curve shows that the top $k = 15$ actions of CALM (GPT-2 and n-gram) are both expected to contain around 30% of all admissible actions in each walkthrough state. However, when k goes from 15 to 30, CALM (GPT-2) can come up with 10% more admissible actions, while the gains are limited for CALM (n-gram). When k is small, CALM (n-gram) benefits from its strong action assumption of one verb plus one object. However, this assumption also restricts CALM (n-gram) from generating more complex actions (e.g. 'open case with key') that CALM (GPT-2) can produce. This can also be seen in the rec_g curve, where the top-30 actions from CALM (GPT-2) contain the gold action in 20% more game states than CALM (n-gram). This gap is larger when it comes to gold actions, because they are more likely to be complex actions that the CALM (n-gram) is

Table 2: Performance of our models (CALM (GPT-2) and CALM (n-gram)) compared to baselines (NAIL, KG-A2C, DRRN) on Jericho. We report raw scores for individual games as well as average normalized scores (avg. norm). *Advent* and *Deephome*'s initial scores are 1 and 36, respectively. Underlined games represent those where CALM outperforms handicap-assisted methods KGA2C and DRRN.

unable to model.

Further, we note that as k increases, the average quality of the actions decreases ($prec_a$ curve), while they contain more admissible actions (rec_a curve). Thus, k plays an important role in balancing exploration (more admissible actions) with exploitation (a larger ratio of admissible actions) for the RL agent, which we demonstrate empirically in § 5.3. We provide several examples of generated actions from both models in the supplementary material.

5.2 Evaluating gameplay on Jericho

We provide scores of our CALM-augmented DRRN agent on individual games in Table 2. To take into account different score scales across games, we consider both the raw score and the normalized score (raw score divided by maximum score), and only report the average normalized score across games.

Of the handicap-free models, CALM (n-gram) achieves similar performance to NAIL, while CALM (GPT-2) outperforms CALM (n-gram) and NAIL by 4.4% and 3.8% on absolute normalized scores, respectively. Relatively, this represents almost a 69% improvement over NAIL. Figure 5 presents a game-wise comparison between CALM (GPT-2) and NAIL.

Variant	**avg. norm**
CALM (default)	9.4%
CALM (20%)	8.1%
CALM (50%)	8.4%
CALM (w/ Jericho)	10.9%
CALM (w/o PT)	6.8%
CALM ($k = 10$)	5.6%
CALM ($k = 20$)	9.6%
CALM ($k = 40$)	9.2%
CALM (random agent)	1.8%

Table 3: Average normalized scores on Jericho for different variants of CALM (GPT-2). CALM (default) is the CALM (GPT-2) model used for results in Table 2.

Surprisingly, even when compared to handicap-assisted models, CALM (GPT-2) performs quite well. On 8 out of 28 games (underlined in Table 2), CALM (GPT-2) outperforms both DRRN and KG-A2C despite the latter having access to ground-truth admissible actions. This improvement is especially impressive on games like DETECTIVE, INHUMANE and SNACKTIME, where our normalized score is higher by more than 20%. We hypothesize CALM excludes some non-useful admissible actions like "throw egg at sword" that humans never issue, which can speed up exploration. Also, it is possible that CALM sometimes discover admissible actions even the handicap cannot (due to the imperfection of state change detection).

5.3 Analysis

What Factors Contribute to Gameplay? We now analyze various components and design choices made in CALM (GPT-2). First, we investigate how much of the model's performance is due to pre-training on text corpora as opposed to training on our ClubFloyd data. Then, we vary the number of actions (k) generated by the model. We also consider combing CALM with a random agent instead of RL. This leads us to the following variants:

1. **CALM (X%)**: These variants are trained with only X% of the transcripts from ClubFloyd. $X = 0$ is equivalent to using a pre-trained GPT-

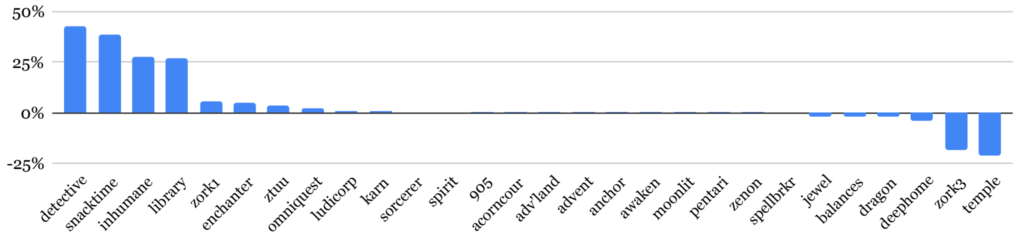

Figure 5: Difference in normalized scores achieved by CALM (GPT-2) and NAIL, in decreasing order.

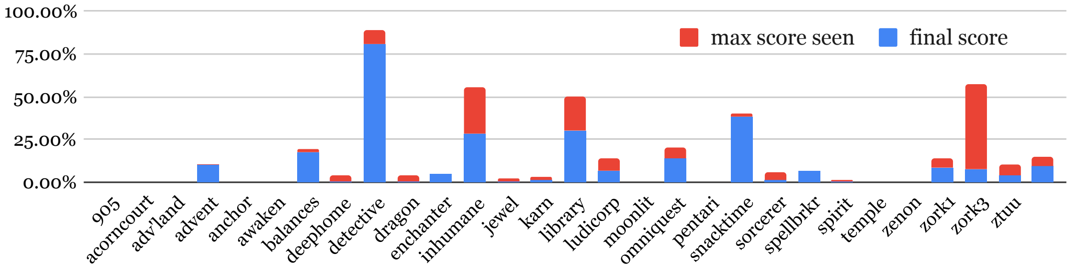

Figure 6: Final scores (blue) and maximum scores (normalized) seen during exploration (red) for CALM (GPT-2). There is a lot of potential for developing better algorithms to learn from high-scoring trajectories.

2 model off-the-shelf – we find that this fails to produce actions that are even parseable by the game engine and therefore is not reported in the table.

2. **CALM (w/ Jericho)**: This variant is trained on additional ClubFloyd data that includes 8 scripts from games contained in Jericho.

3. **CALM (w/o PT)**: This is a randomly initialized GPT-2 model, instead of a pre-trained one, trained on ClubFloyd data. We train this model for 10 epochs until the validation loss converges, unlike previous models which we train for 3 epochs.

4. **CALM ($k = Y$)**: This is a model variant that produces action sets of size Y.

5. **CALM (random agent)**: This model variant replaces DRRN by a random agent that samples uniformly from CALM top-30 actions at each state.

As shown in Table 3, the significant drop in score for CALM without pretraining shows that both pre-training and ClubFloyd training are important for gameplay performance. Pre-training provides general linguistic priors that regularize action generation while the ClubFloyd data conditions the model towards generating actions useful in text-based games.

Adding heldout transcripts from Jericho evaluation games (CALM w/ Jericho) provides additional benefit as expected, even surpassing handicap-assisted KG-A2C in terms of the average normalized score. Counter-intuitively, we find that the greatest performance gains aren't on games featured in the heldout transcripts. See supplementary material for more details.

For the models with different k values, CALM ($k = 10$) is much worse than other choices, but similar to CALM (n-gram) in Table 2. Note that in Figure 4 the recall of admissible actions is similar between GPT-2 and n-gram when $k \leq 10$. We believe it is because top-10 GPT-2 actions are usually simple actions that occur a lot in ClubFloyd (e.g. '*east*', '*get object*'), which is also what n-gram can capture. It is really the complex actions captured when $k > 10$ that makes GPT-2 much better than n-gram. On the other hand, though $k = 20, 30, 40$ achieve similar overall performance, they achieve different results for different games. So potentially the CALM overall performance can be further improved by choosing different k for different games. Finally, CALM (random agent) performs a poor score of 1.8%, and clearly shows the importance of combining CALM with an RL agent to adaptively choose actions.

Is CALM limiting RL? A natural question to ask is whether reducing the action space using CALM results in missing key actions that may have led to higher scores in the games. To answer this, we also plot the maximum scores seen by our CALM (GPT-2) agent during RL in Figure 6. Some games (e.g. 905, ACORNCOURT) are intrinsically hard to achieve any score. However, on other games with non-zero scores, DRRN is unable to stably converge to the maximum score seen in RL exploration. If RL can fully exploit and learn from the trajectories experienced under the CALM action space for each game, the average normalized score would be 14.7%, higher than any model in Table 2, both with and without handicaps.

6 Conclusion

In this paper, we proposed the Contextual Action Language Model (CALM), a language model approach to generating action candidates for reinforcement learning agents in text-based games. Our key insight is to use language models to capture linguistic priors and game sense from humans gameplay on a diverse set of games. We demonstrated that CALM can generate high-quality, contextually-relevant actions even for games unseen in its training set, and when paired with a DRRN agent, outperforms previous approaches on the Jericho benchmark (Hausknecht et al., 2019a) by as much as 69% in terms of average normalized score. Remarkably, on many of these games, our approach is competitive even with models that use ground truth admissible actions, implying that CALM is able to generate high-quality actions across diverse games and contexts.

From the results in Table 2, it is safe to conclude that text-based games are still far from being solved. Even with access to ground truth admissible actions, sparse rewards and partial observability pose daunting challenges for current agents. In the future, we believe that strong linguistic priors will continue to be a key ingredient for building next-level learning agents in these games. By releasing our dataset and code we hope to provide a solid foundation to accelerate work in this direction.

A ClubFloyd Dataset

The ClubFloyd transcripts we collected are gameplay logs generated by a group of people that regularly meet to play interactive fiction games. The participants are experienced at playing text-based games, however they may not be familiar with the game that's being played, and do make several mistakes. We include a snippet of a transcript in Figure 7. We crawled the ClubFloyd website to acquire 426 transcripts, spanning over 500 games.

To process a transcript, we clean the data and extract observations and actions. The data contains several sources of noise, which we remove: the first is non-game information such as chat logs between the humans playing the games; second are meta-actions that humans use to save and load games and navigate menus; and finally, we remove typos, expand common abbreviations ("n" to "north", "x" to "examine", etc.), and filter out any actions that weren't recognized by the game parsers.

Once we have our cleaned observations and actions, we group observations and actions into the

After this entire pre-processing, the dataset contains 223,527 examples.

B CALM Training

In this section, we will provide training details of CALM (GPT-2), CALM (n-gram), and their variants.

B.1 CALM (GPT-2)

We first discuss the CALM (GPT-2) models, and begin with the portion of the ClubFloyd data that they are trained on. We begin with a 12-layer, 768-hidden, 12-head, 117M parameter pretrained OpenAI GPT-2 model.

We note that the number of samples we train on, even in the CALM (GPT-2) model + Jericho games variant, is less than the total samples in the dataset. This is because we do not train on incomplete batches of data, and we omit samples that exceed 256 tokens.

CALM (GPT-2) To train CALM (GPT-2), we take transcripts from ClubFloyd (excluding Jericho games) and order the samples based on the transcript number they came from. This yields a dataset of 193,588 samples. We select the first 90% of the samples as train data, and the last 10% of the samples as validation data.

CALM (GPT-2) 50%, 20%, (+) Jericho To train the 50% and 20% variants, we select without replacement 212 transcripts (94,609 samples), and 85 transcripts (38,334 samples) respectively from the ClubFloyd transcripts (excluding Jericho games). We order the samples based on the transcript they come from, choose the first 90% of the data as our training data and last 10% as validation data.

For the CALM (GPT-2) variant including Jericho games, we include every ClubFloyd transcript, we randomly order the transcripts, order the samples based on the order of the transcripts, and then we select the first 90% of the data as our training data, and the last 10% of the data as validation data. This split contains 206,286 samples.

CALM (GPT-2) Random Initialization For the CALM (GPT-2) variant with random initialization, we begin with a GPT-2 model that has not been pretrained. We only use the transcripts in ClubFloyd that do not correspond to any Jericho game we test on. We randomly order the transcripts, and order the samples based on the order of the transcripts. We select the first 90% of the data as our training data, and the last 10% of the data as validation data.

Parameter Optimization In order to train GPT-2, we minimize the cross-entropy between GPT-2's distribution over actions and the action taken in the ClubFloyd example. We use Adam to optimize the weights of our model with learning rate = 2e-5 and Adam epsilon = 1e-8. For the learning rate we use a linear schedule with warmup. Finally, we clip gradients allowing a max gradient norm of 1.

We include the loss on the train and validation set, as well as the accuracy (defined as the percentage of examples on which the action assigned the

Table 4: Training Metrics for CALM Variants

highest probability by GPT-2 was the ClubFloyd action) in Table 4.

B.2 CALM (n-gram)

In order to train the CALM n-gram model, we consider the set of transcripts in ClubFloyd (excluding Jericho games). Next, we take the set of actions that appear in these transcripts, and train an n-gram model with Laplace α smoothing to model these sequences (Jurafsky and Martin, 2009). We order actions by the transcript they appear in and take the first 70% of the actions as train data and leave the remaining 30% as validation data. For each n, we choose alpha that minimizes perplexity per word on the validation data. We also tried a linear interpolation of these estimates (Jurafsky and Martin, 2009) although we did not observe an improvement over our bigram model. In this model, we estimate $p(a^i|a^{i-3}, a^{i-2}, a^{i-1}) = w_1 p^*(a^i|a^{i-3}, a^{i-2}, a^{i-1}) + w_2 p^*(a^i|a^{i-2}, a^{i-1}) + w_3 p^*(a^i|a^{i-1}) + w_4 p^*(a^i)$ where $\sum_i w_i = 1$, and p^* indicates our m-gram estimate for $p(a^i|a^{i-m+1}, ..., a^{i-1})$.

C Walkthrough Evaluation

In Figure 10, we provide a piece of walkthrough trajectory of Zork1, with GPT-2 and n-gram generated actions at each state. Note that n-gram actions are mostly limited to be no more than two tokens, while GPT-2 can generate more complex actions like "put sword in case".

In Figure 9, we provide game-specific metric curves for Zork1 and Detective. On harder games like Zork1, there is significant gap between GPT-2 and n-gram, while easy games like Detective the gap is very small.

D Gameplay Evaluation

On Zork1, we provide learning curves for CALM (GPT-2) (Figure 11) and CALM (n-gram) (Figure 12). We also provide trail curves for CALM (GPT-2) on Zork3 (Figure 14), a game we are behind NAIL, and trails using different top-$k \in \{10, 20, 30, 40\}$ actions by CALM (GPT-2) on Zork1 (Figure 13).

We provide per-game results for model variants in Table 5. It is interesting that CALM (w/ Jericho) is significantly better than CALM (GPT-2) on the games of Temple and Deephome (non-trivial scores achieved), which are not the games with ClubFloyd scripts added. On the other hand, games like 905 and moonlit have scripts added, but do not get improved.

In the end, we append one example trajectory piece of DRRN + CALM (GPT-2) on Zork1 (Figure 15), where CALM generated action candidates and their Q-values are shown along with observations, actions and scores.

Abstract

The traditional image captioning task uses generic reference captions to provide textual information about images. Different user populations, however, will care about different visual aspects of images. In this paper, we propose a new task, **Captioning with A Purpose** (CAPWAP). Our goal is to develop systems that can be *tailored* to be useful for the information needs of an intended population, rather than merely provide generic information about an image. In this task, we use question-answer (QA) pairs—a natural expression of information need—from users, instead of reference captions, for both training and post-inference evaluation. We show that it is possible to use reinforcement learning to directly optimize for the intended information need, by rewarding outputs that allow a question answering model to provide correct answers to sampled user questions. We convert several visual question answering datasets into CAPWAP datasets, and demonstrate that under a variety of scenarios our purposeful captioning system learns to anticipate and fulfill specific information needs better than its generic counterparts, as measured by QA performance on user questions from unseen images, when using the caption alone as context.

1 Introduction

The image captioning task typically selects for captions having high similarity with generic human references. While this task definition has driven much of the research in the field, the end-purpose of these captions is not always clearly articulated. We argue that (1) generic annotations may not be representative of users' information needs, (2) user questions are a more natural way of articulating information needs, and (3) optimizing captions to provide correct answers to those questions allows training to focus on information need. For example, in the VizWiz mobile application (Bigham et al., 2010), visually impaired users upload images from their everyday lives, along with questions about them that need to be answered. These questions serve as a powerful signal for aspects of the image that they find important.

Task	**Caption**	**Information Need**
Captioning	There is a green bus.	*(Unspecified)*
Visual QA	*(Unspecified)*	Where's it headed?
CAPWAP	At least three people are boarding the #14 bus to Bembridge.	Which bus is this? Where's it headed? How many people are boarding?

Figure 1: The informational purpose of generic captioning is not clearly defined, and VQA provides only reactionary information. The objective of the CAPWAP task is ultimately to provide more informative captions that specifically *anticipate* and *satisfy* users' potential needs. In CAPWAP, we use QA as an *implicit* signal for information need: e.g., in the image above, a good caption that has been generated in advance should be able to be used to answer, *Where is this bus headed?*

Consider the image in Figure 1, where an annotator might provide a generic caption such as *There is a green bus.* This may be used to answer: *What color is the bus?* However, it would provide no utility to a user asking: *Where is this bus headed?* In fact, examples from VizWiz demonstrate a clear disconnect between the type of information provided by

Task	Training Data	Prediction Function	Evaluation
Captioning	{🖼, ref.caption}	{🖼} → pred.caption	Similarity(pred.caption, ref.caption)
Visual QA	{🖼, ref.question, ref.answer}	{🖼, ref.question} → pred.answer	Accuracy(pred.answer, ref.answer)
CapWAP	{🖼, ref.question, ref.answer}	{🖼} → pred.caption	Accuracy(QA(ref.question, pred.caption), ref.answer)

Table 1: The CapWAP task combines elements of generic image captioning with visual question answering. Training consists of images paired with visual questions and answers. A CapWAP model should directly *anticipate* user information needs by outputting *captions* that can be used to answer *future* questions drawn from a distribution similar to the training data. Accordingly, the "QA" function represents the inference of an answer to a question using the generated caption as context. We approximate this with a strong automatic question answering model.

today's systems (e.g., arbitrary descriptions of entities and actions) versus what visually-impaired users need to know (e.g., fine-grained details to help make decisions).

Here, we propose an alternative framing for captioning: Captioning with A Purpose (CapWAP). We do not assume the existence of a *universal* caption distribution. A good caption is highly subjective; different users will care about different aspects of a given image. Instead, we assume a distribution of visual question-answer pairs that are representative of population's information needs. Here we aim to map images to text that can serve as context to answer likely questions under this distribution. At test time, the goal is to anticipate similar user questions for a new image, and implicitly answer them *before* they even need to be asked.

We use image-question-answer triplets as supervision, and require the model to generate from the latent space of captions that provide contextual support for the answer (Table 1). Within our task definition, any sampled caption that can be used to answer these questions is considered useful. Under this formulation, very different captions may be scored identically if they deliver the same content—regardless of word choice. Note that this is different from either standard visual question answering (VQA) or query-focused summarization: the target questions are not available prior to generation; at test time, they are used *only* for evaluation.

Existing approaches cannot be readily applied in this setting, as there are no gold reference captions for training—and off-the-shelf captioning systems transfer quite poorly (§6). To address the new learning challenge that arises in CapWAP, we propose a novel model-in-the-loop reinforcement learning (RL) approach that acts as a strong baseline for this task. Our approach assumes a fixed question answering (QA) system that predicts an answer to a question using some input context. The captioning model receives a reward if it generates text which the QA system can use to predict the correct answer. Applying RL, however, is nontrivial. A naïve exploration of the caption generation space can lead to sparse rewards—resulting in long training times and disappointing quality. We show that our approach can be significantly improved by using a novel, synthetic pre-training routine to push the initial policy towards areas of high-reward.

We repurpose four VQA datasets for CapWAP: VQA (Goyal et al., 2017), GQA (Hudson and Manning, 2019), Visual7W (Zhu et al., 2016), and VizWiz (Gurari et al., 2018). These datasets range in style from synthetic QA pairs (GQA) to natural information-seeking questions asked by visually-impaired users (VizWiz). We find that our method produces significantly more informative captions with respect to the given questions (up to 3.8× exact match), compared to models trained on generic captions from COCO (Lin et al., 2014).

Our key contributions are as follows:

1. We define a new task (CapWAP) that generates image captions for the *purpose* of fulfilling specific information needs expressed by different target user populations.
2. We demonstrate that our information-need-driven model can generate much higher quality captions on this task than those of state-of-the-art traditional *generic* captioning systems.
3. We propose a novel synthetic pre-training routine that greatly improves the performance of reinforcement learning under this new paradigm.

2 Related Work

Since the early days of the field, human-written references have been used for the supervised training and evaluation of text generation systems, including image captioning, summarization, and other related applications (Edmundson, 1969; Lin and Hovy, 2003; Ordonez et al., 2011; Vinyals et al., 2015). Recently, researchers have begun to consider a multitude of different objectives for reference comparison (Böhm et al., 2019; Gao et al., 2019), or even parametric regressions trained on human judgements (Louis and Nenkova, 2013; Peyrard and Gurevych, 2018). Though diverse in approach, each ultimately relies on designing a robust general-purpose metric. In practice, engineering such a metric is challenging—if at all possible (Spärck Jones, 1994, 1999). Here we take a more empirical approach by relying on the information need expressed by users' questions.

Many studies have observed that reference-trained captioning models suffer from systematic usability issues—including being rigid, neglecting relevant image aspects, and regurgitating frequent phrases (Wang et al., 2017; Dai et al., 2017). As a result, much effort has been focused on developing secondary, corrective objectives—for instance, "discriminability" losses encouraging captions to be unique (Dai and Lin, 2017; Liu et al., 2018; Luo et al., 2018). While these measures provide some fixes, they do not necessarily reflect user information needs—a central concept in CAPWAP.

The idea of using QA for assessing information quality has been proposed in recent work for text summarization (Arumae and Liu, 2019; Eyal et al., 2019; Scialom et al., 2019). The primary distinctions with our work are both the domain (images) and how questions are obtained—both of which impact the task objective and learning procedure. In this prior work, questions are generated programmatically (e.g., following Hermann et al., 2015). Such "questions" may not necessarily reflect real user preferences. Our work focuses on QA not as just another method to improve standard reference-based metrics, but as a key, flexible way of formulating user information need—and as such we focus on challenging, *real* QA datasets. Furthermore, we train on this signal, rather than rely on it solely for evaluation (Wang et al., 2020).

Efforts to leverage VQA resources to drive image captioning, and vice-versa, via variations of transfer learning, have also received extensive interest in recent years (Li et al., 2018; Wu et al., 2019; Yang and Xu, 2019). As opposed to optimizing metrics for specific VQA or supervised captioning benchmarks, the primary focus in CAPWAP is on modeling the target user population in order to anticipate the correct information-need.

In a similar vein, VQA and textual QA resources have also been leveraged for active learning (Shen et al., 2019; Li et al., 2017), where the model learns to query its environment for information *it* is uncertain about to help improve its performance on the given task. The key distinction with our work is the *directionality* of the questions. In CAPWAP, the model uses questions posed by the users to infer *their* latent information need—which is a distinctly different, and quite challenging, setting.

3 Problem Formulation

We begin by formulating the CAPWAP task. In our setting, questions and answers are the only source of direct supervision assumed during training. At test time, the model is not given questions in advance, but rather must *anticipate* the information need of the user, and generate captions that answer the forthcoming questions in expectation.

Task Setting: Given an image $\mathbf{x}$ the model must output a caption $\mathbf{y}$, such that $\mathbf{y}$ entails the answer $\mathbf{a}$ for a question-answer pair $(\mathbf{q}, \mathbf{a})$ sampled from some underlying distribution $\mathcal{D}$. Examples from $\mathcal{D}$ are given during training, but are not known in advance by the generation model at test time.

Information Need: We assume that the QA data from $\mathcal{D}$ is derived by the following process:

1. an image $\mathbf{x}$ is drawn from distribution $p(\mathbf{x})$;
2. a question-answer pair $(\mathbf{q}, \mathbf{a})$ targeting an informative detail of $\mathbf{x}$ perceived as important to a user in $\mathcal{D}$ is drawn from distribution $p(\mathbf{q}, \mathbf{a}|\mathbf{x})$.

The operating assumption is that the marginal distribution over $(\mathbf{q}, \mathbf{a})$ pairs represents the visual interests of the *typical* user. In other words, answers to common questions represent the type of information that is often considered important. This is comparable to *content selection* (Peyrard, 2019).

Question Anticipation: We do not assume the existence of a "gold" caption. Rather, the caption $\mathbf{y}$ is assumed to be a latent variable, and $G_\theta(\mathbf{y}|\mathbf{x})$ is a

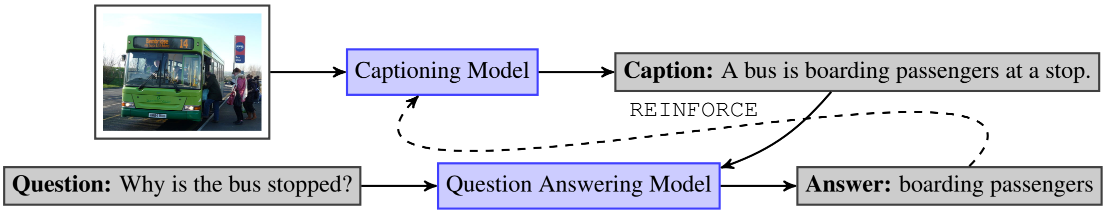

Figure 2: Overview of our proposed approach to the CAPWAP task. The captioning model $G_\theta(\mathbf{y}|\mathbf{x})$ is learned using supervision from question-answer-image triples. Generated text that can be used to answer the question correctly, according to an extractive question answering model, is rewarded in our model-in-the-loop reinforcement learning framework. The questions, answers, and the question answering system are discarded after training.

stochastic generator that we must learn. A sample $\mathbf{y} \sim G_\theta(\mathbf{y}|\mathbf{x})$ should provide *contextual support* for a new, randomly sampled question-answer pair. We estimate this using the accuracy of a pre-trained QA model $\mathcal{M}(\mathbf{q}, \mathbf{y})$, when using $\mathbf{y}$ as context for $\mathbf{q}$. CAPWAP requires maximizing the expectation:

$$\operatorname*{argmax}_{\theta} \mathbb{E}_{G_\theta(\mathbf{y}|\mathbf{x})}\left[\mathbb{E}_{p(\mathbf{q},\mathbf{a}|\mathbf{x})}\left[\mathcal{R}(\mathbf{y}, \mathbf{q}, \mathbf{a})\right]\right] \quad (1)$$

where θ parameterizes $G_\theta(\mathbf{y}|\mathbf{x})$, and we choose our reward to be $\mathcal{R}(\mathbf{y}, \mathbf{q}, \mathbf{a})$, any appropriate accuracy metric for comparing the output of $\mathcal{M}(\mathbf{q}, \mathbf{y})$ with $\mathbf{a}$ (expressed as ACCURACY in Table 1).

CAPWAP vs. Other Tasks: Table 1 compares our setting to those of both standard (generic) captioning and visual question answering. Both standard captioning and CAPWAP models output a single caption per image, but CAPWAP does not compare to references. Both VQA and CAPWAP models are trained and evaluated with QA data, but CAPWAP does not provide the question prior to generation. VQA models output *single answers*, whereas CAPWAP models output anticipatory *contexts*.

4 An Approach to CAPWAP

Given that we only have access to question-answer pairs during training, but not during inference, how can we learn a model for this task? Eq. 1 naturally lends itself to a reinforcement learning (RL) framework where the model receives a reward $\mathbf{r}$ (e.g., $\mathbf{r} = \mathcal{R}(\mathbf{y}, \mathbf{q}, \mathbf{a})$) for each generated caption $\mathbf{y}$ and training QA pair $(\mathbf{q}, \mathbf{a})$. $G_\theta(\mathbf{y}|\mathbf{x})$ can be cast as a policy, and updated with policy gradients.

Optimizing such a policy, however, poses a technical challenge because the model is only rewarded for correct (or partially correct) answers, which is initially a rare event. Transferring $G_\theta(\mathbf{y}|\mathbf{x})$ from *generic* captioning data can be a useful starting point. Our method then follows this recipe:

1. Initialize $G_\theta(\mathbf{y}|\mathbf{x})$ using fully-supervised off-the-shelf captioning data, $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}}) \sim \mathcal{D}_{\text{generic}}$;
2. Fine-tune $G_\theta(\mathbf{y}|\mathbf{x})$ using policy gradient on targeted visual QA data, $(\mathbf{x}, \mathbf{q}, \mathbf{a}) \sim \mathcal{D}_{\text{target}}$.

In Sections 4.1 and 4.2 we detail our model for $G_\theta(\mathbf{y}|\mathbf{x})$, and the above training procedure.

Note that $\mathcal{D}_{\text{generic}}$ is assumed to be *out-of-domain* for our intended captioning purpose, $\mathcal{D}_{\text{target}}$. Since we are interested in diverse user-generated questions and information needs, the generic captioning data can often diverge dramatically from our end goal. To improve transfer, in Section 4.3 we further develop a novel mechanism for automatically generating in-domain synthetic data that can be used as pre-training for guiding $G_\theta(\mathbf{y}|\mathbf{x})$ towards balanced areas of high reward in $\mathcal{D}_{\text{target}}$.

4.1 Model Architecture

We briefly describe our base captioning model, which consists of a Faster R-CNN and Transformer-based encoder-decoder, following the sequence-to-sequence framework common in state-of-the-art image captioning systems (Anderson et al., 2018; Vinyals et al., 2015; Zhou et al., 2019). See Appendix A for full technical details. Given an image $\mathbf{x}$, we first represent it as a sequence of detected object bounding box embeddings, computed from a pre-trained Faster R-CNN model (Anderson et al., 2018). We then generate caption word-pieces $\mathbf{y} = (y_1, \ldots, y_n)$ using a Transformer-based architecture (Vaswani et al., 2017).

4.2 Policy Training

We describe our RL framework for training our captioning model using QA data. See Appendix B for additional technical details, including hyper-parameter settings and optimization choices.

Initialization: We initialize $G_\theta(\mathbf{y}|\mathbf{x})$ using maximum likelihood estimation (MLE) on a corpus of out-of-domain generic captions $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$, as common practice (Ranzato et al., 2016). This warm-starts our policy with an initial set of grounded image concepts, albeit not necessarily the ones we ultimately care about. Given the generic reference $\tilde{\mathbf{y}} = (\tilde{y}_1, \ldots, \tilde{y}_n)$, we minimize the cross-entropy:

$$\mathcal{L}_{XE}(\theta) = -\sum_{i=1}^{n} \log G_\theta(\tilde{y}_i \mid \tilde{\mathbf{x}}, \tilde{y}_{j<i}) \quad (2)$$

QA Model: We implement the QA model $\mathcal{M}$ using a BERT$_{\text{LARGE}}$ extractive model fine-tuned on SQuAD 2.0 (Rajpurkar et al., 2018)—which contains unanswerable questions. As an extractive model, $\mathcal{M}$ predicts a span $\mathbf{y}_{i\ldots j}$. Important for our use-case, $\mathcal{M}$ is both able to be accurate when predicting the answer $\mathbf{a}$ when $\mathbf{a}$ *is* present in $\mathbf{y}$, and also able to abstain from answering when $\mathbf{a}$ is *not* logically entailed (i.e., predict "no answer").

QA Reward: We take $\mathcal{R}(\mathbf{y}, \mathbf{q}, \mathbf{a})$ from Eq. 1 as the F1 score of the predicted answer with the gold answer. We control for reward noise with a confidence threshold for predicting "no answer."

Policy Gradient: We use `REINFORCE` with a baseline (Williams, 1992) to compute the policy gradient $\nabla_\theta \mathcal{L}_{QA}(\theta)$ of the QA reward:

$$-\mathbb{E}_{G_\theta(\mathbf{y}|\mathbf{x})}\left[(\mathcal{R}(\mathbf{y}, \mathbf{q}, \mathbf{a}) - b)\nabla_\theta \log G_\theta(\mathbf{y}|\mathbf{x})\right] \quad (3)$$

We take b as $\mathcal{R}(\hat{\mathbf{y}}, \mathbf{q}, \mathbf{a})$, where $\hat{\mathbf{y}}$ is the argmax (test-time prediction) of G_θ, following the self-critical method of Rennie et al. (2017).

4.3 Synthetic Policy Pre-Training

In the beginning of training, the generated captions typically do not correctly answer many questions, leading to almost no reward signal. More formally, the reward is sparse if the policy $G_\theta(\mathbf{y}|\mathbf{x})$ is not well-initialized. As a result, `REINFORCE` becomes extremely sample-inefficient. When the target distribution is strikingly divergent from the one present in the generic captioning data—a key setting in this work—supervised pre-training on the out-of-domain data does not yield a usable initialization. As a substitute, we derive a method for generating a synthetic dataset of captions $\mathcal{D}_{\text{synthetic}}$ with high-reward as a form of guided policy search (Levine and Koltun, 2013). The full method then consists of three stages that train on the three datasets: $\mathcal{D}_{\text{generic}} \rightarrow \mathcal{D}_{\text{synthetic}} \rightarrow \mathcal{D}_{\text{target}}$.

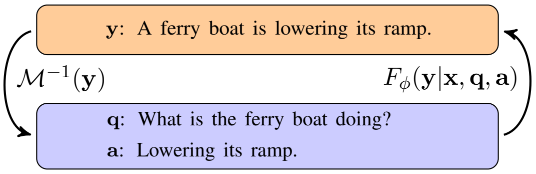

Figure 3: A demonstration of reverse engineering the connections between question generation ($\mathcal{M}^{-1}$) and context generation (F_ϕ). $\mathbf{x}$ is the image (not shown). See Algorithm 1 in Appendix C for full details.

For the extractive QA model to possibly yield a positive reward, the answer must be a span of the caption. When the question and answer are known in advance, it is typically fairly simple to reverse engineer a candidate caption that meets this constraint (e.g., by inverting *wh*-movement). Figure 3 demonstrates this concept. If we have an auxiliary model $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ that can automate this reverse engineering step, we can synthetically generate captions to use for pre-training, as in Eq. 2.[1]

QA Conditional Model: Motivated by this, we learn $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ by explicitly conditioning on QA pairs when generating a caption that supports the answer span by design. Concretely, we include the word-pieces of the question $\mathbf{q} = (q_1, \ldots, q_l)$ and answer $\mathbf{a} = (a_1, \ldots, a_m)$ as inputs when decoding $\mathbf{y}$, while $\mathbf{y}$ satisfies $\mathcal{M}(\mathbf{y}, \mathbf{q}) = \mathbf{a}$.

How do we train $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ effectively without access to any paired data $(\mathbf{x}, \mathbf{q}, \mathbf{a}, \mathbf{y})$? We create automatic $(\tilde{\mathbf{x}}, \hat{\mathbf{q}}, \hat{\mathbf{a}}, \tilde{\mathbf{y}})$ examples from the out-of-domain generic captioning data used in Section 4.2 by using the (text-based) question generation model $\mathcal{M}^{-1}$ of Alberti et al. (2019). At a high level, given a generic caption $\tilde{\mathbf{y}} = (\tilde{y}_1, \ldots, \tilde{y}_n)$, this inverse model (1) picks an answer span $\hat{\mathbf{a}} \subseteq \tilde{\mathbf{y}}$, (2) generates a question $\hat{\mathbf{q}}$ following some inferred distribution $p(\mathbf{q}|\hat{\mathbf{a}}, \tilde{\mathbf{y}})$, and (3) confirms that the sample obeys "round-trip filtering", i.e., that the original QA model answers the synthetic example correctly ($\mathcal{M}(\hat{\mathbf{q}}, \tilde{\mathbf{y}}) = \hat{\mathbf{a}}$). We then train the model for F_ϕ using conditional cross-entropy:

$$\mathcal{L}_{CXE}(\phi) = -\sum_{i=1}^{n} \log F_\phi(\tilde{y}_i \mid \tilde{\mathbf{x}}, \hat{\mathbf{q}}, \hat{\mathbf{a}}, \tilde{y}_{j<i}) \quad (4)$$

Synthetic Data Generation: After training, we transfer $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ with fixed weights to generate reverse engineered captions $\hat{\mathbf{y}}$ using the

---

[1] Methods for constrained decoding (Anderson et al., 2016; Hokamp and Liu, 2017, *inter alia*) that enforce $\mathbf{a} \subseteq \mathbf{y}$ are related, yet complementary, and can be incorporated into any F_ϕ. It is more important to ensure that not only is the answer contained in the caption, but also that it is logically supported.

true $(\mathbf{x}, \mathbf{q}, \mathbf{a}, \texttt{null})$ examples from our target QA datasets. For each example, we decode the top-k captions using beam search, and keep those with $R(\hat{\mathbf{y}}, \mathbf{q}, \mathbf{a}) \geq c$, where c is a threshold (e.g., $c = 1.0$ for an exact match F1 score). These examples paired with the high-scoring captions are used to create the synthetic captions dataset $\mathcal{D}_{\text{synthetic}}$. We then use $\mathcal{D}_{\text{synthetic}}$ as further weak supervision for initializing $G_\theta(\mathbf{y}|\mathbf{x})$, again following Eq. 2. See Appendix C for additional technical details.

5 Experimental Setup

Evaluation: Our primary evaluation assumes a dataset of questions and answers about images. Conceptually, if the correct answers are supported by the generated caption in expectation, then we consider it to be sufficiently informative.[2]

Automatic Evaluation: Our automatic proxy of informativeness utilizes the state-of-the-art extractive question answering model ($\mathcal{M}$) described in Section 4.2 that is trained on SQuAD 2.0.[3] $\mathcal{M}$ is applied to the given QA pair, with the generated caption as the "context." We report EM, measuring exact match with the gold answer, and F1, measuring word overlap. If there are multiple answers, then we take the maximum score over all.

Human Evaluation: For human evaluation we ask raters to judge whether a caption is less, equally, or more informative than another caption with respect to the question-answer pair. We also gather human ratings for two properties that are desirable regardless of the target audience: (1) fluency (whether the caption is grammatical and coherent) and (2) fidelity (whether the caption makes any false assertions regarding what is in the image).

5.1 Datasets

We evaluate our method on four converted visual question answering datasets. We filter questions that are unaswerable, or have 'yes/no' or non-alphabetic answers.[4] Appendix D gives additional size, splitting, and pre-processing details.

COCO (Lin et al., 2014): For all experiments, we use COCO as the source of out-of-domain generic captions for pre-training. COCO contains images covering 80 object categories and various scenes gathered from Flickr, paired with five human-written reference captions.

CapVQA (Goyal et al., 2017): VQA v2.0 originally contains questions written by crowd-workers where the prompt was to write queries that are easy for humans to answer, but challenging for a hypothetical robot that mainly knows only about objects. VQA is the only dataset we consider that fully covers the same images as COCO.

CapGQA (Hudson and Manning, 2019): GQA contains challenging compositional questions derived from scene graphs of everyday images using various human-specified grammars.

CapVisual7W (Zhu et al., 2016): Visual7W contains questions written by crowd-workers about objects that, in general, require richer and longer answers than those in VQA. We use only the "telling" split of the dataset (i.e., the questions that require open-ended natural language answers).

CapVizWiz (Gurari et al., 2018): VizWiz consists of natural visual questions asked by visually-impaired users of a mobile application who were seeking answers to their daily visual needs. Each question is answered by a remote assistant.

5.2 Generic Captioning Models

In addition to our baseline captioning model trained only to maximize the likelihood of COCO references (MLE in the tables), we compare to two state-of-the-art *generic* image captioning methods (also trained on COCO data). Huang et al. (2019) directly optimizes the CIDEr metric with policy gradients, while Luo et al. (2018) optimizes both CIDEr and a "discrimination" loss intended to encourage models to describe each image's uniquely identifying aspects. These models are included in order to highlight the differences in applicability between off-the-shelf models trained for generic image captioning versus those for CAPWAP.

6 Results

In the following, we address several key research questions relating to our approach to CAPWAP, and the broader assumptions, strengths, and limitations of using QA to drive the process.

---

[2] Note that traditional captioning metrics such as ROUGE, BLEU, and CIDEr rely on gold references, which are not available in our new setting (in fact, by our definition, there is no one "gold" caption). Thus, we cannot include them.

[3] For evaluation we turn off the "no answer" option.

[4] Numerical answers that are written out (e.g., *two* vs. *2*) are not disqualified. This requirement simplifies evaluation.

Model	**CapVQA**		**CapGQA**		**CapVisual7W**		**CapVizWiz**	
	EM	F1	EM	F1	EM	F1	EM	F1
Human reference (from COCO)	16.5	25.7	-	-	-	-	-	-
Luo et al. (2018)	12.0	20.1	9.6	13.9	6.5	11.8	4.7	11.8
Huang et al. (2019)	16.0	25.0	9.9	14.9	6.9	14.0	6.0	13.4
Our generic baseline: MLE	16.8	25.2	8.0	11.1	6.9	13.2	4.9	12.6
Our CapWAP model: RL	23.1	32.3	15.7	19.3	**10.5**	**18.4**	**22.5**	**28.5**
Our CapWAP model: RL + SYN	**24.2**	**33.2**	**16.6**	**19.8**	9.2	15.4	19.5	27.8

Table 2: *Does the proposed approach better fulfill information needs?* We show question answering test performance when applying an extractive question answering model on predicted captions (see Table 1). Existing captioning models trained on generic references (rows 2-4)—or even the generic references themselves (row 1)—do not capture the information requested by different QA datasets. Applying our RL method for tailoring towards CapWAP (row 5) leads to more informative captions with respect to those questions (and by extension, for the assumed end-users). Adding synthetic pre-training data (+ SYN) improves results on several datasets (row 6).

A = Purposeful (RL + SYN) vs. **B** = Generic

Dataset	**Informativeness**	
	$A > B$	$B > A$
CapVQA	**27%**	20%
CapGQA	**31%**	20%
CapVisual7W	**38%**	22%
CapVizWiz	**37%**	20%

Table 3: *Do raters think that the proposed approach provides more informative captions?* Human evaluation of the informativeness of captions with respect to our QA datasets agrees with our automatic evaluation—finding our model to have better information coverage than MLE, our baseline without QA rewards.

Train	**Evaluation**			
	CapVQA	CapGQA	CapV7W	CapVizWiz
CapVQA	33.8	14.3	15.6	16.4
CapGQA	24.8	20.2	12.6	13.5
CapV7W	26.0	11.4	15.2	14.0
CapVizWiz	23.9	12.0	12.2	31.3
Generic	25.5	11.7	12.8	14.1

Table 4: *Does the proposed approach tailor to specific information need?* We show transfer performance (dev F1) of the RL + SYN policies learned on different QA datasets. The in-domain F1 peaks indicate that the model is producing distribution-specific captions.

Evaluation of Generic Captions: We begin by empirically verifying our introductory claim that training on generic reference captions can poorly reflect the varying, user-specific information need. Table 2 presents the results of the baseline generic captioning systems when evaluated in terms of how well the predicted captions support QA over different distributions. Though they are strong methods as measured on the COCO benchmark, unsurprisingly, they still fail to capture all the information necessary to answer diverse visual questions. Performance on CapVizWiz is exceptionally poor; the visually-impaired users ask for information strikingly different than what is represented in COCO. The causes of this poor performance go beyond simple limitations in the current state-of-the-art models; the target references themselves are insufficient. For example, on CapVQA, where the images overlap with COCO and thus human captions are directly available, the average performance of these "gold" references is only slightly better—supporting our conjecture that good captions for one purpose are not necessarily good for another, even on the same images.

Adaptation to Information Need: We next test the effectiveness of our proposed approach at tailoring captions to meet the specific information need stipulated by our datasets. Our results in Table 2 demonstrate significant improvements by our QA-driven models (RL and RL + SYN) across all four datasets—achieving an average gain of 8.0 absolute F1. Notably, we improve by 7.5 EM over the average human caption on CapVQA, and by 16.5 EM over the best generic model on CapVizWiz. Table 4 further illustrates that the adaptation process is indeed tailored to the respective QA datasets. The improvements on our automatic QA-based metrics (using the proxy model $\mathcal{M}$) also translate to human judgements. Table 3 presents the results of our human A/B test of our proposed model vs. the MLE baseline. Relative to MLE, we find that our method is significantly more informative with respect to unseen QA pairs across all datasets. As expected, the largest improvements are on the datasets whose questions deviate significantly from the generic COCO content (e.g., CapVizWiz).

Dataset	**Input Image**	**Generic Caption Output**	**Purposeful Caption (RL + SYN) Output**	**Unseen Question**	**Unseen Answer**
CapVQA		a man playing tennis	a man in white shirt and white shorts playing a game of tennis on a grass court	what color is he wearing?	white shirt and shorts
CapGQA		a man riding on the back of a horse	a man riding a horse next to a woman on the right side	what color is the horse the man is to the right of?	brown
CapVisual7W		a couple of people that are standing in the snow	two people posing for a picture taken at a ski slope	why are the kids wearing coats ?	it is cold
CapVizWiz		a plate of food that is on a table	this is a picture of a sweet corn frozen dinner	what kind of tv dinner is this?	lean cuisine

Figure 4: Example outputs[5] comparing our model trained for CAPWAP (RL + SYN) with the baseline model trained on generic COCO references (MLE). These examples are representative of the way in which the various datasets ask about image content. Tendencies include colors for CapVQA, spatial relations for CapGQA, higher-level concepts in CapVisual7W, and OCR in CapVizWiz. Note that our approach to CAPWAP does not (and likely cannot ever perfectly) anticipate *all* unseen questions—but is distributionally closer in terms of content selection.

A = RL + SYN vs. **B** = RL				
Dataset	**Fluency**		**Fidelity**	
	$A > B$	$B > A$	$A > B$	$B > A$
CapVQA	**57%**	26%	**55%**	29%
CapGQA	**84%**	6%	**76%**	11%
CapVisual7W	**69%**	19%	**66%**	22%
CapVizWiz	**38%**	37%	24%	**47%**

Table 5: *Does synthetic data improve secondary measures of caption quality?* Raters find that this strategy dramatically improves fluency and fidelity (§5) when compared to a model with only on-policy sampling.

A = Purposeful (RL + SYN) vs. **B** = Generic		
Dataset	**Fluency** $A \geq B$	**Fidelity** $A \geq B$
CapVQA	37%	33%
CapGQA	30%	**57%**
CapVisual7W	37%	**53%**
CapVizWiz	34%	**72%**

Table 6: *Do more informative captions come at a cost?* Raters find that our tailored "purposeful" approach is less fluent more than half the time (left). Still, this system has greater or equal fidelity to the image content on most datasets (right). At a high level, while the system does give more *relevant* information, it may do so in a less fluent way, a direction we leave for future work.

Importance of Synthetic Pre-training: A deficiency of QA-based rewards is that they neither explicitly enforce text fluency, nor penalize the system when content is produced that is either *not* relevant or *not* true. On the other hand, when reference captions are available, it is easy to learn a fluent language model. Table 5 shows that incorporating synthetic, guiding "silver" samples from our auxiliary QA conditional model $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ (§4.3) to bridge the gap between $\mathcal{D}_{\text{generic}}$ and each considered $\mathcal{D}_{\text{target}}$ dramatically reduces the fluency and fidelity issues that arise from training solely with QA rewards. Ultimately, however, Table 6 shows that our model still suffers on these secondary metrics as compared to the reference-trained MLE baseline. This is a challenge that is shared with nearly all other comparable RL-based methods for text generation (e.g., Guo et al., 2018; Paulus et al., 2018, *et cetera*). Incorporating complementary fluency rewards (e.g., via pre-trained language model perplexity) is a valuable direction for future work.

Qualitative Discussion: The qualitative effect of our method is quite intuitive (see Figure 4 as well as Table 7). For example, many questions in CapGQA ask about spatial relations, which is reflected in the generated captions. On the other hand, CapVizWiz users often ask about detailed information about meals, and the adapted model attempts to provide a more useful description beyond a "plate of food." Of the above datasets, note that only CapVizWiz consists of questions asked by genuinely interested users. Interestingly, this property unearths yet another challenge: CapVizWiz questions can be long-form and quite different from SQuAD, and reverse engineering them (using F_ϕ) for pre-training is noisier (as evidenced by the performance of +SYN

---

[5] Examples are chosen to highlight model differences.

Model	**Dataset**											
	CapVQA			CapGQA			CapVisual7W			CapVizWiz		
	$\|\mathbf{y}\|$	adj%	$\|V^2\|$	$\|\mathbf{y}\|$	adj%	$\|V^2\|$	$\|\mathbf{y}\|$	adj%	$\|V^2\|$	$\|\mathbf{y}\|$	adj%	$\|V^2\|$
Generic: MLE	10.8	6.9	3.6	11.1	7.7	2.5	10.7	6.5	3.1	10.7	9.1	1.3
CAPWAP: RL	16.2	15.8	4.8	15.6	17.5	2.0	20.1	15.5	3.9	5.0	12.2	1.4
CAPWAP: RL + SYN	13.9	11.1	4.8	13.8	8.7	2.0	13.6	7.6	4.4	9.6	7.0	2.6

Table 7: *How do the generated captions differ qualitatively?* We present a number of automatic qualitative measures of caption content calculated over the dev sets: average caption length ($|\mathbf{y}|$), adjective production rate (adj%), and the total vocabulary size of the unique unigrams and bigrams emitted ($|V^2|$). Captions are measured in tokens (PTB-style), adjectives are identified using NLTK (Loper and Bird, 2002), and vocabulary size is measured in thousands. Both CAPWAP methods tend to produce longer captions, presumably with more descriptions (higher number of adjectives). Notably, RL + SYN manages to maintain more "natural" adjective production rates and richer language usage (in terms of bigram usage) than RL only, supporting the human quality ratings in Table 5.

Model	**Reward**	**Dataset**											
		CapVQA			CapGQA			CapVisual7W			CapVizWiz		
		IN	EM	F1	IN	EM	F1	IN	EM	F1	IN	EM	F1
RL + SYN	answer supported	42.5	**24.7**	**33.8**	25.1	16.9	20.2	16.7	**9.1**	15.2	34.3	**22.0**	**31.3**
w/o "no answer"	answer most likely	40.8	23.3	32.3	29.6	**19.1**	**23.8**	16.3	8.9	15.1	33.8	20.8	30.9
w/o QA model	answer present	**46.4**	22.4	31.5	**40.2**	13.9	21.6	**17.4**	8.9	15.2	**39.0**	13.5	26.6
Generic MLE	None	32.9	17.1	25.5	17.0	8.4	11.7	14.2	6.7	12.8	18.5	5.9	14.1

Table 8: *What is the impact of using the QA model to provide rewards?* We present an ablation study across our different datasets when using the QA model with the "no answer" option or not, as well as a simple indicator reward, $\mathbf{1}\{\mathbf{a} \subseteq \mathbf{y}\}$, that simply measures if the answer string is present at all (without running the expensive QA model). Our results show that while the indicator reward increases the indicator metric (IN) the most, these are likely mostly spurious or disfluent generations. Using the QA model improves the F1 and EM scores across all datasets—and in all cases except one improves further when confidence is used.

in Table 5). While the artificial settings of the other datasets are not ideal, their diversity serves to demonstrate the flexibility of our approach.

Ablation Studies: Tables 7 and 8 show the effects of different design choices in our RL and RL + SYN models. A significant challenge for CAPWAP systems, as previously discussed and illustrated in Table 6, is learning information need while maintaining fluency. Table 7 shows how synthetic pre-training regularizes the model to stay closer to human-level production patterns. Similarly, Table 8 shows how using the QA model to provide rewards (as opposed to a simple keyword search) helps the model avoid spurious rewards.

Future Work: The CAPWAP paradigm introduces new challenges for learning effective systems, some of which our approach solves, and others which it still leaves open (e.g., maintaining fluency and fidelty). While some may be addressed by large-scale multi-modal models (Li et al., 2019; Tan and Bansal, 2019), it is still unclear whether they would fully cover the diversity of information that real users are interested in (e.g., OCR).

7 Conclusion

We defined and studied the CAPWAP task, where question-answer pairs provided by users are used as a source of supervision for learning their visual information needs. Our results indicate that measuring caption content by its ability to logically support the answers to typical QA pairs from a target audience is (1) not only feasible, but also (2) a good proxy for uncovering information need. We hope this work will motivate the image captioning field to learn to anticipate and provide for the information needs of specific user communities.

A Model Architecture Details

The captioning architecture we use is a standard Transformer sequence-to-sequence model. As the model is not the main focus, we did not do any extensive hyper-parameter tuning or ablations beyond ensuring that we had a reasonable baseline model on COCO (114 CIDEr on COCO captions).

Image Encoder: For each image $\mathbf{x}$, we take represent the region embeddings $\mathbf{o_i} \in \mathbb{R}^{2048}$ of the bounding boxes for the k most confident object detections. We use the pre-trained Faster R-CNN (Ren et al., 2015) model of Anderson et al. (2018).[6] We then map each region embedding to $\tilde{\mathbf{o}}_i \in \mathbb{R}^d$ using a single dense layer with a ReLU. Inspired by the positional token embeddings in the BERT model (Devlin et al., 2019), we then augment $\tilde{\mathbf{o}}_i$ with learned position (the rasterized coordinate of the bounding box center), segment (a constant "image" component identifier), and confidence (the detection rank of the object) embeddings to obtain the full object representation:

$$\hat{\mathbf{o}}_i = \tilde{\mathbf{o}}_i + \mathbf{p}_i + \mathbf{s}_i + \mathbf{c}_i.$$

Text Decoder: We decode the caption autoregressively—starting with the `[CLS]` token and terminating on `[SEP]`. At each time-step t we concatenate the image embeddings with special delimiters and the word-pieces decoded thus far, to obtain a joint context:

$$\mathbf{h} = \{\texttt{[IMG]}, \hat{\mathbf{o}}_1, \ldots, \hat{\mathbf{o}}_k, \texttt{[CLS]}, \mathbf{w}_1, \ldots, \mathbf{w}_t\},$$

where $\mathbf{w}_i \in \mathbb{R}^d$ is the word piece embedding (the sum of token, position, and segment embeddings). We then encode $\mathbf{h}$ using multi-layer Transformer, and compute the probability of generating w_{t+1} using a softmax over the 30,522 word-piece vocabulary (the BERT vocabulary). For efficiency, we encode whole sequences at a time with a left-to-right attention mask: image regions may attend to all other image regions, and tokens may attend to all previous tokens and image regions.

Hyperparameters: In our experiments we use the top 64 object regions and a 6-layer Transformer with 512 hidden input units, 8 attention heads, and 2,048 hidden units in the intermediate feed-forward layer. During inference we do beam search with a beam size of 3 and a length penalty α of 0.6 (Wu et al., 2016). We implemented our model in Tensorflow (Abadi et al., 2015).

B Model Training Details

QA Model Threshold: During inference, the QA model $\mathcal{M}(\mathbf{q}, \mathbf{y})$ computes the probability of the "no answer" option $p_{\mathcal{M}}(\texttt{NONE}|\mathbf{q}, \mathbf{y})$ and the probability of the most likely answer span $p_{\mathcal{M}}(\mathbf{y}_{i\ldots j}|\mathbf{q}, \mathbf{y})$. We adjust how precise this reward is by treating the log odds ratio c of the "no answer" vs. span options as a hyper-parameter when choosing the prediction $\hat{\mathbf{a}}$:

$$\log\left(\frac{p_{\mathcal{M}}(\mathbf{y}_{i\ldots j}|\mathbf{q}, \mathbf{y})}{p_{\mathcal{M}}(\texttt{NONE}|\mathbf{q}, \mathbf{y})}\right)\begin{cases} > c, & \hat{\mathbf{a}} = \mathbf{y}_{i\ldots j} \\ \leq c, & \hat{\mathbf{a}} = \texttt{NONE} \end{cases}$$

Depending on the value of c, we may only answer if we are confident the answer is supported—not just the most probable (e.g., based on answer-type)—to avoid potentially spurious rewards obtained by guessing or elimination. Table 8 shows an ablation over some choices of c.

Answer Normalization: For both training and evaluation, we normalize the gold and predicted answers by removing articles and punctuation when comparing them (see Rajpurkar et al., 2016).

Policy Gradient: We approximate the policy gradient (Eq. 3) using a single Monte-Carlo sample $\mathbf{y} = (y_1, \ldots, y_n)$ from $G_\theta(\mathbf{y}|\mathbf{x})$. We accelerate training by restricting samples to be from a set of high-probability candidates with non-zero reward (cf. Anderson et al., 2018; Narayan et al., 2018, *inter alia*). We decode using beam search and sample from the top-k beams ($k = 16$).

Training: For MLE pre-training on $\mathcal{D}_{\text{generic}}$ (Eq. 2), all examples are shuffled and divided into mini-batches of 256 examples each. For RL adaptation to $\mathcal{D}_{\text{target}}$ (Eq. 3), we use a mini-batch size of 128. To help regularize the fluency of the model, during RL training we continue to multi-task on the supervised generic captions, as in MIXER (Ranzato et al., 2016). For both settings, we train for a maximum of 120K steps and choose the best

---

Algorithm 1 Synthetic data generation procedure for policy pre-training.

Definitions: $\mathcal{D}_{\text{generic}}$ is assumed out-of-domain generic captioning data with input images $\tilde{\mathbf{x}}$ and supervised reference captions $\tilde{\mathbf{y}}$. $\mathcal{D}_{\text{target}}$ is the in-domain target QA data with input images $\mathbf{x}$, questions $\mathbf{q}$, and answers $\mathbf{a}$. $\mathcal{M}$ is the automatic QA model used in this paper for evaluation (Table 1). $\mathcal{M}^{-1}(\mathbf{y})$ is a pre-trained QA generation model, that takes in some context $\mathbf{y}$ and outputs a predicted QA pair $(\hat{\mathbf{q}}, \hat{\mathbf{a}})$.

```
function TRAIN($\mathcal{D}_{\text{generic}}$, $\mathcal{M}^{-1}$, $T$)
    $\phi \leftarrow$ random                                  ▷ Initialize parameters for $F_\phi$
    for $i = 1$ to $T$ do                                     ▷ Train for $T$ steps
        $\tilde{\mathbf{x}}, \tilde{\mathbf{y}} \sim \mathcal{D}_{\text{generic}}$      ▷ Sample a generic image/caption pair
        $\hat{\mathbf{q}}, \hat{\mathbf{a}} \leftarrow \mathcal{M}^{-1}(\mathbf{y})$   ▷ Generate a synthetic QA pair
        $\mathcal{L} \leftarrow -\log F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$   ▷ Compute loss when conditioning on the QA
        $\phi \leftarrow$ MINIMIZE($\mathcal{L}, \phi$)            ▷ Update the model parameters of $F_\phi$
    return $F_\phi$                                           ▷ Produce $F_\phi$, the synthetic data generator

function GENERATE($\mathcal{D}_{\text{target}}$, $\mathcal{M}$, $F\phi$)
    $\mathcal{D}_{\text{synthetic}} \leftarrow [\,]$               ▷ Initialize synthetic dataset
    for $(\mathbf{x}, \mathbf{q}, \mathbf{a}) \in \mathcal{D}_{\text{target}}$ do     ▷ Iterate target dataset
        $\tilde{\mathbf{y}} \leftarrow \text{argmax}\, F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$   ▷ Conditionally decode a caption for the QA pair
        if $\mathcal{M}(\mathbf{q}, \tilde{\mathbf{y}}) = \mathbf{a}$ then         ▷ Filter for consistency
            APPEND($\mathcal{D}_{\text{synthetic}}$, $(\mathbf{x}, \tilde{\mathbf{y}})$)   ▷ Keep the synthetic sample
    return $\mathcal{D}_{\text{synthetic}}$                     ▷ Yield $\mathcal{D}_{\text{synthetic}}$ for additional pre-training
```

model based on the dev set performance (using COCO CIDEr (Vedantam et al., 2015) for MLE pre-training and QA F1 for RL). For optimization, we use Adam (Kingma and Ba, 2015) with a linear warm-up and decay schedule. Training was performed on a 4 × 4 TPU, and took about 1-2 hours per experiment.

C Synthetic Pre-training Details

QA Conditional Model: We use the same basic architecture for $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ as for the main captioning model $G_\theta(\mathbf{y}|\mathbf{x})$, and only introduce two new "question" segment and "answer" segment embeddings that we add to differentiate the conditional text from the generated text in the Transformer. The full input then becomes:

$$\mathbf{h} = \{\texttt{[IMG]}, \hat{\mathbf{o}}_1, \ldots, \hat{\mathbf{o}}_k, \texttt{[Q]}, \mathbf{q}_1, \ldots, \mathbf{q}_m, \\ \texttt{[A]}, \mathbf{a}_1, \ldots, \mathbf{a}_n, \texttt{[CLS]}, \mathbf{w}_1, \ldots, \mathbf{w}_t\},$$

where the segment delimiter, $\mathbf{q}_i$, and $\mathbf{a}_j$ vectors are defined the same way as—and shared with—the caption's input word-piece embeddings $\mathbf{w}_i$ (see §A). We decode auto-regressively as before.

Training and Generating: We train $F_\phi(\mathbf{y}|\mathbf{x}, \mathbf{q}, \mathbf{a})$ using both the corpus of generic captions used for MLE pre-training in Section 4.2 (i.e., COCO) and additional Wikipedia text. We create automatic $(\mathbf{x}, \mathbf{q}, \mathbf{a}, \mathbf{y})$ and $(\texttt{null}, \mathbf{q}, \mathbf{a}, \mathbf{y})$ examples for COCO and Wikipedia sentences, respectively. To offset biases present in the question generation model (which is out-of-domain for caption-styled text as it is trained on SQuAD), we add $(\mathbf{x}, \texttt{null}, \mathbf{a}, \mathbf{y})$ examples from the generic captions by selecting random spans of $\mathbf{y}$, using the sampler of Joshi et al. (2019) (random spans with Poisson distributed lengths). Algorithm 1 illustrates the full synthetic data generation process.

D Converted Dataset Details

Splits: For the COCO and VQA datasets we use the 'Karpathy' splits from Karpathy and Li (2015). For GQA, we use the 'balanced' splits, but limit to ~5K images each for the new test and dev sets from the original GQA dev set. Both the Visual7W and GQA datasets have images from Visual Genome (Krishna et al., 2016), and thus some (partially) overlap with the 'Karpathy' COCO images. Since we use COCO for pre-training ($\mathcal{D}_{\text{generic}}$), we avoid data leakage by mapping Visual Genome IDs to COCO IDs and either filter questions about images that are in the COCO train or dev sets, or re-

Dataset		**Train**		**Development**		**Test**	
		Images	QA	Images	QA	Images	QA
I	COCO	$113,287$	–	$5,000$	–	$5,000$	–
II	CapVQA	$104,311$	$297,484$	$4,617$	$13,081$	$4,615$	$12,847$
	CapGQA	$69,450$	$611,102$	$5,000$	$43,015$	$4,739$	$41,398$
	CapVisual7W	$20,268$	$93,878$	$3,448$	$16,314$	$4,892$	$22,769$
	CapVizWiz	$10,027$	$10,027$	960	960	$1,905$	$1,905$

Table D.1: Statistics of the datasets used in this paper. Type I: generic/no QA. Type II: target/QA.

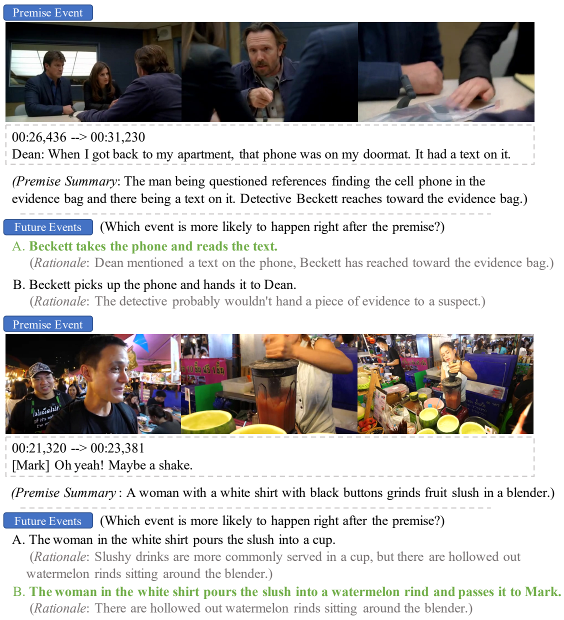
assign the data to match COCO. Finally, on VizWiz, we combine all of the original data and randomly repartition it into test and dev sets of $\sim$1K and $\sim$2K images each, keeping the rest for training.

What is More Likely to Happen Next?
Video-and-Language Future Event Prediction

Jie Lei Licheng Yu Tamara L. Berg Mohit Bansal
Department of Computer Science
University of North Carolina at Chapel Hill
`{jielei, licheng, tlberg, mbansal}@cs.unc.edu`

Abstract

Given a video with aligned dialogue, people can often infer *what is more likely to happen next*. Making such predictions requires not only a deep understanding of the rich dynamics underlying the video and dialogue, but also a significant amount of commonsense knowledge. In this work, we explore whether AI models are able to learn to make such multimodal commonsense next-event predictions. To support research in this direction, we collect a new dataset, named Video-and-Language Event Prediction (VLEP), with 28,726 future event prediction examples (along with their rationales) from 10,234 diverse TV Show and YouTube Lifestyle Vlog video clips. In order to promote the collection of non-trivial challenging examples, we employ an adversarial human-and-model-in-the-loop data collection procedure. We also present a strong baseline incorporating information from video, dialogue, and commonsense knowledge. Experiments show that each type of information is useful for this challenging task, and that compared to the high human performance on VLEP, our model provides a good starting point but leaves large room for future work.[1]



00:26,436 --> 00:31,230
Dean: When I got back to my apartment, that phone was on my doormat. It had a text on it.

(*Premise Summary*: The man being questioned references finding the cell phone in the evidence bag and there being a text on it. Detective Beckett reaches toward the evidence bag.)

(Which event is more likely to happen right after the premise?)

A. **Beckett takes the phone and reads the text.**
(*Rationale*: Dean mentioned a text on the phone, Beckett has reached toward the evidence bag.)

B. Beckett picks up the phone and hands it to Dean.
(*Rationale*: The detective probably wouldn't hand a piece of evidence to a suspect.)

00:21,320 --> 00:23,381
[Mark] Oh yeah! Maybe a shake.

(*Premise Summary* : A woman with a white shirt with black buttons grinds fruit slush in a blender.)

(Which event is more likely to happen right after the premise?)

A. The woman in the white shirt pours the slush into a cup.
(*Rationale*: Slushy drinks are more commonly served in a cup, but there are hollowed out watermelon rinds sitting around the blender.)

B. **The woman in the white shirt pours the slush into a watermelon rind and passes it to Mark.**
(*Rationale*: There are hollowed out watermelon rinds sitting around the blender.)

Figure 1: Video event prediction examples. Given a video (with dialogue) and two future events, the task is to predict which event is more likely to happen following the video. *Top*: an example with a TV show clip. *Bottom*: an example with a YouTube Lifestyle Vlog clip. The correct answer is shown in bold and green. *Premise Summary* and *Rationale* are included for illustration purpose only, they are hidden for the task.

1 Introduction

Given a video clip (*premise event*), humans can often describe logical events that might happen next (*future events*), and interestingly people tend to agree on which future events are more likely to happen than others. Making such predictions requires not only a deep understanding of the rich dynamics underlying the video and dialogue, but also a significant amount of *multimodal commonsense* knowledge about the world. In Figure 1 (*top*), we show an example where commonsense knowledge about inter-human relationships is required, i.e., that a detective typically does not hand evidence to a suspect in a criminal case. Given this knowledge, it is more likely that Beckett (the detective) will take the phone (the evidence) and read the text, than hand the phone to Dean (the suspect).

In this work, we propose *Video-and-Language Event Prediction* (VLEP), a novel dataset and task for fine-grained future event prediction from videos. Given a video with aligned dialogue, and two possible future events, the AI system is required to understand both visual and language semantics from this

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8769–8784,
November 16–20, 2020. ©2020 Association for Computational Linguistics

video, and commonsense world knowledge, and then make a sound and practical judgment about the future, by choosing the more likely event from two provided possible future events. The VLEP dataset contains 28,726 examples from 10,234 short video clips. Each example (see Figure 1) consists of a *Premise Event* (a short video clip with dialogue), a *Premise Summary* (a text summary of the premise event), and two potential natural language *Future Events* (along with *Rationales*) written by people. These clips are on average 6.1 seconds long and are harvested from diverse event-rich sources, i.e., TV show and YouTube Lifestyle Vlog videos.

Collecting such a dataset is a non-trivial task, as crowd-workers may write trivial negatives (less-likely events) that contain *biases* or *annotation artifacts* (Gururangan et al., 2018), such as negation (e.g., *'says nothing'*) or impolite actions (e.g., *'hit someone in the face'*), as shown in Table 1. To mitigate this, we combine two recent effective approaches, adversarial human-and-model-in-the-loop data collection (Nie et al., 2020) and adversarial matching (Zellers et al., 2019a), to build a larger, more-challenging, and less-biased dataset. Specifically, 50% of the examples in VLEP are directly annotated by humans over two rounds: round one of standard data collection, i.e., crowd-workers perform the annotations with no model feedback, and round two of adversarial data collection, i.e., crowd-workers perform the annotations with the goal of fooling our basic models trained on round one data (thus avoiding obvious biases). Our analysis shows that the adversarial data collection helps to mitigate dataset bias (reduce trivial negatives), i.e., we notice that a premise-oblivious model (that does not see the premise event) performs worse on data collected on round two than that of round one. Another 50% of the examples are obtained by performing adversarial matching on the human-annotated positive events (more-likely events), i.e., for each premise event, we sample a positive from other premises as a negative, such that the sampled negative is relevant to the current premise while not being overly similar to the true positive. Overall, our dataset is collected via 3 methods (standard-human, adversarial-human, adversarial-matching), hence maintaining a balance between easy and hard examples while reducing potential biases.

To provide a strong baseline for this challenging multimodal future-prediction task, we propose a transformer-based model to incorporate both visual and textual information from the premise event. We also inject commonsense reasoning knowledge into our model from the ATOMIC dataset (Sap et al., 2019). Our ablation study shows that each part of our model, i.e., video understanding, dialogue understanding, and commonsense knowledge, is useful for the multimodal event prediction. Though our model has shown promising results, it is still not comparable to human performance (67.46% *vs.* 90.50%), indicating the challenging nature of the multimodal event prediction task and the large scope for interesting future work on our VLEP dataset and task.

To summarize, our contributions are 3-fold: (1) We propose a new task, Video-and-Language Event Prediction, which requires a model to make fine-grained, multimodal prediction regarding which future event is more likely to happen following a premise video. (2) We introduce a new dataset VLEP for the task, and use two approaches to gather natural hard-negative future-events: adversarial data collection and adversarial matching. This helps mitigate potential annotation artifacts and biases in the dataset. A detailed analysis of VLEP is provided. (3) We present a strong baseline method to benchmark the proposed dataset, and show that incorporating commonsense knowledge improves performance, indicating future directions for this new task (with a large model-human performance gap).

2 Related Work

Video-and-Language Understanding. Various datasets and tasks have been introduced in this area, such as video captioning (Xu et al., 2016; Rohrbach et al., 2017; Wang et al., 2019; Lei et al., 2020c), video QA (Tapaswi et al., 2016; Jang et al., 2017; Lei et al., 2018), and moment retrieval (Hendricks et al., 2017; Gao et al., 2017; Lei et al., 2020c). Recently, Liu et al. (2020) propose the video-and-language inference task where a model needs to infer whether a statement is entailed or contradicted by a video. While this task requires judging a statement's verification w.r.t. existing events, our task requires predicting future events.

Commonsense Reasoning. Recently, commonsense reasoning has emerged as an important topic in both the language (Zellers et al., 2018, 2019b; Sap et al., 2019) and vision (Vedantam et al., 2015b; Zellers et al., 2019a; Zadeh et al., 2019; Fang et al., 2020) communities. Zellers et al. (2018, 2019b) build multiple-choice QA datasets for commonsense inference with text context, Zellers et al. (2019a); Park et al. (2020) propose datasets for commonsense-based QA and captioning on still images. In this work, we focus on commonsense reasoning with a more complex type of context: video with dialogue, posing challenges for both video understanding and commonsense reasoning.

Bias in Datasets. It is known that *biases* or *annotation artifacts* (Goyal et al., 2017; Gururangan et al., 2018; McCoy et al., 2019; Tsuchiya, 2018; Poliak et al., 2018; Zellers et al., 2019a) exist in standard human annotated datasets (Bowman et al., 2015; Williams et al., 2018; Antol et al., 2015; Tapaswi et al., 2016; Jang et al., 2017; Kim et al., 2017; Lei et al., 2018). For example, negation words such as *nobody*, *no* and *never* are strong indicators of contradictions (Gururangan et al., 2018) in MNLI (Williams et al., 2018). Such superficial patterns are easy for models to exploit, resulting in an overestimate of task performance (Goyal et al., 2017; Gururangan et al., 2018). Zellers et al. (2019a) propose *Adversarial Matching* to mitigate biases in QA, where positive answers are recycled to serve as negatives for other questions. Nie et al. (2020) propose a *Human-And-Model-in-the-Loop Entailment Training* (HAMLET) adversarial data collection strategy to gather challenging examples for NLI. In this work, we adopt both approaches to construct a less-biased and more challenging dataset for the multimodal video+dialogue setting.

3 Dataset

The VLEP dataset contains 28,726 examples from 10,234 TV show and YouTube Lifestyle Vlog video clips. Of these, 50% are collected directly from human annotators over two rounds: (1) round one: standard data collection; (2) round two: adversarial data collection. We collect human examples using Amazon Mechanical Turk (AMT), with an average cost of \$1.10 per example. More detail about the annotators and quality checks are presented in Appendix Section A.2. The other 50% are obtained from human-annotated examples via Adversarial Matching (Zellers et al., 2019a). Hence, overall we build our dataset with 3 collection methods (standard-human, adversarial-human, adversarial-matching), allowing a balance between easy and hard examples while reducing potential biases.

3.1 Video and Language Source

VLEP is built using videos (with English dialogues) from two sources: TV shows and YouTube Vlogs. Both types of videos contain rich physical interactions and dialogues between people and are thus ideal sources for collecting interesting events. We do not use videos from sources like ActivityNet (Caba Heilbron et al., 2015) since they are without dialogues and typically contain fewer events.

TV Show Videos. We use TV show clips from TVQA (Lei et al., 2018). The clips are typically 60-90 seconds long, and are from 6 popular TV shows of 3 genres: 1) sitcom: *The Big Bang Theory, How I Met Your Mother, Friends*, 2) medical drama: *Grey's Anatomy, House*, 3) crime drama: *Castle*.

YouTube Lifestyle Vlogs. While TV shows are good video sources with rich inter-human interactions, they may focus more on scripted content (Lei et al., 2020b). Thus, we also collect a set of YouTube lifestyle vlogs as additional sources, which are typically more natural and live interactive. We first manually identify a list of YouTube channels that contain videos with rich human interactions and dialogues (in English). We filtered out those channels with instructional videos (Miech et al., 2019) or routine videos (Ignat et al., 2019; Fouhey et al., 2018), as they focus more on a single person performing actions, while we desire videos with richer multi-person interactions and dialogues. In addition, the actors in instructional or routine videos typically follow rigid steps (e.g., in cooking videos, they usually follow recipes) to finish a particular task, making it much easier to predict the future events. In the end, we identified 9 channels that contain a diverse set of lifestyle vlog videos on various topics: *travel*, *food*, *daily life* and *family*, etc. We downloaded all videos from these channels that are published after 2017, which were then verified to ensure high quality. The resulting pool contains 971 videos of 10-30 minutes long. Each video is associated with aligned dialogue text, either written by humans or generated from YouTube's Automatic Speech Recognition (ASR) system. We segment the videos into 60-second clips. For each video, we drop the first and the last clip, as most of them are high-level introductions or subscription pleas.

3.2 Round One: Standard Data Collection

As our task is video event prediction, we aim to collect a set of videos annotated with future event pairs (i.e., *more-likely events* and *less-likely events*, also referred to as *positive events* and *negative events*) that are likely to happen right after the 'premise' video. Each event is written in natural language, and we require the positive event to be more likely to happen than the negative event.

With this goal in mind, we create our first annotation task on AMT. We present workers (human *writers*) with a 60-90 seconds long video with aligned dialogue subtitle, to encourage them to write events that are related to both the visual content and the dialogue. Workers are required to first select an interesting event from the video with timestamps, similar to previous works (Lei et al., 2018, 2020c). This event is defined as the *premise event*. We also require workers to write a *premise summary* – a natural language description summarizing the premise event. Following Lei et al. (2018, 2020c), for referring a specific person in the video, workers are instructed to either use the character names (e.g., 'Sheldon') if they are available in the dialogues or provide a referring expression (Kazemzadeh et al., 2014) (e.g., 'the man in blue top') that uniquely refers to a person in the video. Next, given the premise event, workers are required to write two *future events*, one more likely (>50% chance) to happen after the premise event, and one less likely (<50% chance). For example, in Figure 1, the correct answers are the more-likely while the wrong answers are the less-likely. To encourage workers to write more reasonable future event that ground to the premise event,[2] we also require them to provide a *rationale* as to why it is more or less likely. As it is not the focus of this work, we will release these rationales to support research on textual explanation generation/classification tasks (Huk Park et al., 2018; Zellers et al., 2019a).

Each collected example is verified by three human *verifiers*, by ranking the future events conditioned on the premise event. We only accept an example if at least three out of four (one writer + three verifiers) reach an agreement, as Hendricks et al. (2017); Nie et al. (2020). In addition, we also discard examples if one of the verifiers thinks the events are against our instructions (e.g., wrong person reference). In total, we collected 6,458 verified examples from 2329 TV show clips. We split them into 70% training, 15% development, and 15% testing splits such that the videos and their corresponding examples only appear in one split.

Type: **Negation** **Premise Summary**: Amy picks up her phone and reads a text message. **More-likely**: Amy tells her friends what the text message says. **Less-likely**: Amy says **nothing** at all to her friends.
Type: **Impolite Actions** **Premise Summary**: Chandler finds out that Joey used his toothbrush. **More-likely**: Chandler starts arguing with Joey for using his toothbrush. **Less-likely**: Chandler **hits Joey in the face with a punch.**

Table 1: Example annotation artifacts in the negative future events (*Less-likely* events).

3.3 Round Two: Adversarial Data Collection

While being efficient in data collection, we found the collected negative events in round one are sometimes simple and contain *biases* or *annotation artifacts* (Gururangan et al., 2018). In Table 1, we show typical examples of annotation artifacts. For example, we found workers tend to use negation when writing the less-likely event. This particular type is similar to the *visual priming bias* (Zhang et al., 2016) for *yes/no* questions in VQA (Antol et al., 2015) and the *negation word bias* (Gururangan et al., 2018) in MNLI (Williams et al., 2018). To quantitatively study the effect of these annotation artifacts, we fine-tune a RoBERTa-base (Liu et al., 2019) model to classify which event is more likely to happen, with only the future events from round one's training data, i.e., the model has no access to the premise event. On round one's Dev. split, this premise-oblivious model obtains 75.34% accuracy, which is much higher than chance (50%).

Hence, in order to collect harder and less-biased negatives, we make use of an adversarial collection procedure (see Figure 2), in a human-and-model-in-the-loop process (Nie et al., 2020), where models are used to provide real-time feedback to crowdworkers during data collection. Specifically, each submitted result is sent to the model for evaluation and writers are prompted[3] to rewrite their negative event if our model predicts a much higher probability for the more-likely event (p_m) than the less-likely event (p_l), i.e., $p_m - p_l > \Delta$, where Δ is a hyperparameter that controls how difficult we want the collected examples to be and is set to 0.1 empirically. This can be seen as a *soft-adversarial* strategy, unlike Nie et al. (2020) where feedback decisions are made by directly using *hard* model

---

[2] Otherwise, workers sometimes write random events that are not related to the given premise.

[3] Rewrite for at most twice, in total three trials.

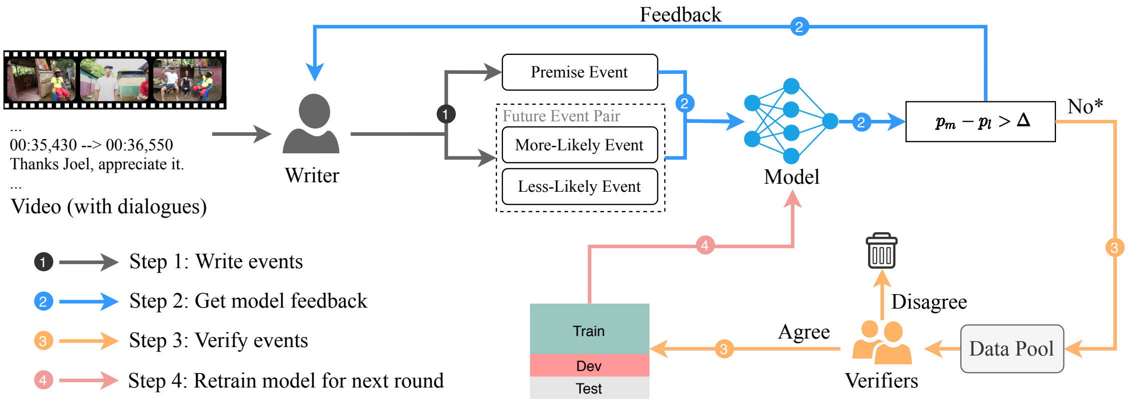

Figure 2: Illustration of our adversarial data collection procedure. p_m and p_l are the probabilities of the more-likely and the less-likely event being happening, respectively. Δ is a hyperparameter that controls how hard we want the collected example to be, it also helps to reduce prediction noises from imperfect models. Δ is set to 0.1 in our experiment. No* or number of trials reaches the maximum limit of three.

predictions (consider it as a special case of our soft-adversarial strategy with $\Delta = 0$). In addition to controlling the difficulty of the collected examples, it also helps us to reduce the prediction noise from imperfect models and avoid forcing workers to write abnormal events in order to fool the model.

We use two models to provide feedback to the writers, a *future event only* model that focuses primarily on reducing the aforementioned annotation artifacts, and a *premise summary + future event* model that can additionally detect and thus reduce simple negatives that are created as contradictions of the premise. For example, with the premise summary, *'Howard tells Bernadette that he has a dominant personality'*, the negative event *'Howard will say that he doesn't have a dominant personality'* is relatively simple as it directly contradicts the premise. Both models are fine-tuned as a sequence classification task from round one's training data, using a pre-trained RoBERTa-base[4] model. The objective is to maximize the probability of the positive event being the correct answer. For the future event only model, we only use the future event for classification, ignoring the premise. For the premise summary + future event model, we concatenate the premise summary and future event text as a single sequence for classification. Note that we use the premise summary as an overall proxy to represent both video and dialogue content to build our adversarial model, considering video and dialogue understanding is still an open research problem in itself.[5] The accuracy of these two models on round one's Dev. split are 75.34% and 76.68%, respectively. During collection, we randomly pick one model from these two models to provide feedback to users. This is similar to the approach used by Nie et al. (2020) where one model is randomly picked from a set of random seeded models. The difference lies in that we use a set of two models with different inputs (architecture) while Nie et al. (2020) use the same architecture with varying random seeds. This strategy can be seen as constructing a pseudo-ensemble model, which provides diverse adversarial feedback to the crowd-workers and helps avoid annotators exploiting vulnerabilities of a single model (Nie et al., 2020), while reducing server load.[6]

In round two, with our adversarial collection procedure, we collected 7,905 verified examples from 4,418 TV show clips and 3,487 YouTube clips. Similar to round one, we split them into 70% training, 15% development, and 15% testing splits.

3.4 Adversarial Matching

With adversarial data collection, we are able to collect harder and less-biased examples. However, this approach is not scalable due to its high cost. On average, each verified example in round two costs $1.70. Inspired by Zellers et al. (2019a) which proposed to use Adversarial Matching to obtain less-biased negatives, we use a similar strategy to create additional examples for our dataset. Given a premise event and its positive event, the goal of ad-

---

[4] Empirically, RoBERTa-large does not yield better performance but longer response time that affects user experience.

[5] In Appendix Section A.3, we show that an oracle model that uses the premise summary as auxiliary input significantly outperforms our video+dialogue model.

[6] As we only need to run one model instead of multiple models in a standard ensemble approach.

Split	#Videos	Pre. Event	Avg. Sen. Len. (#words)		#Examples
		Avg. Len. (s)	Pre. Sum.	Pos. / Neg.	
Train	7,180	6.1	15.2	11.1 / 11.2	20,142
Dev	1,561	6.2	14.7	11.0 / 11.1	4,392
Test	1,493	6.2	15.4	11.0 / 11.1	4,192
Total	10,234	6.1	15.2	11.1 / 11.2	28,726

Table 2: Statistics by Data Split. *Pre. Event*=Premise Event, a short video with dialogue. *Pre. Sum.*=Premise Summary. *Pos. /Neg.*=Positive/Negative future event.

Domain	Genre	#Shows (#Channels)	#Videos	#Examples
TV show	Sitcom	3	4,117	12,248
	Medical	2	1,558	5,198
	Crime	1	1,072	4,306
YouTube Vlogs	Travel, Food	6	2,406	4,812
	Family, Daily	3	1,081	2,162
Total	-	15	10,234	28,726

Table 3: Data Statistics by Genre.

versarial matching is to find a negative from other premise events' positives, such that the matched negative is very relevant to the premise event (so that they are still hard for machines) and at the same time, not overly similar to the true positive (in case they incidentally become a positive event to the premise). Specifically, we use BERTScore (Zhang et al., 2020) and the recommended RoBERTa-Large model fine-tuned on MNLI (Williams et al., 2018) to calculate similarity score $S_{sim}(e_i, e_j)$ between two events e_i and e_j. For relevance, we use a RoBERTa-base model that takes as input the concatenation of a premise summary p_i and a future event e_j and output a relevance score $S_{rel}(p_i, e_j)$. This model is trained to distinguish positive events from randomly sampled events. Next, given dataset examples $\{(p_i, e_i)\}_{i=1}^{N}$, we obtain a negative future event for each premise p_i with maximum-weight bipartite matching (Munkres, 1957; Jonker and Volgenant, 1987) on a weight matrix $\mathbf{W} \in \mathbb{R}^{N \times N}$:

$$\begin{aligned} \mathbf{W}_{i,j} &= \lambda(S_{rel}(p_i, e_j) - \alpha S_{sim}(e_i, e_j)), \\ \lambda &= (1 - 0.5 \cdot \mathbb{1}(p_i, e_j)), \end{aligned}$$

where α=0.1 is a hyperparameter that controls the tradeoff between relevance and similarity, the indicator $\mathbb{1}(p_i, e_j)$ equals 1 if p_i and e_j are from different sources (e.g., different TV shows), otherwise 0. Thus, λ serves as a regularization that penalizes e_j if it is from a different video source than that of p_i – as e_j could potentially be an easy negative that can be distinguished from superficial clues such as character names in different shows.

Genre	Top Unique Verbs
Sitcom	change, offer, hear, should, accept, yell, hang, join, apologize, shut, shout, realize
Medical	die, treat, cry, yell, smile, proceed, examine, approach, argue, save, admit, rush
Crime	kill, shoot, point, question, toss, hang, remove, catch, lie, deny, investigate,
Travel, Food	taste, add, pour, dip, cook, describe, cut, order, serve, stir, prepare, enjoy, buy
Family, Daily	drive, jump, wear, point, smile, touch, climb, dress, set, swim, hide, lay, blow

Table 4: Top unique verbs in each genre.

3.5 Data Analysis

Table 2 shows the overall statistics of the dataset and data splits details. Each example in our dataset is paired with a premise event clip, with an average length of 6.1 seconds. The average length of our positive event (*Pos.*) sentences is very close to that of the negative (*Neg.*) ones (11.1 *vs.* 11.2), suggesting little bias in sentence length. Our videos are curated from TV shows and YouTube vlogs, across five major categories with diverse topics, i.e., *sitcom, medical, crime, travel-food, family-daily*. In Table 3 we show data statistics by genre. Events generally vary by genre. To demonstrate these differences, we show top unique verbs in each genre in Table 4. The top unique verbs in *Crime* genre are usually close to crime and violence, while top unique verbs in *Family, Daily* are usually related to daily activities such as 'drive' and 'wear'. For top unique nouns and additional data analysis (e.g., distribution of examples by reasoning type), please see Appendix Section A.1. For adversarial data collection in round two, the average number of trials is 2.7, i.e., on average the writer has to write their negative event for 2.7 times. For the first trial, 59.21% of the examples are defined as *easy* by our system, i.e., the positive event has a much larger probability of happening than the negative event. With rewriting, only 31.22% of the examples remain *easy*. Moreover, in Table 7 row 1, when trained on our final dataset, we show that our future event only baseline gets much lower performance on the round two subset than that of round one (59.62% *vs.* 74.20%), showing round two examples are less-biased.

4 Method

Given a video with dialogue text, and two future event candidates $\{e_i\}, i \in \{1, 2\}$, our goal is to pre-

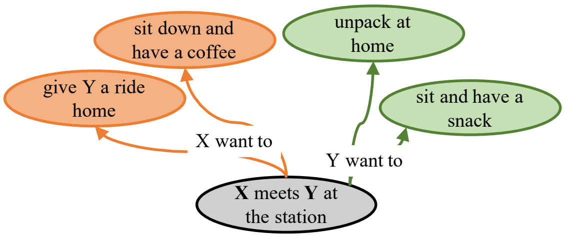

Figure 3: An ATOMIC (Sap et al., 2019) example.

dict which future event is more likely to happen. In the following, we introduce our baseline approach for this new task.

Video Encoding. We encode each video using appearance and motion features at 1 FPS. For appearance, we extract 2048D feature vectors from the ImageNet (Deng et al., 2009) pre-trained ResNet-152 (He et al., 2016). For motion, we extract 2048D feature vectors from the Kinetics (Carreira and Zisserman, 2017) pre-trained ResNeXt-101 (Hara et al., 2018). These features have shown to perform well in several video and language tasks (Miech et al., 2019). We perform L2-normalization and concatenate the features as the video representation. We project these representations into a lower dimension space and add a trainable positional encoding (Devlin et al., 2019) to them. We then use a *transformer encoder* (Vaswani et al., 2017) to further encode the resulting representation, denoted as $E^v \in \mathbb{R}^{T\times d}$.

Text Encoding. For text, we use the contextualized text features from the RoBERTa-base (Liu et al., 2019). We first fine-tune the pre-trained RoBERTa with commonsense knowledge extracted from the ATOMIC dataset (Sap et al., 2019) (see details in the paragraph below) and then use the resulting model for feature encoding. Note that this model is end-to-end trainable during training. We concatenate dialogue and future event candidate as input to the transformer layers, special tokens such as `[CLS]` (Devlin et al., 2019) is also added in the process. We use the extracted token embeddings from the last layer, denoted as $E_i^t \in \mathbb{R}^{L_i\times d}, i \in \{1, 2\}$, where L_i is sentence length (#tokens, including added special tokens) for the concatenation of dialogue and future event e_i. Similar to how we encode video, the resulting text representation is further encoded using another transformer encoder. Without ambiguity, we use the same notation to denote the outputs as $E_i^t \in \mathbb{R}^{L_i\times d}, i \in \{1, 2\}$.

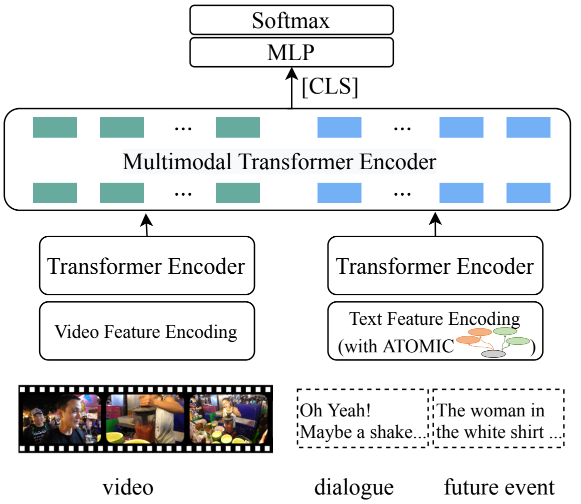

Figure 4: Model overview. We first separately encode video and text, and then use a multimodal transformer encoder to encode information from both modalities. Please see text for details.

Commonsense-based Text Representations. Addressing our challenging future event prediction task requires general world knowledge that is beyond basic visual and language semantic understanding. Thus, we propose to inject the commonsense from the ATOMIC dataset (Sap et al., 2019) into our framework in a simple way. ATOMIC contains events with if-then inferences, e.g., *if X meets Y at the station, then X want to give Y a ride home* (see example in Figure 3). We extract 406K event inferences from the dataset, and replace the person tokens *X* and *Y* with the names from our dataset (Mitra et al., 2019). We then use the extracted event inference sentences to finetune the pre-trained RoBERTa-base model. The fine-tuned model is then used to encode our text inputs.

Multimodal Encoding and Event Classification. To obtain the joint multimodal representation, we concatenate encoded video E^v and text E^t and use a transformer encoder to encode the concatenated representations. This encoder allows information exchange between the two modalities. We use the representation from the `[CLS]` token as the joint representation of video, dialogue and future event e_i, denoted as $g_i \in \mathbb{R}^d, i \in \{1, 2\}$. We gather the joint representation vectors for all future event candidates and pass them through a two-layer MLP with a softmax layer for classification. We train the model using cross-entropy loss that maximizes the scores for the more-likely future events. Figure 4 shows an overview of the overall architecture.

Model	Accuracy (%)
chance	50.00
future only	58.09
video + future	59.03
dialogue + future	66.63
video + dialogue + future	67.46
human (dialogue + future)	76.25
human (video + dialogue + future)	90.50

Table 5: Results on VLEP Test split.

Model	Accuracy (%)
video + dialogue + future	67.46
- ATOMIC fine-tuning	66.96

Table 6: Effect of ATOMIC fine-tuning.

Model	Adv. Matching	Human-Annotated		Overall
	(50%)	R1 (22%)	R2 (28%)	(100%)
future only	50.00	74.20	59.62	58.09
video + future	54.34	69.21	59.19	59.03
dialogue + future	67.60	70.70	61.53	66.63
video + dialogue + future	68.37	70.59	63.26	67.46

Table 7: Performance breakdown by data collection method.

5 Experiments

5.1 Implementation Details

Our models are implemented in PyTorch (Paszke et al., 2017). To speed up training, we use NVIDIA Apex for mixed precision training. We set the hidden size d to be 768 and use a single transformer layer for all our transformer encoders. We use Adam (Kingma and Ba, 2015) optimizer with β_1=0.9, β_2=0.999. Since our model has a pretrained component (RoBERTa), we use a two-phase training strategy. Specifically, we first freeze RoBERTa's weights up to the second last layer and then pre-train the rest of model for 3 epochs with initial learning rate of 1e-4, learning rate warmup over the first 10% of the steps and linear decay the learning rate to 0. We then unfreeze all the weights and finetune the whole model for 3 epochs with learning rate 5e-5 and linearly decay the learning rate to 0. We train the model on a single RTX 2080Ti GPU with batch size 16. We report multiple-choice question answering accuracy.

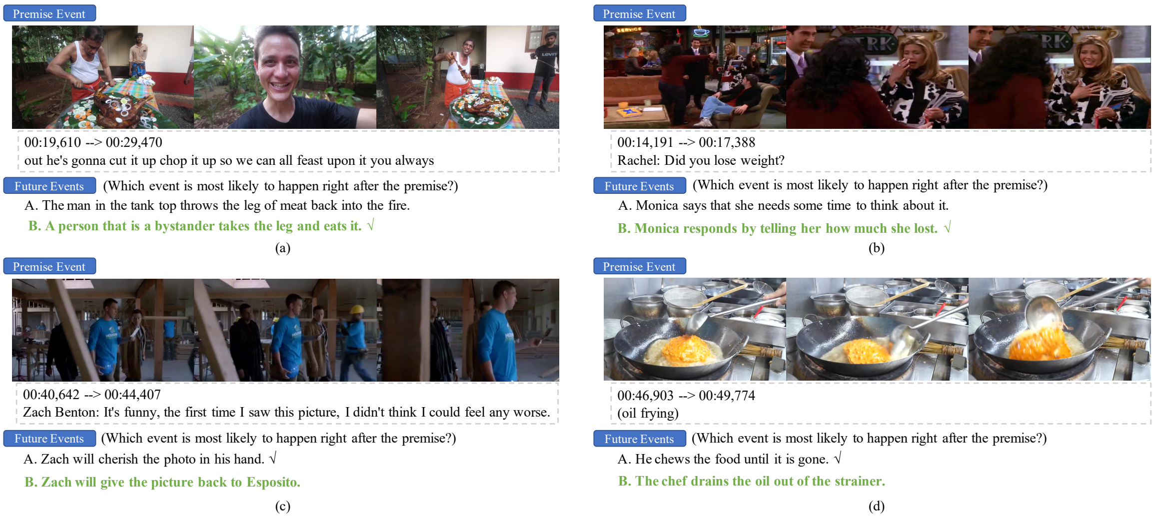
5.2 Results

Are video and dialogue modalities useful? Table 5 shows the results with different input context. The model using future event text only as the input achieves 58.09% accuracy, which is higher than random chance (50%), suggesting there exists slight bias even with our deliberate adversarial collection and matching but is tolerable. Adding video or dialogue as additional input improves the accuracy to 59.03% and 66.63%, respectively. The best performance is achieved when using both video and dialogue, with an accuracy of 67.46%. In Appendix Section A.3, we also present an oracle model with premise summary as auxiliary input.

Human Performance. To obtain human performance, we randomly sampled 400 examples from our test set. We present a premise event (a video with dialogue subtitles or dialogue subtitles only) and its two corresponding future events to a new set of AMT workers and ask them to select which one is more likely to happen after the premise. Each example is answered by 10 different workers to reduce crowdworker variance (Rajpurkar et al., 2018). The final answer is selected by majority vote. Table 5 shows the results. We observe that human performance without video (i.e., only dialogue+future) is 76.25%, while showing the video improves the performance to 90.5%. which shows video information is important for getting the correct answer. Compared with the best model result (67.46%), there is still a large useful gap (23%) for future community work on our challenging task of multimodal event prediction.

Does commonsense knowledge help? In Table 6, we show a model variant that uses text features without ATOMIC sentences for fine-tuning. We see this variant achieves a lower accuracy of 66.96% compared with the fine-tuned accuracy (67.46%).

Impact of Data Collection Method. Table 7 shows the model performance breakdown by different collection methods. For human-annotated data, we show performance on round one (*R1*, standard data collection) and round two (*R2*, adversarial data collection). First, we observe that the accuracy of the *future only* model matches chance on adversarial matching data while being higher on human-annotated data. The main reason is the matched data has less artificial biases than human-annotated ones. Second, for human-annotated data, across all models, we see the performance on round two subset is significantly lower than that of round one, which demonstrates the effectiveness of using our adversarial collection procedure.



00:19,610 --> 00:29,470
out he's gonna cut it up chop it up so we can all feast upon it you always

(Which event is most likely to happen right after the premise?)
A. The man in the tank top throws the leg of meat back into the fire.
B. A person that is a bystander takes the leg and eats it. √
(a)

00:14,191 --> 00:17,388
Rachel: Did you lose weight?

(Which event is most likely to happen right after the premise?)
A. Monica says that she needs some time to think about it.
B. Monica responds by telling her how much she lost. √
(b)

00:40,642 --> 00:44,407
Zach Benton: It's funny, the first time I saw this picture, I didn't think I could feel any worse.

(Which event is most likely to happen right after the premise?)
A. Zach will cherish the photo in his hand. √
B. Zach will give the picture back to Esposito.
(c)

00:46,903 --> 00:49,774
(oil frying)

(Which event is most likely to happen right after the premise?)
A. He chews the food until it is gone. √
B. The chef drains the oil out of the strainer.
(d)

Figure 5: Prediction examples from our best model. Top row shows correct predictions, bottom row shows failure cases. Left column shows human annotated examples, right column shows adversarial matching examples. Ground truth answers are in bold and green, model predictions are indicated by ✓.

word	throws	face	leave	without
PMI (R1)	1.38	1.28	1.25	1.23
PMI (R2)	0.83	0.67	0.66	0.81

Table 8: Top words by PMI in standard collection (R1) and their values in adversarial collection (R2). The values are calculated using PMI(word, less-likely).

Gururangan et al. (2018) shows lexical choice is a strong indicator of the inference class in NLI. To check how our adversarial collection affects the use of words, we use pointwise mutual information (PMI) as in Gururangan et al. (2018). In Table 8 we show top words that are associated with negative class (less-likely event) in standard collection versus their values in our adversarial collection process. We find that the PMI values of these top negative words (e.g., 'throws', 'without', that frequently occur in negative less-likely events) in standard collection clearly drop in adversarial collection, e.g., 'throws' drops from 1.38 to 0.83, making it less indicative of the negative.

Qualitative Examples. We show 4 prediction examples using our best model (video + dialogue + future) in Figure 5. Top row shows two correct prediction examples, where our model is able to predict basic human intention and reaction. Bottom row shows two incorrect predictions, where wrong predictions are mainly caused by the lack of commonsense. For example, to correctly pick the more likely event in Figure 5(c), the model needs to understand that the 'photo' is an evidence of a police investigation. Figure 5(d) shows an example that requires the model to infer the food is not ready for eat yet. More examples are presented in Appendix Section A.4.

6 Conclusion

We introduce a new task, Video-and-Language Event Prediction (VLEP) - given a video with aligned dialogue, and two future events, machines is required to predict which event is more likely to happen. To support this task, VLEP dataset is collected. We present a strong transformer-based baseline that incorporates information from video, dialogue, and commonsense knowledge, each of which is necessary for this challenging task.

Genre	Top Unique Nouns
Sitcom	apartment, group, couch, bottle, game, date, joke, kitchen, story, wine, seat, hug
Medical	patient, doctor, office, surgery, parent, elevator, hospital, nurse, team, case, cane
Crime	gun, picture, photo, paper, information, evidence, police, case, suspect, ground
Travel, Food	host, meat, bite, plate, bowl, chef, piece, sauce, fish, dish, soup, noodle, spoon
Family, Daily	kid, dad, child, dog, son, toy, father, daughter, family, wife, video, candy, hair

Table 9: Top unique nouns in each genre.

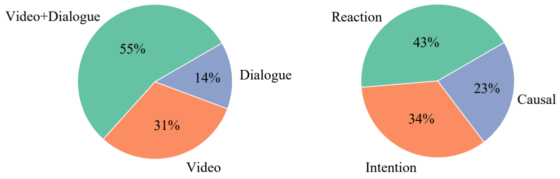

Figure 6: Distribution of examples by premise understanding type (*left*) and by reasoning type (*right*).

A Appendices

A.1 Additional Data Analysis

Our videos are curated from two sources, TV shows and YouTube lifestyle vlogs, across five major categories, i.e., *sitcom, medical, crime, travel-food, family-daily*. Events generally vary by genre. One way to show the difference is by checking the top unique nouns in each genre. To obtain the top unique nouns, we first tokenize and lemmatize the future event sentences. Each resulting token is also tagged with a part-of-speech tag. Next, for each genre, we take the top unique nouns as the ones among the most frequent 100 nouns from one genre but do not appear in those from the other genres combined. We show the top unique nouns in each genre in Table 9. Interestingly, the top unique nouns in *crime* genre are closer to crime and violence, while in *family-daily*, top unique nouns are relatively more family relevant.

Figure 6 (left) shows the distribution of examples by premise understanding type, i.e., what modalities are needed to understand the premise event. Most of the premise events require both video and dialogue understanding. Figure 6 (right) shows the distribution of examples by commonsense reasoning type. We categorize commonsense reasoning into three types by examining the relation between the premise event and the positive future event: (1) intention, e.g., if *X brings two cups of coffee*, then *X (intends to) give Y a cup of coffee*. (2) reaction, e.g., if *X hands Y a form and describes a procedure*, then *Y signs the form and hands it back*. (3) causal, e.g., if *X says they hit a bump*, then *X gets unbalanced and falls off the boat*. The two distributions are obtained by manually annotating 100 randomly sampled examples from VLEP Dev. split.

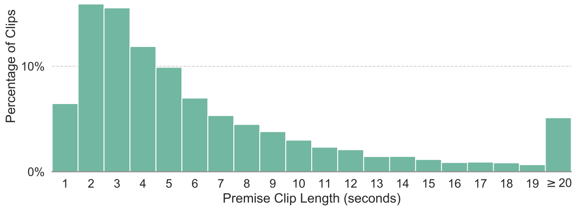

Figure 7: Distribution of premise event length.

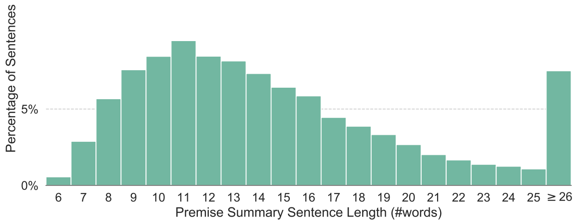

Figure 8: Distribution of premise summary length.

Next, we show the distribution of premise event length and premise summary length in Figure 7 and Figure 8, respectively. In addition, we also show the distribution of positive future event length and negative event length in Figure 9 and Figure 10.

A.2 Additional Data Collection Details

We hire workers from Amazon Mechanical Turk (AMT) to annotate our data. To ensure our data quality, we only allow workers from English-speaking countries to participate in our task. We require workers to have at least 500 HITs approved with an approval rate of 95%. Furthermore, we design a qualification test with 10 multiple-choice questions to ensure that workers well understand our annotation requirement. We show an example question from our qualification test in Figure 11. The workers have to correctly answer at least 7 questions to pass the test. In total, 518 workers participated the test, with a pass rate of 56%. During the data collection, we set up an automatic tool to check if all required annotations have been performed. We also manually review the submitted results and provide prompt feedback to them, encouraging better annotation.

Our data collection instructions and interface for

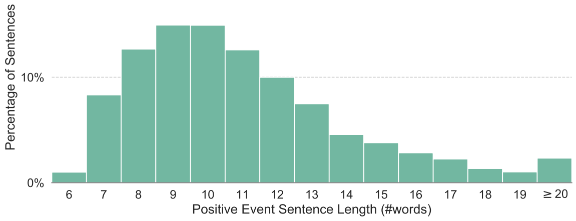

Figure 9: Distribution of positive future event length.

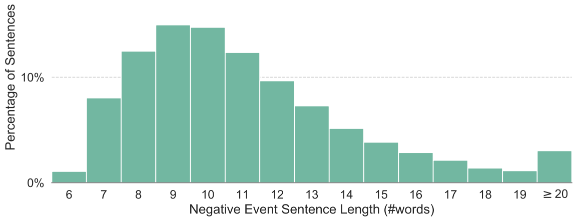

Figure 10: Distribution of negative future event length.

round two (adversarial data collection) are shown in Figure 12 and Figure 13, respectively. Round one collection details are similar to that of the round two, except that we do not require workers to fool our basic models (*robot*). In our annotation process, the actual future events in the videos are not hidden from the workers to ease the collection. The workers can either write the actual future event as the more likely event, or they can hypothesize one when the actual future event in the given video is surprising/rare (such as some events in sitcoms). To ensure the quality of the collected examples, we conduct a strict filtering step in which each example is verified by three extra workers (verifiers) and we only accept examples where at least three out of four (one writer + three verifiers) reach an agreement, as Hendricks et al. (2017); Nie et al. (2020).

A.3 More Results

Oracle Premise Results. As an oracle test, we apply the collected premise summary as an auxiliary input to the model, removing certain obstacles of video-dialogue understanding in our baseline model. We show this oracle model performance in Table 10. Our model with premise summary (oracle) achieves 75.64%, which is significantly higher than the one without it (67.46%), indicating the desire for better video-dialogue understanding.

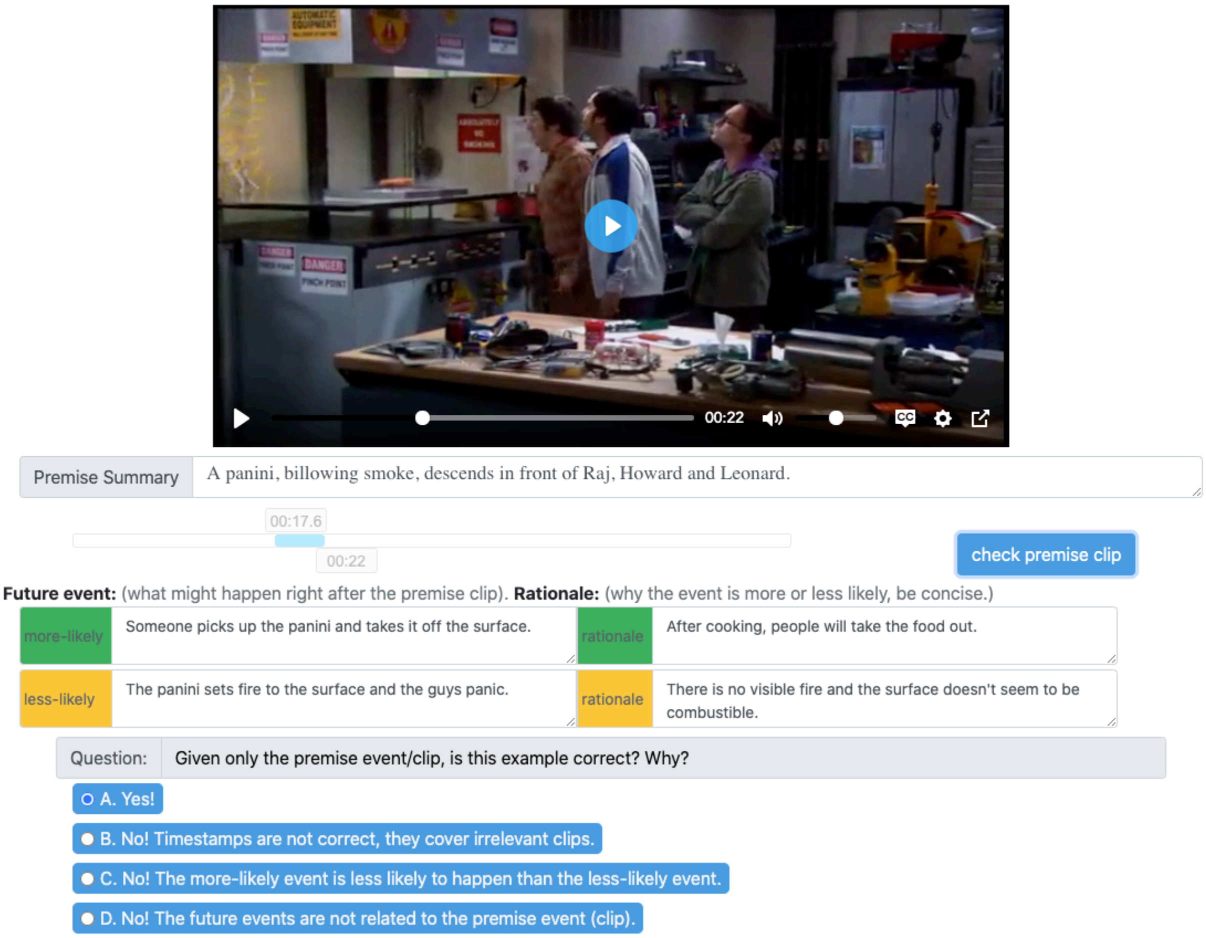
Model	Accuracy (%)
video + dialogue + future	67.46
+ premise summary (oracle)	75.64

Table 10: Oracle performance with premise summary.

Future Event Generation Results. Given the videos, we can also set up an alternative task of using a captioning-style model to generate future event descriptions. We use the MultiModal Transformer from Lei et al. (2020c) as our baseline for this task. This model uses a standard transformer encoder-decoder architecture for caption generation. The video embeddings and dialogue embeddings are concatenated as inputs (Lei et al., 2020a) to the transformer encoder. We use the default model and training configurations from Lei et al. (2020c). With this system, we evaluate generation performance with video and dialogue as inputs. Our video+dialogue model has CIDEr-D (Vedantam et al., 2015a): 19.57, BLEU@4 (Papineni et al., 2002): 1.80, Rouge-L (Lin, 2004): 16.42, and METEOR (Denkowski and Lavie, 2014): 7.58. Note that we only use this generation task to demonstrate that it is possible to generate future event sentences from videos. This may not be as suitable as our default multiple choice setup to serve as an benchmark, since generation is known to be relatively more difficult to evaluate (Liu et al., 2016). Besides, it also requires multiple references (Vedantam et al., 2015a) to be more accurate. Therefore, we recommend future work to use human evaluation if you pursue a generation-based setup on our dataset.

A.4 More Qualitative Examples

We show more correct and incorrect predictions from our best model (video + dialogue + future) in Figure 14 and Figure 15, respectively.



Premise Summary: A panini, billowing smoke, descends in front of Raj, Howard and Leonard.

00:17.6

00:22

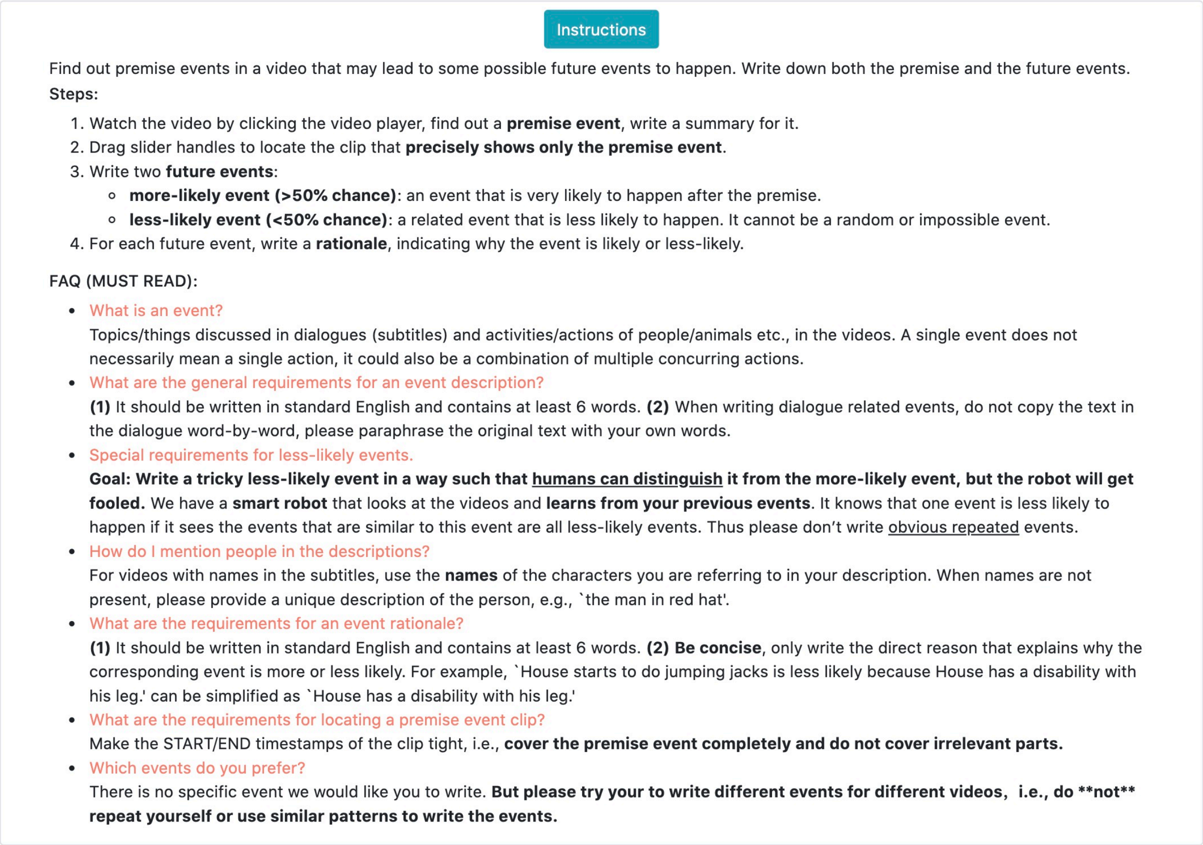
Future event: (what might happen right after the premise clip). **Rationale:** (why the event is more or less likely, be concise.)

more-likely	Someone picks up the panini and takes it off the surface.	rationale	After cooking, people will take the food out.
less-likely	The panini sets fire to the surface and the guys panic.	rationale	There is no visible fire and the surface doesn't seem to be combustible.

Question: Given only the premise event/clip, is this example correct? Why?

- ○ A. Yes!
- ● B. No! Timestamps are not correct, they cover irrelevant clips.
- ● C. No! The more-likely event is less likely to happen than the less-likely event.
- ● D. No! The future events are not related to the premise event (clip).

Figure 11: Example question from our qualification test. Workers have to correctly answer 7 out of 10 questions in the test to participate in our annotation task.



Find out premise events in a video that may lead to some possible future events to happen. Write down both the premise and the future events.

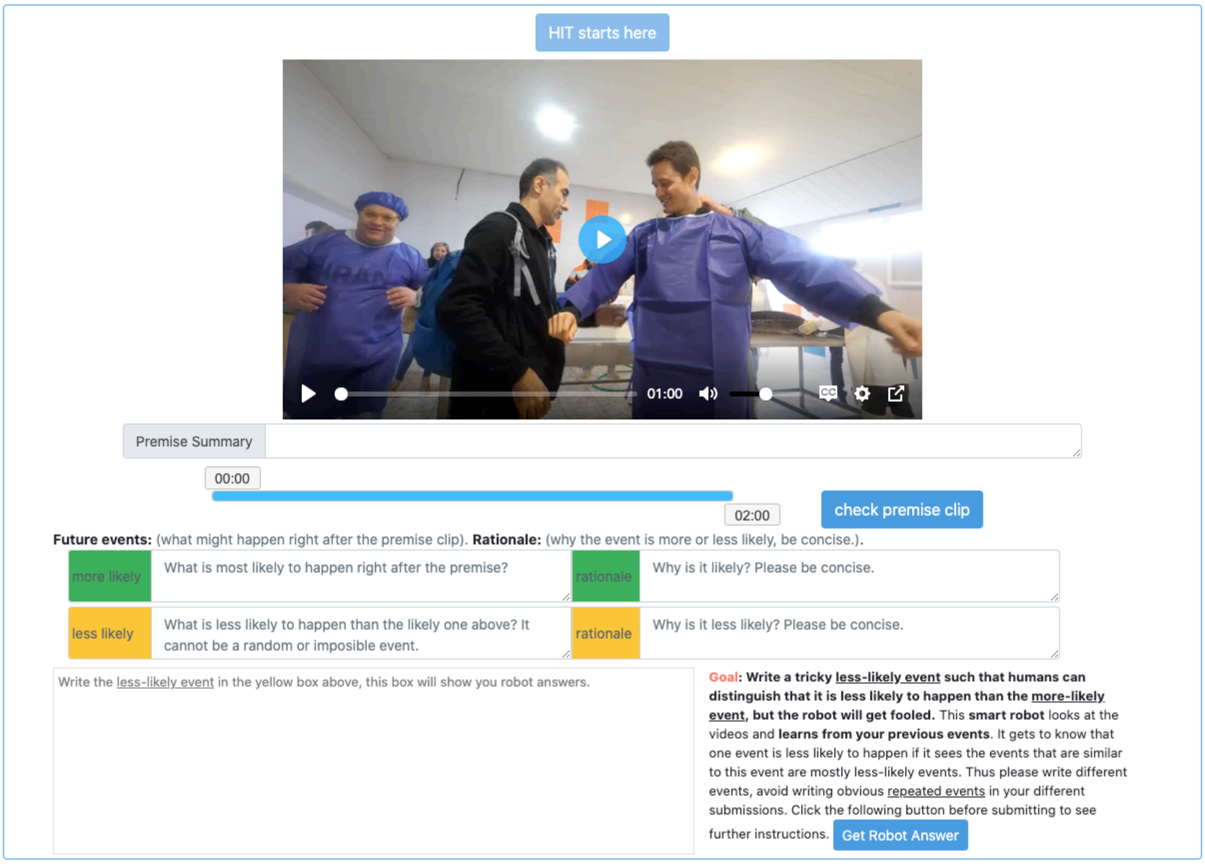
Steps:

1. Watch the video by clicking the video player, find out a **premise event**, write a summary for it.
2. Drag slider handles to locate the clip that **precisely shows only the premise event**.
3. Write two **future events**:
   - **more-likely event (>50% chance)**: an event that is very likely to happen after the premise.
   - **less-likely event (<50% chance)**: a related event that is less likely to happen. It cannot be a random or impossible event.
4. For each future event, write a **rationale**, indicating why the event is likely or less-likely.

FAQ (MUST READ):

- What is an event?
  Topics/things discussed in dialogues (subtitles) and activities/actions of people/animals etc., in the videos. A single event does not necessarily mean a single action, it could also be a combination of multiple concurring actions.
- What are the general requirements for an event description?
  (1) It should be written in standard English and contains at least 6 words. **(2)** When writing dialogue related events, do not copy the text in the dialogue word-by-word, please paraphrase the original text with your own words.
- Special requirements for less-likely events.
  Goal: Write a tricky less-likely event in a way such that humans can distinguish it from the more-likely event, but the robot will get fooled. We have a **smart robot** that looks at the videos and **learns from your previous events**. It knows that one event is less likely to happen if it sees the events that are similar to this event are all less-likely events. Thus please don't write obvious repeated events.
- How do I mention people in the descriptions?
  For videos with names in the subtitles, use the **names** of the characters you are referring to in your description. When names are not present, please provide a unique description of the person, e.g., `the man in red hat'.
- What are the requirements for an event rationale?
  (1) It should be written in standard English and contains at least 6 words. **(2) Be concise**, only write the direct reason that explains why the corresponding event is more or less likely. For example, `House starts to do jumping jacks is less likely because House has a disability with his leg.' can be simplified as `House has a disability with his leg.'
- What are the requirements for locating a premise event clip?
  Make the START/END timestamps of the clip tight, i.e., **cover the premise event completely and do not cover irrelevant parts.**
- Which events do you prefer?
  There is no specific event we would like you to write. **But please try your to write different events for different videos, i.e., do **not** repeat yourself or use similar patterns to write the events.**

Figure 12: Annotation instructions for round two (adversarial data collection).



Future events: (what might happen right after the premise clip). **Rationale:** (why the event is more or less likely, be concise.).

What is most likely to happen right after the premise?

Why is it likely? Please be concise.

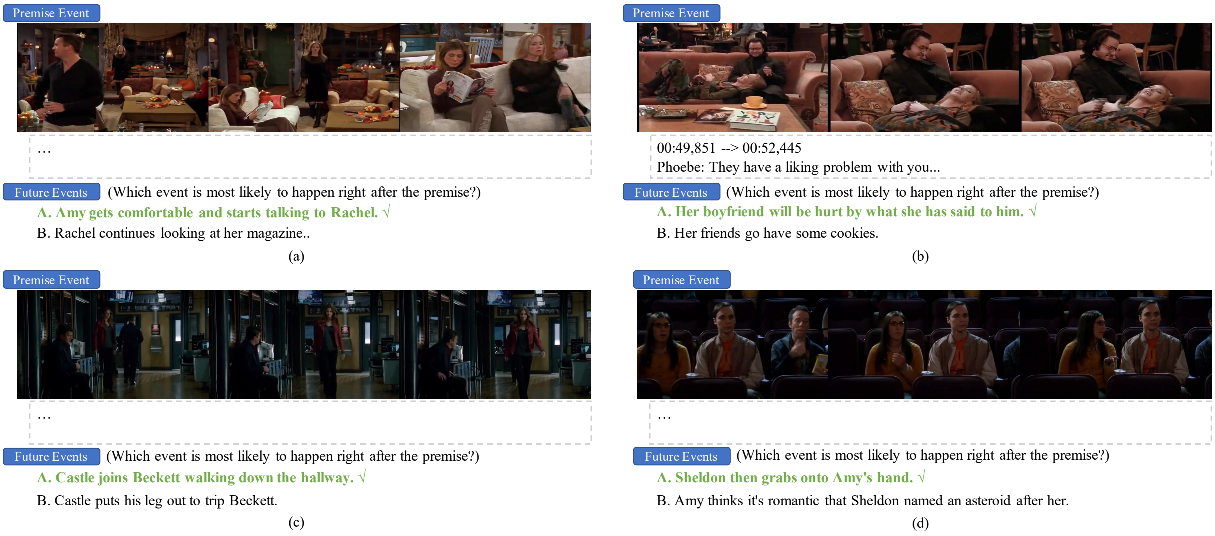
What is less likely to happen than the likely one above? It cannot be a random or impossible event.

Why is it less likely? Please be concise.

Write the less-likely event in the yellow box above, this box will show you robot answers.

Goal: **Write a tricky less-likely event such that humans can distinguish that it is less likely to happen than the more-likely event, but the robot will get fooled.** This **smart robot** looks at the videos and **learns from your previous events**. It gets to know that one event is less likely to happen if it sees the events that are similar to this event are mostly less-likely events. Thus please write different events, avoid writing obvious repeated events in your different submissions. Click the following button before submitting to see further instructions.

Figure 13: Annotation interface for round two (adversarial data collection).



…

(Which event is most likely to happen right after the premise?)

A. Amy gets comfortable and starts talking to Rachel. √

B. Rachel continues looking at her magazine..

(a)

00:49,851 --> 00:52,445

Phoebe: They have a liking problem with you...

(Which event is most likely to happen right after the premise?)

A. Her boyfriend will be hurt by what she has said to him. √

B. Her friends go have some cookies.

(b)

…

(Which event is most likely to happen right after the premise?)

A. Castle joins Beckett walking down the hallway. √

B. Castle puts his leg out to trip Beckett.

(c)

…

(Which event is most likely to happen right after the premise?)

A. Sheldon then grabs onto Amy's hand. √

B. Amy thinks it's romantic that Sheldon named an asteroid after her.

Code and Demo: `https://prior.allenai.org/projects/x-lxmert`

Abstract

Mirroring the success of masked language models, vision-and-language counterparts like VILBERT, LXMERT and UNITER have achieved state of the art performance on a variety of multimodal discriminative tasks like visual question answering and visual grounding. Recent work has also successfully adapted such models towards the generative task of image captioning. This begs the question: *Can these models go the other way and generate images from pieces of text?* Our analysis of a popular representative from this model family – LXMERT – finds that it is unable to generate rich and semantically meaningful imagery with its current training setup. We introduce X-LXMERT, an extension to LXMERT with training refinements including: discretizing visual representations, using uniform masking with a large range of masking ratios and aligning the right pre-training datasets to the right objectives which enables it to paint. X-LXMERT's image generation capabilities rival state of the art generative models while its question answering and captioning abilities remains comparable to LXMERT. Finally, we demonstrate the generality of these training refinements by adding image generation capabilities into UNITER to produce X-UNITER.

1 Introduction

The past year has seen a spate of BERT-style (Devlin et al., 2019) transformer-based architectures (Lu et al., 2019; Chen et al., 2019; Li et al., 2019) proposed for vision-and-language tasks. These models are typically pre-trained on large image captioning corpora, extending ideas from masked language modeling to mask both the image and text modalities and produce state of the art results on a variety of vision and language tasks including visual question answering, visual grounding and image retrieval. These impressive results as well as recent probing mechanisms (Ilharco et al., 2020) suggest that these models are able to capture a variety of semantics in images including objects, attributes and their relationships and ground these in natural language.

While these models have been extensively evaluated over several discriminative tasks, relatively little attention has been paid to their generative capabilities. Bidirectional transformer models like BERT which exploit context preceding and following the current token are not explicitly designed for generation. Recent work for language-only transformers (Wang and Cho, 2019; Dong et al., 2019; Liao et al., 2020) adapt these models towards this capability using sampling procedures. Such techniques have also been adapted successfully for image captioning - inputting an image and sampling the textual side of the model to generate a relevant caption (Zhou et al., 2020). This begs the question: Can we go the other way and sample images from input pieces of text? i.e. *Do vision-and-language BERT models know how to paint?*

In this work, we probe the ability of a powerful and popular representative from this family of models - LXMERT (Tan and Bansal, 2019), to produce high fidelity and semantically meaningful images conditioned on captions. Interestingly, our analysis leads us to the conclusion that LXMERT in its current form does not possess the ability to paint - it produces images that have little resemblance to natural images. This is a somewhat surprising finding given LXMERT's masked training objectives for both modalities and its impressive performance on tasks that seemingly require a similar skill set.

We find that this is largely due to the regression training objective used by this family of models to predict masked features on the visual side. This is

---

[*] This work was done as part of the Pre-Doctoral Young Investigator residency program at the Allen Institute for AI.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 8785–8805,
November 16–20, 2020.

in contrast with the textual side, where they predict masked tokens within a large discrete vocabulary using a classification objective. Regressing features in high dimensional spaces is challenging to optimize and introduces noise at inference. This gets compounded when using iterative sampling procedures to predict the entire set of visual features. A downstream image generator consuming these predictions isn't able to recover from this noise even when fine-tuned on LXMERT's predictions.

We introduce X-LXMERT that builds upon LXMERT and enables it to effectively perform discriminative as well as generative tasks. Our key refinements include: (a) simplifying the visual inputs to use grid features instead of object detection bounding boxes, (b) discretizing visual representations, (c) using uniform masking with a large range of masking ratios to enable the model to predict the entire set of visual clusters at inference time and (d) aligning the right pre-training datasets to the right objectives. When coupled with our proposed image generator, X-LXMERT is able to generate rich imagery that is semantically consistent with the input captions. Importantly, X-LXMERT's image generation capabilities rival state-of-the-art image generation models (designed only for generation), while its question answering capabilities show little degradation compared to LXMERT.

These refinements are not LXMERT-specific. They are designed to be easily applicable to a wide variety of multimodal BERT models. We find that UNITER, a single stream model for vision-and-language tasks, produces very poor images when coupled with a generator, but with our extensions, the resulting X-UNITER produces images of a similar quality to X-LXMERT.

In summary, we present X-LXMERT, a unified multimodal transformer model that can answer questions, and also generate captions and images. Our extensions to enable these capabilities are not tied to LXMERT's underlying architecture. We expect that the entire family of multimodal BERT models can be enhanced with image generative capabilities using our introduced strategy.

2 Related works

Visual-Language transformer models Recent multi-modal pre-training models show significant improvements on a wide range of downstream tasks, including discriminiative (eg., visual question answering) and generation task (eg. image captioning (Zhou et al., 2020)). Some methods use a single transformer architecture to jointly encode text and image (Li et al., 2019; Su et al., 2019; Alberti et al., 2019; Rahman et al., 2020; Li et al., 2020; Chen et al., 2019; Qi et al., 2020; Huang et al., 2020), while others use two-stream architectures (Lu et al., 2019, 2020; Tan and Bansal, 2019). These models typically consume object detection features. We probe this family of models at the task of image generation and present extensions that enable them to reliably generate images.

Sequence generation with undirectional transformer When generating sequences with conventional transformer language models, it is natural to sample tokens from left to right. However, since undirectional transformers (eg. BERT) are not trained with a specific generation order, a line of works has investigated different strategies for sequence generation with undirected models. Wang and Cho (2019) use Gibbs sampling from an all-mask sequence, and Dong et al. (2019); Bao et al. (2020) use causal attention during training for left-to-right generation. Liao et al. (2020); Mansimov et al. (2019); Ghazvininejad et al. (2019) sample masks from a uniform distribution during training for arbitrary order or parallel generation. We adapt these techniques for grid-based image generation.

Text-to-image synthesis Synthesizing images from text descriptions continues to be challenging. Since the pioneering work of Reed et al. (2016), many methods have adopted GANs (Goodfellow et al., 2014) to generate high-fidelity images. Nguyen et al. (2017) generate images that maximizes activation of a pretrained captioning model. Recent works (Zhang et al., 2017, 2018; Xu et al., 2018; Li et al., 2019) use multi-stage generation, where low-resolution images are initially sampled, then gradually upsampled and improved in later stages. These models are specialized toward image generation, whereas our model can not just generate images, but also answer questions and generate captions. Also, our design is modular in nature. While we use a compact image generator with X-LXMERT, one can also replace it with either of the aforementioned model architectures. There is another line of works predicting object layouts from text and generating image based on the layouts (Hong et al., 2018; Tan et al., 2019). These models use bounding box annotations to train layout predictors, while X-LXMERT implicitly learns the layouts only from text and image alignments.

Grid visual representation Compared to bounding box representations which requires expensive object detection annotations, grid representations of images can be naturally obtained from CNNs. Jiang et al. (2020); Huang et al. (2020) have recently shown that these can be almost as powerful as bounding box representations for VQA. Grid representation have been widely used in vision tasks, including self-supervised learning (Oord et al., 2018; Henaff et al., 2019; Trinh et al., 2019; Gidaris et al., 2020; Noroozi and Favaro, 2016) and image generation (van den Oord et al., 2017; Lin et al., 2019). We leverage grid visual representations to enable LXMERT to generate images.

3 Background: Revisiting LXMERT

Over the past year, a large number of transformer based architectures for multimodal data have produced impressive results across a variety of discriminative tasks. Some of these models have been shown to perform very well at the generative task of Image Captioning, but little attention has been paid to the reverse generative task: generating images given text. In this work, we first probe one popular representative from this family - LXMERT (Tan and Bansal, 2019) - in its ability to paint; and propose extensions that enable it to paint.

LXMERT is a cross modality transformer with inputs: image I and text T. This is represented as the sequence $\{v_1, \ldots, v_{\mathcal{T}}, \texttt{CLS}, w_1, \ldots, w_T, \texttt{EOS}\}$ where $\{v_i\}_{i=1}^{\mathcal{T}}$ are image region features, $\{w_j\}_{j=1}^{T}$ are word tokens and CLS and EOS are special tokens. LXMERT outputs embeddings for each input $\{h_{v_i}\}_{i=1}^{\mathcal{T}}$, $\{h_{w_j}\}_{j=1}^{T}$ and $h_{\texttt{CLS}}$, $h_{\texttt{EOS}}$. $h_{\texttt{CLS}}$ is used as the cross-modality output. Internally, LXMERT consists of two types of encoders: single-modality encoders for each modality and a cross-modality encoder using bi-directional cross attention to exchange information and align entities across the modalities.

LXMERT is pretrained on several vision-and-language datasets with five objectives: Masked language modeling (MLM), Masked visual feature regression (MVFR) - reconstructing randomly masked words and regions given the remaining inputs, Masked object classification (MOC) - object classification on masked image regions, Image-text matching (ITM) - image-caption alignment prediction and Question answering (QA) - answering a question given image input. After pretraining, LXMERT is finetuned for various downstream tasks. Unless noted, we use the default settings and hyperparameters of LXMERT in our experiments.

4 Probing LXMERT's Ability to Paint

In order to probe LXMERT's ability to paint, we first modify its input image representation to a *grid based* feature set (Sec. 4.1) and then pass these to an image generator (Sec. 4.2).

4.1 Grid Image Features

Most popular multimodal BERT models use image features extracted from the output of a Faster R-CNN (Ren et al., 2015) object detector. The detected objects typically have various locations and sizes. Passing these features into an image generator poses some challenges: (1) LXMERT is not trained to predict locations of given objects (2) it is not trivial to predict both object classes and their locations simultaneously (3) object detections do not cover backgrounds.

We modify LXMERT to use a uniform $N \times N$ grid and use RoI Pooling to extract the grid features. Note that we use the same detection backbone pretrained on the Visual Genome dataset to maintain parity with the original LXMERT. Our experiments in Sec 6 show that moving to a grid based input causes very little degradation to downstream QA tasks, a finding consistent with Jiang et al. (2020).

Sampling grid features: Given text input, we sample predicted visual features $\{h_{v_i}\}_{i=1}^{\mathcal{T}}$ where $\mathcal{T} = N \times N$ is the number of image regions, using Gibbs sampling in a manner similar to language generation using BERT by Wang and Cho (2019).

4.2 Image Generation

We use a compact image generator inspired by recent state of the art image synthesis methods leveraging Generative Adversarial Networks (GAN) (Goodfellow et al., 2014). Its takes as inputs an $N \times N$ grid of visual features from the pretrained Faster-RCNN network and generates an image. As shown in Fig 1, the input grid features are projected through convolutional layers and then passed to an image generator, which consists of multiple residual blocks (Miyato et al., 2018). Each generator residual block has SPADE layer (Park et al., 2019) which guides generator to outptut high fidelity images given semantic grid layouts. In our experiments, we use an image generator which takes 8×8 grid features and outputs an 256×256 image.

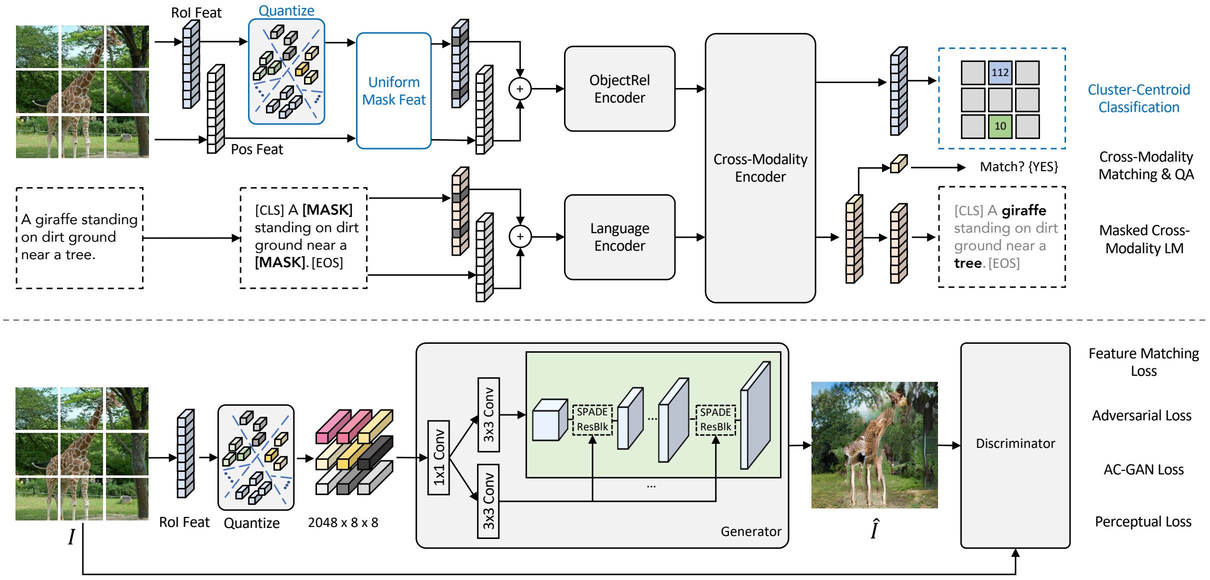

Figure 1: **Top**: Overview of the proposed X-LXMERT model. Blocks in blue are the modifications we make to LXMERT model to enable it to paint. **Bottom**: Overview of the image generation architecture. The input to the model is a natural image that is compressed to a quantized latent map of size 8×8 by RoI Pooling. We use a generator consisting of multiple residual blocks with SPADE layer which encodes 8×8 grid features.

Training the image generator: The generator is pre-trained using 8×8 ground truth Faster-RCNN features, akin to *teacher forcing*, without any inputs from LXMERT. We train the generator with the same loss as Park et al. (2019), but replacing the segmentation map with a grid feature map.

Fig. 2 (b) shows that our generation architecture can successfully reconstruct images using ground truth pre-trained grid features. Note that the generator still displays some reconstruction errors compared with modern auto-encoders such as VQ-VAEv2 (Razavi et al., 2019) primarily due to (1) freezing the encoder backbone in order to match LXMERT's training settings (2) restricting grid features to have a low (and manageable) dimension.

4.3 Can LXMERT Paint?

Our experiments in Section 6 reveal that LXMERT is unable to produce visual features that can be converted to a meaningful image by a generator. Figure 2 shows an example. Recall that the LXMERT loss function includes a regression loss - MVFR - that corresponds to regressing target visual features given the textual and visual context. Unfortunately, at inference, this loss on the validation set remains high, causing the predicted visual features to be fairly noisy. In addition, the Gibbs sampling procedure causes this error to propagate over the entire set of features. The resulting predictions aren't suitable to be used for downstream image generation.

5 X-LXMERT

In this section, we present X-LXMERT[1] that extends LXMERT, enabling it to paint, while still maintaining a high performance on discriminative tasks. X-LXMERT has three key refinements that enable it to paint (Sec. 5.1): discretizing visual representations, using uniform masking with a large range of masking ratios, and aligning the right pre-training datasets to the right objectives. We then leverage Gibbs sampling to generate visual features given textual input (Sec. 5.2).

5.1 From LXMERT to X-LXMERT

Discrete visual representations: We observe that the visual features regressed by LXMERT are not suitable for image generation. Instead, akin to VideoBERT (Sun et al., 2019), we first create a visual vocabulary using K-mean clustering, approximate the target visual features via a nearest neighbor search, and modify LXMERT to predict the cluster ID for each masked visual token. A new Cluster-Centroid Classification objective (CCC) is used to replace the previous regression objective with a high cardinality classification objective. Our experiments show that discretizing visual representations results helps in predicting better visual features, stems the propagation of feature noise over sampling iterations and generates rich imagery.

---

[1] X-LXMERT is an LXMERT with a "display server"

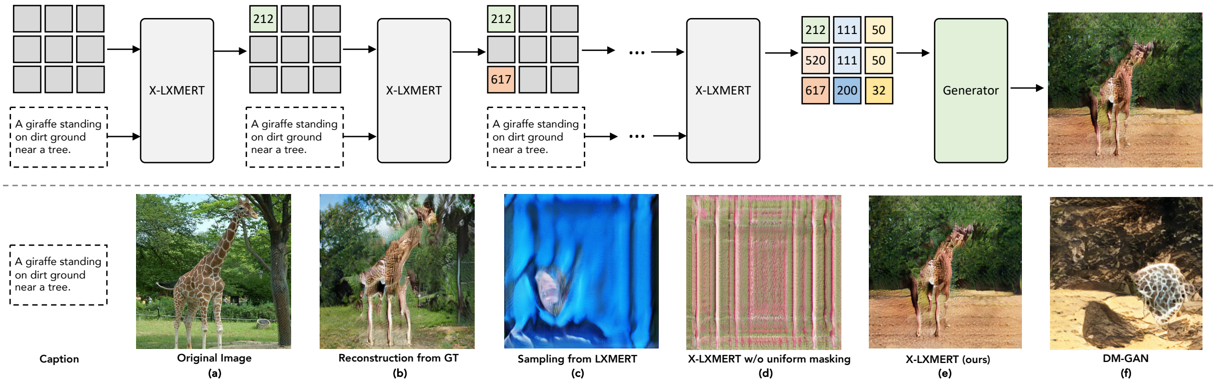

Figure 2: **Top**: Image generation from X-LXMERT. Given the text input and all masked visual feature, we first sample grid features by using Gibbs sampling with multiple iterations. Then the sampled grid features are fed into the generator to generate the image. **Bottom**: Sampled images, from left to right (a) Original image (b) Reconstruction from GT features (c) Sampling from LXMERT + Grid (d) Sampling from X-LXMERT without uniform masking pretraining (e) Our proposed X-LXMERT (f) Generated image from DM-GAN (Zhu et al., 2019).

Uniform instead of Bernoulli masking: Following BERT, LXMERT uses Bernouli sampling (with $p = 0.15$) to determine positions of the masked tokens on the visual and textual features. In order to generate an image from captions, all tokens on the vision side must be masked and predicted. A low probability Bernoulli sampling procedure does not prepare the model well for the generation task, and increasing the probability to very high values leads to poor pre-training. To resolve this, we use Uniform masking on the vision modality. X-LXMERT's uniform masking first samples the masking ratio from a uniform prior distribution ([0,1]), and then samples the desired number of positions randomly. This subjects the model to a variety of masking ratios, and our experiments reveal that this greatly benefits image generation.

Updating pre-training data: LXMERT uses a variety of data to pre-train the model: QA data from multiple sources, caption data from COCO and captions from Visual Genome (VG). Since X-LXMERT uses the CCC loss function, predicting visual features given questions like: "What is shown in the image?" is very ambiguous and results in models that cannot predict visual clusters. Similarly, many captions from VG (e.g., "A bag" or "Glasses on the hair") tend to describe small regions of the image and not the whole image, which makes them unsuited to train the CCC objective. X-LXMERT drops QA data and the captions from VG for CCC objective for visual cluster prediction.

5.2 Sampling Strategies for X-LXMERT

Given text input, predicting the entire set of visual features in one step does not produce good results. Instead, we employ Gibbs sampling to iteratively sample features at different spatial locations. In contrast to text generation, where left-to-right is considered a natural order, there is no natural order for generating images. The grid sampling process starts with N^2 grids filled with the `MASK` special token. The model then iteratively updates locations either one-by-one or multiple in parallel. There are several sampling strategies for sampling locations on the square grid, primarily falling into two buckets: auto-regressive and parallel.

Autoregressive sampling In each iteration, a grid position is sampled, masked and predicted. Then the corresponding `MASK` token is replaced with the predicted one, and the process is repeated until all locations are updated.

- TL→BR: Positions are sequentially chosen from top-left to bottom-right, similar to PixelRNN (van den Oord et al., 2016).
- Random (Liao et al., 2020): Positions are selected in random order. After N^2 steps, locations may be updated more than once.

Non-autoregressive sampling In each iteration, multiple positions are sampled, masked with `MASK`, predicted and then replaced.

- Mask-predict-K (Ghazvininejad et al., 2019): This requires K sampling steps. In the first iteration, all N^2 locations are updated. Then, we linearly decay the number of tokens updated per iteration. For example, for a 2×2 grid whereby $N^2 = 4$, if $K = 4$ then (4, 3, 2, 1) positions are updated in each iteration. Within each iteration, positions with the lowest confidence are updated.

Our experiments show that Mask-Predict-4 consistently produces good results across a variety of generation metrics and we propose using it for X-LXMERT. Our uniform masking aligns well with the linear decay of Mask-Predict and makes the model robust to a varied number of masked locations.

5.3 Training Details

Generator Following (Park et al., 2019), our generator and discriminator are jointly trained with 4 losses: (1) hinge adversarial loss (Lim and Ye, 2017; Tran et al., 2017), (2) AC-GAN loss (Odena et al., 2017), (3) discriminator feature matching loss (Wang et al., 2018) and (4) perceptual loss (Johnson et al., 2016). The coefficients for different loss are $(1, 1, 10, 10)$ respectively. The perceptual loss is calculated with ResNet-50 (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009). We use Adam optimizer (Kingma and Ba, 2015) with $(\beta^1, \beta^2) = (0, 0.999)$ and two-time update rule (Heusel et al., 2017) with learning rate of 0.0004 and 0.0001 for generator and discriminator respectively. We train the generator with batch size 96 for 60 epochs. Note that the generator parameters are fixed after training and not finetuned. Please refer Sec. D for more details.

Pre-training Following LXMERT (Tan and Bansal, 2019), we use AdamW optimizer (Loshchilov and Hutter, 2019) with $(\beta^1, \beta^2) = (0.9, 0.999)$ and learning rate `1e-5` with 5% linear warmup schedule. We train X-LXMERT on with batch size 920 for 20 epochs. Instead of using all pretraining tasks for each step, we first uniformly sample a modality to mask from `[image, text, no-mask]` and run corresponding tasks. Please refer to Sec. C.5 for more details.

Finetuning For each downstream task, a task head consisting of two fully connected layers is trained along with pre-trained X-LXMERT. We used the same parameter setting with LXMERT. Please refer to Sec. C.6 for more details.

6 Experimental Setup

In this section we present experimental setups to evaluate image generation, visual question answering and visual reasoning.

6.1 Evaluating Image Generation

We train and evaluate models using the MS COCO captioning dataset (Lin et al., 2014). We compare X-LXMERT with LXMERT and state-of-the-art text-to-image generation methods: StackGAN (Zhang et al., 2018), PPGN (Nguyen et al., 2017), AttnGAN (Xu et al., 2018), ControlGAN (Li et al., 2019), and DM-GAN (Zhu et al., 2019). Image generation is a particularly difficult task to evaluate, due to the variability in acceptable outputs for a given caption, as well as the subjective nature of perceiving image quality. We present a suite of automated and manual metrics to compare models.

Automated Metrics: Evaluate image quality We use Inception score (IS) (Salimans et al., 2016) to measure image diversity and Fréchet Inception Distance (FID) (Heusel et al., 2017) to measure authenticity; using Inception v3 (Szegedy et al., 2016) as a surrogate net.

Automated Metrics: Evaluate semantics We use two variants of R-precision (Xu et al., 2018), R-prec-easy and R-prec-hard to evaluate if the image is well conditioned on the input text. Given a generated image, a positive caption and negatives, R-precision measures the retrieval rate for the positive caption using a surrogate multi-modal network. We use an independent surrogate - ViLBERT-MT (Lu et al., 2020) for this purpose. R-prec-easy is the variant of R-precision with easy negatives (sampled randomly amongst the caption set). R-prec-hard is the variant with hard negatives (swapping a word in a caption with another word within the same category, e.g., red ⇒ green). We choose words from one of 4 categories: nouns (80 COCO objects), 64 verbs, 10 colors and 10 numbers.

The above automatic metrics, while cheap and reproducible, are noisy because they depend on imperfect surrogate models. The ultimate measure of quality and semantics for image generation continues to be crowd-sourced human studies.

Human Study: Pairwise preferences We conduct a human preference evaluations between X-LXMERT and the best performing model in the automated metrics—DM-GAN. We measure (1) *Semantic preference* by showing two image and asking annotators to select the one that best matches the source caption. (2) *Fidelity preference* by showing the two images alone and asking which appears more realistic. Both evaluations also allow a third option (Tie) to be selected. For each evaluation, 5000 image pairs were used, and 357 unique crowdworkers participated in total (median annotations per worker—17).

Human Study: Our new metric – HUMMUS The above pairwise test is very useful and widely used to evaluate generative models, but measur-

Methods	Text-to-Image Generation							Visual Question Answering			Visual Reasoning

LXMERT*	-	-	-	-	-	-	-	70.9	71.1	59.9	**74.9**	**75.0**

Table 1: Comparing X-LXMERT, LXMERT and baselines on image generation, visual question answering and visual reasoning tasks. The pairwise metric compares LXMERT and DM-GAN; numbers do not sum to 100 due to the TIE option provided to annotators. Note that X-LXMERT and LXMERT*+Grid are the only models that are able to produce results for all tasks. *: Our re-implementation of LXMERT.

ing new models becomes challenging, since they must compare to all old models. To expand human evaluation, we present a novel metric to test semantic consistency between the caption and image inspired by masked token modeling, named - HUmans Measuring seMantics Using maSking (HUMMUS). To compute HUMMUS, human annotators are shown an image and its caption with a single word masked out. They are asked to complete the partial caption based on information in the image, and a match is counted only when a majority of annotators supply the correct word. The total score is reported as a ratio of these successful matches. The task was run on 2800 image-caption pairs (2289 unique images), with 5 annotators per pair. A total of 280 unique crowdworkers completed the task, with a median of 13 images annotated per worker. A high HUMMUS score reveals that the generated images contain the corresponding semantics, well enough to be recognized. The masked word is chosen from one of 3 categories: 80 COCO nouns, verbs and colors.

6.2 Evaluating Visual Question Answering

We train and evaluate models for visual question answering using the VQA2.0 (Goyal et al., 2019) and GQA (Hudson and Manning, 2019) datasets, which provide an image and a question and require the model to generate an answer.

6.3 Evaluating Visual Reasoning

We train and evaluate models for visual reasoning using the NLVR^2 (Suhr et al., 2019) dataset and report numbers on the dev and test-P splits. The NLVR^2 dataset requires models to look at two images and determine if an accompanying caption is True or False. This is a particularly challenging dataset for present day vision and language models.

7 Experimental Results

We now present a comparison of X-LXMERTwith several baselines on the generative and discriminative tasks, along with ablation studies and qualitative results. We also show the generality of our techniques via extending UNITER to create X-UNITER.

7.1 Quantitative Results

Table 1 provides detailed metrics for X-LXMERT and baselines. It also provides generation metrics for the original image in the dataset for the corresponding input text. Note that X-LXMERT and LXMERT+Grid are the only models that are able to produce results for all tasks.

Image Generation As seen, X-LXMERT significantly outperforms LXMERT across all generation metrics. X-LXMERT even outperforms two specialized generation models, comparable to AttnGAN and ControlGAN. Our model is lower compared to DM-GAN in terms of automated metric (IS and FID), however, it is competitive with DM-GAN at semantic metric (R-prec-hard)[3].

Note that X-LXMERT's image generator is much smaller than the one used by DM-GAN (1.7M vs 22.3M parameters). While the transformer employed in X-LXMERT is large, it is a unified tex-

---

[2] We use coco pre-trained model from `https://github.com/MinfengZhu/DM-GAN`

[3] Note: R-prec and HUMMUS are reported only for DM-GAN (the strongest of the 5 baselines), since this was the only model with code and pretrained weights. IS and FID numbers are from their respective publications or from Zhu et al. (2019). The detailed R-prec-hard numbers across categories are presented in the appendix.

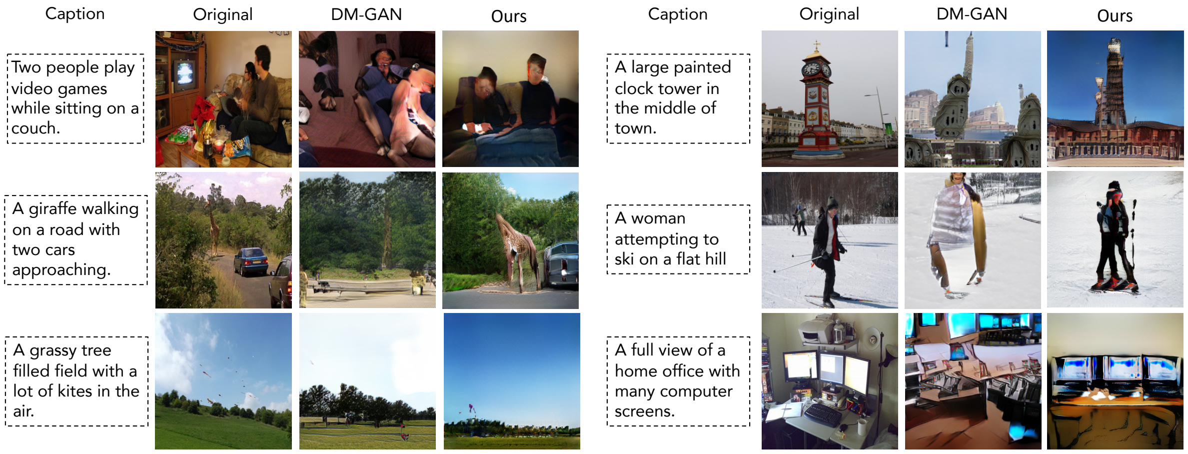

Figure 3: Images generated by DM-GAN^2(Zhu et al., 2019) and images generated by our proposed X-LXMERT.

tual and visual encoder used for multiple tasks and is not finetuned for image generation. We expect X-LXMERT's image quality to improve further when coupled with a larger image generator such as the one by DM-GAN.

Table 1 also presents HUMMUS scores. Here we see that the semantics generated by X-LXMERT is on par with DM-GAN and still significantly better than LXMERT. All models are still a distance away from the original image. HUMMUS matches on the lemmatized forms of masked words to allow for lexical variation, but it misses synonyms and other valid descriptors. This causes the score for the original image to drop to its reported value. See the appendix for R-prec-hard and HUMMUS broken down into categories.

Finally we present human pairwise preference scores between X-LXMERT and DM-GAN (its closest competitor). Here we see that human annotators clearly prefer X-LXMERT to DM-GAN for semantics as well as fidelity.

In summary, X-LXMERT's generation capabilities rival state of the art specialized generation models. In fact, our human studies demonstrate that X-LXMERT produces better results than even DM-GAN, its closest competitor. Our analysis also shows the limitations of current automatic evaluation metric for text-to-image synthesis.

Visual Question Answering Table 1 compares models on the VQA2.0 and GQA datasets. Converting LXMERT to use grid inputs causes a slight or no drop, consistent with findings by Jiang et al. (2020), but hugely simplifies the pipeline. X-LXMERT shows 1.5 - 2.5% drop on these datasets but note that its numbers are still very competitive.

Visual Reasoning Table 1 compares models on NLVR^2 dataset. Consistent with VQA, grid inputs cause a slight drop. X-LXMERT shows a roughly 2% drop but retains most of the massive jumps obtained by LXMERT on NLVR^2 compared to the previous generation of models.

Our implementation of X-LXMERT uses a small 8×8 grid. Increasing the grid size will likely shrink gaps in VQA2.0, GQA and NLVR^2 datasets as per the recent findings by Jiang et al. (2020).

7.2 From X-LXMERT to X-UNITER

The proposed refinements (Sec. 5.1) to enable image generation capabilities are not LXMERT-specific. We apply these changes to UNITER (Chen et al., 2019), a single stream multi-modal transformer architecture. Instead of following (Chen et al., 2019) Table 2 shows that UNITER + Grid produces very poor images, but X-UNITER obtains image generation scores comparable to X-LXMERT–showing the generality of our extensions.

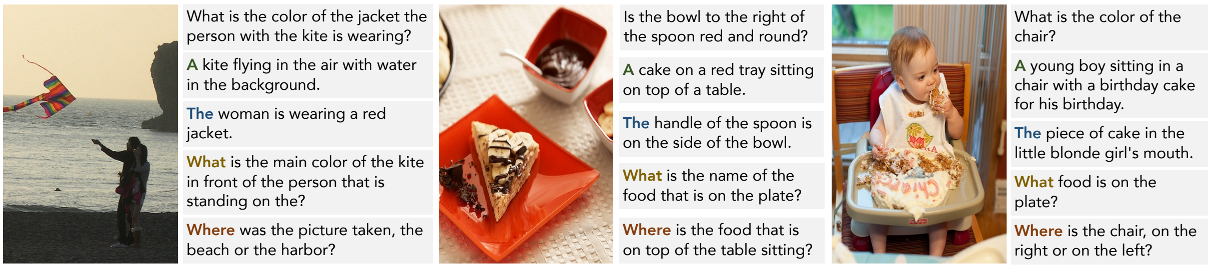
	IS↑	FID↓
UNITER + Grid	2.4	253.5
X-UNITER	**20.1**	**51.4**
LXMERT + Grid	1.6	316.7
X-LXMERT	**22.7**	**37.4**

Table 2: Adding image generation capabilities to LXMERT and UNITER.

7.3 Qualitative Results

Fig 3 shows qualitative examples by X-LXMERT compared to DM-GAN (Zhu et al., 2019). While the images lack fine details, they do a reasonable job at preserving high level semantics, as revealed by the metrics. For complex scene, our model is able to preserve better semantics (e.g. 'two people', 'clock tower' and 'home office') compared to DM-GAN. We do not show images produced by LXMERT since they tend to be incomprehensible.

Figure 4: Intermediate images generated by X-LXMERT at during 140 steps of random position sampling. Images are gradually improved as sampling steps proceed.



What is the color of the jacket the person with the kite is wearing?

A kite flying in the air with water in the background.

The woman is wearing a red jacket.

What is the main color of the kite in front of the person that is standing on the?

Where was the picture taken, the beach or the harbor?

Is the bowl to the right of the spoon red and round?

A cake on a red tray sitting on top of a table.

The handle of the spoon is on the side of the bowl.

What is the name of the food that is on the plate?

Where is the food that is on top of the table sitting?

What is the color of the chair?

A young boy sitting in a chair with a birthday cake for his birthday.

The piece of cake in the little blonde girl's mouth.

What food is on the plate?

Where is the chair, on the right or on the left?

Figure 5: Captions generated by X-LXMERT using Gibbs sampling. We control the samples by providing different prefix word into the model. Those prefix words are common starting word such as '*A*', '*The*', '*What*', '*Where*'.

Ablations	IS↑	FID↓
LXMERT + Grid	1.6	316.7
X-LXMERT	**22.7**	**37.4**
w/o discrete visual representations	1.5	304.4
w/o uniform masking	2.1	227.9
w/o updating pre-training data	21.6	46.1

Table 3: An ablation study for the three refinements.

To better understand the image generation process, We show intermediate images generate by X-LXMERTin Fig 4. We use random autoregressive sampling with 140 steps. Interestingly, the model first coarsely generates salient objects (ex. giraffe, monitors) in the caption followed by details and background.

Our model is able to generate captions given image. For each image, we sample text from X-LXMERT using Gibbs sampling as shown in Fig 5. We control the samples by providing different prefix word into the model. Those prefix words are common starting word such as 'A', 'The', 'What', 'Where'. X-LXMERT can produce long meaningful captions as well as questions (like the ones in VQA datasets).

7.4 Ablation Studies

We examine the effects of our proposed refinements and our sampling strategies to the image generation quality. Table 3 shows that two of the proposed refinements to LXMERT (moving to discrete visual representations and using uniform masking) are critical to produce high quality images. The third refinement – updating pre-training data for the CCC objective – is less critical, but useful nonetheless.

	IS↑/FID↓	R-prec↑ easy/hard	HUMMUS ↑ Noun / Verb / Color / Avg.
Mask-Pred-4	**22.7**/37.4	**40.8/25.1**	**0.55** / **0.42** / 0.50 / **0.49**
TL→BR	19.8/48.5	26.9/18.9	0.45 / **0.42** / 0.41 / 0.43
Random	22.6/**35.9**	39.5/24.7	0.52 / **0.42** / 0.51 / 0.48
Mask-Pred-1	19.5/51.4	36.8/21.4	0.48 / 0.40 / **0.54** / 0.47

Table 4: Image quality across sampling strategies.

Table 4 shows that X-LXMERT is fairly robust to sampling strategy, particularly for image semantics, with the exception of TL→BR which tends to produce worse results. This is interesting in that TL→BR is typically the default strategy used by practitioners (van den Oord et al., 2016, 2017).

8 Conclusion

We develop a probing mechanism and find that LXMERT, a powerful vision-and-language transformer model, is not able to generate meaningful images conditioned on text. We present X-LXMERT, a unified model for image generation, captioning, QA and visual reasoning, and show that our extensions can easily be applied to other vision-and-language transformer models.

A Qualitative samples

More qualitative samples In Fig 6, we show more qualitative examples of images generated by DM-GAN, reconstruction from ground truth clusters, LXMERT, our proposed X-LXMERT with different sampling strategies. Fig 7 shows images generated by X-LXMERT with the same subject placed in a variety of contexts.

B Source code

Please refer to the project page for more details about this research, at `https://prior.allenai.org/projects/x-lxmert`. This includes an animation of the iterative image generation process, a demo of X-LXMERT accessible at `https://vision-explorer.allenai.org/text_to_image_generation` and code available at `https://github.com/allenai/x-lxmert`.

C LXMERT / X-LXMERT details

For a fair comparison, we re-implement LXMERT and LXMERT with grid features. Our models have 226.5M trainable parameters, slightly smaller than 228M of original LXMERT implementation due to weight sharing of MVFR head and MOC head. We use PyTorch (Paszke et al., 2017) and Huggingface Transformers (Wolf et al., 2019) libraries for implementation.

C.1 LXMERT Architecture

LXMERT architecture consists of text embedder, object embedder, transformer backbone, and task-specific heads.

Text embedder A text input is tokenized by WordPiece Tokenizer (Wu et al., 2016) and special tokens `CLS` and `EOS` are concatenated: $\{\texttt{CLS}, w_1, \ldots, w_T, \texttt{EOS}\}$. We use the same vocabulary used in BERT[4] and LXMERT with size 30522. Text is truncated with maximum token length of 20, including two special tokens. 768-dimensional embedding is learned for each token and position. Final text embedding is obtained by sum of token embedding and positional embedding.

Object embedder An input image is resized within minimum length 800 and maximum length 1333 while preserving aspect ratio. We use Faster R-CNN trained on Visual Genome to extract 36 bounding boxes from each image[5]. We take `fc6` feature, which is between `RoI-Pool` layer and final object classification head and has 2048 dimension. This is encoded into 768 dimensional vector followed by layer norm (Ba et al., 2016). Four bounding box coordinates (x_0, x_1, y_0, y_1) are $[0, 1]$-normalized by width and height. Then they are also encoded into 768 dimensional vectors with fully connected layer followed by layer norm. Final object embedding is obtained by element-wise average of object and positional feature.

Transformer backbone Transformer backbone of LXMERT consists of object relation encoder, language encoder and cross modality encoder, which are composed of 9 self-attention layer (Vaswani et al., 2017), 5 self-attention layer, and 5 cross-attention layer respectively. The self-attention layers are same as the ones used in BERT and the dimension of the layers is 768.

Task-specific heads LXMERT is pretrained with five objectives[6] (MLM, MVFR, MOC, ITM, QA) as explained in Sec. 3. For MLM, MVFR, ITM, QA task, a task head consisting of two fully connected layers with GeLU activation (Hendrycks and Gimpel, 2016) and layer norm is trained. For MOC task, a fully connected layer is applied on ouput of MVFR head, similar to original object detection pipeline[7]. For MLM, MVFR, MOC tasks, task heads are applied on cross-modal encoder outputs corresponding to masked tokens. For ITM, QA tasks, tasks heads are applied on `CLS` token.

C.2 X-LXMERT Architecture

X-LXMERT shares most components with LXMERT, except for minor modifications below.

Object embedder → Grid embedder We extract 8 × 8 grid features of `fc6` layer of Faster R-CNN, by giving positional information of 8 × 8 grids into `RoI-Pool` layer. Then we quantize these features with nearest neighborhood search from 10,000 cluster centroids. Remaining are same with object embedder of LXMERT.

---

[4] `bert-base-uncased`

[5] We use PyTorch version (`https://gitlab.com/vedanuj/vqa-maskrcnn-benchmark`), instead of Caffe version (`https://github.com/peteanderson80/bottom-up-attention`) used in original implementation.

[6] We do not use 400 object attributes predicted from Faster R-CNN, which were used by original implementation.

[7] Original implementation trains separate head for MOC task.

Figure 6: More qualitative examples of images generated by X-LXMERT.

Figure 7: Images generated by X-LXMERT demonstrating its ability to place objects within varied contexts.

MOC, MVFR tasks → CCC task We replace MOC, MVFR tasks with CCC task (see Sec. 5.1) for X-LXMERT. For CCC head, we simply modify the output dimension of fully connected layer used in MOC task to the number of clusters (1600 → 10000).

C.3 Datasets

For pretraining, we use same datasets used in LXMERT. We use vision-and-language datasets whose images come from MS COCO (Lin et al., 2014) or Visual Genome (Krishna et al., 2016). Besides the two original captioning datasets, we also aggregate three large image question answering (image QA) datasets: VQA v2.0 (Goyal et al., 2019), GQA balanced version (Hudson and Manning, 2019), and VG-QA (Zhu et al., 2016). Table 5 shows statistics of the datasets. Note that X-LXMERT only uses COCO captions for CCC task.

Image Split	Images	Sentences (or Questions)					
		COCO-Cap	VG-Cap	VQA	GQA	VG-QA	All
MS COCO - VG	72K	361K	-	387K	-	-	0.75M
MS COCO $\cap$ VG	51K	256K	2.54M	271K	515K	724K	4.30M
VG - MS COCO	57K	-	2.85M	-	556K	718K	4.13M
All	180K	617K	5.39M	658K	1.07M	1.44M	9.18M

Table 5: Dataset statistics used in pretraining. Each image has multiple sentences/questions. 'Cap' is caption. 'VG' is Visual Genome. Since MS COCO and VG share 51K images, we list it separately to ensure disjoint image splits. This table is from LXMERT (Tan and Bansal, 2019).

C.4 Visual vocabulary clustering

To create visual vocabularies, we run K-means clustering on Faster R-CNN grid features of COCO `train2014` images. `train2014` has 82783 images, resulting 8 x 8 x 82783 = 5.3M grid features. We use FAISS (Johnson et al., 2017) library for clustering. We sample 2.6M features in training data and run 20 iteration, which takes 2 hours.

C.5 Training

We train LXMERT and X-LXMERT for 20 epochs with mixed precision using Apex[8] (opt-level `O1`). We use AdamW optimizer (Loshchilov and Hutter, 2019) with $(\beta^1, \beta^2) = (0.9, 0.999)$ and learning rate `1e-5` with 5% linear warmup schedule. We use gradient clipping with maximum norm 1.

Instead of using all pretraining tasks for each step, we first uniformly sample a modality to mask from `[image, text, no-mask]` and run corresponding tasks similar to (Chen et al., 2019; Lu et al., 2020). When `image` is selected, we use MVFR, MOC for LXMERT and CCC for X-LXMERT. When `text` is selected, we use MLM. When `no-mask` is selected, we replace given text with a random sentence from training data with 0.5 probability. If the text is replaced, we use ITM. If not, we use ITM and QA.

Training LXMERT takes 60 hours with batch size 1280, and training X-LXMERT takes 40 hours with batch size 920. We use 4 Titan RTX GPUs (4 × 24GB) for training both models.

C.6 Finetuning

During finetuning on VQA/GQA/NLVR^2, a task head consisting of two fully connected layers with GeLU activation and layer norm is trained along with pre-trained LXMERT and X-LXMERT. For VQA/GQA, the parameters are initialized from pretrained QA head. We use AdamW optimizer with learning rate `5e-4`. We train LXMERT and X-LXMERT for 10 epochs for each task. For VQA/GQA/NLVR^2, finetuning takes 3/5/1 hours respectively on 4 Titan RTX GPUs (4 × 24GB).

D Generator details

Our image generation system adopts GAN (Goodfellow et al., 2014) framework and has two networks trained: generator and discriminator.

D.1 Generator Architecture

Our generator consists of multiple residual blocks following SNGAN (Miyato and Koyama, 2018). The generator takes (quantized) 8×8 grid features of Faster R-CNN as input and outputs 256×256 RGB images. We use a generator with 5 residual blocks, where each block bilinearly-upsamples feature map by 2. We use 32 channels of 3x3 kernel for every convolution layer in residual blocks. Note that many existing generator architectures (Miyato and Koyama, 2018; Wang et al., 2018; Karras et al., 2019, 2020) have residual blocks starting from higher dimensions (eg. 512, 1024) in low-resolution then gradually decrease the dimension as feature maps are spatial upsampled. However, we found that using fixed-sized small dimension for all residual blocks makes training more stable. Each residual block has spatially adaptive instance norm (SPADE) (Park et al., 2019; Huang and Belongie, 2017) that guides the residual block using spatial information of 8×8 grid features. After each spatially adaptive instance norm, we multiply spatial gaussian noise on feature maps to make model less focus on local texture following StyleGAN (Karras et al., 2019). We use spectral normalization (Miyato et al., 2018) after each convolution layer in generator. Following StyleGAN-v2 (Karras et al., 2020), we use skip connection for each

---

[8] https://github.com/NVIDIA/apex

residual block to generate final output. Our generator has 1.7M trainable parameters. The detailed architecture of our generator is illustrated at Fig. 8.

D.2 Discriminator Architecture

Discriminator also consists of multiple residual blocks. We use a discriminator with 5 residual blocks, where each residual block downsamples feature map by 2. We use 64 channels of 3x3 kernel for every convolution layer in residual blocks. We use spectral normalization after each convolution layer in discriminator. In contrasts to generator, discriminator (1) uses instance norm (Ulyanov et al., 2016) instead of adaptive instance norm, (2) does not gaussian noise multiplication and (3) does not use skip connection. Output of the 5 residual blocks are 8×8 feature map. Our discriminator have two heads taking these feature maps: (1) adversarial head spatially averaging 8×8 feature map and predicting whether input image is from original image domain or not and (2) classification head predicting cluster ids of 8×8 spatial layouts from input image. Our discriminator has 0.5M trainable parameters. The detailed architecture of our discriminator is illustrated at Fig. 9.

D.3 Dataset

We train our model on COCO `train2014` split, which consits of 82783 images.

D.4 Training

Our generator and discrminator are trained with 4 losses: (1) hinge adversarial loss (Lim and Ye, 2017; Tran et al., 2017), (2) AC-GAN loss (Odena et al., 2017), (3) discriminator feature match loss (Wang et al., 2018) and (4) perceptual loss (Johnson et al., 2016) following (Park et al., 2019). Following pix2pixHD (Wang et al., 2018), coefficients for the losses are (1, 1, 10, 10) respectively. Adversarial loss guides generator to output images close to original images. The rest of the losses guide generator to output images close to specific target images using spatial layout inputs. We use ResNet-50 (He et al., 2016) for perceptual loss. Detail of losses are explained in Sec. D.5.

We use Adam optimizer (Kingma and Ba, 2015) with $(\beta^1, \beta^2) = (0, 0.999)$ and two-time update rule (Heusel et al., 2017) with learning rate of 0.0004 and 0.0001 for generator and discriminator respectively. We train the image generator for 60 epochs with batch size 96. Training takes 15 hours on 8 NVIDIA Titan V GPUs ($8 \times$ 12GB).

D.5 Losses

In below equations, $\hat{X}$ and X refer to generated image and target image respectively.

Adversarial loss

$$L^G_{adv} = -D^{adv}(\hat{X}) \tag{1}$$

$$\begin{aligned} L^D_{adv} &= max(1 - D^{adv}(\hat{X}), 0) \\ &+ max(1 - D^{adv}(X), 0) \end{aligned} \tag{2}$$

where D^{Adv} is discriminator adversarial head.

AC-GAN loss

$$\begin{aligned} L_{ACGAN} = &-\frac{1}{N^2}\sum_{h,w} \log P(D^{cls}_{h,w}(\hat{X})) \\ &-\frac{1}{N^2}\sum_{h,w} \log P(D^{cls}_{h,w}(X)) \end{aligned} \tag{3}$$

where D^{cls} is discriminator classification head.

Discriminator feature match loss

$$L^G_{FM} = \sum_k \frac{1}{H^k W^k C^k} \sum_{h,w,c} \ell_{huber} |D^k(\hat{X}) - D^k(X)| \tag{4}$$

where

$$\ell_{huber}(x) = \begin{cases} 0.5 * x^2, & if\ |x| \leq 1 \\ |x| - 0.5, & otherwise \end{cases}$$

and D^k is discriminator's k-th resblock.

Perceptual loss

$$L^G_{FM-E} = \sum_k \frac{1}{H^k W^k C^k} \sum_{h,w,c} \ell_{huber} |E^k(\hat{X}) - E^k(X)| \tag{5}$$

where E^k is ResNet-50 (He et al., 2016)'s k-th resblock (`conv2_x`, `conv3_x`, `conv4_x`, `conv5_x`).

Total loss

$$\begin{aligned} L^G &= \lambda_{adv} * L^G_{adv} \\ &+ \lambda_{ACGAN} * L_{ACGAN} \\ &+ \lambda_{FM} * L^G_{FM} \\ &+ \lambda_{FM-E} * L^G_{FM-E} \end{aligned} \tag{6}$$

$$\begin{aligned} L^D &= \lambda_{adv} * L^D_{adv} \\ &+ \lambda_{ACGAN} * L_{ACGAN} \end{aligned} \tag{7}$$

where $(\lambda_{GAN}, \lambda_{ACGAN}, \lambda_{FM}, \lambda_{FM-E}) = (1, 1, 10, 10)$.

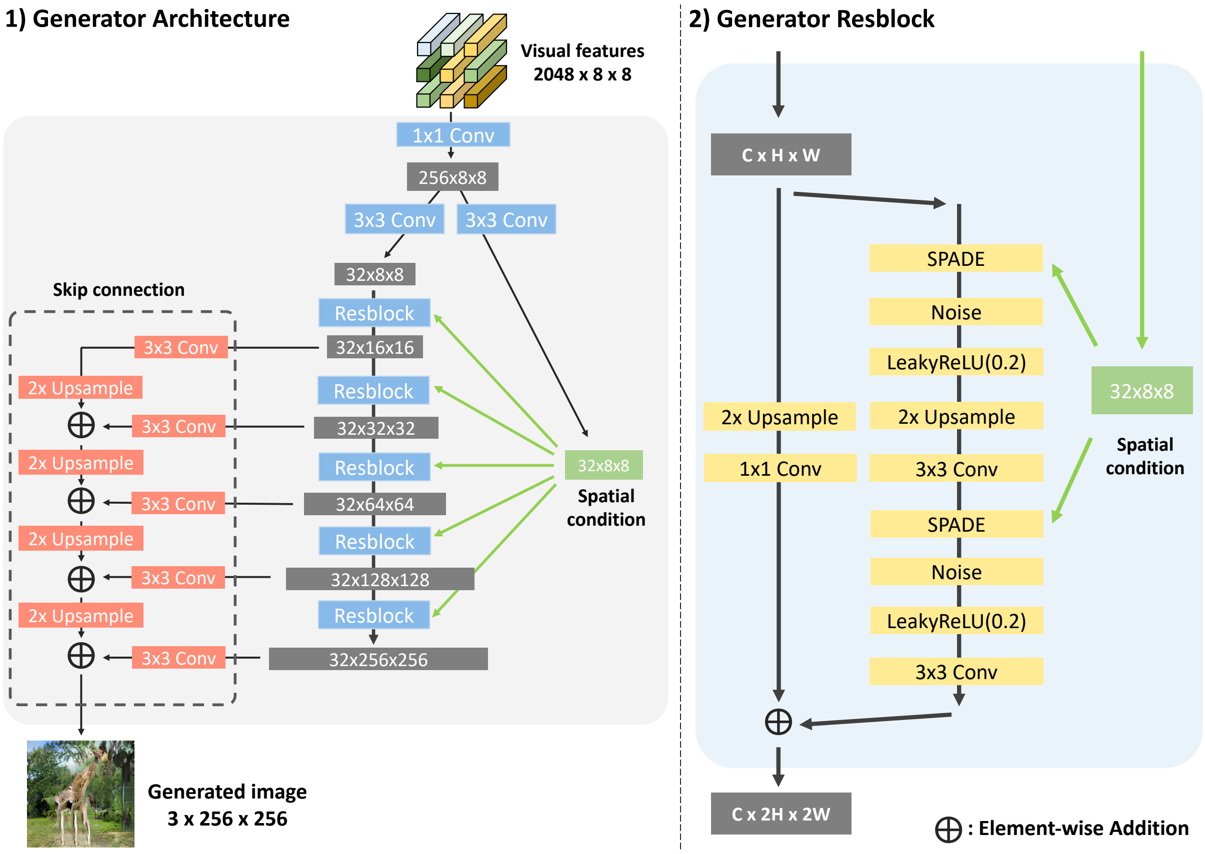

Figure 8: Generator architecture that takes 8x8 grid visual features and generates 256x256 images.

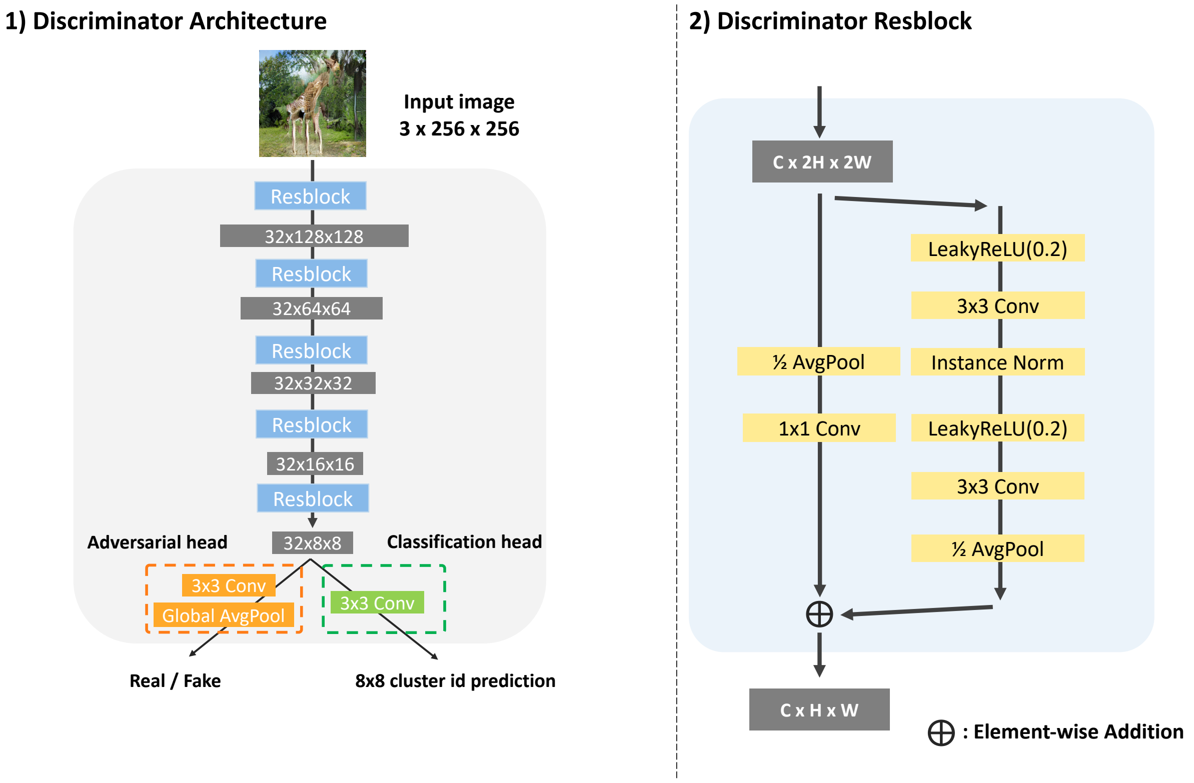

Figure 9: Discriminator architecture that takes 256x256 images.

E Evaluation details

E.1 Image metrics

To calculate image metrics, we follow Xu et al. (2018) and randomly sample 30000 images from MS COCO `val2014` split and sample a caption for each image. Then we generate images from those 30000 captions for each method. We use subset of these 30000 captions for automatic image evaluation.

Inception Score (IS) Following Zhu et al. (2019), we use all 30000 generated images. We use OpenAI implementation[9] to calculate IS.

Fréchet Inception Distance (FID) Following Zhu et al. (2019), we use all 30000 generated images. We use PyTorch port of official implementation[10] to calculate FID.

R-precision-easy We use all 30000 generated images. For R-precision-easy, we sample 99 negative captions for each caption, where all negative captions correspond to different `val2014` images.

R-precision-hard For each R-precision-hard category (noun/verb/color/number), we use 1000 randomly sampled caption that contains a category word. Then we generate 9 negative captions by swapping the detected category word with another word with same category. We use POS-tagging with spaCy[11] to find category words from a caption. We present per-category score of R-precision-hard at table 6.

E.2 Human evaluation

We use Amazon Mechanical Turk[12] for human evaluation.

HUMMUS score For each HUMMUS category (noun/verb/color), we use 100 randomly sampled images. Then we mask out words in the same fashion as in R-precision-hard metric. A total of 280 unique crowdworkers completed the task, with a median of 13 images annotated per worker. We present per-category score of HUMMUS score at table 7. Fig 10 shows screenshot of HUMMUS score (noun category) evaluation task.

Pairwise preference For *Semantic preference* task, we ask annotators (1) 'Which image best matches the caption?' with caption. For *Fidelity preference* task, we ask annotators 'Which image looks more realistic?' without providing the caption. A total of 357 unique crowdworkers completed the task, with a median of 17 annotations performed per worker.

Fig 11 shows screenshot of Semantic preference evaluation task, and Fig 12 shows screenshot of Fidelity preference evaluation task.

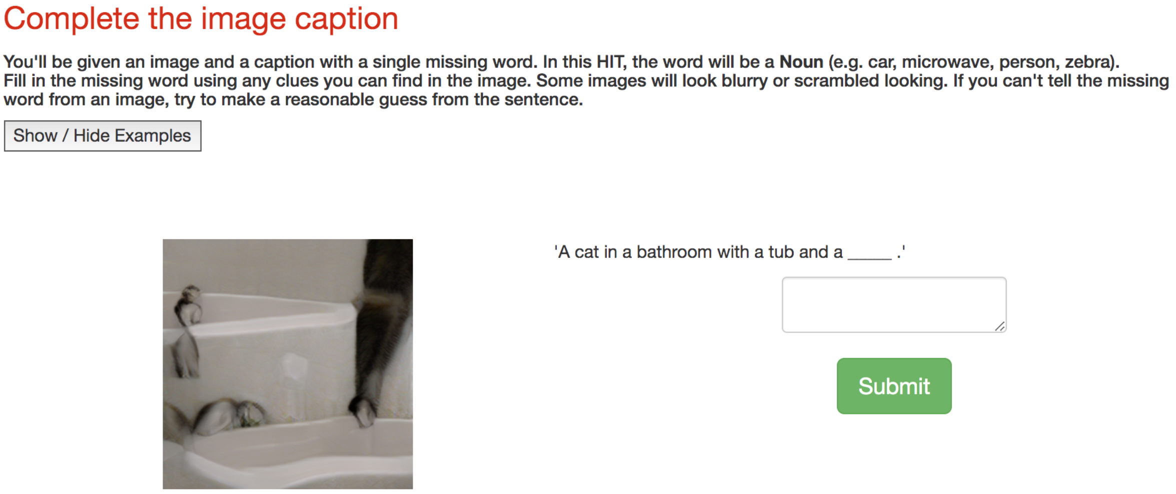
Table 7: Evaluating semantics with HUMMUS.

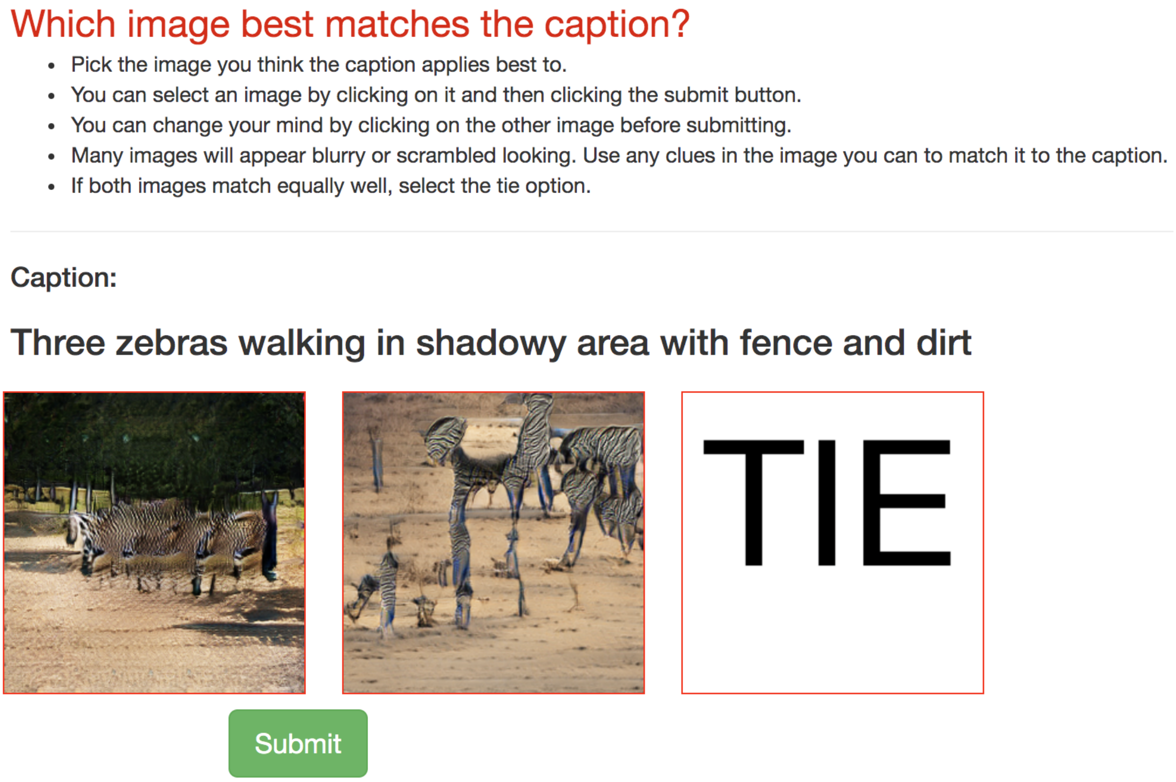


Complete the image caption

You'll be given an image and a caption with a single missing word. In this HIT, the word will be a **Noun** (e.g. car, microwave, person, zebra). Fill in the missing word using any clues you can find in the image. Some images will look blurry or scrambled looking. If you can't tell the missing word from an image, try to make a reasonable guess from the sentence.

'A cat in a bathroom with a tub and a _____ .'

Figure 10: Screenshot of HUMMUS score evaluation system



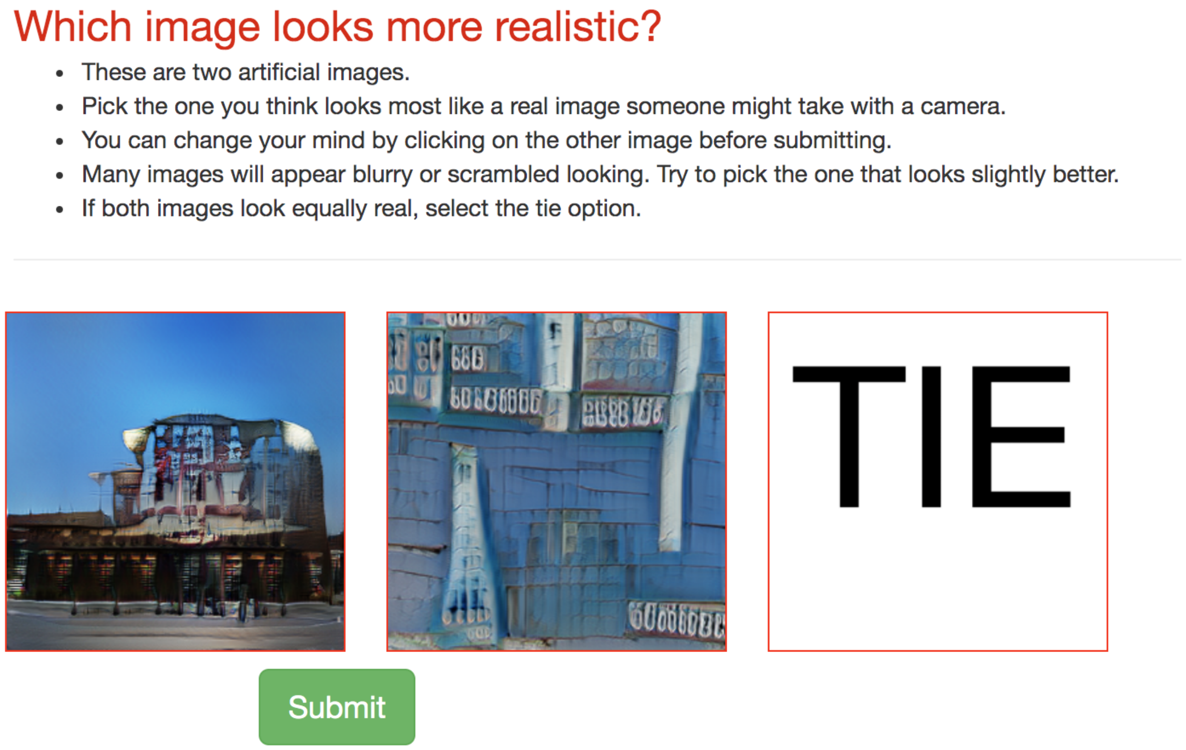
Which image best matches the caption?

- Pick the image you think the caption applies best to.
- You can select an image by clicking on it and then clicking the submit button.
- You can change your mind by clicking on the other image before submitting.
- Many images will appear blurry or scrambled looking. Use any clues in the image you can to match it to the caption.
- If both images match equally well, select the tie option.

Caption:

Three zebras walking in shadowy area with fence and dirt

Figure 11: Screenshot of Semantic preference evaluation system



Which image looks more realistic?

- These are two artificial images.
- Pick the one you think looks most like a real image someone might take with a camera.
- You can change your mind by clicking on the other image before submitting.
- Many images will appear blurry or scrambled looking. Try to pick the one that looks slightly better.
- If both images look equally real, select the tie option.

Abstract

A major challenge in visually grounded language generation is to build robust benchmark datasets and models that can generalize well in real-world settings. To do this, it is critical to ensure that our evaluation protocols are correct, and benchmarks are reliable. In this work, we set forth to design a set of experiments to understand an important but often ignored problem in visually grounded language generation: given that humans have different utilities and visual attention, how will the sample variance in multi-reference datasets affect the models' performance? Empirically, we study several multi-reference datasets and corresponding vision-and-language tasks. We show that it is of paramount importance to report variance in experiments; that human-generated references could vary drastically in different datasets/tasks, revealing the nature of each task; that metric-wise, CIDEr has shown systematically larger variances than others. Our evaluations on reference-per-instance shed light on the design of reliable datasets in the future.

1 Introduction

Natural Language Generation (NLG) is a challenging problem in Natural Language Processing (NLP)—the complex nature of NLG tasks arise particularly in the output space. In contrast to text classification or regression problems with finite output space, generation could be seen as a combinatorial optimization problem, where we often have exponentially many options $|V|^\ell$ (here $|V|$ is the size of the vocabulary and ℓ is the sentence length). With the advances of both Computer Vision and NLP techniques in deep learning, there have been growing interests in visually grounded NLG tasks, such as image captioning (Hodosh et al., 2013; Young et al., 2014; Lin et al., 2014; Vedantam et al., 2015), video captioning (Xu et al., 2016; Wang et al., 2019; Chen and Dolan, 2011) and visual storytelling (Huang et al., 2016). For example, Figure 1 shows an example of image captioning from the popular Flickr30k dataset.

1. This group of folks comprising runners and bikers, some wearing identifying numbers, look like they are getting ready for a marathon.
2. A runner in yellow has a convoy of motorcycles following behind him on a highway as bystanders watch.
3. A man in a yellow shirt is running in a race.

Figure 1: An image with three parallel captions from the Flickr30k dataset. Words in the same colors refer to the same objects.

In this paper, instead of crunching numbers and modifying model architectural designs to achieve new "state-of-the-art" results on leaderboards, we focus on re-assessing the current practices in visually grounded language generation research, including problems, datasets, evaluations, and tasks, from the sample variance angle. Given the differences in annotators' utility function and human visual attention models, how could the sample variance in captions teach us building robust and reliable visually grounded language generation agents?

More specifically, we empirically investigate the variance among the multiple parallel references in different datasets, and its effect on the training performance and evaluation result of corresponding tasks. We further study the number of references per visual instance, and how it affects the training and testing performance. A simple search in ACL Anthology and CVF Open Access Site shows that 58 out of 60 papers on vision-based text generation do not report variance in experimental results, while they often claim that their methods outperform previous state-of-the-art. Our evaluation suggests that the variance cannot be ignored and must be reported, and that CIDEr (Vedantam et al., 2015) has shown higher variance than other metrics. Fi-

nally, introducing more training visual instances in the image and video captioning task on MS COCO and VATEX results in better performance on automatic metrics, while the visual storytelling task in VIST favors more references in the training set. For future dataset collection, we recommend the inclusion of more references when each reference is distinctive and complicated.

2 Research Questions and Settings

To understand sample variance, we conduct a series of experiments on multiple visually grounded NLG datasets, aiming to answer the following questions:

1. *How different are the text references from their parallel pairs?*
2. *How greatly do different selections of references during either training or testing affect the final evaluation results?*
3. *To train a more reliable model, shall we collect more visual instances with limited references or more parallel references for each instance given a fixed budget?*

We focus on multi-reference visually grounded NLG tasks where each visual instance is paired with multiple parallel text references. Below we describe the datasets we investigate into, the models used for training, and the metrics for evaluation.

Datasets Seven commonly used datasets in Table 1 are considered: Flickr8k (Hodosh et al., 2013), Flickr30k (Young et al., 2014), MS COCO (Lin et al., 2014), PASCAL-50S (Vedantam et al., 2015), VATEX_en (English), VATEX_cn (Chinese) (Wang et al., 2019), and VIST (Huang et al., 2016), covering the tasks of image captioning, video captioning, and visual storytelling.

Models We apply an implementation[1] of Xu et al. (2015) for image captioning. We implement the Enc-Dec baseline model proposed by Wang et al. (2019) for video captioning. For visual storytelling, we use the AREL model[2] proposed by Wang et al. (2018).

Metrics We utilize six automatic metrics for natural language generation to evaluate the quality of the generated text, including BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Elliott and Keller, 2013), CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016) and the most recent BERTScore (Zhang* et al., 2020) that is based on the pretrained BERT model.

Task	Dataset	#ref	#len	#train	#val	#test
Image Captioning	Flickr8k	5	11.8	6k	1k	1k
	Flickr30k	5	12.3	29k	1k	1k
	MS COCO'14	5	10.5	83k	5k	5k
	PASCAL-50S	50	8.8	—	—	1k
Video Captioning	VATEX_en	10	15.2	26k	3k	6k
	VATEX_cn	10	14.0	26k	3k	6k
Visual Storytelling	VIST	5	56.8	8k	1k	1k

Table 1: Dataset statistics. *#ref* is the number of parallel references per visual instance; *#len* is the average reference length; *#train, #val*, and *#test* are the number of visual instances of training, validation, and test sets.

We use nlg-eval[3] (Sharma et al., 2017) for the calculation of BLEU, METEOR, ROUGE_L and CIDEr. Note that we applied a patch[4] and choose to use IDF from the MSCOCO Vaildation Dataset when calculating consensus CIDEr score for each dataset. We use the authors' releases for SPICE[5] and BERTScore[6]. BERTScore has been rescaled with baseline scores.

3 Reference Variance within Datasets

In this section, we examine the sample variance among text references within seven visually grounded NLG datasets. To quantify the sample variance, we define a consensus score c among n parallel references $R = \{r_i\}_{i=1}^n$ (where r_i is the i-th text reference) for each visual instance:

$$c = \frac{1}{n}\sum_{i=1}^{n} metric(r_i, R\backslash\{r_i\}) \tag{1}$$

where $metric$ can be any metric in the above section. The consensus score represents the agreement among the parallel references for the same visual instance. Since the number of parallel references varies across datasets, we randomly sample 5 parallel references per instance (the minimum n all datasets used) for a fair comparison. For datasets with more than 5 parallel references per instance, we repeat 10 times and take the average.

A man in a brown shirt rides an elephant into the water.	227
A man rides an elephant into a river.	266
A man riding an elephant into some water of a creek.	271
Man riding an elephant into water surrounded by forest.	277
There are many taxi cabs on the road	4
Heavy city traffic all going in one direction	26
Many cars stuck in traffic on a high way	28
This shot is of a crowded highway full of traffic	28
A city street with lots of traffic and lined with buildings	35

Table 3: Two group of references from MSCOCO dataset and the CIDEr score for each reference within their group. The consensus CIDEr score for the two groups of references are 253.2 and 24.2 respectively.

Table 2 shows the evaluation results. Noticeably, the datasets for the same task have similar consensus BERTScore, which is embedding-based (Kilickaya et al., 2017). Image captioning datasets score the highest on BERTScore consensus, video captioning datasets rank the second, while VIST for visual storytelling has the lowest consensus BERTScore. The descending consensus BERTScore order coincides with task difficulties. Video captioning is more complicated than image captioning due to its dynamic nature. Visual storytelling is even more challenging with the diverse and sophisticated stories in creative writing. Having the lowest consensus scores on all metrics indicates that VIST is a very challenging dataset. Moreover, we notice that CIDEr has the largest standard deviation (both absolutely and relatively) on consensus scores for all datasets. This suggests that CIDEr might be unstable and sensitive to the selection of references.

Table 3 takes a closer look at the high variance of the consensus CIDEr score. By definition, CIDEr score computes cosine similarity between the Term Frequency Inverse Document Frequency (TF-IDF) (Robertson, 2004) weighted n-grams. The reasons for the consensus CIDEr score to have high standard deviation are threefold: (1) N-grams with similar meanings might have totally different TF-IDF weights. Therefore, the CIDEr score is sensitive to word selection and sentence structure. (2) Token frequency differs across datasets. The consensus CIDEr score in Table 2 is calculated on the sentence level. We follow previous work and use IDF from the MSCOCO validation set for reliable results. In the MSCOCO validation set, 'man', 'elephant', and 'river' have more exposure, while 'traffic' and 'highway' are less mentioned. As a result, the first group of references has a much higher consensus CIDEr score than the second group. (3) Moreover, different from other metrics that scale from 0-1, the CIDEr score scales from 0-10. The enlarged scale also contributes to its salient variance.
