	**Ground-truth** *In comparison with study of there is again enlargement of the cardiac silhouette with a pacer device in place. No definite vascular congestion raising the possibility of underlying cardiomyopathy or pleural effusion. No acute focal pneumonia. The right picc line has been removed.*	**BASE** *There is a left pectoral pacemaker with leads terminating in the right atrium and right ventricle. The heart is enlarged. There is no pneumothorax or pleural effusion. The lungs are clear.*	**BASE+RM+MCLN** *In comparison with the study of there is little change in the appearance of the pacer leads which extend to the right atrium and apex of the right ventricle. Continued enlargement of the cardiac silhouette without vascular congestion or pleural effusion. No evidence of pneumothorax.*
	**Ground-truth** *There are low lung volumes. Bibasilar atelectasis have minimally improved. Mild vascular congestion has minimally improved. There are no new lung abnormalities or pneumothorax. Bilateral pleural effusions are small. Right picc tip is at the cavoatrial junction.*	**BASE** *In comparison with the study of there is little overall change. Again there is some indistinctness of pulmonary vessels consistent with elevated pulmonary venous pressure. No evidence of acute focal pneumothorax.*	**BASE+RM+MCLN** *The lung volumes are low. There is a small left pleural effusion with associated atelectasis. The right lung is clear. There is no pneumothorax. The heart size is top normal. The hilar and mediastinal contours are normal. A right subclavian catheter terminate in the mid svc.*

Figure 5: Illustrations of reports from ground-truth, BASE and BASE+RM+MCLN models for two X-ray chest images. To better distinguish the content in the reports, different colors highlight different medical terms.

more detailed information for the generation process so that the decoder tends to produce more diversified outputs than the original Transformer. Particularly, when comparing BASE+RM+MCLN and BASE+RM, the length distribution of the former generated reports is closer to the ground-truth, which can be explained by that, instead of applying memory to the final output, leveraging memory at each layer in Transformer is more helpful and thus controls the decoding process in a fine-grained way. The above observations show that both memory and the way of using it are two important factors to enhance radiology report generation.

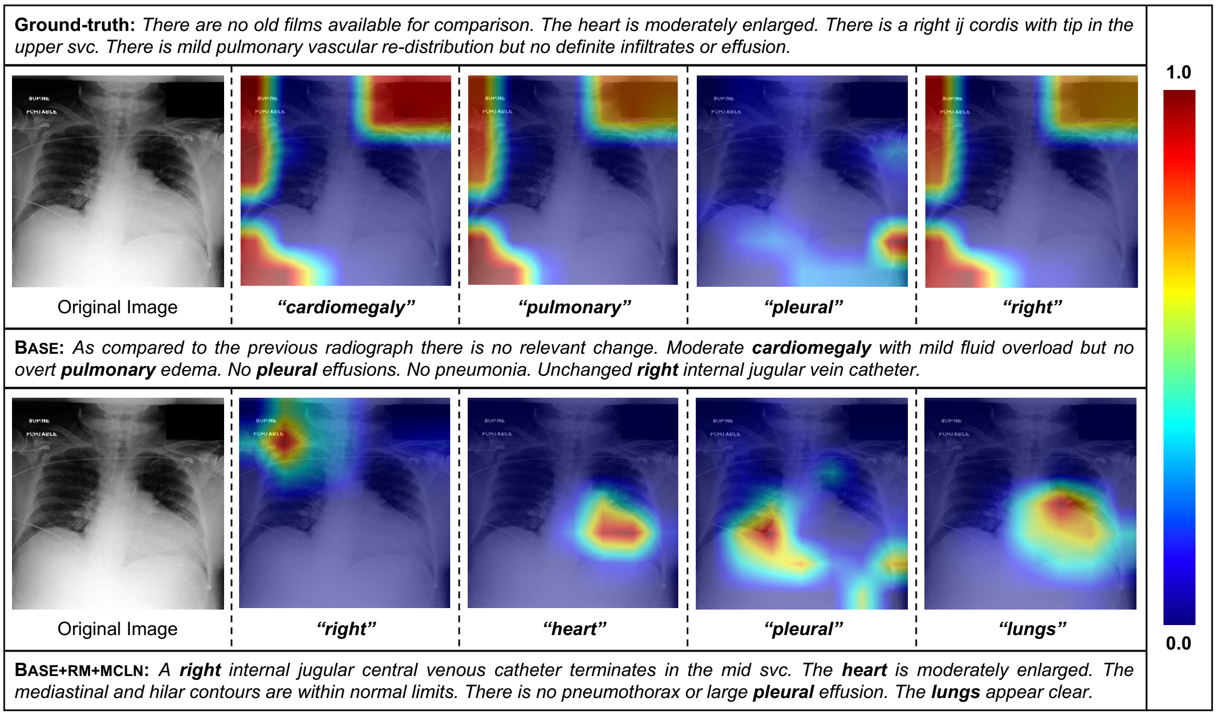
Case Study To further investigate the effectiveness of our model, we perform qualitative analysis on some cases with their ground-truth and generated reports from different models. Figure 5 shows two examples of front and lateral chest X-ray images from MIMIC-CXR and such reports, where different colors on the texts indicate different medical terms. It is observed in these cases that BASE+RM+MCLN is able to generate descriptions aligned with that written by radiologists with similar content flow. For example, in both cases, patterns in the generated reports follow the structure that starting from reporting abnormal findings (e.g., "*cardiac silhouette*" and "*lung volumes*"), and then concluding with potential diseases (e.g., "*pleural effusion*" and "*atelectasis*"). In addition, for the necessary medical terms in the ground-truth reports, BASE+RM+MCLN covers almost all of them in its generated reports while vanilla Transformer did much worse, e.g., the key terms "*enlarged cardiac silhouette*", "*atelectasis*" and "*small pleural effusion*" in the two examples are not generated.

To further investigate different models qualitatively, we randomly select a chest X-ray on the MIMIC-CXR test set and visualize the image-text attention mappings from BASE and BASE+RM+MCLN. Figure 6 shows the intermediate image-text correspondences for several words from the multi-head attentions in the first layer of the decoders. It is observed that BASE+RM+MCLN is better at aligning the locations with the indicated disease or parts. This observation suggests that our model not only enhances the power of radiology report generation, but also improves the interaction between the images and the generated texts.

Error Analysis To analyze the errors from our model, especially in targeting the low CE scores, it is found that the class imbalance is severe on the datasets and affects the model training and inference, where majority voting is observed in the generation process. For example, on MIMIC-CXR, consolidation only accounts for 3.9% in the training set so that the trained model only recognizes that 2.9% results in this case compared with the ground truth 6.3%. Thus how to address the data bias problem is a possible future work to improve the accuracy of the generated radiology reports.

5 Related Work

The most popular related task to ours is image captioning (Vinyals et al., 2015; Xu et al., 2015; Anderson et al., 2018; Wang et al., 2019), which aims to describe images with sentences. Different from them, radiology report generation requires much longer generated outputs, and possesses other features such as patterns, so that this task has its own characteristics requiring particular solutions. For example, Jing et al. (2018) proposed a co-attention



Ground-truth: *There are no old films available for comparison. The heart is moderately enlarged. There is a right ij cordis with tip in the upper svc. There is mild pulmonary vascular re-distribution but no definite infiltrates or effusion.*

BASE: *As compared to the previous radiograph there is no relevant change. Moderate* ***cardiomegaly*** *with mild fluid overload but no overt* ***pulmonary*** *edema. No* ***pleural*** *effusions. No pneumonia. Unchanged* ***right*** *internal jugular vein catheter.*

BASE+RM+MCLN: *A* ***right*** *internal jugular central venous catheter terminates in the mid svc. The* ***heart*** *is moderately enlarged. The mediastinal and hilar contours are within normal limits. There is no pneumothorax or large* ***pleural*** *effusion. The* ***lungs*** *appear clear.*

mechanism and leveraged a hierarchical LSTM to generate reports. Li et al. (2018, 2019) proposed to use a manually extracted template database to help generation with bunches of special techniques to utilize templates. Liu et al. (2019) proposed an approach with reinforcement learning to maintain the clinical accuracy of generated reports. Compared to these studies, our model offers an alternative solution to this task with an effective and efficient enhancement of Transformer via memory.

Extra knowledge (e.g., pre-trained embeddings (Song et al., 2017; Song and Shi, 2018; Zhang et al., 2019) and pretrained models (Devlin et al., 2019; Diao et al., 2019)) can provide useful information and thus enhance model performance for many NLP tasks (Tian et al., 2020a,b,c). Specifically, memory and memory-augmented neural networks (Zeng et al., 2018; Santoro et al., 2018; Diao et al., 2020; Tian et al., 2020d) are another line of related research, which can be traced back to Weston et al. (2015), which proposed memory networks to leverage extra information for question answering; then Sukhbaatar et al. (2015) improved it with an end-to-end design to ensure the model being trained with less supervision. Particularly for Transformer, there are also memory-based methods proposed. For example, Lample et al. (2019) proposed to solve the under-fitting problem of Transformer by introducing a product-key layer that is similar to a memory module. Banino et al. (2020) proposed MEMO, an adaptive memory to reason over long-distance texts. Compared to these studies, the approach proposed in this paper focuses on leveraging memory for decoding rather than encoding, and presents a relational memory to learn from previous generation processes as well as patterns for long text generation. To the best of our knowledge, this is the first study incorporating memory for decoding with Transformer and applied for a particular task, which may provide a reference for studies in the line of this research.

6 Conclusion

In this paper, we propose to generate radiology reports with memory-driven Transformer, where a relational memory is used to record the information from previous generation processes and a novel layer normalization mechanism is designed to incorporate the memory into Transformer. Experimental results on two benchmark datasets illustrate the effectiveness of the memory by either concatenating it with the output or integrating it with different layers of the decoder by MCLN, which obtains the state-of-the-art performance. Further analyses investigate how memory size affects model performance and show that our model is able to generate long reports with necessary medical terms and meaningful image-text attention mappings.

Planning and Generating Natural and Diverse Disfluent Texts as Augmentation for Disfluency Detection

Jingfeng Yang, Diyi Yang, Zhaoran Ma
Georgia Institute of Technology
`{jyang690, makima, dyang888}@gatech.edu`

Abstract

Existing approaches to disfluency detection heavily depend on human-annotated data. Numbers of data augmentation methods have been proposed to alleviate the dependence on labeled data. However, current augmentation approaches such as random insertion or repetition fail to resemble training corpus well and usually resulted in unnatural and limited types of disfluencies. In this work, we propose a simple Planner-Generator based disfluency generation model to generate natural and diverse disfluent texts as augmented data, where the Planner decides on where to insert disfluent segments and the Generator follows the prediction to generate corresponding disfluent segments. We further utilize this augmented data for pretraining and leverage it for the task of disfluency detection. Experiments demonstrated that our two-stage disfluency generation model outperforms existing baselines; those disfluent sentences generated significantly aided the task of disfluency detection and led to state-of-the-art performance on Switchboard corpus. We have publicly released our code at `https://github.com/GT-SALT/Disfluency-Generation-and-Detection`.

1 Introduction

Disfluency is a para-linguistic concept defining the interruption to the flow of speech (Kowal, 2009). As shown in Figure 1, a standard annotation of the disfluency structure indicates the reparandum (the region to repair), an optional interregnum (filled pauses, discourse cue words, etc.) and the associated repair (corrected linguistic materials) (Nakatani and Hirschberg, 1994). Disfluency detection (Lou et al., 2018; Wang et al., 2019) mainly deals with identifying and removing reparandum[1], since interregnum can be easily detected in that they belong to a closed set of words and phrases, e.g. "*uh*" "*I mean*" "*you know*" etc. The output fluent sentences from disfluency detection can serve as clean inputs for most downstream NLP tasks, like dialogue systems, question answering, and machine translation (Wang et al., 2010).

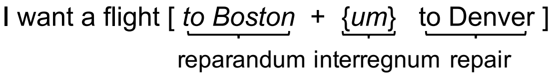

Figure 1: Example of an annotated disfluent sentence.

Type	Example
Repetition	~~they~~ they learn to share.
Deletion	this ~~is~~ just happened yesterday.
Substitution	it's nothing but wood ~~up here~~ down here.

Table 1: Different types of reparandum.

Reparandum in disfluency can be categorized as repetition, deletion and substitution (McDougall and Duckworth, 2017), as shown in Table 1. Repetition occurs when linguistic materials repeat, usually in form of partial words, words or short phrases. Substitution occurs when linguistic materials are replaced in order to clarify a concept or idea. Deletion, also known as false restart, refers to abandoned linguistics materials.

Neural models have achieved reasonable performance in disfluency detection on English Switchboard (SWBD) corpus (Godfrey et al., 1992). Such models involve applying pretrained models to conduct disfluency detection as sequence tagging or seq2seq tasks (Wang et al., 2019, 2018). Recently, data augmentation techniques are also used to generate augmented disfluent sentences for model pretraining. Those models are limited in that the augmented data is generated based on simple heuristics such as random repetition or insertion of ngrams (Wang et al., 2019, 2018). Sentences generated

---

[1] We use reparandum and disfluent segments interchangeably in this paper.

METHODS	EXAMPLE
Random repetition	(1) ~~that 's~~ that 's really good.
Random insertion	(2) ~~of a~~ that 's really good.
Generation (ours)	(3) ~~it 's~~ that 's really good.
Generation (ours)	(4) that would ~~be more~~ be worth doing.

Table 2: Disfluent text generated from random repetition, insertion, and our Disfluency Generation model

by such methods do not resemble natural disfluent sentences and have different distribution of disfluency patterns from original sentences in SWBD dataset. For example, in Table 2, the random insertion of "*of a*" to the example (2) "*of a that's really good*" results in a quite unnatural disfluent text, not representative of our disfluency corpus nor most commonly used practices. As a result, most sentences generated by random insertion are inefficient as augmented samples, and even lead models to deviate from SWBD dataset. This is also supported by Gontijo-Lopes et al. (2020) that suggested the augmented data should have high affinity to the original dataset. Furthermore, based on our small corpus studies, we observed that current disfluency detection models usually struggle with substitution and deletion based disfluencies, largely due to the under-representation of substitution and deletion in current training corpus. Disfluent sentences generated by random repetition or insertion rarely contain substitutions, and are thus inadequate in introducing diverse forms of disfluency.

To address this gap, we propose a generation based data augmentation method to generate natural and diverse disfluent sentences to further improve the performance of disfluency detection. This method is similar to back-translation (Edunov et al., 2018), which has been shown effective as a way of data augmentation in machine translation. Different from classical neural generation models, our generation model is in a two-stage generation manner, motivated by coarse-to-fine decoding (Dong and Lapata, 2018). Specifically, given a fluent sentence as the input, in the first stage, a *Planner* selects the positions of where to insert reparandum; in the second stage, a *Generator* generates disfluent segments accordingly for the predicted areas. Compared to generic end-to-end generation, our two-stage model separates the generation task into two steps: where to generate and what to generate. Such breakdown enables the model to only generate disfluent segments rather than the whole disfluent sentences, and to carry naturally labeled data as augmentation for disfluency detection. As shown in Table 2, the outputs (3) and (4) from our two-stage Planner-Generator model resemble natural disfluent sentences better than random insertion (2), and also introduces more substitutions (example (3) and (4)). We then utilize this Planner-Generator disfluency generation to create augmented training data for the task of disfluency detection. As an additional benefit, the disfluent texts generated by our generation model can be used as inputs of text-to-speech (TTS) systems to generate more natural speech, thus improving the performance of tasks like automatic film dubbing, robotics, dialogue systems, or speech-to-speech translation, as shown by Betz et al. (2015) and Adell et al. (2006).

To sum up, our contributions are as follows:

- We design a simple two-stage Planner-Generator generation model to generate disfluent texts, and demonstrate its effectiveness over various generation baseline models.
- We utilize our generation model to generate natural and diverse augmented disfluent data for the task of disfluency detection, and obtain state-of-the-art performance. We conduct thorough error analysis and discuss specific challenges faced by current approaches.

2 Related Work

Disfluency Generation Betz et al. (2015) and Adell et al. (2006) used heuristic rules to generate filled pauses, repetitions in disfluent speech generation. Their works demonstrate that disfluency generation enhances the naturalness and intelligibility of speech generated by text-to-speech (TTS) systems. Wang et al. (2018) and Wang et al. (2019) randomly inserted or repeated ngrams to generate augmented disfluent sentences. Disfluent sentences generated in this method have low affinity to disfluent sentences from the benchmark dataset, and they contain few substitutions, causing limited diversity. To achieve better affinity and diversity, we design generation based data augmentation which generates natural disfluent sentences that can then be directly used to train the disfluency detection model. We adapt multi-stage coarse-to-fine neural decoders (Dong and Lapata, 2018) for generation tasks to design our disfluency generation model.

Disfluency Detection Disfluency detection models mainly fall into four categories. The first one utilizes noisy channel models (Zwarts and Johnson, 2011; Lou and Johnson, 2018), which require Tree

Adjoining Grammar (TAG) based transducer in the channel model. The second category leverages phrase structure, which is often related to transition-based parsing yet requires annotated syntactic structure (Rasooli and Tetreault, 2013; Yoshikawa et al., 2016; Wu et al., 2015; Jamshid Lou and Johnson, 2020). The third category frames the task as a sequence tagging task (Ferguson et al., 2015; Hough and Schlangen, 2015; Zayats et al., 2016; Lou and Johnson, 2018; Wang et al., 2019), and the last one employs end-to-end Encoder-Decoder models (Wang et al., 2016, 2018) to detect disfluent segments automatically. Traditional disfluency detection models often required additional features (e.g. POS tags) (Wang et al., 2017), syntactic annotations or external tools (e.g. TAG based transducer) (Lou and Johnson, 2018) for learning. Recent disfluency detection approaches leveraged neural representations and obtained comparable results. For instance, Lou et al. (2018) adopted CNN and introduced the Auto-Correlation Operator which models more accurate word relations and similarities in order to capture "rough copies". However, most of them still heavily depend on human-annotated data. As a result, different kinds of data augmentation approaches and pretraining have been designed to alleviate such dependence. For example, Bach and Huang (2019) incorporated ELMo (Peters et al., 2018) to sequence tagging model and Dong et al. (2019) used a pretrained denoising auto-encoder to initialize the encoder-decoder model. Wang et al. (2019) achieved state-of-the-art performance by using data augmentation and BERT (Devlin et al., 2018) in a sequence tagging task, and Wang et al. (2018) obtained similar performance by using the same data augmentation methods in an encoder-decoder fashion. These aforementioned data-augmentation methods created augmented disfluent sentences only by randomly inserting or repeating ngrams. To this end, we introduce generation based data augmentation to first generate disfluencies and then use them for sequence tagging of disfluency detection. Note that there was a similar trend in grammatical error detection. Felice and Yuan (2014); Kasewa et al. (2018) generated sentences with grammatical errors to augment the training data of grammatical error detection.

3 Method

3.1 Disfluency Generation

Our goal is to generate a natural disfluent sentence from a fluent sentence. For this purpose, we introduced a Planner and Generator based model, as shown in Figure 2, which is described as follows.

Let $\boldsymbol{x} = x_1, x_2, \cdots, x_{|x|}$ denote a fluent sentence, $\boldsymbol{y} = y_1, y_2, \ldots, y_{|y|}$ denote the corresponding disfluent sentence. We estimated $p(\boldsymbol{y}|\boldsymbol{x})$ via a two stage generation process:

$$p(\boldsymbol{y}|\boldsymbol{x}) = p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{a})p(\boldsymbol{a}|\boldsymbol{x}), \tag{1}$$

where $\boldsymbol{a} = a_1, a_2, \ldots, a_{|a|}$ is a decision sequence with the same length as $\boldsymbol{x}$. a_i is either 1 or 0, which represents whether a disfluent segment (reparandum) should be added after x_i or not. We assumed a_i are independent of each other and further decomposed our objective as follows:

$$p(\boldsymbol{a}|\boldsymbol{x}) = \prod_i p(a_i|\boldsymbol{x}) \tag{2}$$

$$p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{a}) = \prod_j p(y_j|y_{<j}, \boldsymbol{x}, \boldsymbol{a}) \tag{3}$$

Planner At the first *Planning* stage, we used an encoder e_1 to obtain representations of $\boldsymbol{x}$:

$$\boldsymbol{h} = h_1, h_2, \cdots, h_{|x|} = f_{e_1}(x_1, x_2, \cdots, x_{|x|}) \tag{4}$$

Then we used $\boldsymbol{h}$ to get the decision probability a_i:

$$p(a_i|\boldsymbol{x}) = \mathrm{softmax}(W_1 h_i + b_1) \tag{5}$$

Generator: Encoder We used another encoder e_2 to get the representations of $\boldsymbol{x}$ as the conditional state of the second stage:

$$\hat{\boldsymbol{h}} = \hat{h}_1, \hat{h}_2, \cdots, \hat{h}_{|x|} = f_{e_2}(x_1, x_2, \cdots, x_{|x|}) \tag{6}$$

Encoder e_1 and e_2 can be Bidirectional LSTM or Transformer (Vaswani et al., 2017).

Generator: Decoder $p(y_j|y_{<j}, \boldsymbol{x}, \boldsymbol{a})$ was computed based on the output $(\bar{h}_j)$ of the corresponding step of decoder. As shown in Figure 2, in our **PG** model, the input z_j of j-th step of decoder is determined by the value of corresponding a_i (E is the embedding layer of decoder):

$$z_j = \begin{cases} h_i & \text{if } a_i = 0 \text{ or } (a_i = 1 \text{ and} \\ & y_j \text{ is the first word of reparandum)} \\ E(y_{j-1}) & \text{otherwise,} \end{cases} \tag{7}$$

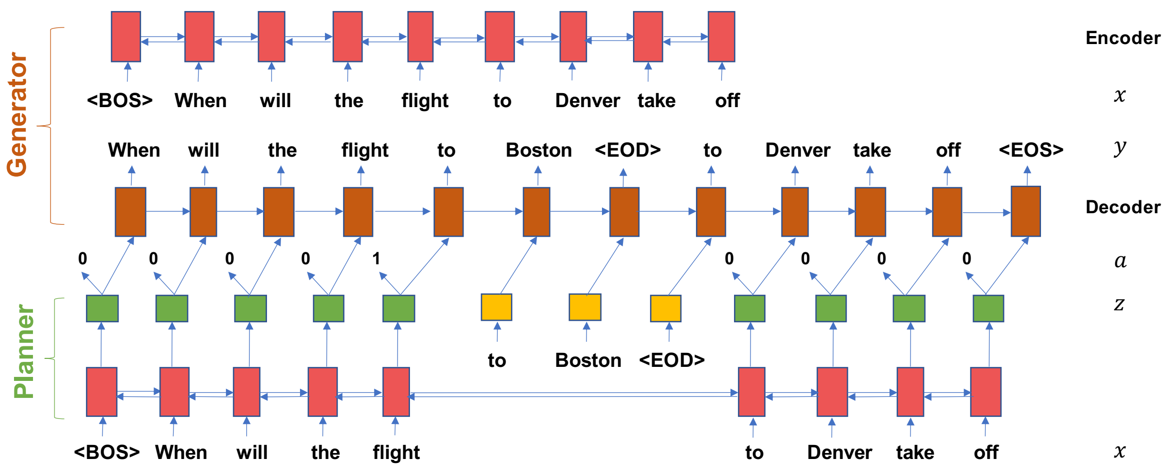

Figure 2: Our two-stage disfluency generation model with Planner and Generator (PG model).

Alternatively, to make the model focus less on local contexts for less copied words, we can use a decoder with less connection with Planner **(PG-LC)**:

$$z_j = \begin{cases} E(x_i) & \text{if } a_i = 0 \\ h_i & \text{if } a_i = 1 \text{ and} \\ & y_j \text{ is the first word of reparandum} \\ E(y_{j-1}) & \text{otherwise,} \end{cases} \tag{8}$$

We can also use a decoder with no connection with Planner **(PG-NC)**, where we separate Generator from Planner and only use the decision sequence to guide generation. This modification is the basis of the models with higher generation diversity:

$$z_j = \begin{cases} E(x_i) & \text{if } a_i = 0 \text{ or } (a_i = 1 \text{ and} \\ & y_j \text{ is the first word of reparandum}) \\ E(y_{j-1}) & \text{otherwise,} \end{cases} \tag{9}$$

We used LSTM as the decoder, and the decoder's hidden vector at the j-th time step is computed by

$$\bar{h}_j = f_{\text{LSTM}}(\bar{h}_{j-1}, z_j) \tag{10}$$

where $\bar{h}_0 = \hat{h}_{|x|}$ if we use the last hidden state of encoder to initialize the first state of decoder; $\bar{h}_0 = \mathbf{0}$ if we do not use such initialization **(ID)**, decreasing the decoder's dependence on the encoder for high diversity of generated disfluent segments.

Based on encoder's hidden vectors $\hat{\boldsymbol{h}}$ and decoder's hidden vectors $\bar{\boldsymbol{h}}$, we used attention and copying mechanism to compute $p(y_j|y_{<j}, \boldsymbol{x}, \boldsymbol{a})$, similarly to See et al. (2017). Alternatively, we also computed it without attention **(AD)** or copying mechanism **(CD)** for high diversity of the generated reparandum. The decoder can also be replaced with Transformer or GPT2 (Radford et al., 2019).

Training and Inference The training objective is to maximize the log likelihood of the disfluent sentence given the fluent sentence:

$$\max \sum_{(\boldsymbol{x},\boldsymbol{a},\boldsymbol{y})\in\mathcal{D}} \log p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{a}) + \log p(\boldsymbol{a}|\boldsymbol{x}), \tag{11}$$

here $\mathcal{D}$ represents all training pairs.

During inference stage, Planner chose 0 or 1 with higher probability in each step to generate the decision sequence $\boldsymbol{a}$. Alternatively, the Planner can also be an oracle Planner, whose predictions are gold decision sequences for the purpose of higher accuracy, or a heuristic Planner, whose predictions are selected according to simple heuristics for higher diversity in data augmentation. When generating the final disfluent sentence $\boldsymbol{y}$, assume y_j is generated based on a_i. If $a_i = 0$, we directly copy x_{i+1} as y_j; if $a_i = 1$, the Generator generates a sequence of words as reparandum before copying x_{i+1}.

3.2 Disfluency Detection

We regarded the disfluency detection task as a sequence tagging task. We denoted i-th sentence with T words as $s_i = \{w_t | t = 1, \ldots, T\}$, the input of our model is $\{s_1, s_2, \ldots, s_N\}$, where N is the number of sentences in the dataset. The corresponding output is $\{q_1, q_2, \ldots, q_N\}$, where q_i is the label sequence of i-th sentence, $q_i = \{l_t | t = 1, \ldots, T\}$. $l_t \in \{I, O\}$, where I (O) represents that the word is in (or outside) the region of reperandum.

3.2.1 Heuristic based Data Augmentation

Pretraining the model on augmented data has been proved as effective (Wang et al., 2019, 2018) before training the model on the SWBD dataset. Note that, compared to multi-task learning and using Sentence Pair Classification Task as an auxiliary task by Wang et al. (2019), our study mainly focuses on sequence tagging pretraining. To generate an augmented disfluent sentence for any fluent sentence, we followed the augmentation method in Wang et al. (2019). First we used the heuristic of randomly choosing one to three positions in a fluent sentence. Then, for each position k:

- *Insertion* : we randomly picked a m-gram (m is randomly selected from one to six) from the news corpus and inserted it to the position k.
- *Repetition* : m (the length of repeated words, randomly selected from one to six) words starting from the position k were repeated.

3.2.2 Generation based Data Augmentation

These augmented sentences generated from *Insertion* are often not natural, since those inserted m-grams are randomly picked from the whole corpus which may be irrelevant to the current sentence. This creates large discrepancies between the distribution of augmented sentences and the original corpus, and further hinders the effectiveness of augmented data. To introduce more natural and diverse generated disfluencies, we introduced this generation based data augmentation mode:

- *Generation*: we used our PG-based model to generate reparandum starting from position k.

3.2.3 Sequence Tagging

For the sequence tagging model, instead of using Transformer or the combination of trainable Transformer and frozen BERT as Wang et al. (2019) did, we directly adopted trainable BERT for both pretraining and fine tuning. First we got the probability of labels of each word:

$$\begin{aligned} \{h_1, h_2, \ldots, h_T\} &= \text{BERT}(\{w_1, w_2, \ldots, w_T\}) \\ p_t &= \text{softmax}(W h_t + b) \end{aligned} \tag{12}$$

Eventually, the goal of the model is to minimize the objective, the cross-entropy (CE) loss:

$$L = \mathbb{E}_{(s,l)} \sum_{t=1}^{T} \text{CE}(l_t, p_t) \tag{13}$$

4 Experiments and Results

4.1 Dataset

For disfluency detection, we used English Switchboard Dataset. Similar to Charniak and Johnson (2001), we split the dataset to training set sw23[$\star$].dps, development set sw4[5-9][$\star$].dps, and test set sw4[0-1][$\star$].dps. Following Hough and Schlangen (2015), we lower-cased the text and removed all punctuation and partial words. For disfluency generation, all sentences with reparandum were treated as disfluent sentences. Specifically, our training set contains 29k disfluent sentences out of 173k sentences. In development set, 2k sentences in a total of 10k sentences are disfluent sentences. In test set, 1.6k sentences out of 7.9k sentences are disfluent sentences.

4.2 Evaluation

To measure whether generated disfluent sentences are natural, we compared them with reference disfluent sentences based on two generation related metrics: BLEU (Papineni et al., 2002) and Sentence Accuracy, i.e. the percentage of the generated sentences that exactly match the ground-truth disfluent sentences.

Furthermore, we evaluated the naturalness of model outputs according to human judgment. Due to budget issue, we only selected the model (PG-NC-AD-ID) and the baseline (*Insertion* & *Repetition*) with the highest diversity based on automatic measures. For those two models, we randomly selected 100 generated disfluent sentences and they were assessed on Amazon Mechanical Turk. We elicited 3 responses per HIT. For each sentence, *Natural* was marked with a score of one, *Unnatural* sentences with 0.5, and zero for *Incomprehensible* ones. Average Human-evaluated Naturalness (HN) score thus ranged from 0 (worst) to 1 (best).

We also designed metrics to measure the diversity of disfluent segments, similarly to Li et al. (2015). Specifically, we calculated the number of new unigrams and bigrams in the generated disfluent segments. The value was scaled by the total number of generated tokens in the disfluent segments (shown as Diverse-1 and Diverse-2 in Table 3). To evaluate disfluency detection, we used standard metrics: Precision, Recall and F-score.

4.3 Training Details

For disfluency detection, we used BERT-base-uncased (Wolf et al., 2019). In both pretraining

	Without Oracle Decision					With Oracle Decision

and fine-tuning stages, we used Adam optimizer with learning rate 1e-5 and batch size 32. For disfluency generation, we trained LSTM with learning rate 1e-2 and Transformer with learning rate 1e-4.

4.4 Models and Baselines

For pretraining, we followed Wang et al. (2019) to use WMT2017 monolingual language model training data as unlabeled data. The data augmentation methods in Section 3.2 were used to generate augmented disfluent sentences. Wang et al. (2019) used 3 million sentences in the sequence tagging task and 9 million sentence pairs in the sentence classification task. We used 3 million sentences for fair comparison and also experimented with 20 million sentences to examine the effect of data size. In Table 4, we show the composition of augmented sentences in all of our models. Note that Wang et al. (2018) and Bach and Huang (2019) treated interregnum and reparandum types equally as disfluent segments when training and evaluating their models, while others in Table 5 only focused on reparandum which is more difficult to detect. Bach and Huang (2019) used a different way of splitting training and development set, whose training set had more data. Given the different setups, we did not compare with Wang et al. (2018) and Bach and Huang (2019).

For disfluency generation, we applied various combinations of our model settings described in 3.1. In **PG-Transformer**, encoders and decoders are all Transformer, while all the other models use LSTM. Planner-Generator (**PG**), PG with less Planner-Generator connection (**PG-LC**), and PG with no Planner-Generator connection (**PG-NC**) are models that generate relatively natural disfluent sentences (high BLEU and Sent Acc). For higher diversity, **PG-CD** is PG without copying mechanism. Likewise, **PG-NC-CD** is PG-NC without copying mechanism, while **PG-NC-AD** is PG-NC without attention mechanism. In the extreme case, **PG-NC-AD-ID** is PG-NC without attention mechanism and encoder-Initialized decoder for high diversity. We used Simple Copy (directly copy input as output), Random *Insertion* & *Repetition* of ngrams, LSTM and Attention based Seq2Seq model, CopyNet and pretrained BART as baselines.

Since our models enable the control of generating reparandum based on any given decision sequences, we examined their performances with and without oracle decision sequences, i.e. the positions of the reparandum in generated sentences are the same as the references.

In order to use our model to generate diverse disfluent sentences, we experimented with different variants of PG and found PG-NC-AD-ID produced better performances. Thus we finally chose PG-NC-AD-ID and the heuristic Planner applying the position choosing heuristic described in Section 3.2.1, since the model-based Planner always chose certain most probable positions, and generated less diverse disfluent sentences, which did not work well as augmented data GPT2 was used to replace the LSTM decoder and trained on a partial pretraining dataset to alleviate the domain gap.

	Setting	Precision	Recall	F-score
LSTM (Zayats et al., 2016)	seq-tagging & ad-hoc features	0.878	0.711	0.786
semi-CRF (Ferguson et al., 2015)	seq-tagging & ad-hoc features	0.900	0.812	0.854
Bi-LSTM (Zayats et al., 2016)	seq-tagging & ad-hoc features	0.918	0.806	0.859
LSTM-NCM (Lou and Johnson, 2018)	seq-tagging	-	-	0.868

Transformer (Wang et al., 2019)	seq-tagging & multitask & 3M pretraining	0.934	0.873	0.902
Transformer & BERT (Wang et al., 2019)	seq-tagging & multitask & 3M pretraining	-	-	0.914
BERT (ours)	seq-tagging	0.949	0.867	0.906
BERT-G3 (ours)	seq-tagging & 3M pretraining	0.946	0.878	0.911
BERT-RI3 (ours)	seq-tagging & 3M pretraining	0.951	0.881	0.915
BERT-GR3 (ours)	seq-tagging & 3M pretraining	0.946	0.890	0.917
BERT-GRI3 (ours)	seq-tagging & 3M pretraining	**0.951**	**0.894**	**0.922**†
BERT-GRI20 (ours)	seq-tagging & 20M pretraining	0.945	**0.902**	**0.923**

Table 5: Results of disfluency detection. F-score is the major metric. "ours" represents our implementations. The mark † denotes that the results are significant with the significance level $p < 0.05$. Specifically, p-value is 0.0003 comparing BERT-GRI3 and BERT. p-value is 0.0259 comparing and BERT-GRI3 and BERT-RI3.

4.5 Disfluency Generation Result

Table 3 shows the disfluency generation results. Despite its relatively high diversity, *Insertion & Repetition* baseline had a low BLEU score and an almost zero Sent Acc, which indicates that disfluent sentences generated in such manners are neither natural nor similar to real disfluency distributions in SWBD dataset. Simple Copy baseline maintained high BLEU yet failed to generate any disfluent sentences with zero Sent Acc. Other neural baselines were able to achieve reasonable BLEU and Sent Acc. However, their results could not serve as augmented data to pretrain sequence tagging models, since there was no indication where were the disfluent segments in output sentences.

All of our proposed PG-based models outperformed *Insertion & Repetition* in terms of BLEU and Sent Acc, which shows that our generated results were closer to natural disfluent sentences than random *Insertion & Repetition* of ngrams were. Among our models, PG-Transformer, PG and PG-LC generated the most natural disfluent sentences, leading to the highest BLEU and Sent Acc. Our LSTM-based models PG and PG-LC outperformed all of the baselines in terms of Sent Acc and BLEU, despite that PG-Transformer was slightly overshadowed by CopyNet in terms of Sent Acc. The performance boost of our PG based models mainly came from our two-stage Planner-Generator process, since the hidden states of the first stage were used as initial input to guide the generation of reparandum in the second stage.

We found that without copying mechanism , PG-CD model harmed Sent Acc but would not drastically decrease BLEU compared with PG. Without the state passing between Planner and Generator Decoder, PG-NC severely harmed Sent Acc as well as BLEU, while it improved the generation diversity. Without copying mechanism and state passing (PG-NC-CD), the diversity boosted significantly. This demonstrates that copying mechanism and state passing between Planner and Generator Decoder together forced the model to generate repetitions. The deletion of those two mechanisms were responsible for increased substitutions and deletions and decreased repetitions in results, leading to a higher diversity of disfluent sentences.

Without the attention between Generator Encoder and Generator Decoder, PG-NC-AD had little improvement in diversity compared to PG-NC-CD. However, when deleting the mechanism of using the last state of Generator Encoder as the initial state of Generator Decoder (PG-NC-AD-ID), diversity increased substantially. This made the Generator Decoder an unconditional language model trained on the dataset. Although the PG-NC-AD-ID model decreased BLEU and Sent Acc, it still generated more natural disfluent sentences than *Insertion & Repetition*, as demonstrated by higher automatic evaluation metrics (BLEU, Sent Acc) and human evaluation metric (HN). Considering that PG-NC-AD-ID outperformed *Insertion & Repetition* in all metrics, we used this model to generate diverse and natural augmented disfluent sentences for disfluency detection. As we expected, with oracle decision sequences, nearly all models achieved significantly better BLEU and Sent Acc.

4.6 Disfluency Detection Result

We used the above generation based augmented data to further improve disfluency detection. The

	Repetition	Substitution	Deletion
Insertion & Repetition	46.64%	13.14%	40.22%
PG	85.68%	13.08%	1.24%
PG-NC-AD-ID	19.80%	25.27%	54.93%

Table 6: Different types of generated disfluecies.

	Repetition	Substitution	Deletion
BERT	0.64%	8.51%	2.74%
BERT-RI3	0.35%	8.83%	2.68%
BERT-GR3	0.40%	8.10%	2.95%
BERT-GRI3	0.40%	7.60%	2.60%

Table 7: The percentage of false negative errors in reference test set of disfluency detection (lower is better).

Type	Count	Percentage
Noisy Annotation	112	24.83%
Substitution (False Negative)	103	22.84%
Deletion (False Negative)	90	19.96%
Repetition (False Negative)	45	9.98%
Ambiguous	38	8.43%
False Positive	21	4.66%
Other	42	9.31%

Table 8: Challenge types in disfluency detection. Ambiguous are cases where annotations and predictions are both correct.

results are shown in Table 5. We found that BERT without pretraining already achieved competitive results. BERT-G3 performed better than BERT, showing the effectiveness of our generation based data augmentation. Our BERT-RI3 performed similarly to Wang et al. (2019), although we did not use Sentence Pair Classification Task as an auxiliary task during pretraining. The reason might be that we fine-tuned the BERT model during both pretraining and SWBD training, while Wang et al. (2019) trained a Transformer during these stages and combined it with a fixed BERT when training on SWBD. Overall, when using *Repetition & Insertion* to do data augmentation, BERT-RI3 performed better than BERT.

After replacing *Insertion* with *Generation*, BERT-GR3 outperformed BERT-RI3 and Wang et al. (2019). When adding *Generation* upon *Repetition* and *Insertion*, BERT-GRI3 achieved even better performance, a new state-of-the-art performance. We also did significance test with Bootstrap (Berg-Kirkpatrick et al., 2012), BERT-GRI3 significantly outperformed BERT-RI3 and BERT with significance level p=0.0259 and p=0.0003 respectively. This not only demonstrated the effectiveness of our disfluency generation based data augmentation, but also showed that disfluencies generated by our generation model are orthogonal to those generated by *Insertion & Repetition*. A comparison between the precision and recall of BERT-GRI3 and BERT revealed that the improvements of pretraining mainly come from its higher recall, indicating that pretraining can help the model to detect more disfluencies while obtaining similar accuracies. When pretraining data size was increased, BERT-GRI20 did not significantly outperform BERT-GRI3.

Impact of Augmented Disfluency Types: We summarized different types of generated disfluencies in Table 6 to show how our model contributed to disfluency detection. *Insertion & Repetition* generated limited substitutions, which caused a lack of natural and diverse disfluencies. Although our PG model achieved state-of-the-art performance in terms of BLEU and Sent Acc, it mainly generated repetitions, leading to low diversity. This was potentially caused by two factors. First, the disfluent segments in the training dataset were dominated by 65.39% repetitions, in comparison to 18.99% substitutions and 15.62% deletions. Second, copying words and phrases during generation for neural models proved to be the most convenient and consistent approach, even without copying mechanism. Our PG-NC-AD-ID model generated more substitutions and deletions compared with PG, leading to the highest diversity. Compared to random *Insertion & Repetition*, it also generated substantially more substitutions, leading to a more effective data augmentation. The decreased number of repetitions can be fixed by combining it with random repetition, like BERT-GR3. Table 7 presents the proportion that was not identified by our disfluency detection models among all repetitions, substitutions and deletions in reference test set. Comparing our generation based augmentation (BERT-GRI3 and BERT-GR3) with other methods (BERT-RI3 and BERT), we found that pretraining on our generated data can reduce substitution errors and improve the final metric recall in Table 5, contributed by increased natural substitutions generated by our disfluency generation model.

4.7 Error Analysis and Challenges

We manually annotated the errors made by our disfluency detection model case by case, and presented a thorough error analysis in terms of different types of errors in Table 8. Note that nearly one fourth "wrong" predictions were in fact correct. These mismatches were caused by improper annotation. For example, the sentence "*the thing* *is is that's not enough*" was annotated as a fluent sentence, while the first "is" should be reparandum. Similar noisy annotation issues in the SWBD dataset were a major hindrance to achieving higher performance. With respect to other errors, we saw much more false negatives than false positives. Among false negatives, errors were dominated by substitutions and deletions, although the proportion of repetitions (65.39%) was much more than substitutions (18.99%) and deletions (15.62%) in the original SWBD dataset. This showed that current models do relatively well in identifying repetitions, while detecting substitutions and deletions is still challenging for the model.

5 Conclusion

This work presents a simple two-stage disfluency generation model to generate natural and diverse disfluent texts. We further used them as augmented data for pretraining and aiding the task of disfluency detection. Experiments demonstrate that our proposed disfluency generation model outperformed existing baselines; those disfluent sentences generated significantly aided the task of disfluency detection and led to state-of-the-art performances.

A Model Parameters

A.1 Disfluency Detection

In disfluency detection, we used BERT-base-uncased (Wolf et al., 2019) for sequence tagging. In both pretraining and fine-tuning stages, we used Adam optimizer with learning rate 1e-5 (searched from [1e-4, 1e-5]) and batch size 32. Hyper-parameters were searched manually according to F-score. We ran 20 epochs for pretraining and ran 20 epochs for training on SWBD dataset. After each epoch, we decayed the learning rate by 0.985.

A.2 Disfluency Generation

For disfluency generation, we used one-layer LSTM with hidden size 300 and a dropout of 0.5 (searched from [0.1, 0.3, 0.5]), and then trained it with learning rate 1e-2 (searched from [1e-2, 1e-3]). Alternatively, we used Transformer with 512 hidden units in attention layer, 2048 hidden units in feed-forward layer, 8 heads, 6 hidden layers, GELU activation (Hendrycks and Gimpel, 2016), and a dropout of 0.1 (searched from [0.1, 0.3, 0.5]), and then trained it with learning rate 1e-4 (searched from [1e-3, 1e-4, 1e-5]). Hyper-parameters were searched manually according to Sent Acc. As we expected, the performance of Transformer is more sensitive to learning rate than LSTM. We used Adam optimizer and batch size 64 for both of them. After each epoch, we decayed the learning rate by 0.985. We trained them for 30 epochs. When we used GPT2 (Wolf et al., 2019) as decoder, it was trained on another 3M WMT2017 mono-lingual language model training data for 10 epochs.

B Computational Requirements

We ran our models on GeForce RTX 2080 GPU. Each disfluency generation model required 1 hour to finish training (GPT2 and Transformer required 4 hours). Each disfluency detection model required 2 hours to finish training on SWBD data. Pretraining disfluency detection models on 3M data required 5 days on 1 GPU. Pretraining models on 20M data required 7 days on 4 GPUs.

C Evaluation Metrics

As for metrics, we used NLTK to compute BLEU. Other metrics are computed by our scripts written according to descriptions in the paper. Metrics on validation sets were close to those reported on test sets for all experiments.

As for Human-evaluated Naturalness on AMT, we provided the description and example sentences of three levels of disfluent sentences (incomprehensible, unnatural and natural). For example, ”Natural disfluent sentence” is ”Perfectly natural speech. Similar to the talk you could probably have with someone in life.” To improve annotation quality, annotators should have >5000 HITs approved, >98% HIT Approval Rate and located in the US. We also require annotators to pass a qualification test consisting of samples with expected answers before they work on the annotation, to make sure that they have a good understanding of our task. Annotators are paid $0.08 for annotating each sentence, and each sentence was rated by three workers.

D Dataset

SWBD dataset is a part of PDTB and WMT2017 mono-lingual language model training data can be downloaded from News Crawl: articles from 2016.

Predicting Clinical Trial Results by Implicit Evidence Integration

Abstract

Clinical trials provide essential guidance for practicing Evidence-Based Medicine, though often accompanying with unendurable costs and risks. To optimize the design of clinical trials, we introduce a novel Clinical Trial Result Prediction (CTRP) task. In the CTRP framework, a model takes a PICO-formatted clinical trial proposal with its background as input and predicts the result, i.e. how the **I**ntervention group compares with the **C**omparison group in terms of the measured **O**utcome in the studied **P**opulation. While structured clinical evidence is prohibitively expensive for manual collection, we exploit large-scale unstructured sentences from medical literature that implicitly contain PICOs and results as evidence. Specifically, we pre-train a model to predict the disentangled results from such implicit evidence and fine-tune the model with limited data on the downstream datasets. Experiments on the benchmark Evidence Integration dataset show that the proposed model outperforms the baselines by large margins, e.g., with a 10.7% relative gain over BioBERT in macro-F1. Moreover, the performance improvement is also validated on another dataset composed of clinical trials related to COVID-19.

1 Introduction

Shall COVID-19 patients be treated with hydroxychloroquine? In the era of Evidence-Based Medicine (EBM, Sackett 1997), medical practice should be guided by well-designed and well-conducted clinical research, such as randomized controlled trials. However, conducting clinical trials is expensive and time-consuming. Furthermore, inappropriately designed studies can be devastating in a pandemic: a high-profile Remdesivir clinical trial fails to achieve statistically significant conclusions (Wang et al., 2020b), partially because it does not attain the predetermined sample size when "competing with" other inappropriately designed trials that are unlikely to succeed or not so urgent to test (e.g.: physical exercises and dietary treatments). Therefore, it is crucial to carefully design and evaluate clinical trials before conducting them.

Proposing new clinical trials requires support from previous evidence in medical literature or practice. For example, the World Health Organization (WHO) has launched a global megatrial, Solidarity (WHO, 2020), to prioritize clinical resources by recommending only four most promising therapies[1]. The rationale for this suggestion comes from the integration of evidence that they might be effective against coronaviruses or other related organisms in laboratory or clinical studies (Peymani et al., 2016; Sheahan et al., 2017; Morra et al., 2018). However, manual integration of evidence is far from satisfying, as one study reports that about 86.2% of clinical trials fail (Wong et al., 2019) and even some of the Solidarity therapies do not get expected results (Mehra et al., 2020).

To assist clinical trial designing, we introduce a novel task: Clinical Trial Result Prediction (CTRP), i.e. predicting the results of clinical trials without actually doing them (§3). Figure 1 shows the architecture of the CTRP task. We define the input to be a clinical trial proposal[2], which contains free-texts of a **P**opulation (e.g.: "COVID-19 patients with severe symptoms"), an **I**ntervention (e.g.: "Active remdesivir (i.v.)"), a **C**omparator (e.g.: "Placebos matched remdesivir") and an **O**utcome (e.g.:"Time to clinical improvement"), i.e. a PICO-formatted query (Huang et al., 2006), and the background of the proposed trial. The output is the trial **R**esult, denoting how (higher, lower, or no difference) I

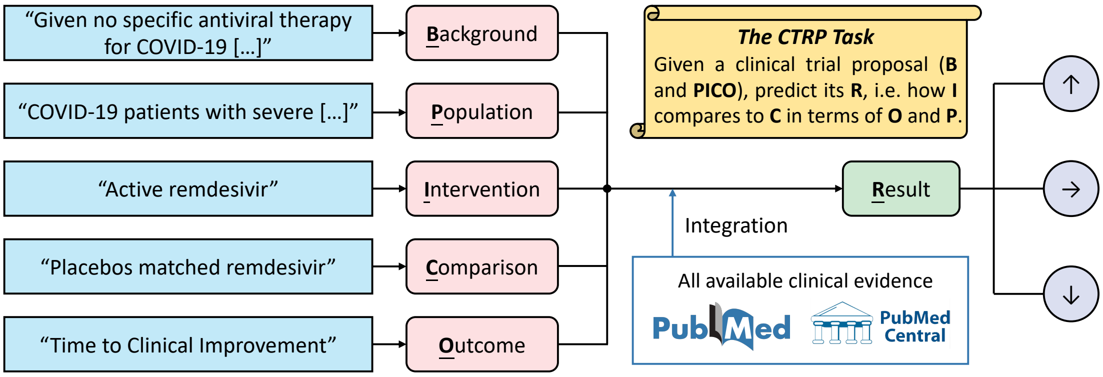

Figure 1: Architecture of the proposed Clinical Trial Result Prediction (CTRP) task.

compares to C in terms of O for P.

One particular challenge of this task is that evidence is entangled with other free-texts in the literature. Prior works have explored *explicit* methods for evidence integration through a pipeline of retrieval, extraction and inference on structured {P,I,C,O,R} evidence (Wallace et al., 2016; Singh et al., 2017; Jin and Szolovits, 2018; Lee and Sun, 2018; Nye et al., 2018; Marshall et al., 2017; Lehman et al., 2019; DeYoung et al., 2020; Zhang et al., 2020). However, they are limited in scale since getting domain-specific supervision for all clinical evidence is prohibitively expensive.

In this work, we propose to *implicitly* learn from such evidence by pre-training, instead of relying on *explicit* evidence with purely supervised learning. There are more than 30 million articles in PubMed[3], which stores almost all available medical evidence and thus is an ideal source for learning. We collect 12 million sentences from PubMed abstracts and PubMed Central[4] (PMC) articles with comparative semantics, which is commonly used to express clinical evidence (§4.1). P, I, C, O, and R are entangled with other free-texts in such sentences, which we denote as implicit evidence. Unlike previous efforts that seek to disentangle all of PICO and R, we only disentangle R out of the implicit evidence using simple heuristics (§4.2). For better learning the ordering function of I/C conditioned on P and O, we also use adversarial examples generated by reversing both the entangled PICO and the R in the pre-training (§4.3). Then, we pre-train a transformer encoder (Vaswani et al., 2017) to predict the disentangled R from the implicit evidence, which still contains PICO (§5.1). The model is named EBM-Net to reflect its utility for Evidence-Based Medicine. Finally, we fine-tune the pre-trained EBM-Net on downstream datasets of the CTRP task (§5.2), which are typically small in scale (§6).

To evaluate model performance, we introduce a benchmark dataset, Evidence Integration (§6.1), by re-purposing the *evidence inference* dataset (Lehman et al., 2019; DeYoung et al., 2020). Experiments show that our pre-trained EBM-Net outperforms the baselines (§6.2) by large margins (§6.3). Clustering analyses indicate that EBM-Net can effectively learn quantitative comparison results (§6.4). In addition, the EBM-Net model is further validated on a dataset composed of COVID-19 related clinical trials (§6.5).

Our contribution is two-fold. First, we propose a novel and meaningful task, CTRP, to predict clinical trial results before conducting them. Second, unlike previous efforts that depend on structured data to understand the totality of clinical evidence, we heuristically collect unstructured textual data, i.e. implicit evidence, and utilize large-scale pre-training to tackle the proposed CTRP task. The datasets and codes are publicly available at `https://github.com/Alibaba-NLP/EBM-Net`.

2 Related Works

Predicting Clinical Trial Results: Most relevant works typically use only specific types or sources of information for prediction (e.g.: chemical structures (Gayvert et al., 2016), drug dosages or routes (Holford et al., 2000, 2010)). Gayvert et al. (2016) predicts clinical trial results based on chemical properties of the candidate drugs. Clinical trial simulation (Holford et al., 2000, 2010) applies pharmacological models to predict the results of a specific intervention with different procedural factors, such as doses and sampling intervals. Some use closely related report information, e.g.: interim

---

[3] `https://pubmed.ncbi.nlm.nih.gov/`

[4] `https://www.ncbi.nlm.nih.gov/pmc/`

analyses (Broglio et al., 2014) or phase II data for just phase II trials (De Ridder, 2005). Our task is (1) more generalizable, since all potential PICO elements can be represented by free-texts and thus modeled in our work; and (2) aimed at evaluating new clinical trial proposals.

Explicit Evidence Integration: It depends on the existence of structured evidence, i.e.: {P, I, C, O, R} (Wallace, 2019). Consequently, collecting such explicit evidence is vital for further analyses, and is also the objective for most relevant works: Some seek to find relevant papers through retrieval (Lee and Sun, 2018); many works are aimed at extracting PICO elements from published literature (Wallace et al., 2016; Singh et al., 2017; Marshall et al., 2017; Jin and Szolovits, 2018; Nye et al., 2018; Zhang et al., 2020); the *evidence inference* task extracts R for a given ICO query using the corresponding clinical trial report (Lehman et al., 2019; DeYoung et al., 2020). However, since getting expert annotations is expensive, these works are typically limited in scale, with only thousands of labeled instances. Few works have been done to utilize the automatically collected structured data for analyses. In this paper, we adopt an end-to-end approach, where we use large-scale pre-training to *implicitly* learn from free-text clinical evidence.

3 The CTRP Task

The CTRP task is motivated to evaluate clinical trial proposals by predicting their results before actually conducting them, as discussed in §1. Therefore, we formulate the task to take as input exactly the information required for proposing a new clinical trial: free-texts of a background description and a PICO query to be investigated. Formally, we denote the strings of the input background as `B` and PICO elements as `P`, `I`, `C`, and `O`, respectively. The task output is defined as one of the three possible comparison results: higher (↑), no difference (→), or lower (↓) measurement `O` in intervention group `I` than in comparison group `C` for population `P`. We denote the result as R, and:

$$R(\mathtt{B},\mathtt{P},\mathtt{I},\mathtt{C},\mathtt{O}) = \begin{cases} \uparrow & \mathtt{O}(\mathtt{I}) > \mathtt{O}(\mathtt{C}) \mid \mathtt{P} \\ \downarrow & \mathtt{O}(\mathtt{I}) < \mathtt{O}(\mathtt{C}) \mid \mathtt{P} \\ \rightarrow & \mathtt{O}(\mathtt{I}) \sim \mathtt{O}(\mathtt{C}) \mid \mathtt{P} \end{cases}$$

Main metrics include accuracy and 3-way macro-averaged F1. We also use 2-way (↑, ↓) macro-averaged F1 to evaluate human expectations (§6.2).

4 Implicit Evidence Integration

In this section, we introduce the Implicit Evidence Integration, which is used to collect pre-training data for comparative language modeling (§5.1).

Instead of collecting explicit evidence with structured $\{\mathtt{B},\mathtt{P},\mathtt{I},\mathtt{C},\mathtt{O}-R\}$ information, we utilize a simple observation to collect evidence *implicitly*: clinical evidence is naturally expressed by comparisons, e.g.: "Blood oxygen is higher in the intervention group than in the placebo group". Free-texts of `P`, `I`, `C`, `O` and `R` are entangled with other functional words that connect these elements in such comparative sentences, where `R` is a free-text version of the structured result R (e.g.: `R` = "higher ... than" translates into $R = \uparrow$). We call these sentences entangled implicit evidence and denote them as $\mathtt{E}_{ent} = \{\mathtt{PICOR}\}$. Then, we disentangle `R` out of the $\mathtt{E}_{ent}$ by heuristics, getting `R` and the left $\mathtt{E}_{dis} = \{\mathtt{PICO}\}$. We also include adversarial instances generated from the original ones. Several examples are shown in Table 1.

Details of implicit evidence collection, disentanglement, and adversarial data generation are introduced in §4.1, §4.2 and §4.3, respectively.

4.1 Collection of Implicit Evidence

We collect implicit evidence from PubMed abstracts and PMC articles[5], where most of the clinical evidence is published. PubMed contains more than 30 million abstracts, and PMC has over 6 million full-length articles. Each abstract is chunked into a background/method section and a result/conclusion section: For the unstructured abstracts, sentences before the first found implicit evidence are included in the background/method section. For the semi-structured abstracts where each section is labeled with a section name, the chunking is done by mapping the section name to either background/method or result/conclusion.

Sentences in abstract result/conclusion sections and main texts that express comparative semantics (Kennedy, 2004) are collected as implicit evidence. They are identified by a pattern detection heuristic, similar to the keyword method described in Jindal and Liu (2006): For expressions of superiority (↑) and inferiority (↓), we detect morpheme patterns of [*more/less/-er* ... *than* ...]. For expression of equality (→), we detect morpheme patterns of [*similar* ... *to* ...] and [*no difference* ... *between* ... *and* ...]. The background/method section serves as the

Table 1: Several examples of implicit evidence. Red, violet and blue denote superiority, equality and inferiority.

corresponding $\mathtt{B}$ for the collected implicit evidence. These sentences are denoted as $\mathtt{E}_{ent}$, which contain entangled PICO-R.

We have collected 11.8 million such sentences. Among them, 2.4 million (20.2%), 3.5 million (29.9%) and 5.9 million (49.9%) express inferiority, equality and superiority respectively.

4.2 Disentanglement of Implicit Evidence

To disentangle the free-text result $\mathtt{R}$ from implicit evidence $\mathtt{E}_{ent}$, we mask out the detected morphemes that express comparative semantics (e.g.: "higher than") as well as other functional tokens that might be exploited by the model to predict the result (e.g.: p values). This generates the masked out result $\mathtt{R}$ and the left part $\mathtt{E}_{dis}$ ($\{\mathtt{PICO}\}$) from $\mathtt{E}_{ent}$ ($\{\mathtt{PICOR}\}$), i.e.: $\mathtt{R} + \mathtt{E}_{dis} = \mathtt{E}_{ent}$. $\mathtt{R}$ is mostly a phrase with a central comparative adjective/adverb (e.g.: "significantly smaller than") and can be directly mapped to R (↓ for the same example).

Nevertheless, $\mathtt{R}$ contains richer information than the sole change direction because of the central adjective/adverb. To utilize such information, we map free-texts of $\mathtt{R}$ to a finer-grained result label $r \in \mathcal{C}$ instead of the 3-way direction, where $\mathcal{C} = \{\mathtt{[POORER]}, \mathtt{[LONGER]}, \mathtt{[SLOWER]}, ...\}$ is a manually-curated vocabulary for such labels and $|\mathcal{C}| = 34$. Each element can be mapped to its antonym in $\mathcal{C}$ by a reversing function Rev: e.g.: $\text{Rev}(\mathtt{[SMALLER]}) = \mathtt{[GREATER]}$ and $\text{Rev}(\mathtt{[NODIFF]}) = \mathtt{[NODIFF]}$. This enables us to generate adversarial examples used below.

4.3 Adversarial Data Generation

We generate adversarial examples from the original ones using a simple rule of ordering: if the result r holds for the comparison $\mathtt{I}/\mathtt{C}$ conditioned on $\mathtt{P}$ and $\mathtt{O}$, the reversed result $\text{Rev}(r)$ must hold for the reversed comparison $\mathtt{C}/\mathtt{I}$ on the same condition. This is similar to generate adversarial examples for natural language inference task by logic rules (Minervini and Riedel, 2018; Wang et al., 2019).

However, Since $\mathtt{E}_{dis} = \{\mathtt{PICO}\}$ is only partially disentangled and $\mathtt{P}$, $\mathtt{I}$, $\mathtt{C}$, $\mathtt{O}$ are still in their free-text forms, we cannot explicitly reverse $\mathtt{I}/\mathtt{C}$ and generate such examples. As an alternative, we reverse the entire sentence order while keeping the word order between any two masked phrases in $\mathtt{E}_{dis}$, getting $\mathtt{E}_{rev}$. For example, if:

$\mathtt{E}_{dis}$ = "[Levels of viral antigen staining in lung sections of GS-5734-treated animals were]$_0$ [MASK] [vehicle-treated animals]$_1$."

and $r = \mathtt{[LOWER]}$, then the reversed evidence is:

$\mathtt{E}_{rev}$ = "[Vehicle-treated animals]$_1$ [MASK] [levels of viral antigen staining in lung sections of GS-5734-treated animals were]$_0$."

and $\text{Rev}(r) = \mathtt{[HIGHER]}$. This implicitly reverses the ordering direction of $\mathtt{I}$ and $\mathtt{C}$ without changing the $\mathtt{P}$ and $\mathtt{O}$.

5 EBM-Net

We introduce the EBM-Net model in this section. Similar to BERT (Devlin et al., 2019), EBM-Net is essentially a transformer encoder (Vaswani et al., 2017), and follows the pre-training – fine-tuning approach: We pre-train EBM-Net by Comparative Language Modeling (CLM, §5.1) that is designed to learn the conditional ordering function of $\mathtt{I}/\mathtt{C}$. The pre-trained EBM-Net is fine-tuned to solve the CTRP task on downstream datasets (§5.2).

5.1 Comparative Language Modeling

We show the CLM architecture in Figure 2. CLM is adapted from the masked language modeling used

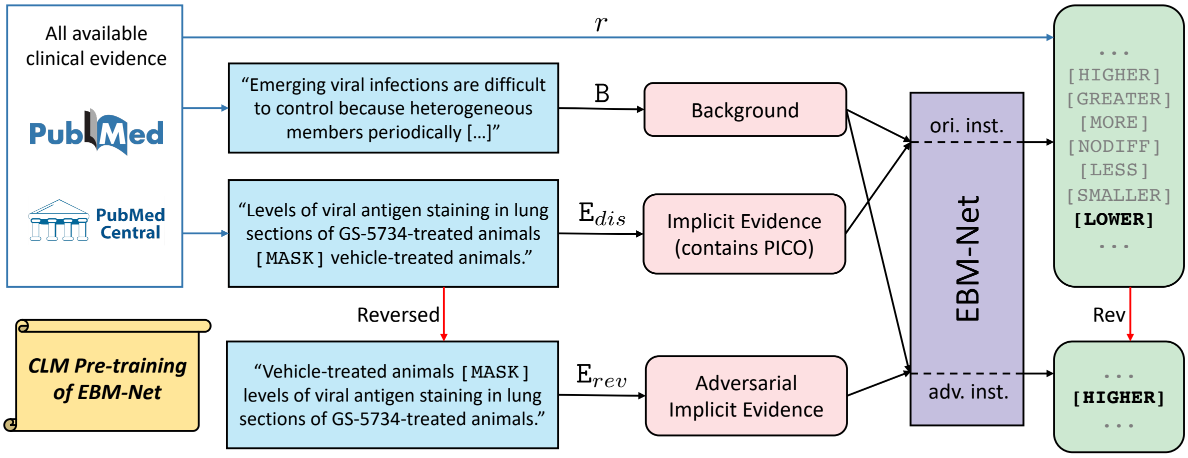

Figure 2: Architecture of CLM pre-training for EBM-Net. (ori.: original; adv.: adversarial; inst.: instance)

in BERT (Devlin et al., 2019), but differentiates from it in that: (1) EBM-Net masks out phrases $\mathtt{R}$ that suggest comparative results and predicts a specific set of comparative labels $\mathcal{C}$; (2) EBM-Net is also pre-trained on adversarial examples generated by comparison rules from the original examples.

During pre-training, EBM-Net takes as input the concatenation of background $\mathtt{B}$ and the corresponding partially disentangled implicit evidence $\mathtt{E}$, i.e.: Input $=$ [`[CLS]`, $\mathtt{B}$, `[SEP]`, $\mathtt{E}$, `[SEP]`], where `[CLS]` and `[SEP]` are the special classification and separation tokens used in the original BERT and $\mathtt{E} \in \{\mathtt{E}_{dis}, \mathtt{E}_{rev}\}$. $\mathtt{B}$ and $\mathtt{E}$ are associated with two different segment types. The special `[MASK]` tokens are only used as placeholders for the masked out $\mathtt{R}$. `[CLS]` hidden state of the EBM-Net is used to predict the CLM label r with a linear layer followed by a softmax output unit:

$$\hat{r} = \mathrm{SoftMax}(W_1 h_{\mathtt{[CLS]}} + b_1) \in [0,1]^{|\mathcal{C}|}$$

We minimize the cross-entropy between the estimated $\hat{r}$ and the empirical r distribution.

At input-level, the adversarial examples only differ from their original examples in word orders between $\mathtt{E}_{dis}$ and $\mathtt{E}_{rev}$. However, their labels are totally reversed from r to $\mathrm{Rev}(r)$. By regularizing the model to learn such conditional ordering function, CLM prevents the pre-trained model from learning unwanted and possibly biased co-occurrences between evident elements and their results.

5.2 CTRP Fine-tuning

During fine-tuning, EBM-Net takes as input the [`[CLS]`, $\mathtt{B}$, `[SEP]`, $\mathtt{E}_{exp}$, `[SEP]`], where $\mathtt{E}_{exp}$ denotes the explicit evidence in the downstream datasets of the proposed CTRP task. For example, $\mathtt{E}_{exp} = [\mathtt{I}, \mathtt{[SEP]}, \mathtt{O}, \mathtt{[SEP]}, \mathtt{C}]$ on the Evidence Integration dataset (§6.1). The sequence of PICO elements in $\mathtt{E}_{exp}$ can be tuned empirically. EBM-Net learns from scratch another linear layer that maps from the predicted CLM label probabilities $\hat{r}$ to 3-way result label R logits. The final predictions are made by a softmax output unit:

$$\hat{R} = \mathrm{SoftMax}(W_2 \hat{r} + b_2) \in [0,1]^3$$

Cross-entropy between the estimated $\hat{R}$ and the empirical R distribution is minimized in fine-tuning.

5.3 Configuration

The transformer weights of EBM-Net (L=12, H=768, A=12, #Params=110M) are initialized with BioBERT (Lee et al., 2020), a variant of BERT that is also pre-trained on PubMed abstracts and PMC articles. The maximum sequence lengths for $\mathtt{B}$, $\mathtt{E}_{dis}$, $\mathtt{E}_{rev}$, $\mathtt{E}_{exp}$ are 256, 128, 128, and 128, respectively. We use Adam optimizer (Kingma and Ba, 2014) to minimize the cross-entropy losses. EBM-Net is implemented using Huggingface's Transformers library (Wolf et al., 2019) in PyTorch (Paszke et al., 2019). Pre-training on 12M implicit evidence takes about 1k Tesla P100 GPU hours.

6 Experiments

6.1 The Evidence Integration Dataset

The Evidence Integration dataset serves as a benchmark for our task. We collect this dataset by repurposing the *evidence inference* dataset (Lehman et al., 2019; DeYoung et al., 2020), which is essentially a machine reading comprehension task for extracting the structured result (i.e.: R) of a given structured ICO query[6] from the corresponding clinical trial report article. Since clinical trial reports already contain free-text result descriptions (i.e.: `R`) of the given ICO, solving the original task does not require the integration of previous clinical evidence. To test such capability for our proposed CTRP task, we remove the result/conclusion part and only keep the background/method part in the input clinical trial report. 34.6% tokens of the original abstracts are removed on average and the remained are used as the clinical trial backgrounds.

Specifically, input of the Evidence Integration dataset includes free texts of ICO elements `I`, `C` and `O` which are the same as the original *evidence inference* dataset, and their clinical trial backgrounds `B`. The output is the comparison result R. Following the original dataset split, there are 8,164 instances for training, 1,002 for validation, and 965 for test.

We also do experiments under the adversarial setting, where adversarial examples generated by reversing both the `I/C` order and the R label (similar to §5.1) are added. This setting is used to test model robustness under adversarial attack.

6.2 Compared Methods

We compare to a variety of methods, ranging from trivial ones like Random and Majority to the state-of-the-art BioBERT model. Two major approaches in open-domain question answering (QA) are tested as well: the knowledge base (KB) approach (MeSH ontology) and the text/retrieval approach (Retrieval + Evidence Inference), since solving our task also requires reasoning over a large external corpus. Finally, we introduce some ablation settings and the evaluation of human expectations.

Random: we report the expected performance of randomly predicting the result for each instance.

Majority: we report the performance of predicting the majority class (→) for all test instances.n

Bag-of-Words + Logistic Regression: we concatenate the TF-IDF weighted bag-of-word vectors of `B`, `P`, `I`, `C` and `O` as features and use logistic regression for learning.

MeSH Ontology: Since no external KB is available for our task, we use the training set as an internal alternative: we map the `I`, `C` and `O` of the test instances to terms in the Medical Subject Headings (MeSH)[7] ontology by string matching. MeSH is a controlled and hierarchically-organized vocabulary for describing biomedical topics. Then, we find their nearest labeled instances in the training set, where the distance is defined by:

$$d(i,j) = \sum_{e \in \{\mathtt{I},\mathtt{C},\mathtt{O}\}} \min \text{TreeDist}(m_i^e, m_j^e)$$

m_i^e and m_j^e are MeSH terms identified in ICO element e of instance i and j, respectively. TreeDist is defined as the number of edges between two nodes on the MeSH tree. The majority label of the nearest training instances is used as the prediction.

Retrieval + Evidence Inference: State-of-the-art method on the *evidence inference* dataset (DeYoung et al., 2020) is a pipeline based on SciBERT (Beltagy et al., 2019): (1) find the exact evidence sentences in the clinical trial report for the given ICO query, using a scoring function derived from a fine-tuned SciBERT; and (2) predict the result R based on the found evidence sentences and the given ICO query by fine-tuning another SciBERT.

Our task needs an additional retrieval step to find relevant documents that might contain useful results of similar trials, as the input trial background does not contain the result information for the given ICO query. Documents are retrieved from the entire PubMed and PMC using a TF-IDF matching between their indexed MeSH terms and the MeSH terms identified in the ICO queries. We then apply the pipeline described above on the retrieved documents. This baseline is similar to but more domain-specific than BERTserini (Yang et al., 2019).

BioBERT: For this setting, we feed BioBERT with similar input to EBM-Net as is described in §5 and fine-tune it to predict the R using its special `[CLS]` hidden state.

Ablations: We conduct two sets of ablation experiments with EBM-Net: (1) Pre-training level, where we exclude the adversarial examples in pre-training, to analyze the utility of CLM against traditional LM. (2) Input level, where we exclude different input elements (`B`, `I`, `C`, `O`) to study their relative importance.

Human Expectations: We define the expected result (R_e) of a clinical trial (e.g.: $R_e = \downarrow$ for `O` = "mortality rate") as the Human Expectation (HE),

---

[6] P is not included in the original dataset as the background of the trial report contains it.

Table 2: Main results on the benchmark Evidence Integration dataset. $\lvert\Delta\rvert$ denotes the absolute value of relative accuracy decrease from the standard to the adversarial setting. All numbers are percentages. (w/o: without)

which is the underlying motivation for conducting the corresponding trial. Generally, $R_e \in \{\uparrow, \downarrow\}$ since significant results are expected. To make fair comparisons, we use the 2-way macro-average F1: F1 (2-way) $= (\text{F1}(\uparrow) + \text{F1}(\downarrow))/2$ as a main metric for evaluations of HE. HE performance is an overestimation of human performance: main biases are due to the shift of input trial distribution from the targeted proposal stage to the actual report stage, which contains fewer trials with unexpected results.

6.3 Main Results

Table 2 shows the main results on the Evidence Integration dataset, where accuracy and F1 (3-way) are used to compare model performance and F1 (2-way) is used for evaluating human expectations.

Results show that EBM-Net outperforms other baselines by large margins in both standard and adversarial settings. While being the strongest baseline, BioBERT is 10.7% relatively lower in macro-F1 (54.33% v.s. 60.15%) and 9.6% relatively lower in accuracy (55.96% v.s. 61.35%) than EBM-Net. The open-domain QA baselines perform even worse: for the MeSH Ontology method, the internal KB of only 8k entries is far from complete; for the Retrieval + Evidence Inference method, the PICO queries are so specific that no exactly relevant evidence can be found in other trials and retrieving only a few trials has limited utilities.

We use $\lvert\Delta\rvert$, the absolute value of relative accuracy decrease to measure model robustness under adversarial attacks. The higher the $\lvert\Delta\rvert$, the more vulnerable a model is. BioBERT has about twice as much (5.1% v.s. 2.7%) $\lvert\Delta\rvert$ in the adversarial setting as EBM-Net does. It suggests that EBM-Net is more robust to adversarial attacks, which is a vital property for healthcare applications. EBM-Net without adversarial pre-training is less robust than EBM-Net as well (3.0% v.s. 2.7%), but not as vulnerable as BioBERT, indicating that robustness can be learned by pre-training with original implicit evidence to some extent and further consolidated by the adversarial evidence.

Unsurprisingly, EBM-Net with full input consistently outperforms all input-level ablations. Among them, `O` is the most important input element as the performance decreases dramatically on its ablation. This is expected as `O` is the standard of comparisons. `B` is the second most important element, since `B` contains methodological details of how the clinical trials will be conducted, which is also vital for result prediction. The performance does not decrease as much without `I` or `C`, since there is redundant information of them in `B`.

On the one hand, the accuracy of EBM-Net surpasses that of HE, mainly because the latter is practically a 2-way classifier. On the other hand, HE outperforms EBM-Net in terms of 2-way F1, but is still unsatisfying (68.86%). This suggests that the proposed CTRP task is hard and there is still room for further improvements.

6.4 Discussions

We study how different numbers of pre-training and fine-tuning instances influence the EBM-Net performance, in comparison to the BioBERT. Figure 3

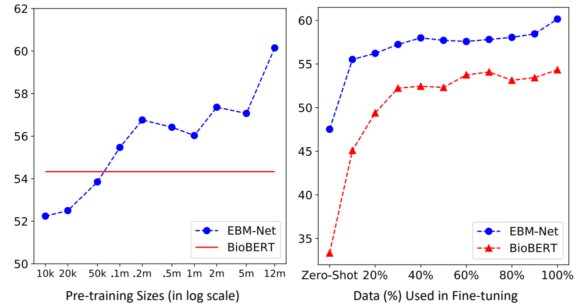

Figure 3: **Left:** EBM-Net 3-way macro-F1 v.s. pre-training sizes compared to BioBERT; **Right:** EBM-Net and BioBERT 3-way macro-F1 v.s. fine-tuning sizes.

shows the results: (**Left**) The final performance of EBM-Net improves log-linearly as the pre-training dataset size increases, suggesting that there can be further improvements if more data is collected for pre-training but the marginal utility might be small. EBM-Net surpasses BioBERT when pre-trained by about 50k to 100k instances of implicit evidence, which are 5 to 10 times as many as the fine-tuning instances. (**Right**) EBM-Net is more robust in a few-shot learning setting: using only 10% of the training data, EBM-Net outperforms BioBERT fine-tuned with 100% of the training data. From zero-shot[8] to using all the training data, EBM-Net improves only by 26.6% relative F1 (from 47.52% to 60.15%) while BioBERT improves largely by 60.0% relative F1 (from 32.77% to 54.33%).

We use t-SNE (Maaten and Hinton, 2008) to visualize the test instance representations derived from EBM-Net `[CLS]` hidden state in Figure 4. It shows that EBM-Net effectively learns the relationships between comparative results: the points cluster into three results ($\uparrow$, $\downarrow$, $\rightarrow$). While there is a clear boundary between the $\downarrow$ cluster (dashed-blue circle) and the $\uparrow$ cluster (dashed-red circle), the boundaries between the $\rightarrow$ cluster (dashed-black circle) and the other two are relatively vague. It suggests that the learnt manifold follows a quantitatively continuous "$\downarrow - \rightarrow - \uparrow$" pattern.

Out of the 373 mistakes EBM-Net makes on the test set, significantly less (11.8%, $p<0.001$ by permutation test) predictions are opposite to the ground-truth (e.g.: predicting $\uparrow$ when the label is $\downarrow$), also suggesting that EBM-Net effectively learn the relationship between comparison results. In addition, we notice that there is a considerable proportion of instances whose results are not predictable without their exact reports. For example, some `I` and `C` differ only quantitatively, e.g.: "4% lidocaine" and "2% lidocaine", and modeling such differences is beyond the scope of our task.

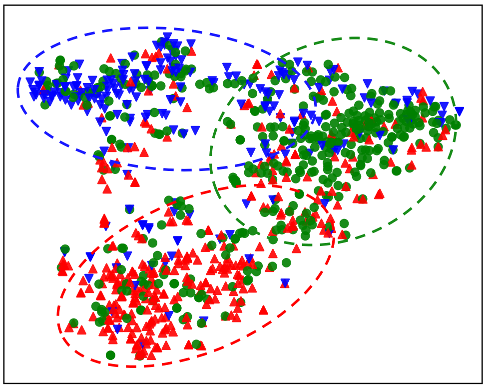

Figure 4: T-SNE visualizations of EBM-Net representations of Evidence Integration test set instances. Red colored ▲, blue colored ▼, and green colored ● refer to the corresponding R equaling $\uparrow$, $\downarrow$ and $\rightarrow$, respectively.

6.5 Validation on COVID-19 Clinical Trials

For analyzing COVID-19 related clinical trials, we further pre-train EBM-Net on the CORD-19 dataset (Wang et al., 2020a)[9], also using the comparative language modeling (§5.1). It leads to a COVID-19 specific EBM-Net that is used in this section.

We use leave-one-out validation to evaluate EBM-Net on the 22 completed clinical trials in COVID-evidence[10], which is an expert-curated database of available evidence on interventions for COVID-19. Again, EBM-Net outperforms BioBERT by a large margin (59.1% v.s. 50.0% accuracy). Expectedly, their 3-way F1 results (45.5% v.s. 36.1%) are close to those in the zero-shot learning setting since not many trials have finished. Accuracy and 2-way F1 performance of HE are 54.5% and 68.9%, and are close to those in Table 2. These further confirm the performance improvement of EBM-Net and the difficulty of the CTRP task.

7 Conclusions

In this paper, we introduce a novel task, CTRP, to predict clinical trial results without actually doing them. Instead of using structured evidence that is prohibitively expensive to annotate, we heuristically collect 12M unstructured sentences

---

[8] Zero-shot performance of BioBERT is defined as the expected results from random predictions.

as implicit evidence, and use large-scale CLM pre-training to learn the conditional ordering function required for solving the CTRP task. Our EBM-Net model outperforms other strong baselines on the Evidence Integration dataset and is also validated on COVID-19 clinical trials.

A Collection of Implicit Evidence

We show several mapping examples from section names to background/method or result/conclusion in Table 4. The implicit evidence collection algorithm is shown in Algorithm 1, which uses the evidence detection algorithm described in Algorithm 2. Dataset statistics are shown in Table 3.

B Disentanglement of Implicit Evidence

Disentanglement of implicit evidence seeks to mask out the R in the implicit evidence and map it to r, which is a finer-grained label of comparison results. We show the distribution of the collected r in Figure 5.

When disentangling the free-text result R, we also mask out the following words:

- Numbers (e.g.: p-values);
- tokens within parentheses (e.g.: interpretations of results);
- Adverb before the central comparative adv/adj (e.g.: “significantly”).

which can be exploited by the model to predict the r during pre-training.

C Comparative Language Modeling

In Table 5, we show several originally collected instances $\mathtt{E}_{dis}$, r, together with their adversarially reversed instances $\mathtt{E}_{rev}$, $\text{Rev}(r)$.

D The Evidence Integration Dataset

In Table 6, we show several examples of Evidence Integration instances and their corresponding ones in *evidence inference*. The Evidence Integration dataset statistics are also shown in Table 3.

E Settings

We show the searched hyper-parameters and their chosen values of different experiments in Table 7. We manually tune the hyper-parameters where the best combination is chosen based on macro-F1 metric in the validation set. The number of hyper-parameter search trials is about 100. Training time of EBM-Net is about 3 min/epoch of standard Evidence Integration and 6 min/epoch of adversarial Evidence Integration on 2 Tesla P100 GPUs at the optimal hyper-parameter setting, and the Inference time is about 100 instances/s on 1 Tesla P100 GPU.

All evaluation metrics are calculated by the `sklearn.metrics` package in Python.

F Results

Validation results of EBM-Net in comparison to BioBERT are shown in Table 8. Results on 22 completed clinical trials in COVID-evidence dataset are shown in Table 9.

Statistic	**Pre-training (original)**	**Standard Evidence Integration (training)**
Avg. Length of `B`	129.0	182.8
Avg. Length of `E`	16.8	16.7*
Avg. Length of `I`	NA	5.7
Avg. Length of `C`	NA	3.7
Avg. Length of `O`	NA	5.3
% of ↑	49.9	31.4
% of →	29.9	44.3
% of ↓	20.2	24.3

Table 3: This table shows the statistics of the pre-training and the downstream Evidence Integration dataset. *Concatenation of `I`, `C`, `O` and two `[SEP]` tokens.

Algorithm 1 Implicit Evidence Collection

```
Input: An abstract $A$ which is a sequence of words (from PubMed).
Output: A list of collected implicit evidence $E$ and its background B from the input article.
$E \leftarrow []$
B $\leftarrow$ “”
if $A$ is structured then
    let $A = [[S_1, L_1], [S_2, L_2], ...]$ where $S_i$ is the i-th sentence and $L_i$ is its section type label
    for $[S_i, L_i]$ in $A$ do
        if $L_i =$ background/method then
            B $\leftarrow$ B $+ S_i$
        else
            if EvidenceDetector($S_i$) $\neq$ False then
                $E$.append(EvidenceDetector($S_i$))
            end if
        end if
    end for
else
    let $A = [S_1, S_2, ...]$ where $S_i$ is the i-th sentence
    BG $\leftarrow$ True
    # BG controls whether a sentence is included in the background
    for $S_i$ in $A$ do
        if EvidenceDetector($S_i$) $\neq$ False then
            BG $\leftarrow$ False
            $E$.append(EvidenceDetector($S_i$))
        else
            if BG then
                B $\leftarrow$ B $+ S_i$
            end if
        end if
    end for
end if
if Full article $F$ is available in PMC then
    let $F = [s_1, s_2, ...]$ where $s_i$ is the i-th sentence
    for $s_i$ in $A$ do
        if EvidenceDetector($s_i$) $\neq$ False then
            $E$.append(EvidenceDetector($s_i$))
        end if
    end for
end if
return $E$, B
```

Algorithm 2 `EvidenceDetector`

```
Input:  A sentence $S$ which is a sequence of words; Sets of adj/adv that suggest superiority ($\mathcal{H}$), inferiority ($\mathcal{L}$) and equality ($\mathcal{E}$)
Output: False if the sentence is not a piece of implicit evidence; Central comparison word $c$ and the change direction $R$ if the sentence is a piece of implicit evidence.
if "than" in $S$ then
  if $S \cap \mathcal{H} \neq \varnothing$ and $S \cap \mathcal{L} = \varnothing$ then

“**Background:** Self-management programs for patients with heart failure can reduce hospitalizations and mortality. However, no programs have analyzed their usefulness for patients with low literacy. We compared the efficacy of a heart failure self-management program designed for patients with low literacy versus usual care. **Methods:** We performed a 12-month randomized controlled trial. From November 2001 to April 2003, we enrolled participants aged 30–80, who had heart failure and took furosemide. Intervention patients received education on self-care emphasizing daily weight measurement, diuretic dose self-adjustment, and symptom recognition and response. Picture-based educational materials, a digital scale, and scheduled telephone follow-up were provided to reinforce adherence. Control patients received a generic heart failure brochure and usual care. Primary outcomes were combined hospitalization or death, and heart failure-related quality of life. ~~**Results:** 123 patients (64 control, 59 intervention) participated; 41% had inadequate literacy. Patients in the intervention group had a lower rate of hospitalization or death (crude incidence rate ratio (IRR) = 0.69; CI 0.4, 1.2; adjusted IRR = 0.53; CI 0.32, 0.89). This difference was larger for patients with low literacy (IRR = 0.39; CI 0.16, 0.91) than for higher literacy (IRR = 0.56; CI 0.3, 1.04), but the interaction was not statistically significant. At 12 months, more patients in the intervention group reported monitoring weights daily (79% vs. 29%, p ¡ 0.0001). After adjusting for baseline demographic and treatment differences, we found no difference in heart failure-related quality of life at 12 months (difference = -2; CI -5, +9). **Conclusion:** A primary care-based heart failure self-management program designed for patients with low literacy reduces the risk of hospitalizations or death.”~~	“Follow-up and thorough education on self-care”	“Standard information about self-care”	“Knowledge about heart failure”	↑
“**Background:** Afghanistan’s national guidelines recommend chloroquine for the treatment of Plasmodium vivax infection, the parasite responsible for the majority of its malaria burden. Chloroquine resistance in P. vivax is emerging in Asia. Therapeutic responses across Afghanistan have not been evaluated in detail. **Methods:** Between July 2007 and February 2009, an open-label, randomized controlled trial of chloroquine and dihydroartemisinin-piperaquine in patients aged three months and over with slide-confirmed P. vivax mono-infections was conducted. Consistent with current national guidelines, primaquine was not administered. Subjects were followed up daily during the acute phase of illness (days 0-3) and weekly until day 56. The primary endpoint was the overall cumulative parasitological failure rate at day 56 after the start of treatment, with the hypothesis being that dihydroartemisinin-piperaquine was non-inferior compared to chloroquine (δ = 5% difference in proportion of failures). ~~**Results:** Of 2,182 individuals with positive blood films for P. vivax, 536 were enrolled in the trial. The day 28 cure rate was 100% in both treatment groups. Parasite clearance was more rapid with dihydroartemisinin-piperaquine than chloroquine. At day 56, there were more recurrent infections in the chloroquine arm (8.9%, 95% CI 6.0-13.1%) than the dihydroartemisinin-piperaquine arm (2.8%, 95% CI 1.4-5.8%), a difference in cumulative recurrence rate of 6.1% (2-sided 90%CI +2.6 to +9.7%). The log-rank test comparing the survival curves confirmed the superiority of dihydroartemisinin-piperaquine over chloroquine (p = 0.003). Multivariate analysis showed that a lower initial haemoglobin concentration was also independently associated with recurrence. Both regimens were well tolerated and no serious adverse events were reported. **Conclusions:** Chloroquine remains an efficacious treatment for the treatment of vivax malaria in Afghanistan. In a setting where radical therapy cannot be administered, dihydroartemisinin-piperaquine provides additional benefit in terms of post-treatment prophylaxis, reducing the incidence of recurrence from 4-8 weeks after treatment. **Trial Registration:** The trial was registered at ClinicalTrials.gov under identifier NCT00682578.~~”	“Dihydroartemisinin - piperaquine”	“Chloroquine”	“Parasite clearance at day 2”	→

Abstract

Clinical prediction models often use structured variables and provide outcomes that are not readily interpretable by clinicians. Further, free-text medical notes may contain information not immediately available in structured variables. We propose a hierarchical CNN-transformer model with explicit attention as an interpretable, multi-task clinical language model, which achieves an AUROC of 0.75 and 0.78 on sepsis and mortality prediction on the English MIMIC-III dataset, respectively. We also explore the relationships between learned features from structured and unstructured variables using projection-weighted canonical correlation analysis. Finally, we outline a protocol to evaluate model usability in a clinical decision support context. From domain-expert evaluations, our model generates informative rationales that have promising real-life applications.

1 Introduction

Electronic medical records (EMRs) store both structured data (e.g., vitals and laboratory measurements) and unstructured data (e.g., nursing and physician notes). Previous clinical prediction tasks have focused on structured data (e.g., Desautels et al., 2016; Gultepe et al., 2013; Ghassemi et al., 2014) which, despite their utility, may not capture all of the useful information in associated text. Clinical decision support systems rarely take advantage of free-text notes due to the complex nature of clinical language and interpretation. Rules and specialized grammars can be applied to circumvent issues around clinical language; however, these methods rely on the presence of certain phrases and spelling, and do not account for the highly variable note structures across departments and hospitals (Yao et al., 2019; Mykowiecka et al., 2009; Assale et al., 2019). Further, opaque models without explainability are often met with resistance in medical contexts (Challen et al., 2019; Ahmad et al., 2018; Gordon et al., 2019). To address these challenges, we propose a novel multi-task language model that also provides rationales for decisions in medicine.

Our multi-task model leverages ClinicalBERT (Alsentzer et al., 2019), which is a transformer-based model pre-trained on clinical corpora. Given the uniqueness of medical text, we introduce a combination of CNN and transformer encoders to capture phrase-level patterns and global contextual relationships. Additionally, we explore latent attention layers to generate rationales.

Based on availability, we use the MIMIC-III database (Johnson et al., 2016) to predict two outcomes: sepsis and mortality in the intensive care unit (ICU). All experiments are conducted on notes written in English. We define the task of sepsis prediction more rigorously than previous work due both to using textual data only, and to emphasize the practicality of this model in real-world applications. Moreover, we use canonical correlation analysis (CCA; Hotelling 1992) to explore relationships between latent features learned from both structured and unstructured data. Finally, we propose an evaluation protocol to examine the usability of our model as an interpretable decision support tool.

2.1 Transformers in the clinical domain

Transformers (Vaswani et al., 2017) have gained popularity given their strong performance and parallelizability. The success of the transformer-based BERT (Devlin et al., 2019) has inspired numerous studies to apply it in various domains. For example, BioBERT was pretrained on PubMed abstracts and articles and was able to better identify biomedical entities and boundaries than base BERT (Lee et al., 2020). Alsentzer et al. (2019) further fine-tuned

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1478–1489,
November 16–20, 2020.

BioBERT on the MIMIC-III clinical dataset (Johnson et al., 2016) and released the model as ClinicalBERT. We use these pretrained BERT-based models as static feature extractors and build layers upon the word embeddings to learn task-specific representations spanning long documents.

2.2 Language model explainability

Explainable AI is an emerging field with no standardized methodology or evaluation metrics. The definition of model explainability also varies by application; however, a generally accepted approach to language model explainability is through extractive rationales (Lei et al., 2016; Mullenbach et al., 2018; Wiegreffe and Pinter, 2019).

The wide application of attention mechanisms has led to an ongoing debate over whether attention can be used as explanation (Serrano and Smith, 2019; Jain and Wallace, 2019; Wiegreffe and Pinter, 2019). Jain and Wallace (2019) claimed that attention scores in recurrent neural networks (RNNs) did not correlate with other feature-importance measures, and adversarial attentions did not affect model predictions, concluding that attention was not explanation. Wiegreffe and Pinter (2019) challenged these assumptions by proposing diagnostic tests that allow for meaningful interpretation of attention, but also showed that adversarial attention distributions failed to achieve the same level of prediction performance as real model attention.

We propose a clinical decision support tool that uses explanations to enhance model usability and reliability. Therefore, we adopt a view similar to that of Wiegreffe and Pinter (2019), in that attention provides plausible rationales for use in practice, even though it may not provide a complete internal representation of the model's behaviour (Serrano and Smith, 2019; Jain and Wallace, 2019).

2.3 Clinical tasks

Sepsis is an extreme systemic inflammatory response to infection. If left untreated, sepsis can lead to life-threatening complications such as organ failure and septic shock. The ability to predict sepsis before symptom onset allows for earlier intervention, thus improving patient outcomes. Previous work on sepsis detection focused on both post-hoc identification as well as predicting the need for early intervention from structured data (Desautels et al., 2016; Taylor et al., 2016; Nemati et al., 2018; Gultepe et al., 2013). As mortality has an explicit label in EMRs, the focus has been on expiry likelihood for early intervention rather than post-hoc identification (Ghassemi et al., 2014; Grnarova et al., 2016). We focus on work that used the MIMIC-III database (Johnson et al., 2016).

Insight (Desautels et al., 2016) provided a method for predicting sepsis from vital signs within a fixed-time window before suspected onset on retrospective data. Gultepe et al. (2013) proposed a similar structured-data model for mortality and sepsis prediction; however, the features were preselected and only considered five measurements. While these methods achieved robust results compared to traditional clinical measures (e.g., MEWS, qSOFA, SIRS; Churpek et al. 2017), none took advantage of the unstructured data found in EMRs.

Culliton et al. (2017) claimed that unstructured data in EMRs contain information not found in the structured variables. They used GloVe word embeddings to represent notes for each patient, and only excluded discharge summaries to minimize explicit mentions of sepsis. Simply excluding discharge summaries, however, is not sufficient to avoid label leakage – a diagnosis may appear in the notes as the clinician becomes aware of symptoms. We carefully filter notes to ensure no label leakage occurs and further refine our definition of sepsis prediction, as described in Section 4. Ghassemi et al. (2014) used topic modeling for textual representations aggregated with structured patient data to predict mortality, but Grnarova et al. (2016) showed that using convolutional document embeddings for each patient outperformed these topic modelling strategies for mortality prediction. Similarly, we deploy convolutional layers in our model to obtain sentence-level embeddings. Horng et al. combined structured and unstructured data for sepsis prediction, using topic models and continuous-bag-of-words (CBOW) to represent text. Despite success, GloVE word embeddings, topic models, and CBOW do not generally capture the complexity and contextual relationships between words in a given text. Specifically, these methods rely primarily on word frequency and collapse multiple meanings of a word into a single representation. To this end, we implement a transformer-based model to represent our clinical notes, which we hypothesize may capture the contextual complexity between tokens more completely.

3 Methods

3.1 Model architectures

The structure of our model is illustrated in Figure 1. We now explain each component in detail.

BERT word embeddings: BERT and its variants have exhibited strong performance in various tasks and we are interested in its application specifically in medical contexts. As shown in Figure 2, medical documents can easily contain thousands of tokens. With the sequence length limit of 512 tokens, using BERT as a fine-tuning language model on long documents is practically challenging or impossible. Instead, we approach this problem in a depth-first manner and use BERT as a static feature extractor on a sentence-by-sentence basis. Such a feature-based approach with BERT has proved to be nearly as effective as the fine-tuning approach in other tasks (Devlin et al., 2019).

We split each document into n sentences of m tokens and use a separate data loader with a sequential sampler to group them into sub-batches. The input is truncated or padded at both the sentence- and token-level. We then feed the sentences into a BERT model and take the mean of the last four encoder layers as token embeddings. For tokenization, we omit two irrelevant tokens `[CLS]`, which is used as a pooling mechanism in fine-tuning models, and `[SEP]`, which is used in next sentence prediction and sentence-pair classification tasks. BERT-related modeling and processing code comes from HuggingFace's Transformers library (Wolf et al., 2019).

Given an input $T = [t_{11}, t_{12} \dots t_{ij} \dots t_{nm}]$, where t_{ij} denotes the j^{th} token of the i^{th} sentence, the BERT feature extractor outputs

$$X = [x_{11} \dots x_{nm}] = BERT(T),$$

where x_{ij} is a d_{emb}-dimensional vector (i.e., the hidden dimension of the BERT configuration) corresponding to t_{ij}.

Convolutional layer: Previous studies using CNNs to process medical notes have achieved good results on tasks such as mortality prediction and ICD-9-CM diagnosis code classification (Grnarova et al., 2016; Mullenbach et al., 2018; Si and Roberts, 2019). Specifically, a qualitative evaluation of text snippets from an attentional CNN indicated the model's ability to learn features that are deemed informative and diagnosis-relevant by a physician (Mullenbach et al., 2018). This suggests that the CNN is suitable for extracting information regarding patient status at the phrase-level. We use a simple 1D convolutional layer along the sequence of each sentence followed by ReLU activation and 1D max-pooling to obtain sentence representations.

Taking X as the input, the CNN outputs an $n \times d_{feature}$ matrix.

$$S = MaxPool(ReLU(Conv(X)))$$

where $d_{feature}$ is the number of output channels of the convolution layer.

Transformer patient encoder: Medical notes frequently contain repeated segments of medical histories as well as plans for future treatment. Although related work in patient-clinician dialogue has explicitly used time-series information (Khattak et al., 2019), the strict temporal order of patient conditions in clinical notes can be disrupted by repeating information. Yet, the highly complex mechanisms of medical outcomes entail that the co-existence of some conditions may change the indication of others. We apply a two-layer transformer encoder on top of sentence features to capture a unified representation among descriptions. This step of encoding results in a matrix

$$S_T = Transformer(S)$$

that shares the same dimension as S.

Although multi-head attention is powerful (Clark et al., 2019), it is not yet clear how to derive rationales for model prediction from such an approach. For model explainability, we instead apply an explicit attention mechanism that is directly implementable and interpretable.

Latent attention: The outputs of the transformer encoders are sentence-level features. To obtain patient representations, we use a latent attention mechanism adapted from similar work in if-then program synthesis (Liu et al., 2016). The goal of latent attention is to dedicate a component of the model to explicitly learning the importance of each unit of explanation such as the sentence or word.

The latent attention scores are calculated from sentence features using a position-wise feed-forward network (Vaswani et al., 2017). Given S_T, an n-dimensional vector a_{input} is computed as

$$a_{input} = FeedForward(S_T)$$

and the attention weight is

$$a = Softmax(a_{input} + a_{mask}),$$

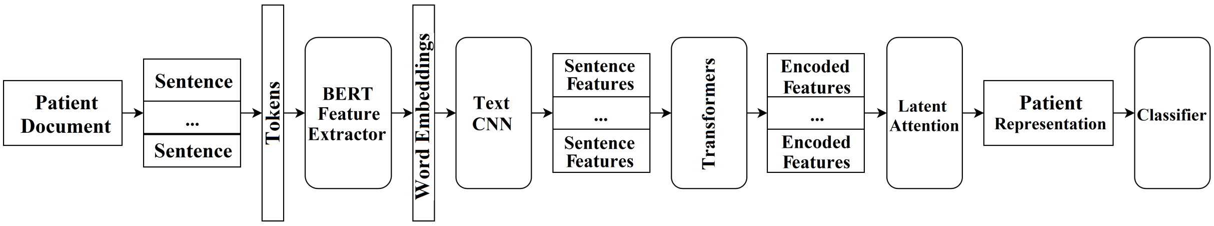

Figure 1: Model architecture and data flow. Each patient document undergoes various levels of feature extraction to arrive at token-, sentence-, and patient-level representations. The explicit attention layer provides a latent representation for a patient. The final, attended-to patient representation is used in the classification task.

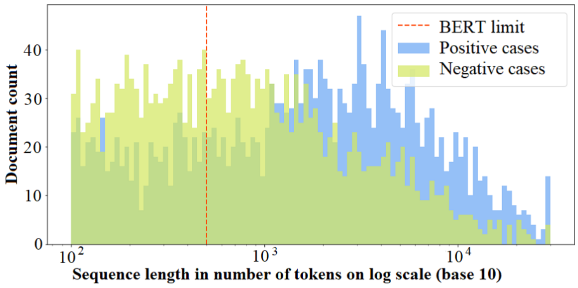

Figure 2: Distribution of documents based on token lengths for the mortality dataset. 2842 out of 5147 documents exceed the token limits of BERT, indicated by the vertical dashed line.

Table 1: Mapping of clinical tests to their corresponding structured variables.

where a_{mask} is an n-dimensional vector for which values unmasked positions are 0 and values at padding positions are $-10,000$.

The final $n_{feature}$-dimensional patient vector p is computed as the weighted sum of sentence features, which we can define as the dot product,

$$p = \sum_{i=1}^{n} S_{T_i} a_i = S_T \cdot a$$

and feeds a linear layer and a softmax classifier.

3.2 Canonical Correlation Analysis

Classic canonical correlation analysis (CCA) provides a set of linear transformations that maximally correlate data points from multiple views (Hotelling, 1992). We use projection-weighted CCA (PWCCA) (Morcos et al., 2018) to investigate the correlation between learned textual features and various structured data that are split into their respective clinical tests, shown in Table 1. Given two vectors, $\mathbf{x} \in \mathbb{R}^{\,d \times n}$ and $\mathbf{y} \in \mathbb{R}^{\,d \times m}$, where n and m denote feature dimensions and d denotes number of data points, the objective is

$$({w_1}^*, {w_2}^*) = \arg\max_{w_1, w_2} \frac{{w_1}' K_{\mathrm{XY}} w_2}{\sqrt{{w_1}' K_{\mathrm{XX}} w_1 {w_2}' K_{\mathrm{YY}} w_2}},$$

where K_{XY} denotes the cross covariance and K_{XX} and K_{YY} denote the covariances.

Following the method of singular value CCA (Raghu et al., 2017), we use singular value decomposition to obtain the weights w_1, w_2. From this, we get a total of min$\{n, m\}$ canonical correlation coefficients. The high dimensionality of the feature representations may result in noisy coefficients that hinder the similarity measurements. We use projection weighting to compute a weighted mean of the canonical variates, which accounts for the importance of CCA vectors relative to the original input (Morcos et al., 2018). The PWCCA similarity between vectors $\mathbf{x}$ and $\mathbf{y}$ is computed with

$$d_{pwcca}(x, y) = 1 - \sum_{c}^{i=1} \alpha_i {\rho}^{(i)}$$

where α_i denotes the normalized importance weights, and $\rho^{(i)}$ the i^{th} CCA coefficient. We use an open-source implementation of PWCCA[1] in our experiments. Understanding the correlated information in patient features between textual and structured data may provide insight on what latent information is learnt from the text.

4 Data

MIMIC-III: MIMIC-III is a clinical database comprising de-identified EMRs of 58,976 hospital admissions to the critical care units of the Beth Israel Deaconess Medical Center (Johnson et al., 2016). All variables are recorded between 2001 and 2012. Note that, although ClinicalBERT is pretrained on MIMIC-III, this does not preclude its use from downstream tasks on the same dataset; Alsentzer et al. emphasize that any impact is negligible given the size of the entire MIMIC-III corpus compared to sub-sampled task corpora. In this study, we choose sepsis and mortality tasks because these are the standard tasks of this dataset. However, our model is not specifically tailored to these tasks, and may be generalized to wide range of potential applications.

Data preprocessing: To avoid data leakage among hospital admissions of the same patient, we only include patients with one hospital admission. We select adult patients from the single-admission group and obtain a base population of 31,245 hospital admissions. We randomly sample negative cases to balance the dataset in both tasks.

For text, we concatenate text from different note entries into one document for each patient and remove punctuation (except periods and commas), masked identifiers, digits, and single characters. When merging patients' notes, we remove sentences that have already appeared in previous notes to avoid repetition. The notes are appended in chronological order according to their timestamps and truncated to a maximum of 50,000 tokens.

For mortality prediction, we do not differentiate note types. For sepsis, we find differences in the frequencies of note *types* between positive and negative populations, which may result in a trivially learned solution. After consulting with clinicians, we exclude note types that are irrelevant to sepsis and select nursing and physician notes only.

Whereas structured variables have explicit timestamps that can be easily related to symptom onset, the timestamp of a note may not. For example, a note containing descriptions of possible infection may be entered after antibiotic administration. Anchoring notes with lab measurement timestamps significantly limits the number of positive cases in our dataset, especially when compared to other studies containing similar sepsis cohorts (Section 2.3). Nonetheless, we view the imposed time-window constraints as necessary to create an honest representation of *prediction*. Discharge summaries and any notes written after patient outcomes occurred are excluded to avoid direct access to the solution. Unfortunately, these steps are not always taken in the literature.

For the structured data used in Section 3.2, we use MIMIC-Extract[2] to ensure a standard patient population. After obtaining time-binned cohort data, we extract measurements within the same time frames as the selected notes.

Sepsis: Systemic inflammatory response syndrome (SIRS), characterized by abnormal body temperature, heart rate, respiratory rate, and white blood cell count, often precedes sepsis. In this task, we aim to predict whether a patient in SIRS would become septic. In contrast to previous work where the negative sepsis populations did not necessarily have SIRS (Section 2.3), our task is more restrictive, as the model must learn features that are distinctive of sepsis onset rather than general indications of SIRS. We use ICD-9-CM codes to label cases, where patients with codes for explicit sepsis, or a combination of infection and either organ failure or SIRS, are considered positive. Although ICD-9-CM codes can be unreliable (O'Malley et al., 2005), we use multiple criteria to deal with false negatives and SIRS as a filter to avoid false positives (Angus and Wax, 2001). We notice that very few notes are recorded before the first onset of SIRS, possibly due to a time delay in writing or logging notes. To compensate for the lack of data, notes before and within 24 hours of the first onset of SIRS are included. To avoid possible label leakage, we remove sentences containing mentions of "*sepsis*" or "*septic*". The final cohort contains 1262 positive cases and 1500 negative cases.

In-ICU mortality: MIMIC-III has an expiry timestamp for patients who died in the hospital, which identifies the positive cohort for in-ICU mortality prediction. To ensure that all samples represent patient conditions in the ICU, we only include notes written within ICU stays. The dataset has 2562 positive cases and 2587 negative cases.

5 Experiments

Our experiments explore 1) differences in prediction due to pretraining, 2) multiview projection, and 3) *evaluable* explainable AI.

5.1 Clinical vs Non-Clinical BERT.

To compare the effect of pretraining BERT with domain-specific clinical data on the overall quality and performance of the model, we substitute BioBERT (Lee et al., 2020) and base BERT (Devlin et al., 2019) as the token embedding component. We run both sepsis and mortality tasks on the different *BERT models and compare the final performance. The results are shown in Table 2.

In comparing performance between tasks, the models achieve better performance in mortality than sepsis. Considering that patients in the negative cases in sepsis task all had SIRS, which is one of the diagnostic criteria of sepsis, the high false positive rate among all three models is expected.

ClinicalBERT models converge faster and outperform the other two models in both sepsis and mortality tasks. BioBERT and BERT models are comparable in performance; however, BioBERT models exhibit a tendency to output positive results, resulting in high recall and high false positive rates. The fact that BioBERT does not perform better than base BERT suggests that clinical-specific pretraining is crucial and cannot be replaced by pretraining on general biomedical corpora.

5.2 Structured vs Textual Data

To investigate the relationships between patient features extracted from structured and text data, we separately train RNN models to learn representations from different groups (see Table 1) of laboratory measurements, and we conduct PWCCA (Figure 3) to compute their similarities to patient features from the language model.

Structured data model: To obtain a single vector from time-series structured data, we construct a 2-layer single-directional GRU network followed by a linear layer to project the mean GRU output to a feature vector that has the same dimension as the language model feature vectors. Only the patients that appear in the language model cohort are selected. Each model is trained for 50 epochs, and the best-performing one is used to extract features.

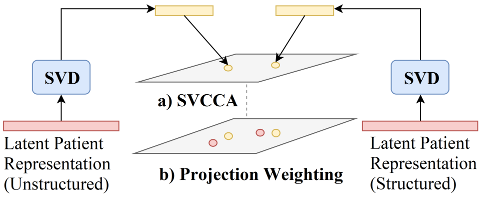

Figure 3: Visualization of PWCCA. The patient representations are taken from the models before the classifier. First, a) a latent space is learned with SVCCA; then, b) The original representation is projected onto the learned latent space, and the PWCCA is computed.

CCA details: To avoid spurious correlations typically found in small datasets, the number of data points (n_{sample}) should be at least five times[3] the feature dimension ($d_{feature}$). Therefore, we include all shared patients between structured and unstructured datasets, and over-sample the data for the sepsis task. We set up random baselines for each test where we randomly generate n_{sample} $d_{feature}$-dimensional vectors using the same sampling strategy as the real features. To ensure that our features are meaningful, we only analyze features extracted by models that reach an AUROC of at least 0.75. It is important to note that we constructed the structured dataset to obtain the patient representation, not to compare model performance. The structured inputs contain measurements after the onset of patient outcomes, so the metrics should not be compared to those of the language model. Additionally, the structured data models fail to learn to predict sepsis from SIRS cohort, so we include negative samples without SIRS whose data are extracted from random time frames. Model performance and PWCCA similarity (described by Morcos et al. (2018)) are listed in Table 3.

Feature correlation: The similarity scores are subject to confounding factors such as noise and sample size. Due to limited data availability, we can only comment on the general patterns. The structured data model and language model converge to correlated solutions, compared to random baselines. We do not observe any clear relationship between structured model performance and similarity. The features learned from *all* lab measurements, which supposedly encode a more comprehensive patient representation than any subgroup alone, are close to the features learned from medical notes, especially in the mortality task. For the sepsis task, the test groups that are highly related

PV	0.5	-	0.5	-
Random	-	0.45	-	0.361

Table 3: Structured model test performance and PWCCA similarity to text features. The *All* category encompasses all test groups and their features. Table 1 shows the full list of features and their corresponding test categories.

to systematic inflammation or organ dysfunction (CBC, BP, IND) show especially strong correlation with the textual features. The results suggest that our language models learn to encode the most relevant patient conditions for each outcome. Future work includes further examining representation correlations, and other multi-view models combining structured and unstructured data as inputs.

5.3 Evaluating Explanations

Evaluating model explainability remains a broad area of research. Our primary objective is a usable model that can be deployed as a real-life decision support tool. Therefore, we focus on human evaluation as our assessment of rationale quality. We outline a novel evaluation protocol that measures the quality of the extracted rationales by leveraging clinical domain expertise. To avoid arbitrary judgements, we work with the physician to tailor the definition of utility for each task; this is expanded upon in the Appendix along with a stand-alone quantitative evaluation on non-clinical data of latent attention as an explanation mechanism.

To obtain succinct meaningful explanations, we calculate an attention threshold score

$$a_{threshold} = \max\left(\frac{1}{n_s}, a_{sentence_i}\right),$$

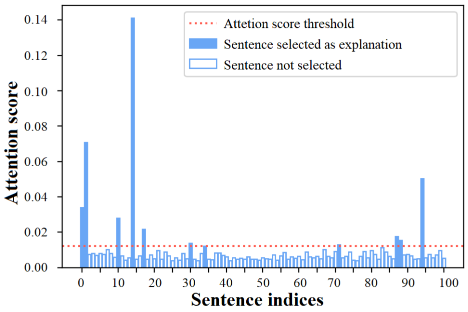

Figure 4: Example attention distribution over sentences in one patient document.

where a denotes attention scores, n_s is the number of sentences, and $i = min(20, \lceil \frac{n_s}{10} \rceil)$. This ensures that selected sentences have higher attention scores than uniform attention and at most 10% of the original texts are included. To avoid burdening the evaluator, at most 20 sentences are selected for documents with more than 200 sentences. Figure 4 shows an example distribution of attention scores and demonstrates our explanation generation criteria. To prevent overly complicated results, we only evaluate the correctly predicted cases.

All independent evaluation uses a command-line user interface.

5.3.1 Labeling task

Labeling is designed to evaluate the informativeness of our generated explanations. Sentences are presented sequentially to an expert physician who chooses at each step to either predict patient outcome or check the next sentence. Sepsis has defined diagnosis criteria that must be followed in clinical practice, and information about such criteria are not necessarily available even in complete documents. However, mortality risk assessment, despite its difficulty, is common in critical care. Therefore, we only conduct the labeling task on the mortality dataset. We compare human predictions to those of our model and note the number of selected sentences necessary for each prediction. A test case fails if the evaluator does not make a decision after reviewing all selected sentences. This

	Pos	**Neg**	**Total**
N_{cases}	119	136	255
Conclusion	98.4%	98.5%	98.5%
Correctness	69.2%	96.3%	82.7%
Sentences Read (c)	4.0	3.5	-
Sentences Read (i)	4.2	8.2	-

Table 4: Labeling task results. We list the number of cases, percentage of concluded cases out of all cases, percentage of correct cases out of total concluded cases, and the average number of sentences read for both correct (c) and incorrect (i) cases.

method evaluates whether the attended sentences are sufficient to provide enough information for a clinical decision, and empirically evaluates the number of sentences needed for rationales.

The results are presented in Table 4. On average, the evaluator reaches a correct conclusion in mortality prediction 82.7% of the time by reading approximately 4 sentences per case (or a selected 0.5% of the note, on average). Such evidence strongly suggests that our model is capable of extracting the most relevant information from long documents. We also observe a general pattern that fewer sentences are needed for a correctly predicted case, which indicates that the ordering of sentences based on attention is generally reliable.

Interestingly, the evaluator almost correctly predicts all negative cases but not positive cases in the mortality task. Multiple reasons may account for the high false negative rate. First, mortality prediction is an intrinsically challenging task for humans. A bias towards survival may naturally occur when a sentence can be interpreted differently based on various contexts. Second, explanations for negative cases are more likely to be independent from the contextual information that are not included in the rationales. Our evaluator comments that a seemingly poor patient condition may translate to completely opposite outcomes depending on the coexistence of other conditions. In real-life applications, providing full documents with highlighted explanations may be an easy solution that helps to direct users' attention to the most important parts without losing reference to additional contexts.

5.3.2 Rating task

In a second evaluation, we sample cases not used in the labeling task. We present model predictions and the entirety of the rationales sentence-by-sentence to an expert physician. The physician is instructed to decide whether each sentence in the rationale contains information that helps explain the model decision. To avoid arbitrary judgements, we work with the physician to develop clear definitions of explanation utility, as shown in the appendix. This method assesses the average informativeness of selected sentences as well as the usability of our model for the purpose of clinical decision support.

	Sepsis			**Mortality**		
	Pos	Neg	Total	Pos	Neg	Total
$N_{sentences}$	1016	464	1480	958	486	1444
N_{cases}	64	54	118	76	52	128
$\%_{helpful}, All$	41.8	95.0	-	61.7	82.7	72.2
$\%_{helpful}, Top\ 4$	-	-	-	75.9	86.4	80.0
$\%_{helpful}, Cases$	96.4	74.1	86.0	-	-	-

Table 5: Rating task results.

Given the characteristics of mortality and sepsis (see the appendix for a detailed discussion), the evaluation is meaningful at the sentence- and case-levels for the two tasks. Table 5 summarizes the results. Between the positive and negatives cases, an average of 72.2% of sentences in the mortality task and 86% of cases in the sepsis task are rated as helpful for understanding model decisions. A closer look at the results shows that 80% of the first four sentences are rated as helpful, which indicates that the specific algorithm that generates rationales should be refined in future work to further exclude sentences with lower attention scores (see Figure 4). Nonetheless, the application of our model as an explainable decision support tool is very promising.

6 Conclusion

Language can provide valuable support to improve clinical decision-making. We conduct a diverse set of experiments to explore several aspects of the applicability of deep NLP in the clinical domain. We also address challenges in extracting medical documents that are representative of a predictive task.

We augment the power of domain-specific BERT and build a hierarchical CNN-Transformer that can potentially be applied to any long-document processing task. The model achieves AUROC scores of 0.75 and 0.78 on sepsis and mortality tasks, respectively. We also address model explainability by experimenting with a simple (yet effective) linear attention mechanism, and emphasize the interaction between models and users in the design of a novel protocol to evaluate explanations. Not only are we able to sufficiently predict cases with performance comparable to models that use structured EMR data, but we are also able to provide useful rationales to support the predictions, as validated by medical domain expertise. This has important implications for real-world application of explainable clinical decision support from text.

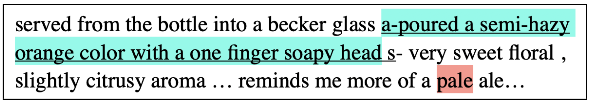
A Appendix A. On explainability evaluation.

Quantitatively validating latent attention as explanation: As previously noted, evaluating language model explanations is not yet standardized. Despite the effort to make human evaluation fair and reliable, such qualitative measurements are still prone to bias and subjectivity. To validate that latent attention can be used as an explanation, we conduct a stand-alone experiment on the *BeerAdvocate* dataset used by McAuley et al. (2012) and adapted by Lei et al. (2016). This is a dataset that has ground-truth annotations of sentences relevant to prediction results. Although the dataset is not crafted for the purpose of rationale evaluation, we use it as a proxy to examine the quality of our attention scores.



served from the bottle into a becker glass a-poured a semi-hazy orange color with a one finger soapy head s- very sweet floral , slightly citrusy aroma … reminds me more of a pale ale…

Blue background: attended tokens in annotation
Red background: attended tokens not in annotation
Underscore: annotation

Figure 5: Test case example of BeerAdvocate dataset.

The full *BeerAdvocate* dataset contains 1.5 million beer reviews describing four aspects (i.e., *appearance, smell, palate, and taste*), each corresponding to a rating on a scale of 0 to 5. Lei et al. (2016) published a subset of 90k reviews selected to minimize correlation between *appearance* and other aspects. In our experiment, we use these 90k reviews for training, and 994 annotated reviews for testing. The training set only has rating labels, whereas the testing set has both rating labels and human annotations of sentence-level relevancy. Since all aspects have the exact same setups, it suffices to use the *appearance* rating prediction as a proof-of-concept.

We build a model with only two components, described in Section 3.1, namely BERT (pretrained base-case model) and latent attention. We feed static token embeddings from BERT to a latent attention layer, which output sequence representations to be used for regression through a linear layer with a sigmoid activation. We train the model for 20 epochs and select the best performing one for testing.

In contrast to our clinical model, this model only attends to individual tokens and only generates word-level explanations. For words separated by the WordPiece tokenizer, we merge the tokens and average the attention weights. For each sentence, we sort the words based on their attention weights and take the top n words as the prediction rationale, where n equals the total length of the human-annotated sentences. We only use attention mechanisms without additional constraints, such as selection continuity, which makes the testing task even more challenging, as the annotations are ranges of words.

The model is evaluated according to mean squared error (MSE) and rationale precision

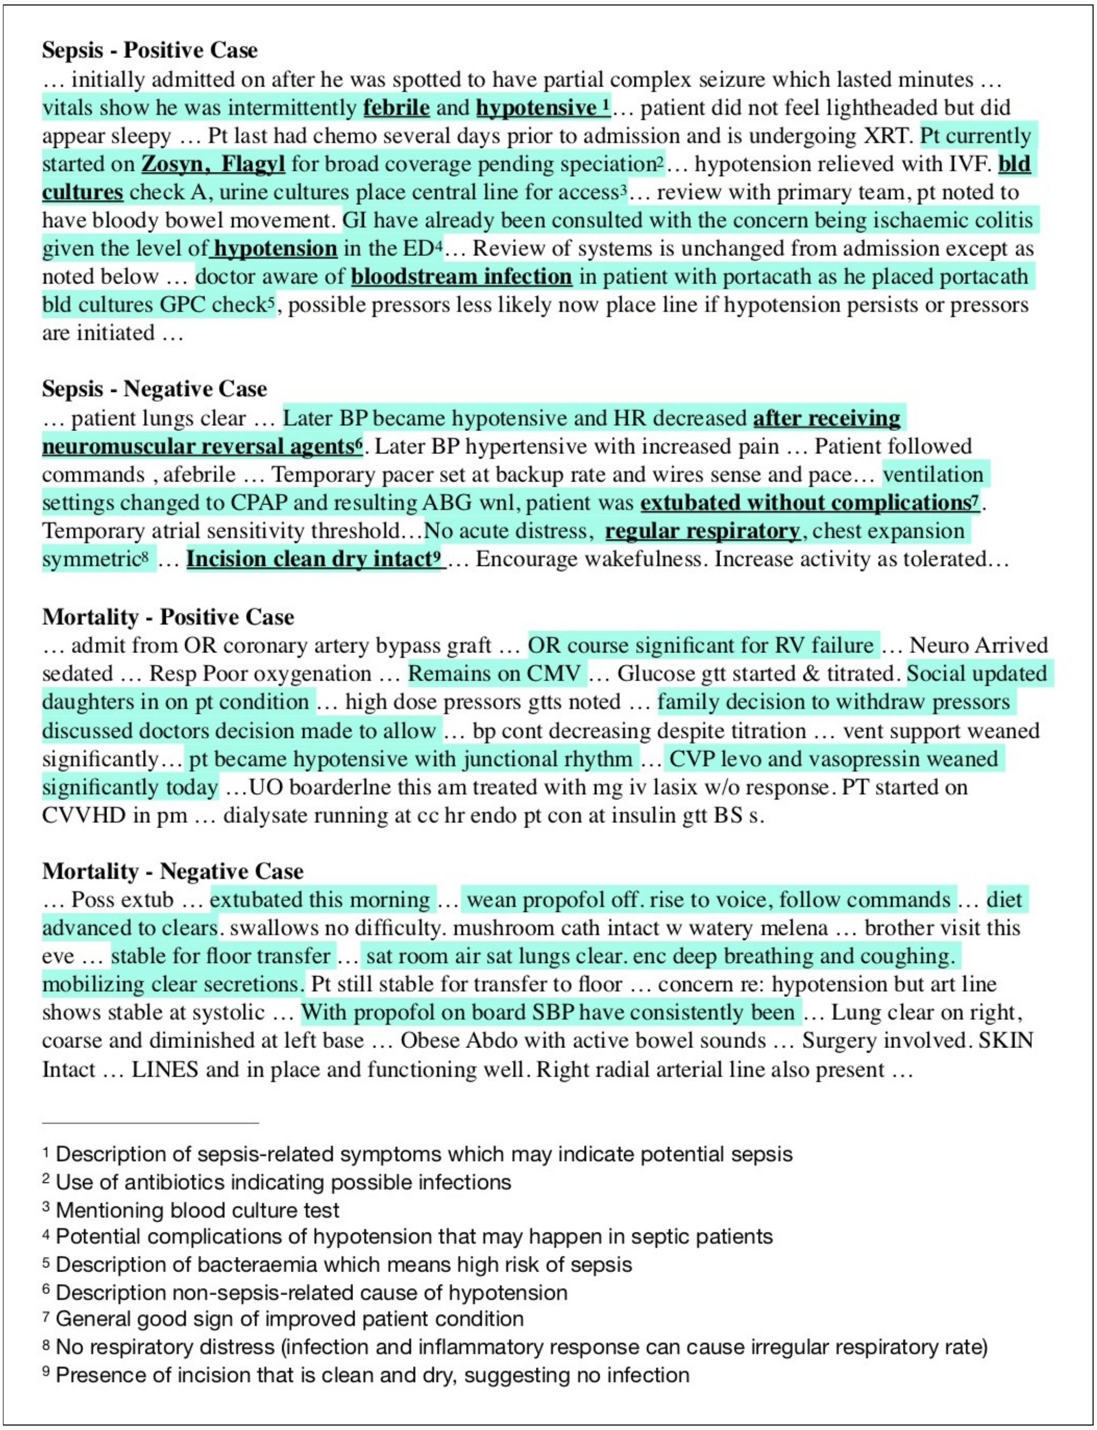
$$P_{rationale} = \frac{\sum_{i=1}^{N} |S_i \cup A_i|}{\sum_{i=1}^{N} |S_i|},$$

where N is the number of test cases, y is the ground truth rating of appearance, $\hat{y}$ is the predicted rating, A_i is the set of word indices in the annotated covers, S is the set of word indices selected as model explanations, and $|S| = |A|$.

Our model reaches a rationale precision of 76.39%, which indicates that our most attended words are mostly consistent with the annotations. Figure 5 shows an example of *appearance* test results. The experiment demonstrates the usability of latent attention as an explanation mechanism.

Definition of explanation utility in the rating task: For mortality, each sentence is evaluated individually based on how the described situation would contribute to a patient's survival rate. Sentences describing highly life-threatening complications (such as multiple organ failures) support a positive prediction, whereas sentences indicating improving conditions (such as stable lab measurements) support a negative prediction. In both cases, these sentences are considered helpful. Sentences that are irrelevant (i.e., that support neither a positive nor negative prediction) are considered unhelpful in both populations.

Many of the conditions that present themselves with sepsis onset (such as hypotension) can have numerous etiologies. Diagnostic criteria specify that bacteremia (i.e., bacteria in the bloodstream) must be present in order to predict the development of sepsis. Yet the administration of antibiotics is also not considered as a direct indication of bacteremia without other indications of potential sepsis. Therefore, sentences describing sepsis-related symptoms are not rated as helpful in understanding a positive sepsis prediction until the indication of infection (for example, compromised skin integrity)



Sepsis - Positive Case

also appears, and vice versa. For negative cases, sentences that are either irrelevant to sepsis or explain other origins of sepsis-related symptoms are rated as helpful. Given this definition, the existence of any helpful sentences means the explanation is valid for a positive case. Similarly, the existence of any unhelpful sentences invalidates a negative case.

Examples of sepsis and mortality explanations are shown in Figure 6. We truncate and edit these texts to avoid data disclosure.

A Knowledge-driven Generative Model for Multi-implication Chinese Medical Procedure Entity Normalization

Abstract

Medical entity normalization, which links medical mentions in the text to entities in knowledge bases, is an important research topic in medical natural language processing. In this paper, we focus on Chinese medical procedure entity normalization. However, non-standard Chinese expressions and combined procedures present challenges in our problem. The existing strategies relying on the discriminative model are poorly to cope with normalizing combined procedure mentions. We propose a sequence generative framework to directly generate all the corresponding medical procedure entities. we adopt two strategies: category-based constraint decoding and category-based model refining to avoid unrealistic results. The method is capable of linking entities when a mention contains multiple procedure concepts and our comprehensive experiments demonstrate that the proposed model can achieve remarkable improvements over existing baselines, particularly significant in the case of multi-implication Chinese medical procedures.

1 Introduction

Named entity normalization (NEN), which is also known as entity linking, is one of the fundamental tasks within natural language processing (Hachey *et al.*, 2013; D'Souza, 2015; Fang *et al.*, 2016; Wu *et al.*, 2018). Medical entity normalization is a typical problem of NEN in the medical domain, which aims at linking references or mentions of medical terminology to standard entities in a given medical knowledge base (KB) such as the International Statistical Classification of Diseases and Related Health Problems 9th Revision (ICD-9).

Due to the nature of the domain, although different occupational or writing habits can result in standard entities having different literal expressions, the linked standard entities of a given medical mention should always be unique. Thus, unlike NEN as applied generally(Hachey *et al.*, 2013; Luo *et al.*, 2015; Wu *et al.*, 2018; Aguilar *et al.*, 2019), in the medical domain, the main challenge is not ambiguity – the same entity mention may be linked to different concepts, it is variation – the same underlying concept can be linked by different entity mentions. However, different from the normalization task of the medical entity with simple nominal structure, such as disease (Kang *et al.*, 2012; D'Souza and Ng, 2015) or anatomical body (Wang *et al.*, 2019), Chinese medical procedure normalization have to face the challenge of multi-implication – a mention which contains multiple procedure concepts should link to multiple standard procedure entities in KB. To clarify, these linked entities are instances of concepts in KB and have no parent-child relationships on each other.

Figure 1 shows some examples of Chinese medical combined procedure entity normalization. In case 1, the mention left of the dotted line implicates two procedure concepts and links to two different standard entities, where the word "颅神经 (cranial nerve)" is omitted from the mention. Besides, features in the textual level are not detailed enough to identify the exact number of procedures in given mentions such as case 2, which is a Tri-combined procedure but with only one "+" delimiter. Hence how to identify the number of linking entities for a given mention is crucial for Chinese medical procedure normalizing.

Previous studies which adopt the discriminative model to solve the problem of variation in medical entity normalization (Li *et al.*, 2017; Luo *et al.*, 2018; Ji *et al.*, 2019; Deng *et al.*, 2019) involve two basic steps: First, entity candidates are selected from all entities in KB through artificially designed rules (Li *et al.*, 2017) or text similarity methods,

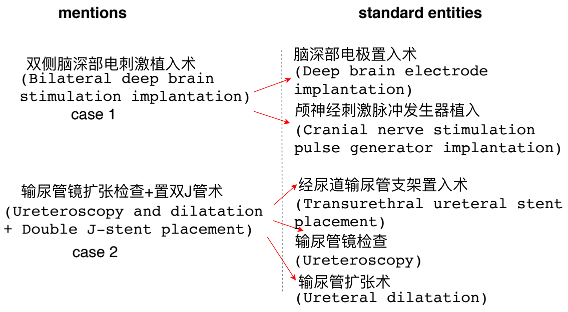

Figure 1: Example of multi-implication Chinese medical procedure entity normalization

such as BM25 (Ji *et al.*, 2019); Then, a discriminative model is used to measure semantic similarity score between the original mention and selected candidates and get the highest one as the normalization result. We refer to these approaches simply as "selecting and re-ranking (SR)." SR strategies based on neural networks have proven to be efficient when dealing with "uni-implication" entity normalization problems, in which a mention links to only one standard entity in a given KB. However, those works fail to pay attention to the multi-implication problem. The most significant weakness of SR is that it cannot identify the number of linking entities but default to the "uni-implication" problem for each given mention.

To tackle the "multi-implication" challenge, we propose a sequence generative framework to directly generate all the corresponding standard entities. However, since a generative model makes unrealistic independence assumptions about the joint distribution of features and classes (Toutanova, 2006), two methods are introduced to constrain the model output, as follows. **1) Constraint decoding**. Normally, entities in KB is grouped together in categories and each entity is assigned to a corresponding category label (e.g. label 8 refers to Operations on eyelids in ICD-9-CM Vol. 3 Procedure Codes). For this reason, we give each entity in the KB a unique category label and derive a label prefix tree for each category to accommodate all the entities belonging to it. Then, the generative model will, in turn, decode the category label and standard entities when given the input mention. At each decoding step, we construct a constraint character set by tracing previously generated characters with corresponding label prefix trees. Finally, we integrate the constraint set into our model to restrict the generated characters belonging to its corresponding category. **2) Catebory-based refining**. Entities under the same label always share common information. Inspired by Li *et al.* (2018), we propose a category-based refinement strategy in order to make the model parameters better fit the category of input mentions. To achieve this, for each input mention, we first adopt the general model to normalize it and obtain the category information from the output. Then we redistribute the original test dataset into several sub-test datasets based on category. Finally, for each sub-test dataset, we find sentence pairs within the same categories from the training data and use them to fine-tune the parameters of the general model. In addition, we propose a "generating and re-ranking" strategy. For each mention, several standard entity candidates are produced by a generative model via a beam search method instead of selecting candidates from the given KB. Then, a pre-trained discriminative model is used to score and re-rank all the candidates.

Overall, we make the following contributions in this paper.

- We propose a sequence generative framework to handle the "multi-implication" problem in Chinese medical procedure entity normalization tasks. To the best of our knowledge, the "multi-implication" problem has not been addressed in any previous research.
- We design novel approaches to constrain the generative model to capture category labels and word-formation from a KB while avoiding unrealistic results.
- Our detailed experimental analysis on Chinese medical procedure entity normalization tasks realizes remarkable improvements over existing methods.

2 Proposed method

The main idea underlying this work is based on introducing a sequence generative framework to directly generate all linked standard entities at once, which can then normalize both "uni-implication" and "multi-implication" types of mentions in an end-to-end fashion. In this section, we introduce the proposed category-based constraint decoding and model-refining methods, which can avoid generating unrealistic results and adapt the test sets belonging to particular categories. As the basis of our work, we first introduce two definitions used in

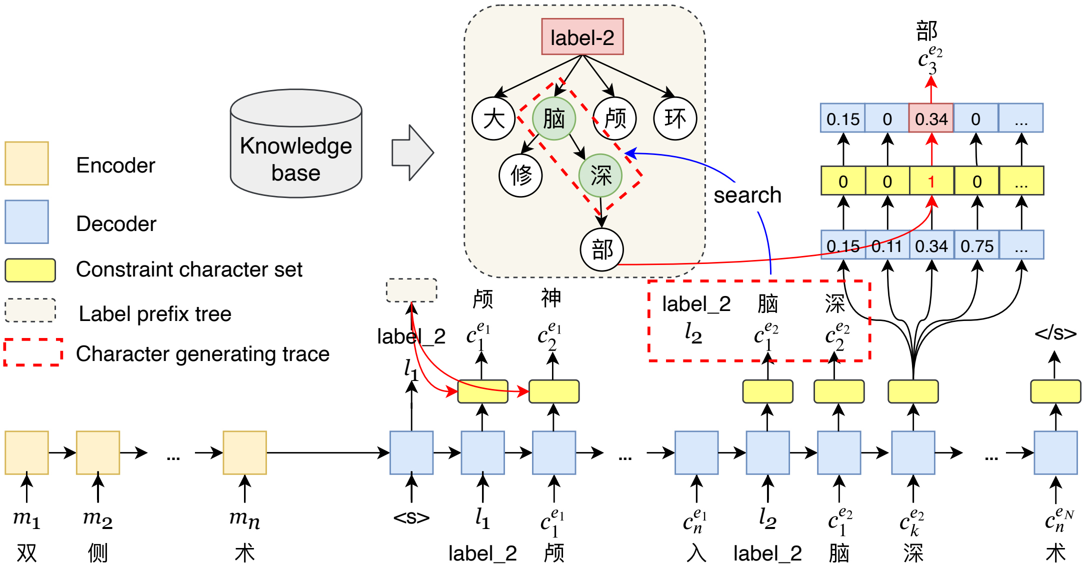

Figure 2: The overall structure of category-based constraint decoding

the proposed methods.

Definition 1 (character generating trace): The character generating trace is the order of characters in standard entities.

Definition 2 (previous trace): The previous trace of a character c_i consists of two parts: a categary label l and a generated character sequence $s = c_1, c_2, ..., c_{i-1}$ under l.

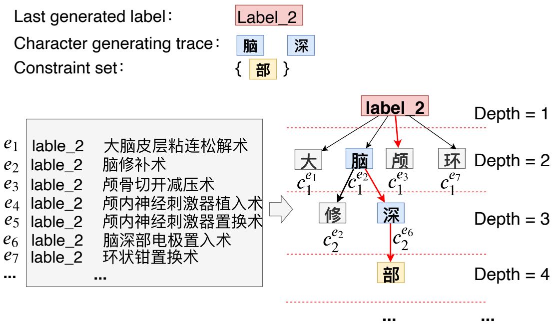
Considering the excellent performance of an existing self-attention-based transformer (Vaswani *et al.*, 2017), we implement our method based on this architecture. The input and output of encoder and decoder are all character-based sequences.

2.1 Category-based constraint decoding

Given an input mention M, the decoder is used to generate all corresponding entities $\{e_1, e_2, ..., e_N\}$ in one output sequence. To apply the category constraint to make the results more reliable, the model decoder should ensure that the character generated at each time step can follow the **character-generating trace** of the previous output. The proposed model decodes both entities and their corresponding category labels. First, the decoder generates a category label for an entity. Next, the decoder reads all entities under the generated label in a KB and constructs a prefix tree. Finally, the decoder generates the entity characters. At each decoding step a character constraint set will be looked up from the prefix tree based on the label and previously generated characters, and be used to constrain the present time-step output. This process is repeated until a sequence stop symbol is generated by the decoder, to indicate that all entities have been generated. Whenever a new category label is generated, a new prefix tree is created from the KB and replaces the old one.

Figure 2 presents an example to illustrate the proposed decoding method. To generate the third character of the second entity c_3^{e2}, we first obtain the character constraint set from a prefix tree. The prefix tree is created based on the latest generated label l_2. Then, the decoder traces the prefix tree in the order of $l_2 c_1^{e2} c_2^{e2}$ to obtain the character constraint set for c_3^{e2}. Finally, the constraint set is transformed into a mask matrix, with the conditional probability output by the model. The details of the label prefix tree and constraint character set are introduced in the following subsections.

2.1.1 Label prefix tree



e_1	lable_2	大脑皮层粘连松解术
e_2	lable_2	脑修补术
e_3	lable_2	颅骨切开减压术
e_4	lable_2	颅内神经刺激器植入术
e_5	lable_2	颅内神经刺激器置换术
e_6	lable_2	脑深部电极置入术
e_7	lable_2	环状钳置换术
...		...

Figure 3: Example of tracing a prefix tree

To improve the efficiency of searching a character-generating trace, we derive each category in the KB using a prefix tree to accommodate

Algorithm 1: Construction of prefix tree

```
   Input: Category label $l$; Knowledge base KB
   Output: prefix tree of $l$
1  Extracting all entities under the category $l$ in
     KB $\rightarrow S_l$ ;
2  initialize a tree $T$ ;
3  rootNode($l$)$\rightarrow T$ ;
4  for $i$ in $1, 2, ..., len(S_l)$ do
5      selectEntity($i$) $\rightarrow e_i$ ;
6      root $\rightarrow$ parentNode ;
7      for $m$ in $1, 2, ..., len(e_i)$ do
8          selectChar($m$)$\rightarrow c^{e_i}_m$ ;
9          initNode($c^{e_i}_m$, $m$,parentNode)$\rightarrow d^i_m$ ;
10         getChildList(parentNode) $\rightarrow cList$ ;
11         if $d^i_m$ not in $cList$ then
12             addNode($d^i_m$)$\rightarrow T$ ;
13         end
14         $d^i_m$ $\rightarrow$ parentNode ;
15     end
16 end
```

Algorithm 2: Obtaining character constraint set

```
   Input: prefix tree $T$; previous trace
          tuple$(label, s)$; label set $L$;
          ENDSYMBOL
   Output: character constraint set $C$
1  if $len(s)$ = 0 then
2      $C$ = getChildList(root) ;
3  end
4  else
5      root $\rightarrow$ parentNode ;
6      for $i$ in $1, 2, ...,len(s)$ do
7          getChildList(parentNode) $\rightarrow cList$ ;
             for $d$ in $cList$ do
8                if $getValue(d)$ = $s_i$ then
9                    $d \rightarrow$ parentNode ;
10               end
11         end
12     end
13     getChildList(parentNode) $\rightarrow C$ ;
14 end
15 if $C = \emptyset$ then
16     $L\cup$ ENDSYMBOL $\rightarrow C$ ;
17 end
```

the character-generating trace of all the candidates. Here, we use the example in Figure 3 to illustrate the construction and tracing of a prefix tree. We assume that the previously generated characters are "脑，深", which are the first and second decoder steps after the latest generated category label "label_2." The procedure for constructing prefix tree T is illustrated in **Algorithm 1**. The first step is to search the KB and collect n entities under the category "label_2" into a set $S_{label\_38} = e_1, e_2, ..., e_n$ (line 1). The formation of entities in the KB is the same as in the textbox (bottom left). The root of this prefix tree is the category label and its depth is the maximum length of the entity in S (line 2-3). For each entity e_i in S_{label_38}, we traverse its character $c^{e_i}_m$, and add it to the tree if its parent node $c^{e_i}_{m-1}$ has no node that is the same as it, where m indicates the position within e_i (lines 4-16).

With the prefix tree in place, we can now obtain the character constraint set C by following the previous trace of "(label_2, [脑，深])". **Algorithm 2** shows the procedure. If the generated character sequence s is null, the returned constraint set will be the list of child nodes from the root node (lines 1, 2); otherwise, the prefix tree will be traced until the last character in s and the returned constraint set $\{$部$\}$ is a child node list of the last character "深" (lines 5-13). Note that if the constraint set is empty, which means the last character in s is a leaf node, it will be changed to the set of all category labels joined with a sequence-ending symbol.

2.1.2 Constraint character set

The constraint character set C_t is used to restrict the original conditional probability $p(y_t|y_{<t})$ of the generative model output:

$$\hat{p}(y_t|y_{<t}) = \lambda p(y_t|y_{<t})$$
$$\lambda = \begin{cases} 0 & y_t \in C_t \\ 1 & y_t \notin C_t \end{cases} \quad (1)$$

where y_t is the character generated by the decoder at time step t, and λ is a constraint operator.

2.2 Category-based model refining

The parameters of the general fixed model cannot best-fit each test item (Li *et al.*, 2018). Thus, we propose to refine the general model to obtain a category-specific model for each test data. As illustrated in Figure 4, the proposed model-refining strategy comprises the following steps.

(1) Learn a general model M_G (Section 2.1) based on all of the training data $D = (s_1, t_1), (s_2, t_2), ..., (s_n, t_n)$.

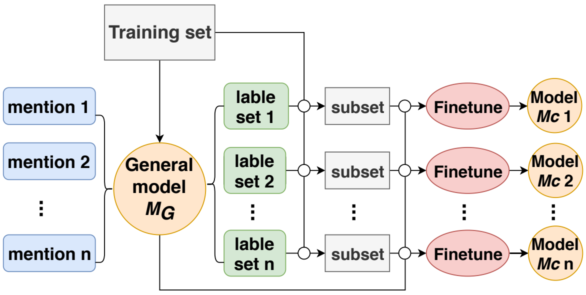


Figure 4: Procedure of category-based model refining

(2) Use the general model M_G to generate the corresponding results $\hat{t}$ for each given mention $\hat{s}$ in the test set and record the generated category label set $\hat{l}$ (Algorithm 3, line 1-2).

(3) For each $\hat{s}$, we extract a training subset $\hat{D}$ from the training data, consisting of mention-entity pairs whose category label set is a subset of $\hat{l}$ (Algorithm 3, line 3-9).

(4) Fine-tune the general model with each new training subset $\hat{D}$ to obtain a category-specific model M_C (Algorithm 3, line 10).

This procedure can be formulated as two-stage optimization. The first stage is to to find a set of network parameters θ to maximize the log-likelihood of the whole training data D.

$$\hat{\theta} = \arg\max_{\theta}\{log \prod_{i=1}^{n} P(t_i|s_i;\theta)\} \qquad (2)$$

The second stage is to find a set of parameters in the neighbourhood of $\hat{\theta}$ to maximize the log likelihood of a subset of training data $\hat{D}$.

$$\bar{\theta} = \arg\max_{\theta\in\mathcal{N}(\hat{\theta})}\{log \prod_{s_i\sim s} P(t_i|s_i;\theta)\} \qquad (3)$$

One thing to note is that the data size used for fine tuning is small, usually containing only a few mention-entity pairs. So we need to be careful about overfitting. To this end, we go over the tuning data for only one pass.

2.3 Generating and re-ranking

As the standard entities can be generated by the proposed sequence generative model, we now call the strategy “generating and re-ranking” (GR). As illustrated in Figure 5, instead of selecting candidates from the KB and re-ranking the semantic similarity between candidates with input mentions, we generate the candidates directly by adopting a beam search in our decoder. Given an input mention, the beam search decoder with beam size k will output k results, where each result may contain one or more entities due to the “multi-implication” problem. All these entities are grouped as a candidate set of the input mention and any duplicates are removed. The calculation of semantic similarity can be implemented by various neural network structures, such as ABCNN (Yin *et al.*, 2016), LSTM (Hochreiter and Schmidhuber, 1997; Limsopatham and Collier, 2016), and bidirectional encoder representations from Transformers (BERT) (Devlin *et al.*, 2019; Ji *et al.*, 2019). Considering the state-of-the-art performance of BERT in semantic similarity learning, which could also be applied to entity normalization tasks (Ji *et al.*, 2019), we calculate the semantic similarity between input mentions with candidates by adopting a BERT-based method as introduced

```
Algorithm 3: Obtain category-specific model
  Input: Training data
         $D = (s_1, t_1), (s_2, t_2), ..., (s_n, t_n)$;
         Testing mention $\hat{s}$; General model $M_G$
  Output: category-specific model $M_C$ ;
1 Inference($M_G$,$\hat{s}$) $\rightarrow \hat{t}$ ;
2 getLableSet($\hat{t}$) $\rightarrow \hat{l}$ ;
3 initialize a training subset $\hat{D}$ ;
4 foreach $(s_i, t_i)$ in $D$ do
5     getLableSet($t_i$) $\rightarrow l_i$ ;
6     if $l_i \subset \hat{l}$ then
7         addItem($s_i, t_i$) $\rightarrow \hat{D}$ ;
8     end
9 end
10 Finetune($M_G, \hat{D}$) $\rightarrow M_C$ ;
```

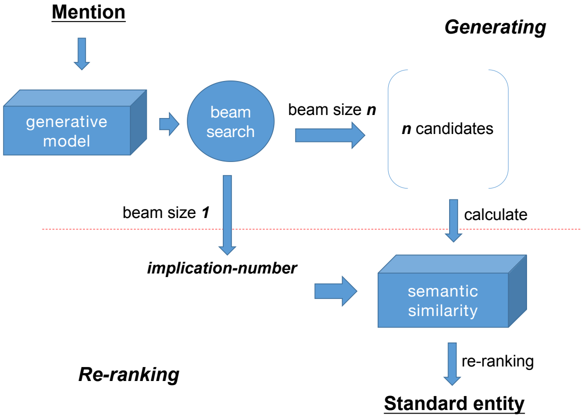

Figure 5: The overall framework of generating and re-ranking

by (Ji *et al.*, 2019). For the "multi-implication" mentions, we calculate the similarity score for each generated entity candidate and select the top n candidates as the final result of the linked standard entities of the input mention. The selecting number n is determined by the number of entities output by beam size 1.

3 Experimental settings

In this section, we describe the datasets used in our experiments, and the details of training and evaluation.

3.1 Data

The datasets used in this paper were provided from the CHIP 2019 clinical entity normalization task[1]. Table 1 shows examples of training data provided for the task. The special characters "##" in standard entities is used as a delimiter between each entity for multi-implication mentions. All the mentions in the training and evaluation datasets refer to clinical procedures extracted from Chinese electronic medical records, and their corresponding standard entities are annotated based on the ICD9-2017-PUMCH procedure codes knowledge base. The knowledge base contains 9,867 standard entities and each entity is assigned to a unique category label. Table 2 shows the detailed statistics on "uni-implication" and "multi-implication" procedure mentions. We annotated the data with category labels by using the given procedure codes dictionary, and arranged the data into the following formation.

- **Mention**: 双 侧 脑 深 部 电 刺 激 植 入 术
- **Standard entity**: label_02 脑 深 部 电 极 置 入 术 label_01 颅 神 经 刺 激 脉 冲 发 生 器 植 入

The category labels are annotated ahead of entities, and both mentions and standard entities are split into characters. Owing to the sparsity of training data, we augmented our training set by simply adding all the data in the given knowledge base and taking each of the standard entities as the mention of itself.

3.2 Training details

We used the Transformer toolkit[2] to implement all the described methods. The vocabulary is shared and its size is 1,550. We used the same configuration as *Transformer base* adopted by (Vaswani *et al.*, 2017), which contains a six-layer encoder and a six-layer decoder with 512-dimensional hidden representations. The mini-batch size was set to 128 and 150 training epochs. We used the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.0003. Owing to the high cost of pre-training BERT, we directly adopted *BERT-base*[3] parameters pre-trained by Google in the Chinese general corpus and fine-tuned the semantic similarity task (in Section 2.3) with a batch size of 32 and 30 training epochs.

Mentions	**Translation**	**Standard entities**	**Translation**
左甲状腺切除术	Left thyroidectomy	单侧甲状腺切除术	Unilateral thyroidectomy
输尿管镜检查+扩张+置双J管术	Ureteroscopy + dilatation+Double J-stent placement	经尿道输尿管支架置入术##输尿管镜检查##输尿管扩张术	Transurethral ureteral stent placement **##** Ureteroscopy**##** Ureteral dilatation
右侧甲状腺全切除术+左侧甲状腺次全切除术	Right totalthyroidectomy + Left subthyroidectomy	单侧甲状腺切除伴他叶部分切除术	Unilateral thyroidectomy with partial lobectomy
双侧脑深部电刺激植入术	Bilateral deep brain stimulation implantation	脑深部电极置入术##颅神经刺激脉冲发生器植入	Deep brain electrode implantation **##** Cranial nerve stimulation pulse generator implantation

Table 1: Examples of training data

Datesets	uni-implication	multi-implication	total
Train	3,801	199	4,000
Test	2889	111	3,000

Table 2: Data statistics

3.3 Baseline and evaluation metrics

We compared our models with three baselines, as follows.

- **Edit-distance**. A basic method focusing on the number of procedures transforming one string to another.
- **BERT-based ranking** (Devlin *et al.*, 2019). A typical "search and re-rank" method that gives the best performance on English biomedical entity normalization. Since the data used in this study are in Chinese, we replaced the original English pre-trained BERT model with a pre-trained Chinese model *BERT-base*.

[2] https://github.com/Kyubyong/transformer

[3] https://github.com/google-research/bert

Method	uni-implication	multi-implication	total
Edit-distance	50.8	—	48.3
BERT-based ranking	88.6	—	84.2
Transformer$_{\text{base}}$	87.5	24.5	84.3
Transformer$_{\text{CD}}$	88.5	32.7	85.6
Transformer$_{\text{CD+refine}}$	90.2	40.9	87.7
Transformer$_{\text{CD+refine+GR}}$	**91.1**	**52.4**	**89.3**

Table 3: Performance of different methods in terms of accuracy. Emboldened scores denote the best performance.

- **Transformer$_{\text{base}}$**. The basic transformer model without the proposed constraint decoding and model-refining methods.

Following (Devlin *et al.*, 2019), we evaluate the performance of different methods in terms of accuracy, which was the percentage of entity mentions that were correctly normalized. Considering the "multi-implication" problem in our data, we adopt a more strict definition of accuracy as follow:

$$acc = \frac{\sum_{i=1}^{n} \lfloor p_i r_i \rfloor}{n} \tag{4}$$

n is the total number of test data, a_i and c_i represent the precision rate and recall rate of implicated standard entities of the ith mention respectively. In other word, the normalization result of a given procedure mention can only be correct when both the number and text of generated standard entities are completely correct.

4 Results and analysis

Table 3 presents the accuracy scores of the baseline and proposed models. The subscripts "CD", "refine", and "GR" correspond to the three methods proposed in Section 2. As shown in Table 3, all of the proposed models gave better results than the three baseline models in the total column. The proposed Transformer$_{\text{CD+refine+GR}}$ model, which applies all the methods proposed in Section 2, achieves the best accuracy in both uni-implication and multi-implication data, being over 5% better than that of the state-of-the-art discriminative model-based method BioBERT.

It can also be observed that confined to the "SA" strategy, although the BioBERT model can achieve competitive accuracy in uni-implication mention normalization, it cannot deal with multi-implication mentions at all. In contrast, including the baseline Transformer$_{\text{base}}$, all sequence generative models have the ability to normalize multi-implication mentions. Hence, our proposed models can achieve much better performance in both uni-implication and multi-implication mention normalization than the baseline models.

Methods	uni-implication	multi-implication	total
BERT-based ranking	100%	—	96.3%
Delimiter "+"	96.6%	70.3%	95.6%
Transformer$_{\text{CD+refine+GR}}$	98.6%	76.4%	97.7%

Table 4: Accuracy of implication-number prediction

Method	OOD rate
Transformer$_{\text{base}}$	8.3%
Transformer$_{\text{CD}}$	0

Table 5: Rate of generated entities out of dictionary (OOD)

4.1 Prediction of the number of references

We conducted further experiments to verify the ability of the proposed model to predict the number of standard entities that should be linked. For comparison, we adopt a text-feature based method to identifies the number of linking entities by simply thinking of "+" in a given procedure mention as a delimiter. Table 4 shows the accuracy of Transformer$_{\text{CD+refine+GR}}$, delimiter "+", and BioBERT in predicting the number of references. As BioBERT always gives one standard entity for each input procedure mention, its accuracy of prediction for uni-implication mentions is naturally 100% correct. The proposed sequence generative method Transformer$_{\text{CD+refine+GR}}$ can get 2% and 6% higher accuracy than simply adopting delimiter "+" in uni-implication and multi-implication mentions respectively. The results demonstrate that our method has good ability in the implication-number prediction of both uni-implication and multi-implication.

4.2 Effect of integrating category-based constraint decoding

A generated entity cannot be the correct standard entity if it is not contained in the given dictionary (or the KB referenced in the above sections), which we call the out-of-dictionary (OOD) problem. We are interested to see whether our proposed category-based constraint decoding can avoid the OOD problem. Table 5 presents the OOD rate of the proposed Transformer$_{\text{CD}}$ and baseline Transformer$_{\text{base}}$. As shown in Table 5, the OOD problem is com-

	Candidates per mention	Standard entity recall
BM25	10	86%
Beam size 2	2.4	88%
Beam size 3	3.7	88.7%
Beam size 5	5.2	89.1%
Beam size 7	7.3	89.2%

Table 6: Number of candidates per mention and rate of standard entity recall for the candidate set generated by different beam sizes of the proposed sequence generative model, compared against those selected by the traditional IR model BM25

pletely solved by category-based constraint decoding.

Figure 6 provides an illustrative example of entity normalization. In this example, the baseline model generates the character "头", which should never appear after a previous trace of "(label_77,[尺, 骨])". The proposed model avoids this error because the constraint set masks all unexpected characters based on the previous trace.

Input mention: 右尺骨头切除术
(Right ulna resection)
Reference: 尺骨部分切除术
(Partial ulna resection)
Transformer$_{base}$: label_77 尺骨头切除
Transformer$_{CD}$: label_77 尺骨部分切除术

Figure 6: Entity normalization example, in which the proposed method is able to obtain a realistic result while the baseline model does not.

4.3 Candidates generated by beam search decoder

As described in Section 2.3, we adopted a beam-search decoder to generate candidates instead of selecting candidates from a given dictionary. As we used the same BERT-based text similarity method, i.e., *BioBERT*, the quality of generated candidates has a decisive influence on the final performance. Table 6 reports the number of candidates per mention and the rate of standard entity recall for the candidate sets that were conducted using two types of strategy. For the traditional IR model BM25, which is used by *BioBERT*, the top 10 candidates are retrieved for each mention and a standard entity recall of 86% was obtained. Regarding the proposed method, although there is not much difference in standard entity recall between the candidate sets generated by different beam sizes, all candidate sets could achieve a better standard entity recall than BM25 with a much smaller number of candidates per mention, which proves that our GR strategy is more efficient.

Entity Mention	token	character
token	81.2	83.6
character	82.5	84.3

Table 7: Performance of different granularity

4.4 Character-based vs. token-based

We investigate the influence of different granularity, we compare four different combined conditions in Table 5. Here we use Transformer$_{base}$ (the 4th row in Table 3) for the sake of simplicity. However the token-based generated results are unsatisfactory (e.g. token2token with accuracy of 81.2% while the character-based baseline achieves 84.3%), in our view, from three faults: 1) Error propagation could be introduced by tokenizer because of the medical domain specificity. 2)Chinese is written without spaces between words and it is difficult to determine word boundaries. 3)token-based vocabulary brings more OOV problems.

5 Related work

There are two areas related to our work:

Entity normalization: Most of the entity normalization studies consider the domain-specific knowledge base or dictionary as the scope of standard entities. Early methods Bunescu and Paşca (2006) and Zheng *et al.* (2010) design discriminative features, such as the TF-IDF, to compare the similarity of candidate entity with entity description and feed to the ranking framework. Popular approaches Leaman *et al.* (2013); Limsopatham and Collier (2016); Li *et al.* (2017); Ji *et al.* (2019) handle this as a sentence-pair classification task. Leaman *et al.* (2013) first proposed a pairwise learning-to-rank technique that adopts a vector-space model to measure the text similarity between medical entity mentions and standard entity in KB. Deep neural networks have also been proposed to normalize biomedical entities. Limsopatham and Collier (2016) and Li *et al.* (2017) adopted a convolutional neural network (CNN) and a recurrent neural network (RNN) to present the deep semantic matching between query mentions and candidate entities in a KB. Kolitsas *et al.* (2018) proposed a neural end-to-end entity linking system that jointly discovers and links entities in a text document. Luo *et al.* (2018) propose a multi-task framework in the clinical setting to normalize the disease and procedure mentions jointly. Ji *et al.* (2019) proposed an entity normalization architecture by fine-tuning a pre-trained BERT. However, these studies all concentrate on normalizing the mention with one unique standard entity in the KB.

Sequence generation: Sutskever *et al.* (2014) was the first to propose an encoder-decoder method to facilitate end-to-end learning of the sequence generation. After that, many studies (Bahdanau *et al.*, 2014; Luong *et al.*, 2015; Vaswani *et al.*, 2017) were focused on perfecting the encoder-decoder architecture. Zhao *et al.* (2018) proposed a recommendation strategy to alleviate the erroneous translations problem in neural machine translation by integrating a phrase table. Different from general sentence generation, the scope of generated standard entities should be strictly restricted, and our model can extract the constraint from a given knowledgeable and integrate it into the decoder. Li *et al.* (2018) proposed a dynamic neural machine translation that gives each test sentence a best-fitting network parameter. This work uses a similarity search to obtain training data according to the test sentence.

6 Conclusions and Future Work

In this paper, we propose a sequence generative learning framework with a category-based constraint decoding and model-refining mechanism for Chinese medical procedure normalization. The proposed model can achieve the end-to-end generation of all corresponding standard entities for all types of input mentions, especially for "multi-implication" mentions. The "generating and re-ranking" strategy is employed to integrate the proposed generative model with a discriminative similarity re-ranking method to further improve normalization performance. Our comprehensive experimental results demonstrate that the proposed model significantly outperforms the baseline methods. Furthermore, the proposed model can be applied to the normalization of both "uni-implication" and "multi-implication" Chinese medical procedure mentions. Notwithstanding, considering the complexity of the domain specificity and the scarcity of training data, this challenging task is far from being solved. In the future, we plan to focus on how to improve the performance of medical entity normalization when resources are limited.

Acknowledgments

We thank the three anonymous reviewers for their careful reading of our paper and their many insightful comments and suggestions. We would like to thank Jian Sun, Si Chen, and Chen Xue for their invaluable contributions in shaping the early stage of this work. We thank Jinan Xu, Yang Zhao, and Junnan Zhu for their valuable and constructive suggestions.

Abstract

The extraction of labels from radiology text reports enables large-scale training of medical imaging models. Existing approaches to report labeling typically rely either on sophisticated feature engineering based on medical domain knowledge or manual annotations by experts. In this work, we introduce a BERT-based approach to medical image report labeling that exploits both the scale of available rule-based systems and the quality of expert annotations. We demonstrate superior performance of a biomedically pretrained BERT model first trained on annotations of a rule-based labeler and then fine-tuned on a small set of expert annotations augmented with automated backtranslation. We find that our final model, CheXbert, is able to outperform the previous best rule-based labeler with statistical significance, setting a new SOTA for report labeling on one of the largest datasets of chest x-rays.

1 Introduction

The extraction of labels from radiology text reports enables important clinical applications, including large-scale training of medical imaging models (Wang et al., 2017). Many natural language processing systems have been designed to label reports using sophisticated feature engineering of medical domain knowledge (Pons et al., 2016). On chest x-rays, the most common radiological exam, rule-based methods have been engineered to label some of the largest available datasets (Johnson et al., 2019). While these methods have generated considerable advances, they have been unable to capture the full diversity of complexity, ambiguity and subtlety of natural language in the context of radiology reporting.

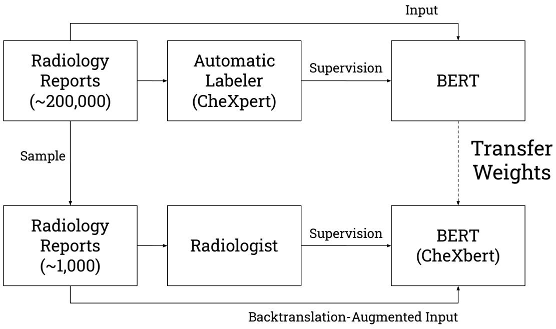

Figure 1: We introduce a method for radiology report labeling, in which a biomedically pretrained BERT model is first trained on annotations of a rule-based labeler, and then fine-tuned on a small set of expert annotations augmented with automated backtranslation.

More recently, Transformers have demonstrated success in end-to-end radiology report labeling (Drozdov et al., 2020; Wood et al., 2020). However, these methods have shifted the burden from feature engineering to manual annotation, requiring considerable time and expertise for high quality. Moreover, these methods do not take advantage of existing feature-engineered labelers, which represent state-of-the-art on many medical tasks.

We introduce a simple method for gaining the benefits of both existing radiology report labelers and expert annotations to achieve highly accurate automated radiology report labeling. This approach begins with a biomedically pretrained BERT model (Devlin et al., 2019; Peng et al., 2019) trained on the outputs of an existing labeler, and performs further fine-tuning on a small corpus of expert annotations augmented with automated backtranslation. We apply this approach, shown in Figure 1, to the task of radiology report labeling of chest x-rays, and call our resulting model *CheXbert*.

CheXbert outperforms the previous best reported labeler (Irvin et al., 2019) on an external dataset,

November 16–20, 2020.

MIMIC-CXR (Johnson et al., 2019), with an improvement of 0.055 (95% CI 0.039, 0.070) on the F1 metric, and is only 0.007 F1 away from a radiologist performance benchmark. We expect this method of training medical report labelers is broadly useful for natural language processing within the medical domain, where collection of expert labels is expensive, and feature engineered labelers already exist for many tasks.

2 Related Work

Many natural language processing systems have been developed to extract structured labels from free-text radiology reports (Pons et al., 2016; Yadav et al., 2016; Hassanpour et al., 2017; Annarumma et al., 2019; Savova et al., 2010; Wang et al., 2018; Chen et al., 2018; Bozkurt et al., 2019). In many cases, these methods have relied on heavy feature engineering that include controlled vocabulary and grammatical rules to find and classify properties of radiological findings. NegEx (Chapman et al., 2001), a popular component of rule-based methods, uses simple regular expressions for detecting negation of findings and is often used in combination with ontologies such as the Unified Medical Language System (UMLS) (Bodenreider, 2004). NegBio (Peng et al., 2017), an extension to NegEx, utilizes universal dependencies for pattern definition and subgraph matching for graph traversal search, includes uncertainty detection in addition to negation detection for multiple pathologies in chest x-ray reports, and is used to generate labels for the ChestX-Ray14 dataset (Wang et al., 2017).

The CheXpert labeler (Irvin et al., 2019) improves upon NegBio on chest x-ray report classification through more controlled extraction of mentions and an improved NLP pipeline and rule set for uncertainty and negation extraction. The CheXpert labeler has been applied to generate labels for the CheXpert dataset and MIMIC-CXR (Johnson et al., 2019), which are amongst the largest chest x-ray datasets publicly available.

Deep learning approaches have also been trained using expert-annotated sets of radiology reports (Xue et al., 2019). In these cases, training set size, often driving the performance of deep learning approaches, is limited by radiologist time and expertise. Chen et al. (2017) trained CNNs with GloVe embeddings (Pennington et al., 2014) on 1000 radiologist-labeled reports for classification of pulmonary embolism in chest CT reports and improved upon the previous rule-based SOTA, peFinder (Chapman et al., 2011). Bustos et al. (2019) trained both recurrent and convolutional networks in combination with attention mechanisms on 27,593 physician-labeled radiology reports and apply their labeler to generate labels. More recently, Transformer-based models have also been applied to the task of radiology report labeling. Drozdov et al. (2020) trained classifiers using BERT (Devlin et al., 2019) and XLNet (Yang et al., 2020) on 3,856 radiologist labeled reports to detect normal and abnormal labels. Wood et al. (2020) developed ALARM, an MRI head report classifier on head MRI data using BioBERT (Lee et al., 2019) models trained on 1500 radiologist-labeled reports, and demonstrate improvement over simpler fixed embedding and word2vec-based (Mikolov et al., 2013) models (Zech et al., 2018).

Our work is closely related to approaches to reduce the number of expert annotations required for training medical report labelers (Callahan et al., 2019; Ratner et al., 2020; Banerjee et al., 2018). A method of weak supervision known as data programming (Ratner et al., 2018) has seen successful application to medical report labeling: in this method, users write heuristic labelling functions that programmatically label training data. Saab et al. (2019) used data programming to incorporate labeling functions consisting of regular expressions that look for phrases in radiology reports, developed with the help of a clinical expert in a limited time window, to label for intracranial hemorrhage in head CTs. Dunnmon et al. (2019) demonstrated that in under 8 hours of cumulative clinician time, a data programming method can approach the efficacy of large hand-labeled training sets annotated over months or years for training medical imaging models, including chest x-ray classifiers on the task of normal / abnormal detection. Beyond data programming approaches, Drozdov et al. (2020) developed a fully unsupervised approach utilizing a Siamese Neural Network and Gaussian Mixture Models, reporting performance similar to the CheXpert labeler without requiring any radiologist-labeled reports on the simplified task of normal / abnormal detection. Concurrently developed to our work is the CheXpert++ labeler (McDermott et al., 2020), which was trained on the outputs of the rule-based CheXpert labeler and showed improved performance after a single additional epoch of fine-tuning on expert-labeled report sentences.

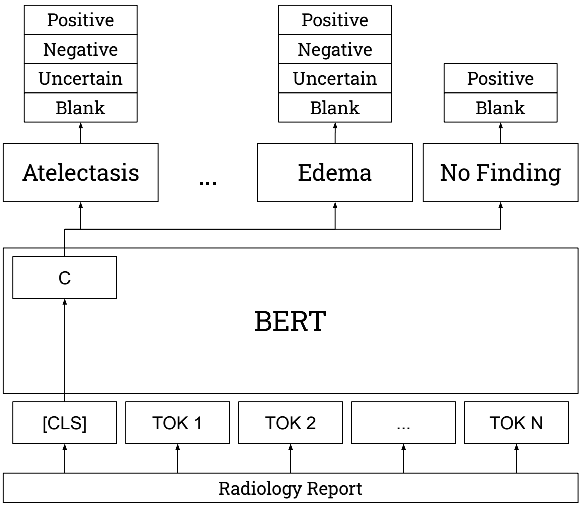

Figure 2: Model architecture. The model contains 14 linear heads, one for each medical observation, but only 3 heads are shown here.

3 Methods

3.1 Task

The report labeling task is to extract the presence of one or more clinically important observations (e.g. consolidation, edema) from a free-text radiology report. More formally, a labeler takes in as inputs sentences from a radiology report and outputs for 13 observations one of the following classes: blank, positive, negative, and uncertain. For the 14th observation corresponding to *No Finding*, the labeler only outputs one of the two following classes: blank or positive.

3.2 Data

Two existing large datasets of chest x-rays, CheXpert (Irvin et al., 2019) (consisting of 224,316 images), and MIMIC-CXR (Johnson et al., 2019) (consisting of 377,110 images) are used in this study. Both datasets have corresponding radiology reports that have been labeled for the same set of 14 observations using the CheXpert labeler (Irvin et al., 2019), from the *Impression* section, or other parts of the radiology report.

A subset of both datasets also contain manual annotations by expert radiologists. On CheXpert, a total of 1000 reports (*CheXpert manual set*) were reviewed by 2 board certified radiologists with disagreement resolution through consensus. On MIMIC-CXR, a total of 687 reports (*MIMIC-CXR test set*) were reviewed by 2 board certified radiologists and manually labeled for the same 14 medical observations as in CheXpert. In this study, CheXpert is used for the development of models, and the MIMIC-CXR test set is used for evaluation.

Some reports from the same patient appear multiple times in the CheXpert dataset. Removing duplicate reports as well as the CheXpert manual set from the CheXpert dataset results in 190,460 reports, the class prevalences for which are shown in Table B1 of the Appendix. We remove excess spaces and newlines from all reports.

3.3 Model Architecture

All models use a modification of the BERT-base architecture (Devlin et al., 2019) with 14 linear heads (as shown in Figure 2): 12 heads correspond to various medical abnormalities, 1 to medical support devices, and 1 to 'No Finding'. Each radiology report text is tokenized, and the maximum number of tokens in each input sequence is capped at 512. The final-layer's hidden state corresponding to the CLS token is then fed as input to each of the linear heads.

3.4 Training Details

For all our models, unless otherwise specified, we fine-tune all layers of the BERT model, including the embeddings, and feed the CLS token into the 14 linear heads to generate class scores for each medical observation. BERT-Base contains $\sim$ 110 million parameters, and the linear heads contain $\sim 40,000$ parameters.

All models are trained using cross-entropy loss and Adam optimization with a learning rate of 2×10^{-5}, as used in Devlin et al. (2019) for fine-tuning tasks. The cross-entropy losses for each of the 14 observations are added to produce the final loss. During training, we periodically evaluate our model on the dev set and save the checkpoint with the highest performance averaged over all 14 observations. All models are trained using 3 TITAN-XP GPUs with a batch size of 18.

3.5 Evaluation

Models are evaluated on their average performance on three retrieval tasks: positive extraction, negative extraction, and uncertainty extraction. For each of the tasks, the class of interest (e.g. negative for the negative extraction and uncertain for the uncertainty extraction) is treated as the positive class, and the other classes are considered negative. For each of the 14 observations, we compute a weighted average of the F1 scores on each of the above three tasks, weighted by the support for each class of interest, which we call the *weighted-F1* metric, henceforth simply abbreviated to F1.

We report the simple average of the F1 across all of the observations. We include the 95% two-sided confidence intervals of the F1 using the non-parametric percentile bootstrap method with 1000 bootstrap replicates (Efron and Tibshirani, 1986).

4 Experiments

4.1 Supervision Strategies

We investigate models trained using three strategies: trained only on radiologist-labeled reports, trained only on labels generated automatically by the CheXpert labeler (Irvin et al., 2019), and trained on a combination of the two.

Radiologist Labels **T-rad** is obtained by training the model on the CheXpert manual set, fine-tuning all weights. As baselines, we also train models that freeze all weights in the BERT layers, and only update the weights in the linear heads: **T.cls-rad** is identical to T-rad in architecture, while **T.token-rad** averages the non-padding output tokens as the input into the linear heads rather than using the CLS token output. All models are trained using a random 75%-25% train-dev split on the CheXpert manual set, and are trained until convergence.

Automatic Labels **T-auto** is obtained using labels generated by the rule-based CheXpert labeler, described in Irvin et al. (2019). T-auto is trained using a random 85%-15% train-dev split of the CheXpert dataset, different from the models trained on radiologist labels. T-auto is trained for 8 epochs, since slightly higher dev performance is observed compared to the typical 2-4 epochs for BERT fine-tuning tasks.

Hybrid Labels **T-hybrid** is obtained by initializing a model with the weights of T-auto, and then fine-tuning it on radiologist-labeled reports, as for T-rad.

Results As shown in Table 1, T-rad achieves an F1 of 0.705 $(0.680, 0.725)$, significantly higher than the performance of the baselines with T.cls-rad at 0.286 $(0.265, 0.305)$, and T.token-rad at 0.396 $(0.374, 0.416)$. T-auto achieves a higher F1 of 0.755 $(0.731, 0.774)$. Superior performance is obtained by T-hybrid, with an F1 of 0.775 $(0.753, 0.795)$.

4.2 Biomedical Language Representations

We investigate the effect of having models pretrained on biomedical data. For the following models, we use an identical training procedure to T-rad, but initialize the weights differently. **Tbio-rad** is obtained by using BioBERT weight initializations (Lee et al., 2019). BioBERT was obtained by further pretraining the BERT weights on a large biomedical corpus comprising PubMed abstracts (4.5 billion words) and PMC full-text articles (13.5 billion words). **Tclinical-rad** is obtained by using Clinical BioBERT weight initializations (Alsentzer et al., 2019), which were obtained by further pretraining the BioBERT weights on 2 million clinical notes from the MIMIC-III database. Finally, **Tblue-rad** is obtained by using BlueBERT, a BERT model pretrained on PubMed abstracts and clinical notes (MIMIC-III) (Peng et al., 2019).

Results As shown in Table 1, Tbio-rad achieves an F1 of 0.616 $(0.587, 0.639)$ and Tclinical-rad achieves an F1 of 0.677 $(0.651, 0.699)$, lower than T-rad. However, Tblue-rad achieves an F1 of 0.741 $(0.714, 0.763)$, higher than T-rad. The drop in performance with Tbio-rad and Tclinical-rad may possibly be attributed to using different vocabulary, sequence length, and other configurations (stopping procedure, embedding dimensions) than those used by Tblue-rad, which uses the configurations provided in Devlin et al. (2019).

4.3 Data Augmentation using Backtranslation

We investigate the use of backtranslation to improve the performance of the models. Backtranslation is designed to generate alternate formulations of sentences by translating them to another language and back. Although backtranslation has been successfully used to augment text data in a variety of NLP tasks (Yu et al., 2018; Poncelas et al., 2018), to our knowledge, the technique is yet to be applied to a medical report extraction task. In this experiment, we augment the CheXpert manual set using Facebook-FAIR's winning submission to the WMT'19 news translation task (Ng et al., 2019) to generate backtranslations. Although this submission includes models that produce German/English and Russian/English translations, initial experiments with Russian did not demonstrate semantically correct translations, so we only continued experiments with German. We use beam search with a beam size of 1 to select the single

	Model	F1 (95% CI)
Training Strategy	T-rad	0.705 (0.680, 0.725)
	T.cls-rad	0.286 (0.265, 0.305)
	T.token-rad	0.396 (0.374, 0.416)
	T-auto	0.755 (0.731, 0.774)
	T-hybrid	0.775 (0.753, 0.795)

Average	0.798 (0.775, 0.816)	0.055 (0.039, 0.070)

Table 2: The F1 scores for CheXbert as well as improvements over the CheXpert labeler on the MIMIC-CXR test set, in descending order of improvement, and reported with 95% confidence intervals.

most likely translation. We perform this experiment using our best models: **Tblue-rad-bt** is obtained by using an identical training procedure to Tblue-rad on the augmented dataset (which is twice the size of the CheXpert manual set). **Tblue-hybrid-bt** is obtained by first training a BlueBERT-based labeler on automatically generated CheXpert labels, and then fine-tuning on radiologist-labeled reports of the CheXpert manual set, augmented by backtranslation. We also report the performance of T-rad-bt and T-hybrid-bt.

Results As shown in Table 1, T-rad-bt achieves an F1 score of 0.729 $(0.702, 0.749)$, higher than that of T-rad. Similarly, T-hybrid-bt achieves an F1 of 0.795 $(0.772, 0.815)$. Tblue-rad-bt achieves an F1 of 0.770 $(0.747, 0.790)$, higher than that of the CheXpert labeler. Tblue-hybrid-bt achieves a superior F1 score of 0.798 $(0.775, 0.816)$.

4.4 Comparison to previous SOTA and radiologist benchmark

We compare the performance of our best model to the previous best reported labeler, the CheXpert labeler (Irvin et al., 2019), and to a radiologist benchmark. CheXpert is an automated rule-based labeler that extracts mentions of conditions like pneumonia by searching against a large manually curated list of words associated with the condition and then classifies mentions as uncertain, negative, or positive using rules on a universal dependency parse of the report. For the radiologist benchmark, the annotations by one of the 2 radiologists on the MIMIC-CXR test set is used, while the other is used as ground truth. We report the improvement of our best model, Tblue-hybrid-bt, which we also call **CheXbert**, over the CheXpert labeler by computing the paired differences in F1 scores on 1000 bootstrap replicates and provide the mean difference along with a 95% two-sided confidence interval.

Results We observe that CheXbert has a statistically significant improvement ($p < 0.001$) over the existing SOTA, CheXpert, which achieves a score of 0.743 $(0.719, 0.764)$. Notably, we also find that Tblue-rad-bt, the best model trained only on manually labeled radiology reports, performs at least as well as the CheXpert labeler.

Table 2 shows the F1 per class (along with 95% confidence intervals) for CheXbert and for the improvements over CheXpert. CheXbert records an improvement in all but 2 medical conditions, and a statistically significant improvement in 9 of the 14 conditions. The largest improvements are observed for Pneumonia [0.151 $(0.093, 0.206)$], Fracture [0.120 $(0.019, 0.236)$], Consolidation [0.105 $(0.029, 0.192)$], Enlarged Cardiomediastinum [0.100 $(0.038, 0.166)$], and No Finding [0.097 $(0.007, 0.182)$]. Further significant improvements are observed for Pleural Other [0.056 $(0.008, 0.124)$], Cardiomegaly [0.051 $(0.018, 0.086)$], Pneumothorax [0.046 $(0.015, 0.076)$] and Support Devices [0.021 $(0.004, 0.040)$]. Overall, CheXbert achieves a statistically significant improvement on F1 of 0.055 $(0.039, 0.070)$. The board-certified radiologist achieves an F1 of 0.805 $(0.784, 0.823)$, which is 0.007 F1 points higher than the performance of CheXbert.

Training times For all our models except the baselines, training on radiologist-labeled reports takes $\sim$ 30 minutes, training on the radiologist-labeled reports augmented via backtranslation takes $\sim$ 50 minutes. Training on the larger automatically labeled report set takes $\sim$ 7 hours.

Inference times We benchmark the time taken by CheXbert and CheXpert to label all 190,460 report impressions in the CheXpert dataset. On a system with 32GB RAM and 1 CPU core, the CheXbert model takes $\sim$ 3.7 hours. This is an order of magnitude faster than the 36 hours required for CheXpert. With a single TITAN-XP GPU, the CheXbert model's inference time reduces to $\sim$ 18 minutes.

5 Analysis

5.1 T-auto versus CheXpert

We analyze whether T-auto, which is trained exclusively on labels from CheXpert (a rules-based labeler), can generalize beyond those rules.

We analyze specific examples in the CheXpert manual test set which T-auto correctly labels but CheXpert mislabels. On one example, T-auto is able to correctly detect uncertainty expressed in the phrase "cannot be entirely excluded," which CheXpert is not able to detect because the phrase does not match any rule in its ruleset. Similarly, on another example containing "no evidence of pneumothorax or bony fracture," T-auto correctly labels fracture as negative, while CheXpert labels fracture as positive since the phrasing does match any negation construct part of its ruleset. T-auto, in contrast to CheXpert, also recognizes conditions with misspellings in the report like "cariomegaly" in place of "cardiomegaly" and "mediastnium" in place of "mediastinum". Examples of T-auto correctly labeling conditions mislabeled by CheXpert are provided in Table B4 of the Appendix. Table B5 of the Appendix contains examples of CheXpert correctly labeling conditions mislabeled by T-auto. An example of each case is shown in the top two rows of Table 3.

5.2 CheXbert versus T-auto and CheXpert

We analyze how CheXbert improves on T-auto and CheXpert using examples which CheXbert correctly labels but T-auto and CheXpert incorrectly label.

CheXbert is able to correctly detect conditions that CheXpert and T-auto are not able to. On one example, T-auto and CheXpert both mislabel a "mildly enlarged heart" as blank for cardiomegaly, while CheXbert correctly labels it positive. On another containing "Right hilum appears slightly more prominent" (an indicator for enlarged cardiomediastinum), CheXbert correctly classifies enlarged cardiomediastinum as positive, while T-auto and CheXpert do not detect the condition.

Furthermore, CheXbert correctly labels nuanced expressions of negation that both CheXpert and T-auto mislabel. On the example containing "heart size is slightly larger but still within nor-

Report Segment and Labels	Reasoning
...two views of chest demonstrate *cariomegaly* with no focal consolidation... Cardiomegaly CheXpert: Blank ✗ T-auto: Positive ✓	T-auto, in contrast to CheXpert, recognizes conditions with misspellings in the report like "cariomegaly" in place of "cardiomegaly".
...consistent with acute and/or chronic pulmonary edema.... Edema CheXpert: Positive ✓ T-auto: Uncertain ✗	T-auto incorrectly detects uncertainty in the edema label, likely from the "and/or"; CheXpert correctly classifies this example as positive.
...Normal heart size, mediastinal and hilar contours are unchanged in appearance... Enlarged Cardiomediastinum CheXpert: Negative ✗ T-auto: Negative ✗ CheXbert: Uncertain ✓	T-auto and CheXpert both incorrectly label this example as negative for enlarged cardiomediastinum; CheXbert correctly classifies it as uncertain, likely recognizing that "unchanged" is associated with uncertainty of the condition. The condition cannot be labeled positive or negative without more information.

Table 3: Phrases from reports where CheXpert, T-auto, and CheXbert provide different labels. The correct label is indicated by a checkmark in the first column. The CheXpert versus T-auto comparisons are conducted on the CheXpert manual set. The CheXbert versus T-auto/CheXpert comparison is conducted on the MIMIC-CXR test set.

mal range," CheXpert and T-auto mistakenly label cardiomegaly as positive, while CheXbert correctly labels cardiomegaly as negative. On another example containing the phrase "interval removal of PICC lines", CheXpert and T-auto detect "PICC lines" as an indication of a support device but are unable to detect the negation indicated by "removal", which CheXbert correctly does.

Additionally, CheXbert is able to correctly detect expressions of uncertainty that both CheXpert and T-auto mislabel. On an example containing "new bibasilar opacities, which given the clinical history are suspicious for aspiration," CheXbert correctly identifies lung opacity as positive while CheXpert and T-auto incorrectly detect uncertainty (associating "suspicious" as a descriptor of "opacities"). More examples which CheXbert correctly labels but CheXpert and T-auto mislabel can be found in Table B6 of the Appendix. A selected example is shown in the last row of Table 3.

5.3 Report Changes with Backtranslation

We analyze the phrasing and vocabulary changes that backtranslation introduces into the reports. Backtranslation frequently rephrases text. For instance, the sentence "redemonstration of multiple right-sided rib fractures" is backtranslated to "re-demonstration of several rib fractures of the right side". Backtranslation also introduces some error: the phrase "left costophrenic angle" is backtranslated to "left costophrine angle" ("costophrine" is not a word), and the phrase "left anterior chest wall pacer in place" is backtranslated to "pacemaker on the left front of the chest wall", which omits the critical attribute of being in place. In many examples, the backtranslated text paraphrases medical vocabulary into possible semantic equivalents: "cutaneous" becomes "skin", "left clavicle" becomes "left collarbone", "osseous" becomes "bone" or "bony", "anterior" becomes "front", and "rib fracture" becomes "broken ribs". More backtranslations with analyses are provided in Table B7 of the Appendix. Additionally, a physician validated that the backtranslation outputs used correct radiology language and maintained the semantics of the original report. The results are provided in Table A1 of the Appendix.

6 Limitations

Our study has several limitations. First, our hybrid/auto approaches require an already-existing labeler. Second, our report labeler has a maximum input token size of 512 tokens, but this may be easily extended to work with longer medical/radiology reports. In the CheXpert dataset, we found that only 3 of the 190,460 report impressions were longer than 512 tokens. Third, our task is limited to the 14 observations labeled for, and we do not test for the model's ability to label rarer conditions. However, CheXbert can mark No Finding as blank, which can indicate the presence of another condition if the other 13 conditions are also blank. Fourth, the ground truth labels for the MIMIC-CXR test set were determined by a single board-certified radiologist, and the use of more radiologists could demonstrate a truer comparison to the radiologist benchmark. Fifth, while we do test performance on a dataset from an institution unseen in training, additional datasets across institutions could be useful in further establishing the model's ability to generalize.

7 Conclusion

In this study, we propose a simple method for combining existing report labelers with hand-annotations for accurate radiology report labeling. In this method, a biomedically pretrained BERT model is first trained on the outputs of a labeler, and then further fine-tuned on the manual annotations, the set of which is augmented using backtranslation. We report five findings on our resulting model, CheXbert. First, we find that CheXbert outperforms models trained only on radiologist-labeled reports, or only on the existing labeler's outputs. Second, we find that CheXbert outperforms the BERT-based model not pretrained on biomedical data. Third, we find that CheXbert outperforms models which do not use backtranslation. Fourth, we find that CheXbert outperforms the previous best labeler, CheXpert (which was rules-based), with an improvement of 0.055 (95% CI 0.039, 0.070) on the F1 metric; we also find that the best model trained only on manually labeled radiology reports (Tblue-rad-bt) performs at least as well as the CheXpert labeler. Fifth, we find that CheXbert is 0.007 F1 points from the radiologist performance benchmark, suggesting that the gap to ceiling performance is narrow.

We expect this method of training medical report labelers is broadly useful within the medical domain, where collection of expert labels can produce a small set of high quality labels, and existing feature engineered labelers can produce labels at scale. Extracting highly accurate labels from medical reports by taking advantage of both sources can enable many important downstream tasks, including the development of more accurate and robust medical imaging models required for clinical deployment.

Acknowledgments

We would like to acknowledge the Stanford Machine Learning Group (`stanfordmlgroup.github.io`) and the Stanford Center for Artificial Intelligence in Medicine and Imaging (`AIMI.stanford.edu`) for infrastructure support. Thanks to Alistair Johnson for support in the radiologist benchmark, to Jeremy Irvin for support in the CheXpert labeler, Alex Tamkin for helpful comments, and Yifan Peng for helpful feedback.

A Physician validation of backtranslation quality

Table A1: Physician validation of backtranslation output quality on a set of 100 randomly sampled reports from the CheXpert manual set and their backtranslations.

Score	Valid radiology language	Preserves semantic information
1	6	14
2	48	26
3	46	60

Although the CheXbert model shows empirical improvements using backtranslated reports, backtranslation can introduce additional noise into the reports. A physician validated the quality of the backtranslation outputs. For this experiment, we randomly sampled 100 reports from the CheXpert manual set. The physician read each original report and its backtranslation, and assigned a score for whether the backtranslation a) used valid radiology language, and b) maintained the semantics of the report. For each of tasks a) and b), the expert assigned a score of 1 (worst), 2 or 3 (highest).

For task a), a score of 3 means the backtranslation contained near-perfect radiology language, a 2 means the backtranslation had only minor deviations from valid radiology language, and 1 means the backtranslation had a major deviation from valid radiology language.

For task b), a score of 3 means the backtranslation fully preserved the semantics of the original, a 2 means the backtranslation contained minor semantic errors, and a 1 means the backtranslation had a major change or loss of semantic information compared to the original report.

B Additional results

Table B1: After removing duplicate reports for the same patient from the CheXpert dataset (excluding the CheXpert manual set), we are left with a total of 190,460 reports. Labels for these reports are provided by the CheXpert labeler. The class prevalences of this set are displayed for each medical condition.

Condition	**Positive**	**Negative**	**Uncertain**	**Blank**
Atelectasis	29,818 (15.66%)	1,018 (0.53%)	29,832 (15.66%)	129,792 (68.15%)
Cardiomegaly	23,302 (12.23%)	7,809 (4.10%)	6,682 (3.51%)	152,667 (80.16%)
Consolidation	12,977 (6.81%)	19,397 (10.18%)	24,345 (12.78%)	133,741 (70.22%)
Edema	49,725 (26.11%)	15,867 (8.33%)	11,746 (6.17%)	113,122 (59.39%)
Enlarged Cardiomed.	9,129 (4.79%)	15,165 (7.96%)	10,278 (5.40%)	155,888 (81.85%)
Fracture	7,364 (3.87%)	1,960 (1.03%)	488 (0.26%)	180,648 (94.85%)
Lung Lesion	6,955 (3.65%)	758 (0.40%)	1,084 (0.57%)	181,663 (95.38%)
Lung Opacity	94,156 (49.44%)	5,006 (2.63%)	4,404 (2.31%)	86,894 (45.62%)
No Finding	16,795 (8.82%)	NA	NA	173,665 (91.18%)
Pleural Effusion	77,028 (40.44%)	25,097 (13.18%)	9,565 (5.02%)	78,770 (41.36%)
Pleural Other	2,481 (1.30%)	210 (0.11%)	1,801 (0.95%)	185,968 (97.64%)
Pneumonia	4,647 (2.44%)	1,851 (0.97%)	15,907 (8.35%)	168,055 (88.24%)
Pneumothorax	17,688 (9.29%)	47,566 (24.97%)	2,704 (1.42%)	122,502 (64.32%)
Support Devices	107,601 (56.50%)	5,319 (2.79%)	910 (0.48%)	76,630 (40.23%)

Table B2: Dev set F1 scores for all our models. The dev set for all rad models and T-hybrid consists of 250 randomly sampled reports from the CheXpert manual set. The dev set for T-auto is a random 15% split of the CheXpert dataset. The dev set for all models using backtranslation is obtained by augmenting the 250 randomly sampled reports from the CheXpert manual set by backtranslation. Tblue-hybrid-bt is first trained on labels generated by the CheXpert labeler, and then fine-tuned on radiologist labels augmented by backtranslation. Before fine-tuning on radologist labels, it obtains an F1 of 0.977 on the 15% dev split of the CheXpert dataset.

	Model	F1
Training Strategy	T-rad	0.848
	T.cls-rad	0.411
	T.token-rad	0.518
	T-auto	0.977
	T-hybrid	0.904
Biomedical Representations	Tbio-rad	0.760
	Tclinical-rad	0.802
	Tblue-rad	0.866
With Backtranslation Augmentation	T-rad-bt	0.846
	T-hybrid-bt	0.905
	Tblue-rad-bt	0.865
	Tblue-hybrid-bt (CheXbert)	0.912

Table B3: The differences in the number of times labels were correctly assigned by one model versus another model. For example, in the first column named "T-auto > CheXpert," we report the difference between the number of times T-auto correctly classifies a label and the number of times CheXpert correctly classifies a label. We record the differences between a pair of models by category (blank, positive, negative, uncertain) and by total. These occurrences are obtained on the MIMIC-CXR test set.

	T-auto > CheXpert	**CheXbert > CheXpert**	**CheXbert > Radiologist**
Blank	0	29	56
Positive	-22	11	56
Negative	14	45	9
Uncertain	16	46	-3
Total	8	131	118

Table B4: Examples where T-auto correctly assigns a label while CheXpert misassigns that label on the CheXpert manual set. We include speculative reasoning for the classifications.

Example & Labels	**Reasoning**
...redemonstration of diffuse nodular air space opacities which are unchanged from prior examination **which may represent air space pulmonary edema versus infection**, as clinically correlated... Edema CheXpert: Positive ✗ T-auto: Uncertain ✓	T-auto appears to detect uncertainties indicated by words like "may" and "versus" on conditions. In this case, this phrase did not match an uncertainty detection rule in the CheXpert classifier.
... there has been interval development of left basilar patchy airspace opacity, which likely represents atelectasis, **although consolidation cannot be entirely excluded**... Consolidation CheXpert: Positive ✗ T-auto: Uncertain ✓	Unlike CheXpert, T-auto correctly detects uncertainty conveyed in the phrase "cannot be entirely excluded".
1. no radiographic evidence of acute cardiopulmonary disease. 2. **no evidence of pneumothorax or bony fracture**. Fracture CheXpert: Positive ✗ T-auto: Negative ✓	In this example, T-auto is able to detect a negation indicated by "no evidence of". CheXpert is not able to pick up this negation construction as part of its ruleset.

Table B5: Examples where CheXpert correctly assigns a label while T-auto misassigns that label on the CheXpert manual set. We include speculative reasoning for the classifications.

Example & Labels	**Reasoning**
...2.**mild cardiomegaly**. persistent small bilateral pleural effusions, left greater than right... Cardiomegaly CheXpert: Positive ✓ T-auto: Uncertain ✗	T-auto mistakenly labels "mild cardiomegaly" as uncertain for cardiomegaly.
...2.there are diffuse increased interstitial markings and prominence of the central vasculature, **consistent with acute and/or chronic pulmonary edema**... Edema CheXpert: Positive ✓ T-auto: Uncertain ✗	T-auto may have incorrectly detected uncertainty from "and/or," which is a conjunction between "acute" and "chronic".

Table B6: Examples where CheXbert correctly assigns a label while both T-auto and CheXpert misassign that label on the MIMIC-CXR test set. We include speculative reasoning for the classifications.

Example & Labels	Reasoning
New bibasilar opacities, which given the clinical history are suspicious for aspiration, possibly developing pneumonia. Lung Opacity CheXpert: Uncertain ✗ T-auto: Uncertain ✗ CheXbert: Positive ✓	The word "suspicious" does not modify "opacities" in this sentence. Although CheXbert correctly identifies this, CheXpert and T-auto misclassify the "opacities" as uncertain.
...Coalescent areas in the left upper and lower zones **could well reflect regions of consolidation**. The right lung is essentially clear... Consolidation CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Uncertain ✓	CheXbert correctly detects that consolidation is uncertain, as indicated by the phrase "could well reflect".
Removal of dialysis catheter with no evidence of pneumothorax. **Heart is mildly enlarged** and is accompanied by vascular engorgement and new septal lines consistent with interstitial edema... Cardiomegaly CheXpert: Blank ✗ T-auto: Blank ✗ CheXbert: Positive ✓	Due to a ruleset limitation, CheXpert only looks at "the heart" or "heart size" but not "heart" independently when checking for mentions of cardiomegaly. However, CheXbert recognizes mentions of cardiomegaly implied by phrases like "heart is mildly enlarged".
No previous images. There is hyperexpansion of the lungs suggestive of chronic pulmonary disease. Prominence of engorged and ill-defined pulmonary vessels is consistent with the clinical diagnosis of pulmonary vascular congestion, though in the absence of previous images it is difficult to determine whether any this appearance could reflect underlying chronic pulmonary disease. **The possibility of supervening consolidation would be impossible to exclude** on this single study, especially without a lateral view. No evidence of pneumothorax. Consolidation CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Uncertain ✓	CheXbert correctly detects uncertainty for consolidation indicated by the word "possibility". Both T-auto and CheXpert misclassify consolidation.
1. Left suprahilar opacity and fiducial seeds are again seen, although appears slightly less prominent/small in size, although as mentioned on the prior study, could be further evaluated by chest CT or PET-CT. 2. **Right hilum appears slightly more prominent** as compared to the prior study, which may be due to patient positioning, although increased right hilar lymphadenopathy is not excluded. Enlarged Cardiomediast. CheXpert: Blank ✗ T-auto: Blank ✗ CheXbert: Positive ✓	The right hilum appearing more prominent is an indicator of enlarged cardiomediastinum, which is clinically understood. If the hilum is growing, then the entire mediastinum is growing. Although both CheXpert and T-auto mislabeled this report impression, CheXbert successfully labeled it positive for enlarged cardiomediastinum.

Example (cont.) & Labels (cont.)	**Reasoning (cont.)**
As compared to the previous radiograph, there is no relevant change. The reduced volume of the right hemithorax with areas of lateral pleural thickening. The areas of pleural thickening are constant, size and morphology. Unchanged perihilar areas of fibrosis. **Unchanged size and aspect of the cardiac silhouette**, no pathologic changes in the left lung. Cardiomegaly CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Uncertain ✓	CheXbert correctly identifies uncertainty, as the cardiac silhouette is "unchanged," which means that it cannot be labeled positive or negative without additional information regarding the previous state. Both CheXpert and T-auto incorrectly label this example as positive for cardiomegaly.
AP chest compared to ___: Small-to-moderate left pleural effusion has increased slightly over the past several days. Moderate enlargement of the cardiac silhouette accompanied by mediastinal vascular engorgement is also slightly more pronounced. Pulmonary vasculature is engorged but there is no edema. Consolidation has been present without appreciable change in the left lower lobe since at least ___. **Mediastinum widened** at the thoracic inlet by a combination of tortuous vessels and mediastinal fat deposition. Right jugular introducer ends just above the junction with left brachiocephalic vein. Enlarged Cardiomediast. CheXpert: Blank ✗ T-auto: Blank ✗ CheXbert: Positive ✓	CheXbert correctly identifies enlarged cardiomediastinum from the phrase "mediastinum widened," which is a slightly different way of describing enlarged cardiomediastinum that CheXpert and T-auto both miss.
Moderately enlarged heart size, stable since ___. **No findings concerning for pulmonary edema** or pneumonia. Edema CheXpert: Uncertain ✗ T-auto: Uncertain ✗ CheXbert: Negative ✓	Unlike T-auto and CheXpert, CheXbert correctly labels edema as negative, presumably understanding that the initial phrase "no findings" applies to both edema and pneumonia.
AP chest compared to ___ and ___: As far as I can tell, given the severe anatomic distortion of the chest cage and its contents, lungs were clear on ___. Small region of opacification may have been developing lateral to the left hilus on ___, and today there is a suggestion of some new opacification at the base of the lung, but these observations are far from certain. I am not even confident that conventional radiographs, should the patient be able to cooperate for them, would clarify the issue. CT scanning, if feasible, would certainly confirm if the lungs are clear, but in the absence of a baseline study **it might be difficult to distinguish atelectasis from pneumonia**. Pleural effusion is minimal if any. Heart is probably not enlarged. Nasogastric tube is looped in the stomach. Right PIC line ends in the mid SVC. No pneumothorax. Atelectasis CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Uncertain ✓	The report states that "it might be difficult to distinguish atelectasis from pneumonia" which indicates uncertainty, and this is correctly identified by CheXbert. CheXpert and T-auto simply label atelectasis as positive.

Example (cont.) & Labels (cont.)	Reasoning (cont.)
Two frontal views of the chest show new mild interstitial pulmonary edema. Interval increase in mediastinal caliber therefore is probably due to distention of mediastinal veins. **Heart size is slightly larger but still within normal range**. Pleural effusions are minimal, if any. No focal pulmonary abnormality. No pneumothorax. ET tube is in standard placement and a nasogastric tube passes below the diaphragm and out of view. Cardiomegaly CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Negative ✓	Although CheXpert and T-auto mistakenly label cardiomegaly as positive given the phrase the ”heart is slightly larger,” the following phrase ”but still within normal range” implies that cardiomegaly is negative. CheXbert correctly classifies this example as negative for cardiomegaly.
As compared to the previous radiograph, the pre-existing right upper lobe **pneumonia is completely resolved**. The pre-existing signs of mild fluid overload, however, are still present. The pre-existing cardiomegaly is unchanged. Several calcified lung nodules are also unchanged. Unchanged alignment of the sternal wires. No acute pneumonia, no pleural effusions. Pneumonia CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Negative ✓	CheXbert correctly labels pneumonia as negative, as implied by the phrase ” pneumonia is completely resolved,” while CheXpert and T-auto both mislabel pneumonia as positive.
Subsegmental right lung base atelectasis. Increasing loss of vertebral body height at T11. Stable L1 compression fracture. Right shoulder humeral DJD. **Interval removal of PICC lines**. Support Devices CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Negative ✓	CheXbert, presumably using a semantic understanding of the word “removal”, correctly labels support devices as negative. CheXpert and T-auto pick up on “PICC lines” but do not detect the negation. Both incorrectly label support devices as positive.
AP chest compared to ___: Small-to-moderate left pleural effusion has increased slightly over the past several days. Moderate enlargement of the cardiac silhouette accompanied by mediastinal vascular engorgement is also slightly more pronounced. Pulmonary vasculature is engorged but there is no edema. Consolidation has been present without appreciable change in the left lower lobe since at least ___. Mediastinum widened at the thoracic inlet by a combination of tortuous vessels and mediastinal fat deposition. **Right jugular introducer ends just above the junction with left brachiocephalic vein**. Support Devices CheXpert: Blank ✗ T-auto: Blank ✗ CheXbert: Positive ✓	A jugular introducer is a support device that wasn’t included in CheXpert’s list of mentions for support devices. Consequently CheXpert and T-auto, which trains on CheXpert labels, both incorrectly label support devices as blank. CheXbert, however, correctly labels support devices as positive.

Example (cont.) & Labels (cont.)	Reasoning (cont.)
1. Interval removal of the sternal wires with placement of new sternal closure devices, mediastinal staples and tubes. Lungs are well inflated with linear streaky opacities seen at the left base likely representing scarring and/or subsegmental atelectasis. No evidence of pulmonary edema, pneumothorax, pleural effusions or focal airspace consolidation to suggest pneumonia. **Slight lucency at the left apex is felt to be related to underlying emphysema rather than representing a pneumothorax**. Pneumothorax CheXpert: Positive ✗ T-auto: Positive ✗ CheXbert: Negative ✓	CheXbert correctly labels pneumothorax as negative, as the radiologist notes that the observation is related to emphysema rather than pneumothorax. In this complex negation, T-auto and CheXpert incorrectly label pneumothorax as positive.

Table B7: Examples of additional data samples generated using backtranslation on radiologist-annotated reports from the CheXpert manual set. Augmenting our relatively small set of radiologist-annotated reports with backtranslation proved useful in improving performance of our labeler on the MIMIC-CXR test set.

Original Report	Backtranslation	Changes
1. marked cardiomegaly with a configuration that raises concern for a pericardial effusion. possible mild edema. 2. healed left-sided rib fractures.	1. pronounced cardiomegaly with a configuration that raises concerns about a pericardial effusion. possible mild edema. 2. healed left-sided rib fractures.	"marked" is changed to the synonym "pronounced", and "raises concern for" is rephrased as "raises concerns about".
1. redemonstration of right side pleural effusion and bibasilar atelectasis unchanged from comparison. 2. redemonstration of multiple right-sided rib fractures.	1. redemonstration of the pleural effusion of the right side and the bibasilar atelectasia unchanged compared to the comparison. 2. redemonstration of several rib fractures of the right side.	"right side pleural effusion" is rephrased as "pleural effusion of the right side", "unchanged from comparison" is rephrased to "compared to the comparison" and "multiple right-sided rib fractures" is rephrased as "several rib fractures of the right side". However, "atelectasis" is incorrectly changed to "atelectasia".
1. single ap portable semiupright view of the chest demonstrates no change in medical support devices. 2. persistent dense retrocardiac opacity and small to moderate left pleural effusion present. right perihilar opacity appears resolved. 3. stable cardiomediastinal silhouette. no pulmonary edema. 4. multilevel degenerative changes of the spine.	1. single ap portable semi-upright view of the breast showing no change in medical aids. 2. persistent dense retrocardiac opacity and small to moderate left pleural effusion presented. right perihilar opacity appears resolved. 3. stable cardiomediastinal silhouette. no pulmonary edema. 4. multi-level degenerative changes of the spine.	"semiupright" becomes "semi-upright", "medical support devices" is changed to "medical aids", "present" is changed to "presented" and "multilevel" is changed to "multi-level". However, "chest" is incorrectly changed to "breast".

Abstract

Meaning representation is an important component of semantic parsing. Although researchers have designed a lot of meaning representations, recent work focuses on only a few of them. Thus, the impact of meaning representation on semantic parsing is less understood. Furthermore, existing work's performance is often not comprehensively evaluated due to the lack of readily-available execution engines. Upon identifying these gaps, we propose UNIMER, a new unified benchmark on meaning representations, by integrating existing semantic parsing datasets, completing the missing logical forms, and implementing the missing execution engines. The resulting unified benchmark contains the complete enumeration of logical forms and execution engines over three datasets × four meaning representations. A thorough experimental study on UNIMER reveals that neural semantic parsing approaches exhibit notably different performance when they are trained to generate different meaning representations. Also, program alias and grammar rules heavily impact the performance of different meaning representations. Our benchmark, execution engines and implementation can be found on: `https://github.com/JasperGuo/Unimer`.

1 Introduction

A remarkable vision of artificial intelligence is to enable human interactions with machines through natural language. Semantic parsing has emerged as a key technology for achieving this goal. In general, semantic parsing aims to transform a natural language utterance into a logic form, i.e., a formal, machine-interpretable *meaning representation* (MR) (Zelle and Mooney, 1996; Dahl et al., 1994).[1] Thanks to the recent development of neural networks techniques, significant improvements have been made in semantic parsing performance (Jia and Liang, 2016; Yin and Neubig, 2017; Dong and Lapata, 2018; Shaw et al., 2019).

MR	Geo	ATIS	Job
Prolog	-	-	91.4
Lambda	90.4	91.3	85.0
FunQL	92.5	-	-
SQL	78.0	69.0	-
Prolog	89.6	-	92.1
Lambda	-	-	-
FunQL	-	-	-
SQL	82.5	79.2	-

Table 1: State-of-the-art performance for MRs on Geo, ATIS, and Job. The top table shows exact-match accuracy whereas the bottom table shows execution-match accuracy. Most existing work focuses on evaluating only a small subset of dataset × MR pairs, leaving most of the table unexplored. A finer-grained table is available in the supplementary material (Table 8).

Despite the advancement in performance, we identify three important biases in existing work's evaluation methodology. First, although multiple MRs are proposed, most existing work is evaluated on only one or two of them, leading to less comprehensive or even unfair comparisons. Table 1 shows the state-of-the-art performance of semantic parsing on different dataset × MR combinations, where the rows are the MRs and the columns are the datasets. We can observe that while Lambda Calculus is intensively studied, the other MRs have not been sufficiently studied. This biased evaluation is partly caused by the absence of target logic forms in the missing cells. Second, existing work often compares the performance on different MRs directly (Sun et al., 2020; Shaw et al., 2019; Chen et al., 2020) without considering the confounding

[1] In this paper, we focus on *grounded* semantic parsing, where meaning representations are grounded to specific knowledge bases, instead of ungrounded semantic parsing.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1520–1540,
November 16–20, 2020. ©2020 Association for Computational Linguistics

role that MR plays in the performance,[2] causing unfair comparisons and misleading conclusions. Third, a more comprehensive evaluation methodology would consider both the exact-match accuracy and the execution-match accuracy, because two logic forms can be semantically equivalent yet do not match precisely in their surface forms. However, as shown in Table 1, most existing work is only evaluated with the exact-match accuracy. This bias is potentially due to the fact that execution engines are not available in six out of the twelve dataset × MR combinations.

Upon identifying the three biases, in this paper, we propose UNIMER, a new unified benchmark, by unifying four publicly available MRs in three of the most popular semantic parsing datasets: Geo, ATIS and Jobs. First, for each natural language utterance in the three datasets, UNIMER provides annotated logical forms in four different MRs, including Prolog, Lambda Calculus, FunQL, and SQL. We identify that annotated logical forms in some MR × dataset combinations are missing. As a result, we complete the benchmark by semi-automatically translating logical forms from one MR to another. Second, we implement six missing execution engines for MRs so that the execution-match accuracy can be readily computed for all the dataset × MR combinations. Both the logical forms and their execution results are manually checked to ensure the correctness of annotations and execution engines.

After constructing UNIMER, to obtain a preliminary understanding on the impact of MRs on semantic parsing, we empirically study the performance of MRs on UNIMER by using two widely-used neural semantic parsing approaches (a seq2seq model (Dong and Lapata, 2016; Jia and Liang, 2016) and a grammar-based neural model (Yin and Neubig, 2017)), under the supervised learning setting.

In addition to the empirical study above, we further analyze the impact of two operations, i.e., *program alias* and *grammar rules*, to understand how they affect different MRs differently. First, *Program alias*. A semantically equivalent program may have many syntactically different forms. As a result, if the training and testing data have a difference in their syntactic distributions of logic forms, a naive maximum likelihood estimation can suffer from this difference because it fails to capture the semantic equivalence (Bunel et al., 2018). As different MRs have different degrees of syntactic difference, they suffer from this problem differently. Second, *Grammar rules*. Grammar-based neural models can guarantee that the generated program is syntactically correct (Yin and Neubig, 2017; Wang et al., 2020; Sun et al., 2020). For a given set of logical forms in an MR, there exist multiple sets of grammar rules to model them. We observe that when the grammar-based neural model is trained with different sets of grammar rules, it exhibits a notable performance discrepancy. This finding alias with the one made in traditional semantic parsers (Kate, 2008) that properly transforming grammar rules can lead to better performance of a traditional semantic parser.

In summary, this paper makes the following main contributions:

- We propose UNIMER, a new unified benchmark on meaning representations, by integrating and completing semantic parsing datasets in three datasets × four MRs; we also implement six execution engines so that execution-match accuracy can be evaluated in all cases;
- We provide the baseline results for two widely used neural semantic parsing approaches on our benchmark, and we conduct an empirical study to understand the impact that program alias and grammar rule plays on the performance of neural semantic parsing;

2 Preliminaries

In this section, we provide a brief description of the MRs and neural semantic parsing approaches that we study in the paper.

2.1 Meaning Representations

We investigate four MRs in this paper, namely, Prolog, Lambda Calculus, FunQL, and SQL, because they are widely used in semantic parsing and we can obtain their corresponding labeled data in at least one semantic parsing domain. We regard Prolog, Lambda Calculus, and FunQL as domain-specific MRs, since the predicates defined in them are specific for a given domain. Consequently, the execution engines of domain-specific MRs need to be significantly customized for different domains, requiring plenty of manual efforts. In contrast, SQL is a domain-general MR for querying relational

---

[2] In (Kate et al., 2005; Liang et al., 2011; Guo et al., 2019), it was revealed that using an appropriate MR can substantially improve the performance of a semantic parser.

MR	Logical Form
Prolog	answer(A, (flight(A) , tomorrow(A) , during_day(A, B) , const (B, period (morning)), from(A, C) , const(C, city(Pittsburgh)), to(A, D), const (D, city(Atlanta))))
Lambda Calculus	(lambda A:e ((flight A) ∧ (during_day A morning:pd) ∧ (from A Pittsburgh:ci) ∧ (to A Atlanta:ci) ∧ (tomorrow A)))
FunQL	answer (flight (tomorrow (intersect (during_day (period (morning)) , from (city (Pittsburgh)) , to (city (Atlanta))))))
SQL	SELECT flight_id FROM … WHERE city_1.city_name = ‘pittsburgh’ AND city_2.city_name = ‘atlanta’ AND date_day_1.year = 1991 AND date_day_1.month_number = 1 AND date_day_1.day_number = 20 AND departure_time BETWEEN 0 AND 1200

Table 2: Examples of meaning representations for utterance “what flights do you have in tomorrow morning from pittsburgh to atlanta?” in the ATIS domain.

databases. Its execution engines (e.g., MySQL) can be used directly in different domains. Table 2 shows a logical form for each of the four MRs in the ATIS domain.

Prolog has long been used to represent the meaning of natural language (Zelle and Mooney, 1996; Kate and Mooney, 2006). Prolog includes first-order logical forms, augmented with some higher-order predicates, e.g., `most`, to handle issues such as quantification and aggregation. Take the first logical form in Tables 2 as an example. The uppercase characters denote variables, and the predicates in the logical form specify the constraints between variables. In this case, character `A` denotes a variable, and it is required to be a flight, and the flight should depart tomorrow morning from Pittsburgh to Atlanta. The outer predicate `answer` indicates the variable whose binding is of interest. One major benefit of Prolog-style MRs is that they allow predicates to be introduced in the order where they are actually named in the utterance. For instance, the order of predicates in the logical form strictly follows their mentions in the natural language utterance.

Lambda Calculus is a formal system to express computation. It can represent all first-order logic and it naturally supports higher-order functions. It represents the meanings of natural language with logical expressions that contain constants, quantifiers, logical connectors, and lambda abstract. These properties make it prevalent in semantic parsing. Consider the second logical form in Table 2. It defines an expression that takes an entity `A` as input and returns true if the entity satisfies the constraints defined in the expressions. Lambda Calculus can be typed, allowing type checking during generation and execution.

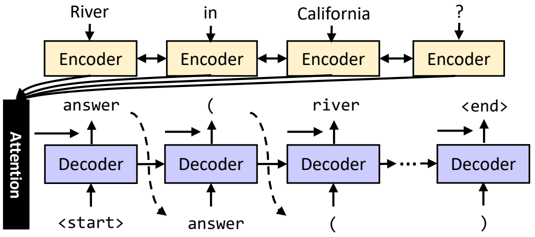
FunQL, abbreviated for Functional Query Language, is a variable-free language (Kate et al., 2005). It abstracts away variables and encodes compositionality via its nested function-argument structure, making it easier to implement an efficient execution engine for FunQL. Concretely, unlike Prolog and Lambda Calculus, predicates in FunQL take a set of entities as input and return another set of entities that meet certain requirements. Considering the third logical form in Table 2, the predicate `during_day(period(morning))` returns a set of flights that depart in the morning. With this function-argument structure, FunQL can directly return the entities of interest.

SQL is a popular relational database query language. Since it is domain-agnostic and has well-established execution engines, the subtask of semantic parsing, Text-to-SQL, has received a lot of interests. Compared with domain-specific MRs, SQL cannot encapsulate too much domain prior knowledge in its expressions. As shown in Table 2, to query flights that depart tomorrow, one needs to specify the concrete values of year, month, and day in the SQL query. However, these values are not explicitly mentioned in the utterance and may even change over time.

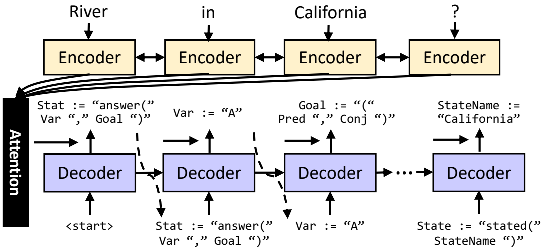
It is important to note that although these MRs are all expressive enough to represent all meanings in some domains, they are not equivalent in terms of their general expressiveness. For example, FunQL is less expressive than Lambda Calculus in general, partially due to the elimination of variables and quantifiers.

2.2 Neural Semantic Parsing Approaches

During the last few decades, researchers have proposed different approaches for semantic parsing. Most state-of-the-art approaches are based on neural models and formulate the semantic parsing problem as a sequence transduction problem. Due to the generality of sequence transduction, these ap-



(a) Seq2Seq Model



(b) Grammar-based Model

Figure 1: Illustrations of the seq2seq model and the grammar-based model with utterance “Rivers in California?” and its corresponding logical form in Prolog.

proaches can be trained to generate any MRs. In this work, without loss of generality, we benchmark MRs by evaluating the seq2seq model (Dong and Lapata, 2016; Jia and Liang, 2016) and the grammar-based model (Yin and Neubig, 2017) under the supervised learning setting. We select the two models because most neural approaches are designed based on them.

Seq2Seq Model. Dong and Lapata (2016) and Jia and Liang (2016) formulated the semantic parsing problem as a neural machine translation problem and employed the sequence-to-sequence model (Sutskever et al., 2014) to solve it. As illustrated in Figure 1a, the encoder takes an utterance as input and outputs a distributed representation for each word in the utterance. A decoder then sequentially predicts words in the logical form. When augmented with the attention mechanism (Bahdanau et al., 2014; Luong et al., 2015), the decoder can better utilize the encoder's information to predict logical forms. Moreover, to address the problem caused by the long tail distribution of entities in logical forms, Jia and Liang (2016) proposed an attention-based copying mechanism. That is, at each time step, the decoder takes one of two types of actions, one to predict a word from the vocabulary of logical forms and the other to copy a word from the input utterance.

Grammar-based Model. By treating a logical form as a sequence of words, the seq2seq model cannot fully utilize the property that logical forms are well-formed and must conform to certain grammars of an MR. To bridge this gap, Yin and Neubig (2017) proposed a grammar-based decoder that outputs a sequence of *grammar rules* instead of words, as presented in Figure 1b. The decoded grammar rules can deterministically generate a valid abstract syntax tree (AST) of a logical form. In this way, the generated logical form is guaranteed to be syntactically correct. This property makes it widely used in a lot of code generation and semantic parsing tasks (Sun et al., 2020; Wang et al., 2020; Bogin et al., 2019). The grammar-based decoder can also be equipped with the attention-based copying mechanism to address the long-tail distribution problem.

3 Benchmark

To provide an infrastructure for exploring MRs, we construct UNIMER, a unified benchmark on MRs, based on existing semantic parsing datasets. Currently, UNIMER covers three domains, namely Geo, ATIS, and Job, each of which has been extensively studied in previous work and has annotated logical forms for at least two MRs. All natural language utterances in UNIMER are written in English.

Geo focuses on querying a database of U.S. geography with natural language. To solve the problem, Zelle and Mooney (1996) designed a Prolog-style MR and annotated 880 (utterance, logical form) pairs. Popescu et al. (2003) and Kate et al. (2005) proposed to use SQL and FunQL to represent the meanings, respectively. Almost the same time, Zettlemoyer and Collins (2005) proposed to use Lambda Calculus and manually converted the Prolog logical forms to equivalent expressions in Lambda Calculus. Following their work, we adopt the standard 600/280 training/test split.

ATIS is a dataset of flight booking questions. It consists of 5,418 questions and their corresponding SQL queries. Zettlemoyer and Collins (2007) proposed to use Lambda Calculus to represent the meanings of natural language and automatically map these SQL queries to its equivalent logical forms in Lambda Calculus. Following the work of Kwiatkowski et al. (2011), we use the standard 4480/480/450 training/dev/test split.

Job is a dataset about job announcements posted in the newsgroup austin.jobs (Califf and Mooney, 1999). It consists of 640 utterances and their corresponding Prolog logical forms that query computer-related job postings. Similarly, in Geo, Zettlemoyer and Collins (2005) proposed using Lambda Calculus and manually converted them to equivalent expressions in Lambda Calculus. We use the same training-test split with them, containing 500 training and 140 test instances.

Since not all the four MRs that we introduce in Section 2.1 are used in these three domains, we semi-automatically translate logical forms in one MR into another. This effort enables researchers to explore MRs in more domains and make a fair comparison among them. Take the translation of Lambda Calculus to FunQL in ATIS as an example. We first design predicates for FunQL based on those defined in Lambda Calculus and implement an execution engine for FunQL. Then, we translate logical forms in Lambda Calculus to FunQL and compare the execution results to verify the correctness of the translation. In this process, we find that there is no ready-to-use Lambda Calculus execution engine for the three domains. Hence, we implement one for each domain. These engines, on the one hand, enable evaluations of semantic parsing approaches with both exact-match accuracy and execution-match accuracy. On the other hand, they enable exploration of weakly supervised semantic parsing with Lambda Calculus. In addition, we find some annotation mistakes in logical forms and several bugs in existing execution engines of Prolog and FunQL. By correcting the mistakes and fixing the bugs in the engines, we create a refined version of these datasets. Section A.1 in the supplementary material provides more details about the construction process.

We plan to cover more domains and more MRs in UNIMER. We have made UNIMER along with the execution engines publicly available.[3] We believe that UNIMER can provide fertile soil for exploring MRs and addressing challenges in semantic parsing.

4 Experimental Setup

Based on UNIMER, we take the first attempt to study the characteristics of different MRs and their impact on neural semantic parsing.

4.1 Experimental Design

Meaning Representation Comparison. To understand the impact of MRs on neural semantic parsing, we first experiment with the two neural approaches described in Section 2.2 on UNIMER, and we compare the resulting performance of different MRs with two metrics: *exact-match accuracy* (a logical form is regarded as correct if it is syntactically identical to the gold standard),[4] and *execution-match accuracy* (regarded as correct if a logical form's execution result is identical to that of the gold standard).[5]

Rule	Description
Shuffle	Shuffle expressions in Select, From, Where, and Having clauses
Argmax	Express Argmax/min with OrderBy and Limit clause instead of subquery
In2Join	Replace In clause with Join clause

Table 3: Three basic transformation rules for SQL.

Program Alias. To explore the effect of program alias, we replace a different proportion of logical forms in a training set with their aliases (semantically equivalent but syntactically different logical forms), and we re-train the neural approaches to quantify its effect. To search for aliases of a logical form, we first derive multiple transformation rules for each MR. Then, we apply these rules to the logical form to get its aliases and randomly sample one. We compare the execution results of the resulting logical forms to ensure their equivalence in semantics. Table 3 presents three transformation rules for SQL. We provide a detailed explanation of transformation rules and examples for each MR in Section A.3 of the supplementary material.

Grammar Rules. To understand the grammar rules' impact on grammar-based models, we provide two sets of grammar rules for each MR. Each set of rules can cover all the logical forms in the three domains. We compare the performance of models trained with different sets of rules. Specifically, Wong and Mooney (2006) and Wong and Mooney (2007) have induced a set of grammar rules for Prolog and FunQL in Geo. We directly use them in Geo and extend them to support logical forms in ATIS and Job. As for SQL, Bogin et al. (2019) have induced a set of rules for SQL in the Spider benchmark, and we adapt it to support the SQL queries in the three domains that we study.

---

[3] Our benchmark, execution engines and and our implementation can be found on: `https://github.com/JasperGuo/Unimer`

[4] Following Dong and Lapata (2016), we sort the sub-expressions in the conjunction predicate of Lambda Calculus before comparison.

[5] It should be acknowledged that using the execution-match accuracy to evaluate a parser is not enough, as there exist spurious programs that lead to the same execution results with the gold standard but have different semantics.

When it comes to Lambda Calculus, we use the one induced by Yin and Neubig (2018). For comparison, we also manually induce another set of grammar rules for the four MRs. Section A.4 in the supplementary material provides definitions of all the grammar rules.

4.2 Implementations

We implement each approach with the AllenNLP (Gardner et al., 2018) and PyTorch (Paszke et al., 2019) frameworks. To make a fair comparison, we tune the hyper-parameters of approaches for each MR on the development set or through cross-validation on the training set, with the NNI platform.[6] Due to the limited number of test data in each domain, we run each approach five times and take the average number. Section A.2 in the supplementary material provides the search space of hyper-parameters for each approach and the preprocessing procedures of logical forms.

Multiple neural semantic parsing approaches (Dong and Lapata, 2016; Iyer et al., 2017; Rabinovich et al., 2017) adopt the data anonymization techniques to replace entities in utterances with placeholders. However, the techniques are usually ad-hoc and specific for domains and MRs, and they sometimes require manual efforts to resolve conflicts (Finegan-Dollak et al., 2018). Hence, we do not apply data anonymization to avoid bias.

5 Experimental Results

5.1 Meaning Representation Comparison

Table 4 presents our experimental results on UNIMER. Since we do not use data anonymization techniques, the performance is generally lower than that shown in Table 1 and Table 8, but the performance is on par with the numbers reported in ablation studies of previous work (Dong and Lapata, 2016; Jia and Liang, 2016; Finegan-Dollak et al., 2018). We can make the following three observations from the table.

First, neural approaches exhibit notably different performance when they are trained to generate different MRs. The difference can vary by as much as 20% in both exact-match and execution-match metrics. This finding tells us that an apple-to-apple comparison is extremely important when comparing two neural semantic parsing approaches. However, we notice that some papers (Sun et al., 2020; Shaw et al., 2019; Chen et al., 2020) do not clearly note the MRs used in baselines and compare with them using different metrics; the attained result can be somewhat misleading.

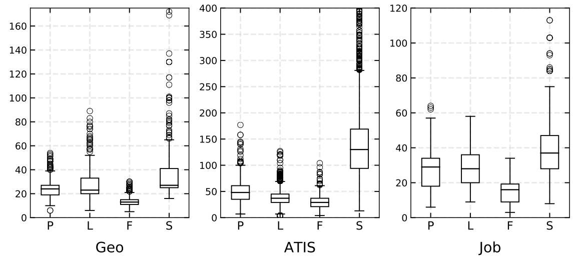


Figure 2: Statistics of logical forms in the training set of Prolog (P), Lambda Calculus (L), FunQL (F) and SQL (S). The y-axis indicates the number of production rules in each logical form.

Second, domain-specific MRs (Prolog, Lambda Calculus, and FunQL) tend to outperform SQL (domain-general) by a large margin. For example, in Geo, the execution-match accuracy of FunQL is substantially higher than that of SQL in all approaches. This result is expected because a lot of domain knowledge is injected into domain-specific MRs. Consider the logical forms in Table 2. There is a predicate `tomorrow` in all three domain-specific MRs, and this predicate can directly align to the description in the utterance. However, one needs to explicitly express the concrete date values in the SQL query; this requirement can be a heavy burden for neural approaches, especially when the values will change over time. In addition, a recent study (Finegan-Dollak et al., 2018) in Text-to-SQL has shown that domain-specific MRs are more robust against generating never-seen logical forms than SQL, because their surface forms are much closer to natural language.

Third, among all the domain-specific MRs, FunQL tends to outperform the others in neural approaches. In Geo, FunQL outperforms the other MRs in both metrics by a large margin. In Job, the grammar-based (w/ copy) model trained with FunQL achieves the state-of-the-art performance. One possible reason is that FunQL is more compact than the other MRs, due to its elimination of variables and quantifiers. Figure 2 shows box plots about the number of grammars rules in the AST of a logical form. We can observe that while FunQL has almost the same number of grammar rules with the other MRs (Table 5), it has much fewer grammar rules involved in a logical form than the others

Table 4: Experimental results of the seq2seq model and the grammar-based model. We highlight the best performance of each approach and MR in both metrics. The poor SQL exact-match accuracy in ATIS is caused by the different distribution of SQL queries in test set. Iyer et al. (2017) rewrote the SQL queries in test set to improve their execution efficiency.

MR	Geo		ATIS		Job	
	# Vo	# Ru	# Vo	# Ru	# Vo	# Ru
Prolog	146	234	503	732	170	230
Lambda	180	245	466	532	200	208
FunQL	152	188	494	706	195	208
SQL	187	269	530	656	211	227

Table 5: Statistics of logical forms in different MRs. '# Vo' and '# Ru' indicate the vocabulary size and the number of grammar rules of an MR, respectively.

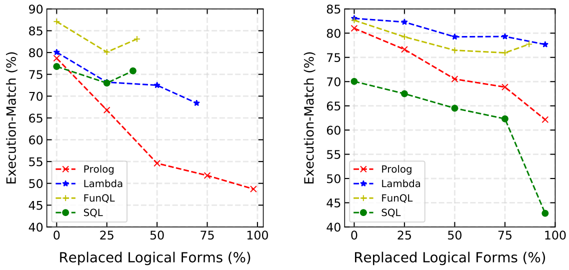
on average. This statistic is crucial for neural semantic parsing approaches as it directly determines the number of decoding steps in decoders.

A similar reason can be used to explain that the performance on SQL is lower than others. As Figure 2 shows, SQL has larger medians of the number of grammar rules, and it also has much more outliers than domain-specific MRs. It makes neural models more challenging to learn.

Interestingly, this finding contradicts the finding in CCG-based semantic parsing approaches (Kwiatkowksi et al., 2010), in which they show that Lambda Calculus outperforms FunQL in the Geo domain. The reason is that compared with Lambda Calculus, the deeply nested structure of FunQL makes it more challenging to learn a high-quality CCG lexicon, which is crucial for CCG parsing. In contrast, neural approaches do not rely on a lexicon and directly learn a mapping between source and target languages.

5.2 Program Alias

Figure 3 shows the execution-match accuracy of the seq2seq (w/ copy) model with different proportions of logical forms in the training set replaced with aliases.[7] Since not all the logical forms have aliases, the curves in Figure 3 stop at different points. Among all the domain-specific MRs, FunQL has the fewest logical forms with aliases, while Prolog has the largest. For example, in Geo, only 42% of FunQL logical forms in the training set have aliases, while more than 70% of logical forms in Lambda Calculus and Prolog have aliases.



(a) Geo

(b) ATIS

Figure 3: Execution-match accuracy of the seq2seq (w/ copy) model when different proportions of logical forms in training set are replaced with their aliases.

MR	Geo		ATIS	
	Exact	Execution	Exact	Execution
Prolog	24.2%	15.1%	7.0%	5.4%
Lambda	11.9%	8.6%	6.2%	0.9%
FunQL	24.7%	8.0%	7.0%	4.1%
SQL	19.4%	4.9%	9.1%	3.6%

Table 6: Relative decline of performance when 25% of logical forms in training data are replaced with aliases.

---

[7] We have experimented with the grammar-based model and observed similar results.

MR	Grammar	Geo	ATIS
Prolog	G1	72.6 ±1.2	**77.5** ±0.9
	G2	**75.7** ±2.3	76.2 ±1.0
Lambda	G1	75.1 ±1.4	74.9 ±1.5
	G2	**75.6** ±1.5	**77.4** ±1.3
FunQL	G1	74.5 ±1.7	74.0 ±2.2
	G2	**78.2** ±0.4	**77.5** ±0.9
SQL	G1	68.2 ±2.4	**63.7** ±1.3
	G2	**70.2** ±1.0	61.3 ±1.7

Table 7: Execution-match accuracy of the grammar-based model (w/o Copy). 'G1' denotes the grammar rules induced by (Wong and Mooney, 2006, 2007; Yin and Neubig, 2018; Bogin et al., 2019); 'G2' denotes the grammar rules induced by ourselves.

From the figure, we have two main observations. First, in both domains, as more logical forms are replaced, the performance of all MRs declines gradually. Among all the MRs, the performance of Prolog declines more seriously than the others in both domains. In other words, it suffers from the program alias problem more seriously. The trends of Lambda Calculus and FunQL in ATIS are impressive, as their performance decreases only slowly. Selecting an MR with the less effect of program alias could be a better choice when we need to develop a semantic parser for a new domain, because we can save many efforts in defining annotation protocols and checking consistency, which could be extremely tedious. Second, the exact-match accuracy declines more seriously than execution-match. Table 6 provides the relative declines in both exact-match and execution-match metrics when 25% of logical forms are replaced. We find that the exact-match accuracy declines more seriously than execution-match, indicating that under the effect of program alias, exact-match may not be suitable as it may massively underestimate the performance. At last, given a large number of semantically equivalent logical forms, it would be valuable to explore whether they can be leveraged to improve semantic parsing (Zhong et al., 2018).

5.3 Grammar Rules

Table 7 presents the experimental results of the grammar-based (w/o copy) model trained with different sets of grammar rules. As the table shows, there is a notable performance discrepancy between different sets of rules. For example, in ATIS, we can observe 2.5% absolute improvement when the model is trained with G2 for Lambda Calculus. Moreover, G2 is not always better than G1. While the model trained with G2 for Prolog outperforms G1 in Geo, it lags behind G1 in ATIS. This observation motivates us to consider what factors contribute to the discrepancy. We had tried to explore the search space of logical forms defined by different grammar rules and the distribution drift between the AST of logical forms in the training and test set. However, the exploration results cannot consistently explain the performance discrepancy. As our important future work, we would explore whether or not the discrepancy is caused by better alignments between utterances and grammar rules. Intuitively, it would be easier for decoders to learn the set of grammar rules having better alignments with utterances.

We can learn from these results that similar to traditional semantic parsers, properly transforming grammar rules for MRs can also lead to better performance in neural approaches. Therefore, grammar rules should be considered as a very important hyper-parameter of grammar-based models, and it is recommended to mention the used grammar rules in research papers clearly.

6 Related Work

Meaning representations for semantic parsing. Recent work has shown that properly designing new MRs often helps improve the performance of neural semantic parsing. Except for the four MRs that we study, Liang et al. (2011); Liang (2013) presented DCS and lambda DCS for querying knowledge bases and demonstrated their advantages over Lambda Calculus. Guo et al. (2019) proposed SemQL, an MR for relational database queries, and they showed improvements in the Spider benchmark. Wolfson et al. (2020) designed an MR, named QDMR, for representing the meaning of questions through question decomposition. Instead of designing new MRs, Cheng et al. (2019) proposed a transition-based semantic parsing approach that supports generating tree-structured logical forms in either top-down or bottom-up manners. Their experimental results on various semantic parsing datasets using FunQL showed that top-down generation outperforms bottom-up in various settings. Our work aims to investigate the characteristics of different MRs and their impact on neural semantic parsing.

Ungrounded semantic parsing. Except for the grounded MRs studied in this work, there are also ungrounded MRs that are not tied to any particular applications, such as AMR (Banarescu et al., 2013), MRS (Copestake et al., 2005; Flickinger et al., 2017), and UCCA (Abend and Rappoport, 2013). Abend and Rappoport (2017) conducted a survey on ungrounded MRs to assess their achievements and shortcomings. Hershcovich et al. (2019) evaluated the similarities and divergences in the content encoded by ungrounded MRs and syntactic representation. Lin and Xue (2019) carried out a careful analysis on AMR and MRS to understand the factors contributing to the discrepancy in their parsing accuracy. Partly inspired by this line of work, we conduct a study on grounded MRs and investigate their impact on neural semantic parsing. Hershcovich et al. (2018) proposed to leverage annotated data in different ungrounded MRs to improve parsing performance. With UNIMER, we can explore whether it is feasible in grounded semantic parsing.

Extrinsic parser evaluation. Another line of research that is closely related to our work is extrinsic parser evaluation. Miyao et al. (2008) benchmarked different syntactic parsers and their representations, including dependency parsing, phrase structure parsing, and deep parsing, and evaluated their impact on an information extraction system. Oepen et al. (2017) provided a flexible infrastructure, including data and software, to estimate the relative utility of different types of dependency representations for a variety of downstream applications that rely on an analysis of grammatical structure of natural language. There has not been work on benchmarking MRs for grounded semantic parsing in neural approaches, to the best of our knowledge.

Weakly supervised semantic parsing. In this paper, we focus on supervised learning for semantic parsing, where each utterance has its corresponding logical form annotated. But the similar evaluation methodology could be applied to weakly supervised semantic parsing, which receives wide attention because parsers are only supervised with execution results and annotated logical forms are no longer required (Berant et al., 2013; Pasupat and Liang, 2015; Goldman et al., 2018; Liang et al., 2018; Mueller et al., 2019). We also notice that various MRs have been used in weakly supervised semantic parsing, and it would be valuable to explore the impact of MRs in such settings.

7 Conclusion

In this work, we propose UNIMER, a unified benchmark on meaning representations, based on established semantic parsing datasets; UNIMER covers three domains and four different meaning representations along with their execution engines. UNIMER allows researchers to comprehensively and fairly evaluate the performance of their approaches. Based on UNIMER, we conduct an empirical study to understand the characteristics of different meaning representations and their impact on neural semantic parsing. By open-sourcing our source code and benchmark, we believe that our work can facilitate the community to inform the design and development of next-generation MRs.

Implications. Our findings have clear implications for future work. First, according to our experimental results, FunQL tends to outperform Lambda Calculus and Prolog in neural semantic parsing. Additionally, FunQL is relatively robust against program alias. Hence, when developers need to design an MR for a new domain, FunQL is recommended to be the first choice. Second, to reduce program alias' negative effect on neural semantic parsing, developers should define a concrete protocol for annotating logical forms to ensure their consistency. Specifically, given an MR, developers should identify as many as possible sources where program alias can occur. Take SQL as an example. To express the `argmax` semantics, one can either use subquery or the OrderBy clause.[8] Having identified these sources, developers need to determine using which expression in what context, e.g., `argmax` is always expressed with subquery, and the unordered expressions in conjunctions are always sorted by characters.

A Supplemental Material

Algorithm 1: Translation of Lambda Calculus Logical Forms to FunQL

```
Input: A Lambda Calculus logical form $p$
Output: A FunQL logical form $f$
$types$ = InferTypes($p$);
$tokens$ = Tokenize($p$);
$expressions, stack = [], []$;
$i = 0$;
for $t \in tokens$ do
    if $t ==$ '(' then
        Append($stack$,$i$);
    else if $t ==$ ')' then
        $j =$ = Pop($stack$);
        $e$ = Search($expressions, j, i$);
        Remove($e$);
        $ne$ = Translate($tokens[j : i]$, $e$,
          $types$);
        Append($expressions, ne$);
    $i+ = 1$;
end
$f = expressions[0]$;
```

A.1 Details of Benchmark Construction

Geo. Since the four MRs we study have annotated logical forms and have execution engines except for Lambda Calculus in Geo, we directly use them (SQL taken from (Finegan-Dollak et al., 2018), Prolog taken from (Jia and Liang, 2016), FunQL taken from (Wong and Mooney, 2006), and Lambda Calculus taken from (Kwiatkowksi et al., 2010)). We implement an execution engine with Haskell for Lambda Calculus. With these resources, we cross-validate the correctness of annotations and execution engines by comparing the execution results of logical forms. As a result, we found nearly 30 Prolog logical forms with annotation mistakes and two bugs in the execution engines of Prolog and FunQL.

ATIS. There are only annotated logical forms for Lambda Calculus and SQL in ATIS. We directly use Lambda Calculus logical forms provided by (Jia and Liang, 2016) and SQL queries provided by (Iyer et al., 2017). To provide annotations for FunQL and Prolog, we semi-automatically translate Lambda Calculus logical forms to equivalent logical forms in FunQL and Prolog. Algorithm 1 presents the pseudo code for translating a Lambda Calculus logical form to FunQL. Basically, we first

Table 8: Performance of semantic parsing approaches, where $*$ denotes neural approaches and $\dagger$ denotes approaches using data anonymization techniques. 'λ' denotes Lambda Calculus. 'Exact' and 'Exec' denote exact-match and execution-match, respectively.

perform a type inference for variables in the logical form, since some predicates in Lambda Calculus can take different types of variables as input, e.g., for the predicate `to(A,B)`, variable `B` can be either an airport or a city. Then, we tokenize the input logical form and recursively translate each sub-expression in the logical form into FunQL expressions based on the predicates we design for FunQL. Translation from Lambda Calculus to Prolog is performed in a similar way. The source code for translation is also available in our Github repository. We also implement execution engines for Lambda Calculus, Prolog, and FunQL.

Job. There are only annotated logical forms for Lambda Calculus and Prolog in Job. We directly use Prolog logical forms provided on the website.[9] To provide annotations for FunQL, we semi-automatically translate Prolog logical forms to equivalent logical forms in FunQL with an algorithm similar to Algorithm 1. In terms of SQL, the logical forms in Job are relatively simple and can be expressed with the `SELECT`, `FROM` and `WHERE` clauses of SQL. We simply translate each sub-expression in Prolog to an expression in `WHERE` clause and use a conjunction to join the resulting expressions. Since we cannot find the annotated Lambda Calculus logical forms provided by (Zettlemoyer and Collins, 2005), we also translate the Prolog logical forms to Lambda Calculus. We implement execution engines for Lambda Calculus and FunQL.

A.2 Model Configuration

Preprocessing of Prolog and Lambda Calculus As Prolog and Lambda Calculus have variables, we need to standardize their variable naming before training. Following (Jia and Liang, 2016), we preprocess the Prolog logical forms to the De Brujin index notation. We standardize the variable naming of Lambda Calculus based on their occurrence order in logical forms.

Attention Copying Mechanism. In Geo and Job, we use the standard copy mechanism, i.e., directly copying a source word to a logical form. In ATIS, following (Jia and Liang, 2016), we leverage an external lexicon to identify potential copy candidates, e.g., `slc:ap` can be identified as a potential entity for description "salt lake city airport" in utterance. When we copy a source word that is part of a phrase in the lexicon, we write the entity associated with that lexicon entry to a logical form.

Hyper-Parameters. For the seq2seq model, the embedding dimension of both source and target languages ranges over {100, 200}. We select a one-layer bi-directional LSTM as an encoder. The hidden dimension of the encoder ranges over {32, 64, 128, 256}. Similarly, a one-layer LSTM is selected as the decoder. Its hidden dimension is as same as the encoder. In terms of attention, we select bi-linear as the activation function, where the hidden dimension is 2 times that of the encoder. We employ dropout at training time with rate ranging over {0.1, 0.2, 0.3}. We select batch size from {16, 32, 48, 64}, and select learning rate from {0.001, 0.0025, 0.005, 0.01, 0.025, 0.05}. Following (Dong and Lapata, 2016), we use the RMSProp algorithm to update the parameters. The smoothing constant of RMSProp is 0.95. We initialize all

---

[9] http://www.cs.utexas.edu/ ml/nldata/jobquery.html

parameters uniformly at random within the interval $[-0.1, 0.1]$.

Similarly, for the grammar-based model, a one-layer bi-directional LSTM is used as an encoder and another LSTM is employed as a decoder. The layers of the decoder is selected from {1, 2}. The hidden dimension of the encoder ranges over {64, 128, 256}. The hidden dimension of the decoder is 2 times that of the encoder. The hidden dimension of both the grammar rule and non-terminal is selected from {64, 128, 256}. We also employ dropout in the encoder and decoder at training time with rate selected from {0.1, 0.2, 0.3}. We select batch size from {16, 32, 48, 64}, and select learning rate from {0.001, 0.0025, 0.005, 0.01, 0.025, 0.05}. We use the Adam algorithm to update the parameters.

For both models, gradients are clipped at 5 to alleviate the exploding gradient problem, and early stopping is used to determine the number of epochs. We provide the detailed configurations of the NNI platform in our Github repository.

A.3 Search for Aliases for Logical Forms.

```
Algorithm 2: Search for Program Alias
  Input: A logical form $p$
  Output: A set of aliases of the input logical
          form $aliases$
ast = Parse(p);
aliases = [];
for r ∈ Rules do
    C = Apply(ast, r);
    for c ∈ C do
        if IsEquivalent(p, c) then
            Append(aliases,c);
    end
end
```

Rule	Description
Prolog	
Shuffle	Shuffle expressions in conjunction
Remove	Remove redundant expressions
Merge	Put expressions into higher-order predicates
Lambda Calculus	
Shuffle	Shuffle expressions in conjunction
Replace	Replace semantically equivalent predicates
FunQL	
Shuffle	Shuffle expressions in conjunction
Remove	Remove redundant expressions
Swap	Swap unit relation predicate
Replace	Replace semantically equivalent predicates
SQL	
Shuffle	Shuffle expressions in Select, From, Where, and Having clauses
Argmax	Express Argmax/min with OrderBy and Limit clause instead of subquery
In2Join	Replace In clause with Join clause

Table 9: Transformation rules for Prolog, Lambda Calculus and FunQL.

Algorithm 2 presents the way we search for aliases for a logical form. Transformation rules can be categorized into two groups based on whether they are domain-specific. Considering the following two logical forms:

(lambda A:e (exists B (and (flight B) (fare B A))))

(lambda A:e (exists B (and (flight B) (equals (fare B) A))))

they are semantically equivalent due to the multiple meaning definitions of `fare`. There are also domain-general transformation rules, e.g., permuting the expressions in the conjunction predicate:

(lambda A:e (exists B (and (flight B) (fare B A))))

(lambda A:e (exists B (and (fare B A) (flight B))))

In this work, we primarily consider domain-general transformation rules and only when there is limited aliases found by domain-general rules, we use domain-specific rules. Table 9 presents the transformation rules we used in Geo domains. Rules in ATIS are similar. We provide examples below to illustrate the rules.

Prolog Shuffle:

answer(A,(area(B,A),const(B,stateid(Texas))))

answer(A,(const(B,stateid(texas)),area(B,A),))

Prolog Remove:

answer(A,(loc(B,A),city(B),const(B,cityid(Austin,_))))

answer(A,(loc(B,A),const(B,cityid(Austin,_))))

Prolog Merge:

answer(A,(state(A),loc(B,A),highest(B,place(B))))

answer(A,(highest(B,(place(B),loc(B,A),state(A)))))

FunQL Swap:

answer(count(major(city(loc_2(stateid(Texas))))))

answer(count(city(major(loc_2(stateid(Texas))))))

FunQL Replace:

answer(city(loc_2(largest(state(all)))))

answer(city(loc_2(largest_one(area_1(state(all))))))

SQL Argmax:

SELECT city.city_name FROM city WHERE city.population = (SELECT MAX(c1.population) FROM city as c1 WHERE c1.state_name = ‘arizona’) and city.state_name = ‘arizona’;

MR	Geo	ATIS
Prolog	98.0%	96.2%
Lambda Calculus	69.7%	95.3%
FunQL	42.5%	87.9%
SQL	38.5%	95.5%

Table 10: Number of logical forms in training set of Geo and ATIS that have aliases.

SELECT city.city_name FROM city WHERE state_name = 'arizona' ORDER BY city.population DESC LIMIT 1;

SQL In2Join:

SELECT river.river_name FROM river WHERE river.traverse IN (SELECT state.state_name FROM state WHERE state.area = (SELECT MAX(s1.area) FROM state as s1));

SELECT river.river_name FROM river, state WHERE river.traverse = state.state_name AND state.area = (SELECT MAX(s1.area) FRORM state as s1);

Table 10 presents the number of logical forms in the training set of Geo and ATIS that have aliases, from which we can see that with these simple rules, we are able to find a lot of aliases. Since the logical forms in Geo are generally simpler than that of ATIS, the number of Geo is lower than ATIS.

A.4 Grammar

We present the grammar rules used in our experiments for Geo (Figure 4-11). The grammar rules for different MRs in ATIS follow a similar definition. It is important to note that although all logical forms in an MR can be modeled by both G1 and G2, they are not necessarily equivalent in expressiveness. For example, `answer(largest(place(all)))` is a syntactically correct but semantically incorrect FunQL logical form in Geo, because the predicate `largest` is not allowed to take places as input. However, G2 of FunQL still can accept this logical form, while G1 cannot, because G1 explicitly encodes type constraints in the its rules. Nevertheless, the performance of G1 is lower than G2 in both Geo and ATIS domains, which is surprising. For all the grammar rules we present, G1 and G2 for Prolog and Lambda Calculus and equivalent. G1 and G2 for FunQL and SQL are not equivalent.

Abstract

Computational and cognitive studies of event understanding suggest that identifying, comprehending, and predicting events depend on having structured representations of a sequence of events and on conceptualizing (abstracting) its components into (soft) event categories. Thus, knowledge about a known process such as "*buying a car*" can be used in the context of a new but analogous process such as "*buying a house*". Nevertheless, most event understanding work in NLP is still at the ground level and does not consider abstraction. In this paper, we propose an Analogous Process Structure Induction (`APSI`) framework, which leverages analogies among processes and conceptualization of sub-event instances to predict the whole sub-event sequence of previously unseen open-domain processes. As our experiments and analysis indicate, `APSI`[1] supports the generation of meaningful sub-event sequences for unseen processes and can help predict missing events.

1 Introduction

Understanding events has long been a challenging task in NLP, to which many efforts have been devoted by the community. However, most existing works are focusing on procedural (or *horizontal*) event prediction tasks. Examples include predicting the next event given an observed event sequence (Radinsky et al., 2012) and identifying the effect of a biological process (i.e., a sequence of events) on involved entities (Berant et al., 2014). These tasks mostly focus on predicting related events in a procedure based on their statistical correlations in previously observed text. As a result, understanding the meaning of an event might not be crucial for these *horizontal* tasks. For example, simply selecting the most frequently co-occurring event can offer acceptable performance on the event prediction task (Granroth-Wilding and Clark, 2016).

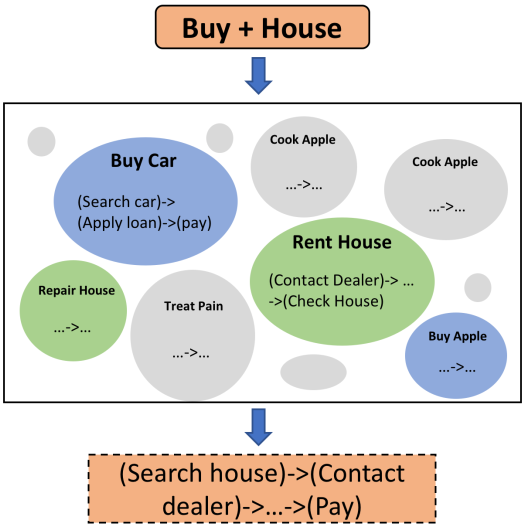

Figure 1: An illustration of leveraging known processes to predict the sub-event sequence of a new process.

Computational and cognitive studies (Schank and Abelson, 1977; Zacks and Tversky, 2001) suggest that inducing and utilizing the hierarchical structure[2] of events is a crucial component of how humans understand new events and can help many aforementioned *horizontal* event prediction tasks. Consider the example in Figure 1. Assume that one has never bought a house, but is familiar with how to "buy a car" and "rent a house"; referring to analogous steps in these two relevant processes would still provide guidance for the target process of "buy a house". Motivated by this hypothesis, our work proposes to directly evaluate a model's event understanding ability. We define this as the

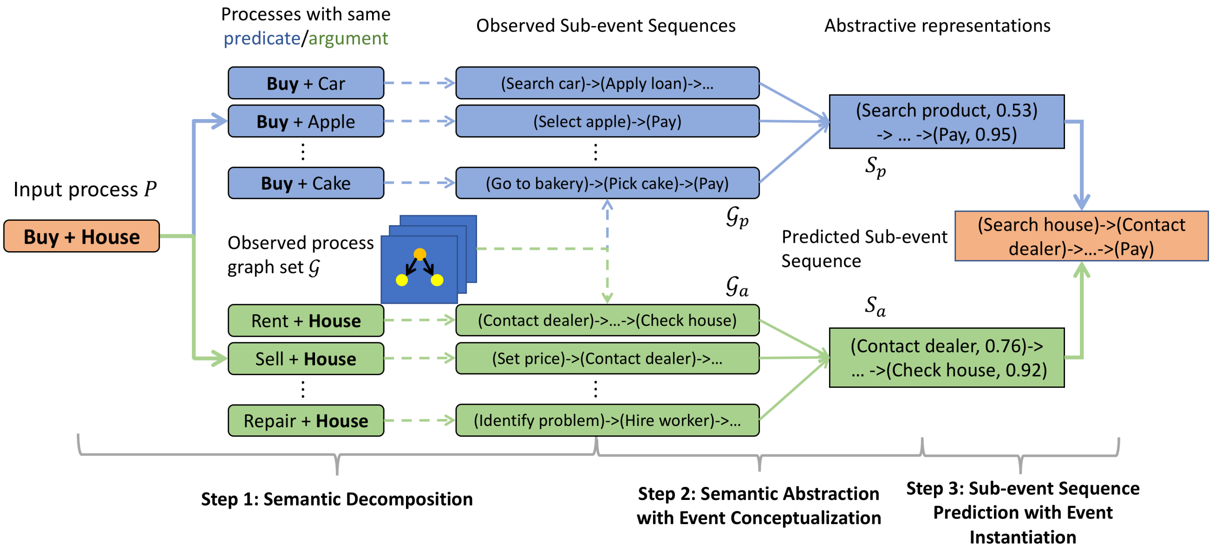

Figure 2: Demonstration of the proposed APSI framework. Given a target process P, we first decompose its semantics into two dimensions (i.e., predicate and argument) by grouping processes that share a predicate or an argument. For each such group of processes, we then leverage the observed process graphs $\mathcal{G}$ to generate an abstract and probabilistic representation for their sub-event sequences. In the last step, we merge them with an instantiation module to produce the sub-event sequence of P.

ability to identify *vertical* relations, that is, to predict the sub-event sequence of a new process[3]. We require models to generate the sub-event sequence for a previously unobserved process given observed processes along with their sub-event sequences, which we refer to as “the observed process graphs" in the rest of this paper. This task is more challenging than “conventional" event predictions tasks, since it requires the *generation* of a sub-event sequence given a new, previously unobserved, process definition.

To address this problem, we propose an Analogous Process Structure Induction (APSI) framework. Given a new process definition (e.g., ‘buy a house’), we first decompose it into two dimensions: predicate and argument. For each of these, we collect a group of processes that share the same predicate (i.e., ‘buy-*ARG*’) or same argument (i.e., ‘*PRE*-house’), and then induce an abstract and probabilistic sub-event representation for each group. Our underlying assumption is that processes that share the same predicate or argument could be analogous to each other, and thus could share similar sub-event structures. Finally, we merge these two abstract representations, using an instantiation module, to predict the sub-event structure of the target process. By doing so, we only need a small number of analogous processes (as we show, 20, on average) to generate unseen sub-events for the target process. Intrinsic and extrinsic evaluations show that APSI outperforms all baseline methods and can generate meaningful sub-event sequences for unseen processes, which are proven to be helpful for predicting missing events.

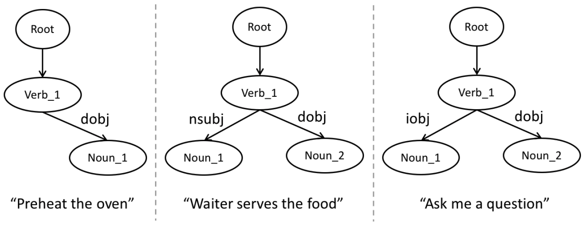

Figure 3: Examples of Sub-Event Representations.

The rest of the paper is organized as follows. Section 2 introduces the Analogous Process structure induction (APSI) framework. Section 3 describes our intrinsic and extrinsic evaluation, demonstrating the effectiveness of APSI and the quality of the induced process knowledge. We discuss related works in Section 4 and conclude this paper with Section 5.

2 The APSI Framework

Figure 2 illustrates the details of the proposed APSI framework. Given an unseen process P, a target sub-event sequence length k, and a set of

---

[3] A process is a more coarse-grained event by itself. We use this term to distinguish it from sub-events.

observed process graphs $\mathcal{G}$, the task is to predict a k-step sub-event sequence $[E'_1, E'_2, ..., E'_k]$ for P. Each process graph $G \in \mathcal{G}$ in the input contains a process definition P^G and an n-step temporally ordered sub-event sequence $[E^G_1, E^G_2, ..., E^G_n]$. We assume that each process P is described as a combination of a predicate and an argument (e.g., 'buy+house') and each sub-event $E \in \mathcal{E}$ is given as verb-centric dependency graph as used in (Zhang et al., 2020b) (see examples in Figure 3). In APSI, we decompose the target process into two dimensions (i.e., predicate and argument). For each target process, we collect a group of observed process graphs that share either the predicate or the argument with the target process; we assume that processes in these groups have sufficient information for predicting the structure of the target process. We then leverage an event conceptualization module to induce an abstract representation of each process group. Finally, we merge the two abstract, probabilistic representations and instantiate it to generate a ground sub-event sequence as the final prediction. Detailed descriptions of APSI components are introduced as follows.

2.1 Semantic Decomposition

Each process definition P is given as a predicate and its argument, which we term below the two "dimensions" of the process definition. We then collect all process graphs in $\mathcal{G}$ that have the same predicate as P into $\mathcal{G}_p$ and those that have the same argument into $\mathcal{G}_a$. We assume that these two sets provide the information needed to generate an abstract process representation that would guide the instantiation of the event steps for P.

2.2 Semantic Abstraction

The goal of the semantic abstraction step is to acquire abstract representations S_p and S_a for $\mathcal{G}_p$ and $\mathcal{G}_a$ respectively, to help transfer the knowledge from the grounded observed processes to the target new process. To do so, we first need to conceptualize observed sub-events in $\mathcal{G}_p$ and $\mathcal{G}_a$ (e.g., "eat an apple") to a more abstract level (e.g., "eat fruit"). Clearly, each event could be conceptualized to multiple abstract events. For example, "eat an apple" can be conceptualized to "eat fruit" but also to "eat food", and the challenge is to determine the appropriate level of abstraction. On one hand, the conceptualized event cannot be too general, as we do not want to lose touch with the original event, and, on the other hand, if it is too specific, we will not aggregate enough instances of sub-events into it, thus we will have difficulties transferring knowledge to the new unseen process. To automatically achieve the balance between these conflicting requirements and select the best abstract event for each observed sub-event, we model it as a weighted mutually exclusive set cover problem (Lu and Lu, 2014) and propose an efficient algorithm, described below, to solve it. We then merge the repeated conceptualized events and determine their relative positions.

2.2.1 Modeling Event Conceptualization

For each event E, we first identify all potential events that it can be conceptualized to. If two subevents E_1 and E_2 can be conceptualized to the same event C, we place E_1 and E_2 into the set $\mathcal{E}_C$. To qualitatively guide the abstraction process we introduce below a notion of *semantic loss* that we incur as we move up to more abstract representations. To measure the semantic loss during the conceptualization, we assign weight to each set:

$$W(\mathcal{E}_C) = \frac{1}{\sum_{E \in \mathcal{E}_C} F(E, C)}, \qquad (1)$$

where $F(E, C)$ is a scoring function, defined below in Eq. 2, that captures the amount of "semantic details" preserved due to abstracting from E to C. With this definition, the event conceptualization problem can be formalized as finding exclusive[4] sets (such as C) that cover all observed events with minimum total weight. In the rest of this section, we first introduce how to collect potential conceptualized events for each E, how we define F, and how we solve this discrete optimization problem.

Identifying Potential Conceptualizations Assume that sub-event E contains m words $w^E_1, w^E_2, ..., w^E_m$, each corresponds to a node in Figure 3; for each of these, we can retrieve a list of hypernym paths from WordNet (Miller, 1998). For example, given the word "house", WordNet returns two hypernym paths[5]: (1) "house"→"building"→"structure"→...; (2) "house"→"firm"→"business"→.... As a result, we can find $\prod_{w \in E} L(w)$ potential conceptualized events for E, where $L(w)$ is the number of w's hypernyms. We denote the potential conceptualized event set for E as $\mathcal{C}_E$ and the overall set as $\mathcal{C}$.

---

[4] No sub-event can appear in two selected sets.

[5] We omit the synset number for clear representation.

Algorithm 1 Event Conceptualization

INPUT: Set of events $\mathcal{E}$. Each $\mathbf{E} \in \mathcal{E}$ is associated with a set of potential conceptualization events $\mathcal{C}_E$. The overall conceptualized event set $\mathcal{C}$.

```
Initialize event partition set $\mathcal{P} := \emptyset$.
while $\mathcal{E} \neq \emptyset$ do
    for Each $E \in \mathcal{E}$ do
        for Each $C \in \mathcal{C}_E$ do
            $\mathcal{E}_C := \emptyset$.
            Compute $F(E, C)$ using Eq. (2).
        end for
    end for
    for Each $C \in \mathcal{C}$ do
        for Each $E \in \mathcal{E}$ do
            if $C \in \mathcal{C}_E$ then
                $\mathcal{E}_C := \mathcal{E}_C \cup \{E\}$.
            end if
        end for
        Compute $W(\mathcal{E}_C)$ using Eq. (1).
    end for
    Select $\mathcal{E}_{C_{min}}$ with the minimum $W$ score.
    $\mathcal{E} := \mathcal{E} \setminus \mathcal{E}_{C_{min}}$
    $\mathcal{P} := \mathcal{P} \cup \{\mathcal{E}_{C_{min}}\}$.
end while
```

OUTPUT: Partition of n event subsets $\mathcal{P} = \{\mathcal{E}_1, \mathcal{E}_2, ..., \mathcal{E}_n\}$, where each subset $\mathcal{E}_i$ corresponds to a unique conceptualized event C_i.

Conceptualization Scoring As mentioned above, for each pair of a sub-event E and its potential conceptualization C, we propose a scoring function $F(E, C)$ to measure how much "semantic information" is preserved after the conceptualization. Motivated by Budanitsky and Hirst (2006) and based on the assumption that the more abstract the conceptualized event is, the more semantic details are lost, we define $F(E, C)$ to be:

$$F(E, C) = \prod_{i=1}^{m} w^{D(w_i^E, w_i^C)}, \tag{2}$$

where $D(w_i^E, w_i^C)$ is the depth from w_i^E to w_i^C on the taxonomy path, and w is a hyper-parameter[6] measuring how much "semantics" is preserved following each step of the conceptualization.

Conceptualization Assignment Now we are able to model the procedure of finding proper conceptualized events as a weighted mutually exclusive set cover problem. Note that this is an NP-complete problem and requires a prohibitive computational cost to obtain the optimum solution (Karp, 1972). To obtain an efficient solution that is empirically sufficient for assigning conceptualized events with reasonable amount of instances, we develop a greedy procedure as described in Algorithm 1. For each retrieved process graph set $\mathcal{G}_p$ or $\mathcal{G}_a$, we collect all its sub-events as $\mathcal{E}$ and use it as the input for the conceptualization algorithm. In each iteration, we first compute the conceptualization score F for all the (E, C) pairs and then compute the weight score for all conceptualization sets $\mathcal{E}_C$. After selecting the set with minimum weight, $\mathcal{E}_{C_{min}}$, we remove all the events covered by it from $\mathcal{E}$ and repeat the process until no event is left. After the conceptualization, we merge sub-events that are conceptualized to the same event and represent them with the resulting conceptualized event C, whose weight is defined to be $\overline{W}(C) = \frac{1}{W(\mathcal{E}_C)}$. Compared with the naive algorithm, which first expands all possible subsets (i.e., it includes all subsets of $\mathcal{E}_C$ for all C) and then leverages the sort and filter technique to select the final subsets, we reduce the time complexity from $O(|\mathcal{C}| \cdot |\mathcal{E}|^2)$ to $O(n \cdot |\mathcal{C}| \cdot |\mathcal{E}|)$, where n is the number of conceptualized events and is typically much smaller than $|\mathcal{E}|$.

2.2.2 Conceptualized Event Ordering

After conceptualizing and merging all sub-events, we need to determine their loosely temporal order (e.g., whether they typically appear at the beginning or the end of these sub-event sequences). Let the set of selected conceptualized events be $\mathcal{C}^*$. For each $C \in \mathcal{C}^*$, we define its order score $T(C)$, indicating how likely C is to appear first, as:

$$T(C) = \sum_{C' \in \mathbf{C}^*} \theta\Big(\sum_{E_C \in \mathcal{E}_C} \sum_{E_{C'} \in \mathcal{E}_{C'}} t(E_C, E_{C'}) - t(E_{C'}, E_C) \Big), \tag{3}$$

where θ is the unit step function and $t(E_C, E_{C'})$ represents how many times E_C appears before $E_{C'}$ in an observed process graph.

2.3 Sub-event Sequence Prediction

In the last step, we leverage the two abstract representations we got for the predicate and argument of the target process definition to predict its final sub-events. To do so, we propose the following instantiation procedure. We are given the abstract representations S_p and S_a, for the predicate and argument, respectively. Each is a set of conceptualized events associated with weights and order scores. For each conceptualized event $C_p \in S_p$, using each event $C_a \in S_a$, we can generate a new instantiated event $\hat{C}_p$. For example, if C_p is "cut fruit" and C_a is 'buy an apple', then our model

---

[6] In practice, we use two separate hyper-parameters w_v and w_n for verbs and nouns, respectively.

would create the new event "cut an apple". Specifically, for each $w \in C_p$, if we can find a word $\hat{w}$ such that $\hat{w}$ is a hyponym of w, we will replace w with $\hat{w}$ and repeat this process until no hyponym can be detected in C_p. We denote the generated event by $\hat{C}_p$. To account for the semantic loss during the instantiation procedure, we define the weight and order score of $\hat{C}_p$ as follows:

$$\hat{W}(\hat{C}_p) = \overline{W}(C_p) \cdot F(\hat{C}_p, C_p) \cdot \frac{\sum_{C'_a \in S_a} \overline{W}(C'_a)}{\overline{W}(C_a)} \quad (4)$$

$$\hat{T}(\hat{E}_p) = T(C_p) \cdot F(\hat{C}_p, C_p) \cdot \frac{\sum_{C'_a \in S_a} \overline{W}(C'_a)}{\overline{W}(C_a)}, \quad (5)$$

Similarly, we apply the same procedure to C_a with C_p, and denote the resulted event $\hat{C}_a$. We then repeatedly merge instantiated events by summing up their weights and averaging their order scores. In the end, we select top k sub-events based on the weights and sort them based on the order score as the sub-event sequence prediction.

3 Evaluation

In this section, we conduct intrinsic and extrinsic evaluations to show that APSI can generate meaningful sub-event sequences for unseen processes, which can help predict the missing events.

3.1 Dataset

We collect process graphs from the WikiHow website[7] (Koupaee and Wang, 2018). In WikiHow, each process is associated with a sequence of temporally ordered human-created steps. For each step, as shown in Figure 3, we use the tool released by ASER (Zhang et al., 2020b) to extract events and construct the process graphs. We select all processes, where each step has one and only one event, and randomly split them into the train and test data. As a result, we got 13,501 training process graphs and 1,316 test process graphs[8], whose average sub-event sequence length is 3.56.

3.2 Baseline Methods

We compare with the following baseline methods:
Sequence to sequence (Seq2seq): One intuitive solution to the sub-event sequence prediction task would be modeling it as a sequence to sequence problem, where the process is treated as the input and the sub-event sequence the output. Here we adopt the standard GRU-based encoder-decoder framework (Sutskever et al., 2014) as the base framework and change the generation unit from words to events. For each process or sub-event, we leverage pre-trained word embeddings (i.e., GloVe-6b-300d (Pennington et al., 2014)) or language models (i.e., RoBERTa-base (Liu et al., 2019)) as the representation, which are denoted as Seq2seq (GloVe) and Seq2seq (RoBERTa).
Top One Similar Process: Another baseline is the "top one similar process". For each new process, we can always find the most similar observed process. Then we can use the sub-event sequence of the observed process as the prediction. We employ different methods (i.e., token-level Jaccard coefficient or cosine similarity of GloVe/RoBERTa process representations) to measure the process similarity. We denote them as Top one similar process (Jaccard), (GloVe), and (RoBERTa), respectively.

For each process, we also present a randomly generated sequence and a human-generated sequence[9] as the lower-bound and upper-bound for sub-event sequence prediction models.

3.3 Intrinsic Evaluation

We first present the intrinsic evaluation to show the quality of the predicted sub-event sequences of unseen processes. For each test process, we provide the process name and the sub-event sequence length[10] to evaluated systems and ask them to generate a fixed-length sub-event sequence.

3.3.1 Evaluation Metric

Motivated by the ROUGE score (Lin, 2004), we propose an event-based ROUGE (E-ROUGE) to evaluate the quality of the predicted sub-event sequence. Specifically, similar to ROUGE, which evaluates the generation quality based on N-gram token occurrence, we evaluate how much percentage of the sub-event and time-ordered sub-event pairs in the induced sequence is covered by the human-provided references. We denote the evaluation over single event and event pairs as E-ROUGE1 and E-ROUGE2, respectively. We also provide two covering standards to better understand the prediction quality: (1) "String Match": all words in the predicted event/pairs must be the same as the referent event/pairs; (2) "Hypernym Allowed": the predicted and referent event must

---

[7] https://www.wikihow.com.

[8] We do not need a development set because the proposed solution APSI is not a learning-based method.

[9] The human-generated sequence is randomly selected from the WikiHow and excluded during the evaluation.

[10] We select the majority length of all references.

Model	String Match E-ROUGE1	 E-ROUGE2	Hypernym Allowed E-ROUGE1	 E-ROUGE2

(b) Advanced Setting (for each sub-event, we predict and evaluate all words)

Table 1: Intrinsic evaluation results of the induced process structures. On average, we have 1.7 human-generated sub-event sequences as the references for each test process. Best performing models are marked with the bold font.

have the same dependency structure, and for the words on the same graph position, they should be the hypernym of or same as each other. For example, if the referent event is "eat apple" and the predicted event is "eat fruit", we still count it as a match. The "String Match" setting is stricter, but the "Hypernym Allowed" setting also has its unique value to help better understand if our system is predicting relevant sub-events.

3.3.2 Implementation Details

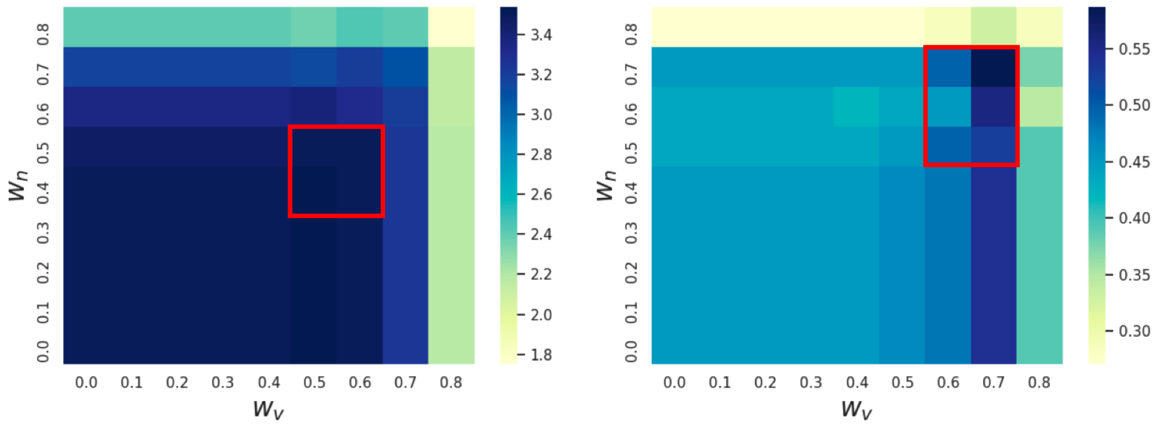
In terms of training, we set both w_v and w_n to be 0.5 for our model. For the seq2seq baselines, we set the learning rate to be 0.001 and train the models until they converge on the training data. All other hyper-parameters following the original paper. In terms of the evaluation, we also provide two settings. (1) Basic: we follow previous works (Glavas et al., 2014) to predict and evaluate events based on verbs; (2) Advanced: we predict and evaluate events based on all words.

3.3.3 Result Analysis

We show the results in Table 1. In general, there is still a notable gap between current models' performance and human performance, but the proposed APSI framework can indeed generate sufficiently relevant sub-events. For example, if we only consider the verb. Even in the string match setting, 14.8% of the predicted event and 6.6% of the ordered event pairs are covered by the references, which is much better than the random guess and nearly half of the performance of human beings. If hypernym is allowed, 36% and 19% of the predicted event and event pairs are covered. Besides that, if we take all words in the event into consideration, the task becomes more challenging. Specifically, even human can only achieve 11.63 E-ROUGE1 and 5.59 E-ROUGE2, which suggests that low scores achieved by current models are probably due to the limitation of the current dataset (e.g., on average, we only have 1.7 references for each test process). If more references are provided, the performance of all models will also increase. In the rest of the intrinsic evaluation, we present more detailed analysis based on the advanced setting (string match) and a case study to help better understand the performance of APSI.

3.3.4 Effect of the Instantiation Module

One key step in our framework is how to leverage the two abstract representations to predict the fi-



(a) E-ROUGE1 (b) E-ROUGE2

Figure 4: Hyper-parameter influence on the quality of APSI generated sub-event sequences. For both w_v and w_n, 0 indicates no conceptualization and the larger the value, the deeper the conceptualization is. Best performing ranges are marked with red boxes, which indicate that the suitable conceptualization level is the key to APSI's success.

Model	E-ROUGE1	E-ROUGE2

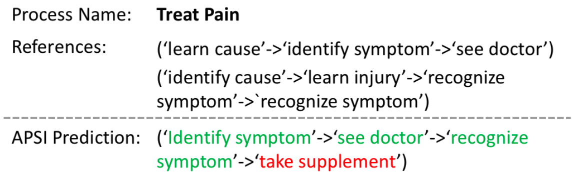
Table 2: Performance of different merging methods.

nal sub-event sequence. In APSI, we propose an instantiation module, which jointly leverages the two representations to generate detailed events. To show its effect, we compare it with two other options: (1) Simple Merge: Merge two representation and select the top k sub-events based on the weight; (2) Normalized: First normalize the weight of all sub-events based on each representation and then select the top k sub-events.

From the result in Table 2, we can see that due to the imbalanced distribution of the two representations, simply choosing the most weighted sub-events is problematic. On average, for each predicate, we can collect 18.04 processes, while we can only collect 1.92 processes for each argument. As a result, the sub-events in the predicate representation typically have a larger weight. Thus if we simply merge them, most of the predicted sub-events will come from the predicate representation. Ideally, the "normalized" method can eliminate the influence of such imbalance, but it also amplifies the noise and achieves worse empirical performance. Differently, the proposed instantiation module uses events in one representation as the reference to help instantiate the events in the other one. As a result, we jointly use these two representations to generate a group of detailed events, and then we can select the top k generated new events. By doing so, we do not only go detailed from the abstract representation but also avoid the imbalanced distribution issue.



Process Name:	**Treat Pain**

3.3.5 Hyper-parameter Analysis

In APSI, we use two hyper-parameters w_v and w_n to control the conceptualization and instantiation depth we want over verbs and nouns respectively. 0 means no conceptualization and the larger value indicates more conceptualization we encourage. We show the performance of APSI with different hyper-parameter combinations in Figure 4, from which we can see that a suitable level of conceptualization is the key to the success of APSI. If no conceptualization is allowed, all the predicted events are restricted to the observed sub-event, thus we cannot predict "search house" after seeing "search car" and some events about the house. On the other hand, if we do not restrict the depth of conceptualization, all the sub-events will be conceptualized to be too general. As a result, even with the instantiation module, we could not predict the detailed sub-event as we want.

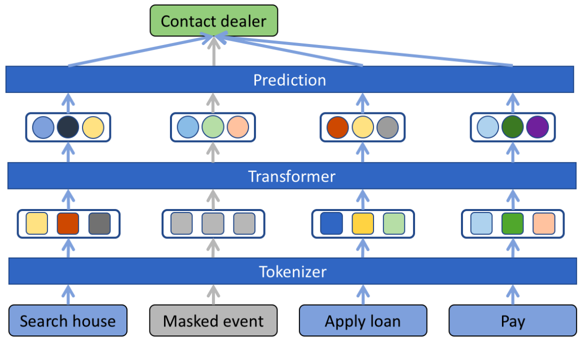

Figure 6: Demonstration of the event masked LM. Pre-trained language models are trained to predict the masked event given other events as the context.

Model	Accuracy	Δ
RoBERTa-based Event LM	73.59%	-
+ Seq2seq (GloVe)	73.06%	-0.53%
+ Seq2seq (RoBERTa)	72.33%	-1.26%
+ Top1 similar (Jaccard)	72.76%	-0.83%
+ Top1 similar (GloVe)	74.14%	0.55%
+ Top1 similar (RoBERTa)	74.16%	0.57%
+ APSI	74.78%†	1.19%
+ Human	76.97%‡	3.38%

Table 3: Results on the event prediction task. † and ‡ indicate the statistical significance over the baseline with p-value smaller than 0.01 and 0.001 respectively.

3.3.6 Case Study

Figure 5 shows an example that we use to analyze the current limitations of APSI. We can see that APSI can successfully predict events like "identify symptoms", but fails to predict event "identify causes". Instead, it predicts "take supplements". This is because APSI learns to predict such sequence from other processes like "treat diarrhea" or other diseases in the observed process graphs. Treating those diseases typically does not involve identifying the cause, which is not the case for treating pain. And, treating diseases often involves taking medicines, which can be conceptualized to "take supplement". As no events about pain helps instantiate "supplement", APSI just predicts it.

3.4 Extrinsic Evaluation

As discussed by (Rumelhart, 1975), the knowledge about process and sub-events can help understand event sequences. Thus, in this section, we investigate whether the induced process knowledge can help predict the missing events. Given a sub-event sequence, for each event in the sequence, we can use the rest of the sequence as the context and ask models to select the correct event against one negative event example. To make the task challenging, instead of random sampling, we follow Zellers et al. (2019) to select similar but wrong negative candidates based on their representation (i.e., BERT (Devlin et al., 2019)) similarity. We use the same training and test as the intrinsic experiment and as a result, we got 13,501 training sequences and 7,148 test questions.

The baseline method we are comparing with is the event-based masked language model[11], whose demonstration is shown in figure 6. We use pre-trained RoBERTa-base (Liu et al., 2019) to initialize the tokenizer and transformer layer and all sequences of training processes as the training data. To show the value of understanding the relationship between process and their sub-event sequence, for each sub-event sequence in the test data, we first leverage the process name and different structure prediction methods to predict sub-event sequences and use them as additional context to help the event masked LM to predict the missing event. To show the effect upper bound of adding process knowledge, we also tried adding the process structure provided by human beings as the context[12], which is denoted as '+Human'. All models are evaluated based on accuracy.

From the results in Table 3, we can make the following observations. First, adding high-quality process knowledge (i.e., APSI and Human) can significantly help the baseline model, which indicates that adding knowledge about the process can help better understand the event sequence. Second, the effect of process knowledge is positively correlated with their quality as shown in Table 1. Adding a low-quality process structure may hurt the performance of the baseline model due to the introduction of the extra noise. Third, the current way of using process knowledge is still very simple and there is room for better usage of the process knowledge, as the research focus of this paper is predicting process structure rather than applying it, we leave that for the future work.

---

[11] On our dataset, the RoBERTa based event LM model outperforms existing LSTM-based event prediction models.

[12] We randomly select another sub-event sequence that describes the same process from WikiHow, which could be different from the currently tested sequence. As a result, adding such sequence cannot help predict all missing events.

4 Related Works

Throughout history, considering the importance of events in understanding human language (e.g., commonsense knowledge (Zhang et al., 2020a)), many efforts have been devoted to define, represent, and understand events. For example, VerbNet (Schuler, 2005) created a verb lexicon to represent the semantic relations among verbs. After that, FrameNet (Baker et al., 1998) proposed to represent the event semantics with schemas, which has one predicate and several arguments. Apart from the structure of events, understanding events by predicting relations among them also becomes a popular research topic (e.g., TimeBank (Pustejovsky et al., 2003) for temporal relations and Event2Mind (Rashkin et al., 2018) for causal relations). Different from these *horizontal* relations between events, in this paper, we propose to understand event *vertically* by treating each event as a process and trying to understand what is happening (i.e., sub-event) inside the target event. Such knowledge is also referred to as event schemata (Zacks and Tversky, 2001) and shown crucial for how humans understand events (Abbott et al., 1985). One line of related works in the NLP community is extracting super-sub event relations from textual corpus (Hovy et al., 2013; Glavas et al., 2014). The difference between this work and them is that we are trying to understand events by directly generating the sub-event sequences rather than extracting such information from text. Another line of related works is the narrative schema prediction (Chambers and Jurafsky, 2008), which also holds the assumption that event schemata can help understand events. But their research focus is using the overall process implicitly to help predict future events while this work tries to understand events by knowing the relation between processes and their sub-event sequences explicitly.

5 Conclusion

In this paper, we try to understand events *vertically* by viewing them as processes and predicting their sub-event sequences. Our APSI framework is motivated by the notion of analogous processes, and attempts to transfer knowledge from (a very small number of) familiar processes to a new one. The intrinsic evaluation demonstrates the effectiveness of APSI and the quality of the predicted sub-event sequences. Moreover, the extrinsic evaluation shows that, even with a naive application method, the process knowledge can help better predict missing events.

Abstract

We introduce **S**entence-level **L**anguage **M**odeling, a new pre-training objective for learning a discourse language representation in a fully self-supervised manner. Recent pre-training methods in NLP focus on learning either bottom or top-level language representations: contextualized word representations derived from language model objectives at one extreme and a whole sequence representation learned by order classification of two given textual segments at the other. However, these models are not directly encouraged to capture representations of intermediate-size structures that exist in natural languages such as sentences and the relationships among them. To that end, we propose a new approach to encourage learning of a contextualized sentence-level representation by shuffling the sequence of input sentences and training a hierarchical transformer model to reconstruct the original ordering. Through experiments on downstream tasks such as GLUE, SQuAD, and DiscoEval, we show that this feature of our model improves the performance of the original BERT by large margins.

1 Introduction

Recent representation learning methods in NLP such as BERT (Devlin et al., 2019) have focused on learning two types of representations: the bottom-level – a contextual representation centered at a single word, trained by recovering randomly masked tokens or predicting previous and next words, and the top-level text, implicitly represented as a single [CLS] symbol and trained by predicting a relation between input segments, which usually consist of multiple sentences. However, natural language text has, in contrast, a very dominant hierarchical structure, with words grouped together into intermediate semantic units such as phrases and then sentences to convey the full meaning of a given text. Neither the transformer architecture nor the pre-training task leverages this hierarchy, treating the language as a flat sequence of tokens instead.

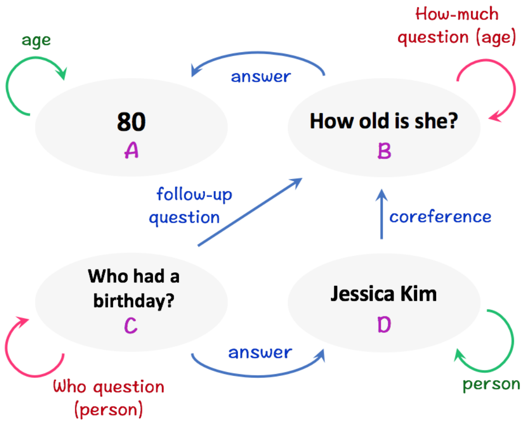

Figure 1: An example of a shuffled conversation and potential features that can aid in reconstructing the original sentence ordering, C → D → B → A.

Inspired by prior works about sentence-based representations for recurrent networks (Kiros et al., 2015; Hill et al., 2016; Gan et al., 2017; Jernite et al., 2017; Logeswaran et al., 2018; Gong et al., 2016; Chen et al., 2016), we seek to incorporate a more explicit hierarchy into the transformer by extending it with the capacity to learn contextualized sentence-level representations. Equipping the model with such a capacity allows it to learn languages at multiple levels of granularity, ranging from fine-grain connections across words to high-level discourse relations between sentences and paragraphs.

Predicting an original sequence of sentences requires deep understanding of natural language, including a variety of phenomena such as discourse relations, coreference, temporal dependencies, entailments, narratives, and so on. Figure 1 shows a set of statements from a conversation in the CoQA dataset (Reddy et al., 2019), and clues that can potentially be used to reconstruct their original ordering. To figure out the correct order, in this case

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1551–1562,

C-D-B-A, a model has to understand that D and A are answers to questions C and B respectively and that 'she' in B refers to D, and it may need to know that B is a follow-up question on C. Not only are the semantics of separate sentences important but the relationships between them are crucial in solving this task. We therefore seek to encourage the model to capture these vital properties by training it to reconstruct the original sentence ordering.

To achieve this, we propose a pre-training objective that extends the word-level language modeling to analogously learn representations for sentences. Typical word-level language models are trained by guessing the neighbors of given words or by predicting masked words based on their context. Applying the same idea at a higher level, our approach learns representations that support predicting the next sentence representation among shuffled sentences for given previous representations, based on the semantic relations between them.

To allow the model to be effectively trained with the new unshuffling objective, we propose a pointer-based neural module that is specialized to predict the sentence order, called the Sequence Reconstructor (SR). In the SR, each sentence is represented by a sentential token that is inserted in front of it. A pointer network layer stacked on the transformer decoder is trained to point at the next contextualized sentence representation based on the previous sentence representations.

We show that our method achieves robust improvements over standard BERT's performance on the following downstream NLP tasks: GLUE for Natural Language Inference (Wang et al., 2018), SQuAD for Question Answering (Rajpurkar et al., 2018), and DiscoEval (Chen et al., 2019) for discourse aware sentence representations. We match the score of Text-To-Text Transfer Transformer Base (T5$_{\text{BASE}}$) (Raffel et al., 2020), a state-of-the-art model that uses BERT$_{\text{BASE}}$ hyperparameters, while using only half the parameters, shorter training (3/8 tokens overall), and a fraction (1/37) of the data compared to T5. Moreover, we investigate the effect of the proposed objective through a qualitative analysis of the neighbor sentences of sentences that have similar sentential representations. We show that the results support our aim of enriching the transformer model with sentence-level language understanding.

The contributions of our work are threefold: 1) we propose a new self-supervised pre-training objective that extends a word-level language modeling strategy to the sentence-level; 2) we propose a pointer-based neural module to train the model for this objective, and demonstrate it leads to significant improvements over diverse NLP tasks; and 3) we provide a qualitative analysis showing that the learned contextualized sentence representations embed more subtle and rich structural, semantic, and relational information.

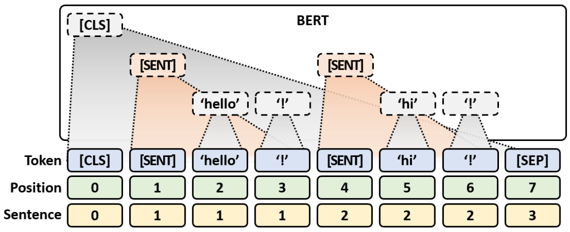

Figure 2: Intended representation scope of each contextualized sentence representation

2 Proposed Method

In this section, we describe the details of our proposed methods. A conventional representation model is extended with sentence representations to gather sentence information and a Sequence Reconstructor (SR) to predict their original ordering. Fine-tuning architectures are modified to inject sentence representation into downstream NLP tasks.

2.1 Pre-training with Sentence Unshuffling

Our model consists of an encoder for contextualizing input texts that uses a conventional transformer model like BERT, and a decoder that reconstructs the original ordering. We begin by splitting the input text into target segment units, sentences in this case, and shuffle them to remove their original ordering. We then add special tokens at the beginning of each segment, which will be used as sentence representations aggregating their meaning from their surroundings. We define a sentence-level language model (SLM) loss for reconstructing the original sentence ordering by making a sequence of predictions with a pointer network. Finally, the model is trained by sum of this loss and the standard masked language modeling (MLM) loss to pre-train the model. Through this pre-training objective, representations of sentences are properly contextualized by their neighboring sentence representations. Although we only consider sentence representations in this paper, our method can easily be extended to other syntactic levels such as

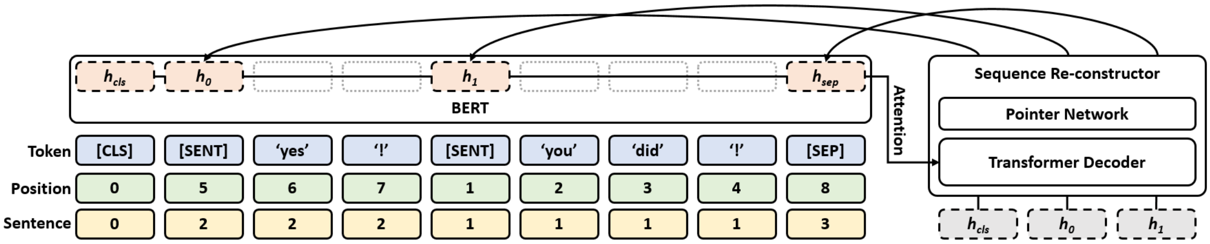

Figure 3: An overview of the architecture for the sentence unshuffling. Input sentences are randomly shuffled and the original ordering is reconstructed by our Sequence Reconstructor model using the sentence representations.

phrases or paragraphs. We provide further detail about each of these components in the followings.

Sentence Representation: We insert a sentence token, [SENT] in front of every sentence, that is meant to represent each sentence and aggregate its meaning from its surroundings. Similarly to positional and segment-level embeddings in the original BERT model, and to distinguish sentences and limit the scope of the sentence representations, we add trainable sentence embeddings indicating the index of each sentence to each of the word representations in order to support potential sentence-level aggregation as in ERNIE (Sun et al., 2020). Figure 2 shows trainable embeddings added to inputs and the scope of input tokens that are represented by each contextualized representation.

Sequence Shuffling: Input sentences are shuffled by manipulating their positional and sentence embeddings (as the positional encoding is the only clue to derive the actual sequences in a transformer architecture, unlike traditional RNNs). For example, the inputs of Figure 3 are a pair of swapped sentences. Position embeddings of the first sentence are 5 to 7 and those of the second sentence are 1 to 4. The sentence embedding are similarly swapped as well. Note that importantly the model can perform the unshuffling task only based on the semantics of the sentences and the relations between them, rather than by using the positional embeddings, since these are shuffled together with the sentences (namely, if sentence X and Y are swapped, so are their positional embeddings). For each iteration, only half of the batches are shuffled to allow the model to see some of the input in its natural ordering.

Sequence Reconstructor: SR is our conditional decoder consists of a pointer network and transformer decoder similar to Gong et al. (2016) and Logeswaran et al. (2018). It predicts the original ordering of the shuffled input as depicted in Figure 3. After encoding the shuffled inputs by BERT, we consider the contextualized embeddings: $C = [h_{cls}, h_0, ..., h_{N-1}, h_{sep}]$ that correspond to the N sentence tokens we have inserted into the input sequence, along with the first ([CLS]) and last ([SEP]) tokens. It is passed to the Sequence Reconstructor for the task of reconstructing the original sentence ordering.

The embeddings in C, except the last h_{sep}, are sequentially processed through a transformer decoder (Vaswani et al., 2017) to obtain output w_i while attending on the whole C and embeddings processed in the previous steps, $\{C_j\}_{j=0}^{i-1}$. Each processed output will be used to predict the sentence i in step i (Note that indexes of sentence representations in C are shifted by 1 due to h_{cls} inserted in front).

$$w_i = \text{TransformerDecoder}(C_i, \{C_j\}_{j=0}^{i-1}, C) \tag{1}$$

Then, we compute a probability distribution over the sentence representations using a pointer network. Each probability represents the likelihood of each sentence to come up next at step i, aiming to predict their original ordering:

$$\mathrm{P}_i = \text{Softmax}(w_i C^T) \tag{2}$$

We calculate a cross-entropy loss to match for each contextualized sentence embedding the probability distribution of the predicting ordering with the golden positions. $\mathrm{P}_i = \{p_{i,j}\}_{j=0}^{N+1}$ is the predicted probabilities of sentence j-1 (due to a shift by h_{cls}) appearing at position i, and o_i is a one hot ground-truth vector of the correct position at step i. Finally, we average the losses for all positions $i = 0, \ldots, N$:

$$\mathcal{L}_{\text{slm}} = -\frac{1}{N+1} \sum_{i=0}^{N} \sum_{j=1}^{N+1} \mathrm{o}_{i,j} \log{(p_{i,j})} \tag{3}$$

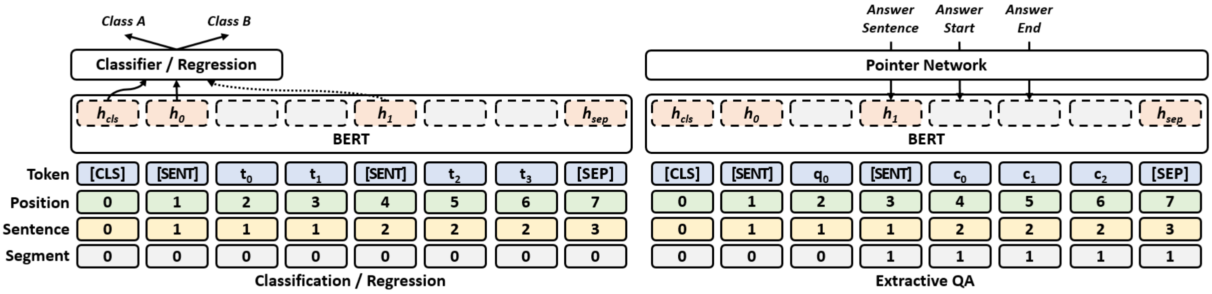

Figure 4: Fine-tuning Architectures. Sentence representations are concatenated to the [CLS] representation before being fed into the output layer for downstream classification (or regression) tasks and used to predict an answer sentence for extractive QA tasks.

Intuitively, the decoder learns how to transform a representation of sentence to the next sentence's representation recurrently by attending on the whole sentence representations from the encoder and previously transformed embeddings.

One important design choice here is that the Sequence Reconstructor only sees C, which are contextualized embeddings of [CLS], the sentence tokens, and [SEP] while other contextualized word representations are masked out. The model should find out the original sequence using only sentence representations and this will enforce the encoder to embed all necessary information into the contextualized sentence embedding instead of spreading them over all embeddings.

Overall, the whole model is trained by minimizing a sum of the standard masked language model loss as in the original BERT design and our new sentence-level language model loss.

$$\mathcal{L} = \mathcal{L}_{mlm} + \mathcal{L}_{slm} \tag{4}$$

Note that the SR module only adds about 7.1% overhead in computation time to the standard transformer encoder and only during the pre-training stage. It is lightweight compared to the full transformer stack in terms of computation and number of parameters, because it performs re-ordering over a small number of sentential tokens (20 in a 512 token sequence) using shallow decoder stacks (3 layers).

2.2 Fine-tuning

The original fine-tuning methods of BERT are slightly modified to encourage the model to use sentence representations learned during pre-training for downstream NLP tasks. Figure 4 shows the overall fine-tuning architecture for extractive QA and classification and regression tasks.

Classification and regression: The contextualized sentence embeddings of given sentences are concatenated to the [CLS] embedding. Depending on the sentence number of the task, one or two sentence tokens are concatenated before being fed into the output layer.

Extractive QA: For extractive tasks, we add an answer sentence prediction that finds the sentence token corresponding to the answer, using a pointer network to an existing answer span prediction. To distinguish the question and the context, segment embeddings as in BERT are used while other tasks use the same segment index for all inputs. The final loss is the sum of three independent pointer networks losses: 1) the answer start index, 2) the answer end index, and 3) the answer sentence index.

3 Experiments

3.1 Benchmark Datasets

To measure the excellence of our propose SLM on various downstream tasks, we conduct experiments with three well-known benchmarks: General Language Understanding Evaluation (GLUE), the Stanford Question Answering (SQuAD) v1.1 and v2.0, and Discourse Evaluation (DiscoEval) (Chen et al., 2019). We exclude the WNLI task from GLUE following BERT which always achieves 65.1 accuracy of the majority class. RST-DT task is also excluded from DiscoEval which requires a tree structure encoding. Metrics used are Matthew's correlation for CoLA, F1 for MRPC, Spearman's correlation for STS-B, Exact Match (EM) / F1 for SQuAD, and accuracy for rest of tasks. We report development set results for SQuAD to compare with other models, both development and test set scores for GLUE, and test set scores for DiscoEval.

Table 1: GLUE results. BERT dev scores are produced by same hyperparameter searches using the official pre-trained models. Bolded are the highest scores among Base-size models. XLNet and ELECTRA's scores are averages except MNLI-mm that are not reported in the papers.

3.2 Experimental Setup

For the experiments, we follow BERT$_{\text{BASE}}$'s hyperparameters and corpus. Our model is trained with 512 length-256 batch size using Wikipedia dumps and BookCorpus (Zhu et al., 2015). We split inputs into sentences using the NLTK toolkit (Loper and Bird, 2002), which are then re-shuffled for every epoch. In terms of data preprocessing, when each input is fed into the model, we set the maximum count M of sentences to process as 20 in our experiments. If exceeded, we randomly merge pairs of adjacent sentences and treat them as a single sentence until the required sentence count is reached. We perform this preprocessing step in order to deal with an uncommonly large number of sentences. For the masked language model objective, we randomly mask up to three continuous word tokens using a geometric distribution, $Geo(p = 0.2)$ following the findings of T5 (Raffel et al., 2020) and SpanBERT (Joshi et al., 2020), but sentence tokens are not masked. The models are pre-trained for 1M and 3M steps and optimized by Adam with linear weight decaying using a learning rate 1.5e-4. Any other configuration not mentioned here is the same as the original BERT model.

Fine-tuning is done by a hyperparameter search of learning rate: $\{$1e-5, 3e-5, 5e-5, 1e-4$\}$ and epoch between 2 to 15 depends on the tasks. We select the run with the best development set score among five runs for each parameter combination for more stable results. For GLUE test set results, predictions from models with the best development score are submitted. All results of downstream NLP tasks in this paper are results of a single model trained with a single task. For DiscoEval(Chen et al., 2019) tasks, we freeze the encoder and only fine-tune the output layer following Chen et al. (2019).

Although the recent state-of-the-art models such as ALBERT (Lan et al., 2019) or T5 use extremely large model and training data, we follow BERT$_{\text{BASE}}$'s model size because of practical limitations of computation resources. We believe that the BASE settings allow for a robust comparison to the current leading approaches.

4 Results

We compare our SLM model with the original BERT, XLNet (Yang et al., 2019), ELECTRA (Clark et al., 2019), ERNIE 2.0 (Sun et al., 2020), CONPONO (Iter et al., 2020), BART (Lewis et al., 2020) and T5 which are the current state-of-the-art for the benchmark datasets we use. We mainly compare with models using BERT$_{\text{BASE}}$ hyperparameters.

4.1 GLUE results

Table 1 shows the performance of our method on the GLUE dataset for all tasks except WNLI. Our method significantly improves the downstream NLP tasks in the GLUE dataset. While most tasks are improved from the original BERT, improvement of RTE by 12.1 points is the most significant. We assume this is because our model learns the relationship of sentences thanks to our objective and it is the most effective on the entailment task with relatively small data like RTE. While our average test score is the highest among Base-size models that is 0.3 points higher than T5$_{\text{BASE}}$, some scores

Model	SQuAD v1.1 EM / F1	SQuAD v2.0 EM / F1
BERT$_{\text{BASE}}$	80.8 / 88.5	75.2 / 78.3
XLNet$_{\text{BASE}}$	-	78.5 / 81.3
BART$_{\text{BASE}}$	- / 90.8	-
ELECTRA$_{\text{BASE}}$*	84.5 / 90.8	80.5 / 83.3
T5$_{\text{BASE}}$	**85.4** / 92.1	-
BERT$_{\text{LARGE}}$	84.1 / 90.9	78.7 / 81.9
BERT$_{\text{LARGE-WWM}}$	86.7 / 92.8	82.6 / 85.4
SLM$_{\text{BASE}}$(1M)	84.6 / 91.5	80.7 / 83.7
SLM$_{\text{BASE}}$(3M)	85.3 / **92.2**	**81.9 / 84.9**

Table 2: Fine-tuning results on the SQuAD v1.1 and v2.0 development sets. The scores of BERT on SQuAD v2.0 are produced using the official pre-trained models and others are taken from their papers. Bolded are the highest scores among Base-size models. *mean scores over 10 runs.

are even comparable with large models trained by more total tokens and data. Our average score is 0.9 points higher than BERT$_{\text{LARGE}}$. Our SST-2 score is higher than BERT and ELECTRA's scores and MRPC score is higher than BERT, XLNet, and ELECTRA.

4.2 SQuAD results

As shown in Table 2, our method significantly improves the performance on both SQuAD v1.1 and v2.0. It exceeds the original BERT$_{\text{BASE}}$ model by 3.0 and 5.4 points F1 and 3.8 and 5.5 points EM for v1.1 and v2.0 respectively when it is equally trained for 1M steps. When it is sufficiently trained for 3M steps, additional gains are achieved by 0.7 and 1.2 points EM/F1. Finally, it achieves a tie score with the T5$_{\text{BASE}}$ model in SQuAD v1.1. This is an impressive result because T5 is an encoder-decoder model which uses twice as many parameters and is trained by 2.7-times more total tokens and astonishingly 37-times more data.

Model	**SP**	**BSO**	**DC**	**SSP**	**PDTB-E/I**
BERT$_{\text{BASE}}$	53.1	68.5	58.9	80.3	41.9 / 42.4
BERT$_{\text{LARGE}}$	53.8	69.3	59.6	80.4	44.3 / 43.6
RoBERTa$_{\text{BASE}}$	38.7	58.7	58.4	79.7	39.4 / 40.6
CONPONO$_{\text{BASE}}$	60.7	76.8	72.9	80.4	42.9 / 44.9
SLM$_{\text{BASE}}$(1M)	72.4	84.1	75.4	**81.5**	45.9 / 46.3
SLM$_{\text{BASE}}$(3M)	**73.4**	**84.5**	**76.1**	**81.5**	**46.4 / 47.8**

Table 3: Test set results of DiscoEval datasets except RST-DT. Scores of other models are from Chen et al. (2019) and Iter et al. (2020)

4.3 DiscoEval Results

Table 3 shows the test set results on DiscoEval. Our method achieves improvements with a large margin on all tasks over the previous state-of-the-art model, CONPONO (Iter et al., 2020). This result reveals that our method learns discourse relations better with our sentence unshuffling objective. Especially, an improvement on SP, finding the original position of a given sentence, is the most significant by 12.7 points higher than CONPONO. This is because sentence positions for a given sentence can be found by finding the next sentence which means the SP task is a reduced problem of our sequence reconstruction task. The improvements on SSP, predicting whether the given sentence belongs to the Abstract section, is relatively little because it has less in common with the SLM objective.

Model	SQuAD v1.1 EM / F1	SQuAD v2.0 EM / F1
Original Sentences	82.7 / 89.8	76.5 / 79.4
Shuffled Sentences	**83.2 / 90.1**	**77.4 / 80.5**

Table 4: The results on SQuAD datasets of models trained with original and shuffled sentences.

5 Analysis

5.1 Sentence representation in BERT

To gain motivation for our approach, we begin by running a simple experiment to measure the level of hierarchical understanding of the standard BERT model using the masked language model objective. We train two models: one with sentences in the original ordering and another with the sentences shuffled. The latter model is expected to lose the hierarchical semantics at the discourse level as the shuffling breaks the relations implied by the natural ordering. In practice, the SQuAD results detailed in Table 4 show a model trained with the shuffled sentences in fact outperforms the model trained with the sentences in the original ordering. These results indicate that BERT does not take advantage of the global, sentence-level, structure of the text but rather apparently captures a shallower understanding that does not translate into an improvement in reading comprehension performance.

5.2 Effect of our proposed method

In this section, we perform ablation studies to show the impact of our proposed methods. We trained 5 models with different configurations discarding different aspects of the model. We use SQuAD and four tasks from GLUE which are large enough to derive stable comparisons.

Shuffled Batch: Amount of shuffled batches that need to be balanced between learning by seeing

Shuf. Batch	Seq. Recon.	Sent. Repr.	SQuAD v1.1 EM / F1	SQuAD v2.0 EM / F1	MNLI m / mm	QNLI	SST-2	QQP	Avg.
50%	✓	✓	**84.6 / 91.5**	**80.7 / 83.7**	**86.6 / 86.4**	**93.0**	**93.7**	**91.6**	**88.0**
100%	✓	✓	84.2 / 91.2	80.3 / 83.4	86.1 / 86.2	92.9	93.5	91.4	87.7
100%		✓	83.7 / 90.7	77.3 / 80.4	85.4 / 85.6	92.3	93.0	91.3	86.6
0%		✓	82.8 / 90.1	76.8 / 79.8	85.3 / 85.5	92.2	93.0	91.1	86.3
0%			82.7 / 89.8	76.5 / 79.4	84.7 / 84.6	91.7	92.8	91.1	85.9

Table 5: Ablation study on our proposed methods

and predicting the original sequence.

Sequence Reconstructor: Whether the model is trained with a loss from sentence-level objective and the sequence reconstructor model.

Sentence Representation: Whether the model uses sentence representation tokens and embeddings.

While all features increase performance individually, the biggest gains stem from the sequence reconstruction objective with both the shuffled and original orderings. This combination increases SQuAD v1.1 EM / F1 by 1.9 / 1.7 points and v2.0 by 4.2 / 4.3 points respectively. MNLI-m/mm accuracies are similarly improved by 1.9 and 1.8 points. Other tasks are also slightly improved. Notably, our best performing model is achieved by shuffling the sentence ordering only for half of the input batches, to allow the model experiencing also the natural ordering. Removing the ordering from all batches rather than half of them leads to slight reductions of 0.1-0.5 points for most tasks, which might result from the model's lack of exposure to natural input ordering that would be necessary for some tasks.

One interesting point is that just adding a sentence representation or shuffling the input are each individually increasing the performance even without the sentence-level objective. We conjecture that some of the sentence representations can be learned from the standard word-level prediction loss without the specific objective based on the explicit sentence representation. Shuffling input might help by adding regularization effects and making the model more robust against noisy permutations as well.

5.3 What information is learned by SLM?

For a more intuitive understanding of what is learned from the unshuffling objective, we search the closest sentences to query sentences using a cosine distance of sentence representations from our pre-trained model. Sentences with typical discourse labels from samples in Jernite et al. (2017) are used as queries to see whether our model captures a variety of different discourses and 1M sentence pairs from Gutenberg BookCorpus (Lahiri, 2014) are used as targets to search. Table 6 shows the Top 3 closest sentences for each query sentence with discourse labels. We additionally pick one of the highly ranked results to show diversities of similarities between queries and retrievals. We mark query and retrieved sentences in bold and show previous sentences together. Semantically similar phrases are marked in blue while potential clues to discourse relations are in red. Results that do not match the query's discourse label are marked by ×.

As we can see from the table, most of the retrieved sentences share a mixture of syntactic, semantic and discourse-level aspects with the given queries, especially in regard to their relationships with their surrounding context. Even without any fine-tuning and filtering of the retrieved results, most of the highly ranked ones share a similar discourse relation with their prior sentences to that of the query sentences. Some discourse relations are commonly indicated by conjunctive words, and then the retrieved sentences have conjunctions of the relevant discourse sense, e.g. *"in fact"*, and *"soon"* for *strengthen*, and words indicating similar temporal relations for *temporal*. In other cases, when the results differ in the conjunctive words, they still hold high-level structural similarities to the query sentences. This is especially true for the *elaboration* and *list* relations. Finally, we notice that semantically similar phrases are also captured by the retrieved results. In the *contrast* example, results contain phrases like *"all was still"*, and *"no other sound came from"* which correspond to the word *"silence"* in the query. It is noticeable that overall our model seems to focus more on the relational aspect than the semantic and syntactic aspects. This serves as a qualitative evidence for the effectiveness of the new unshuffling objective: while all aspects are needed for sentence understanding, we conjecture that the relational component is the one most vital for the un-shuffling task as it naturally demands an understanding of the

Discourse	Sources and Nearest Neighbors
Contrast	**Q** : The waterwheel hammered on. **Otherwise there was silence.**
×	1) A portion of the burning log fell on to the hearth. **Then there was silence**
	2) The bees still worked on, and the butterflies did not rest from roving, their smallness seeming to shield them from the stagnating effect that this turning moment of day had on larger creatures. **Otherwise all was still.**
	3) A class in spelling, big boys and little girls, toed a crack in front of the waster's desk. **The rest of the school droned away on appointed tasks in the drowsy interlude.**
×	4) Fra Girolamo, give her-the Crucifix, said the voice of Fra Girolamo. **No other sound came from the dying lips.**
Strengthen	**Q** : It doesn't hurt at all. **In fact it's exhilarating.**
	1) We have no great political guns aboard. **On the contrary, the majority of the passengers are Americans.**
	2) I don't believe in the faults. **They're just a joyous softening of the outline - more beautiful than perfection.**
	3) I never regarded Ealer's readings as educational. **Indeed, they were a detriment to me.**
	7) We have no sympathy at all with the moral indignation of our time against M. Zola. **It is simply the indignation of Tartuffe on being exposed.**
Elaboration	**Q** : Then I became a woman. **A strong one at that.**
	1) Christianity was the last great religious synthesis. **It is the one nearest to us.**
	2) I wanted you to care for me so that I could influence you. **It wasn't easy.**
	3) It got on my nerves - the women I saw. **Worse than any man.**
	9) He's past his seventy now, - ever so much; but he's just as modest as a young girl. **A deal more modest than some of them.**
Return	**Q** : He had a point. **Still for good measure, I pouted.**
	1) Logically - if not legally - there is apparently an inference of the interchange of matrimonial consent here. **I stick to my own opinion, nevertheless.**
	2) To him I was a squeezed lemon. **Nevertheless I took his hint.**
	3) It was almost dark. **Yet I must walk away.**
	9) He spoke not a word. **I pitied him from the bottom of my heart.**
Temporal	**Q** : It limped closer at a slow pace. **Soon it stopped in front of us.**
	1) The current carried them on and on, but not so swiftly as it was carrying the tree. **Soon they were approaching the bend.**
	2) Then he got down from his post and loafed along the sidewalk, still observing and occasionally commenting. **Presently he dropped into my wake and followed along behind.**
	3) Slowly, patiently, watchfully, the hunter followed. **After a while he stopped with a satisfied grin.**
	12) The mass fell into columns by threes and fours to accommodate itself to the narrow road, and strode briskly along southward in the wake of the leaders. **In a few minutes the Hogan cabin was reached.**
List	**Q** : I saw flowers on the ground. **I heard birds in the trees.**
×	1) He saw a garden. **We saw a wilderness.**
	2) I heard the pulse of the besieging sea throb far away all night. **I heard the wind fly crying, and convulse tumultuous palms.**
×	3) I took several long walks while collecting objects of natural history. **The country is pleasant for exercise.**
	5) My maid is a treasure. **My dressmaker is charming.**

relationships between the sentences.

6 Related Work

Contextualized Representation learning for NLP: Self-supervised representation learning became popular after contextualization methods were introduced. ELMo (Peters et al., 2018) dynamically contextualizes representations of adjacent words using bi-directional recurrent encoders. BERT (Devlin et al., 2019) adopted a deep transformer encoder and has proposed the masked language modeling objective incorporating a bi-directional context. After the success of BERT, researchers started exploring various new pre-training objectives such as span boundary representations (Joshi et al., 2020), reordering of local permutations (Wang et al., 2019), detecting incorrectly replaced tokens (Clark et al., 2019), combining multiple tasks (Sun et al., 2020), a decoder-based masked word prediction (Song et al., 2019), and so on.

Another line of works tried to scale up the model with more parameters, training data, and computation resources. RoBERTa (Liu et al., 2019) trains BERT$_{\text{LARGE}}$ model with 10x more data for 16x more iterations. ALBERT (Lan et al., 2019) uses the xxlarge model whose parameters are reduced by weight sharing and factorizations. T5 proposes a multi-task encoder-decoder architecture that uses up-to about 33x weight parameters, 37x data size compared to the original BERT$_{\text{LARGE}}$ model.

Sentence Representation Models: Several works tried to learn sentence representations using adjacent sentences, especially in recurrent networks. SkipThoughts (Kiros et al., 2015) and FastSent (Hill et al., 2016) proposed an encoder-decoder architecture that encodes a sentence and generates the next and previous sentences. These works focus on independent representations of single independent sentences and do not consider the dynamic contextualization using neighboring sentences.

We believe that, similar to words, sentence representations should also be properly contextualized in order to embed richer meaning including relationships to other sentences. HLSTM (Chang et al., 2019) considered contextualization of sentence representations by incorporating previous step's sentence representation for word prediction. HIBERT (Zhang et al., 2019) proposed a hierarchical transformer encoder trained by recovering masked sentences, focusing in particular on summarization. However, both of these models are trained by performing prediction at the word level, wheres our sentence unshuffling approach demands fine understanding of the relations among the sentences at the more global discourse level.

Learning from Sentence Ordering: There are prior works about learning contextualized sentence representations by recovering the original sequence of sentences. Gong et al. (2016) and Logeswaran et al. (2018) proposed RNN-based pointer networks for reconstructing the sequence order. However, they utilized hierarchical models that encode each sentence separately without any access to other sentences. This fact not only restricts long-term contextualization of words and sentences but also limits downstream tasks due to the dedicated architectures. On the other hand, our method encodes multiple sentence representations at the same time with both inner and inter-sentence contextualization.

The effect of predicting textual segment order in pretrained language models has been widely investigated as well. BERT proposed the Next Sentence Prediction task (NSP) which predicts whether two given text segments are from the same documents or not. The results of SpanBERT (Joshi et al., 2020) question the value of NSP, suggesting this might be due to noise from merging 2 unrelated texts from different documents. Consequently, ALBERT (Lan et al., 2019) and StructBERT (Wang et al., 2019) added sentence ordering objectives by predicting the order of text segments. BART (Lewis et al., 2020) proposed the Sentence Permutation task which is similar with ours. It predicts the original sequence of sentences using an auto-regressive decoder, which reconstructs the whole sentences by word prediction. However, their approach does not provide any representation of each sentence. Moreover, while SLM shows strong task improvements, that is not the case for these models.

7 Conclusions

In this paper, we proposed the Sentence-level Language Modeling objective for contextualized sentence representation learning. Our approach extends a word-level language modeling strategy to the sentence-level by reconstructing the original order of shuffled sentences. In addition, we designed a special Sequence Reconstructor (SR) module to learn to perform the sentence re-ordering. It reconstructs the original order by pointing to the next sentence among encoded sentence representations using a pointer network and a transformer decoder. We evaluated the effect of the proposed idea on three benchmarks, GLUE, SQuAD, and DiscoEval, and showed consistent improvements over the previous approaches. We matched performance with the state-of-the-art model with the same model size using much fewer parameters, computation, and data. Through a qualitative analysis, we showed that our model can embed not only semantic but also relational features of sentences. We are excited about future work that could extend our motivation and further aim at incorporating stronger hierarchy into the language model architectures and the pre-training tasks.

A Training Details

We provide details of hyperparameters and corpus we used for pre-training and fine-tunings. Table 7 shows all the detailed hyperparamters. We mainly used BERT-Base size (12 layers, 12 attention headers, 768 hidden size, and 110M parameters). Pre-training a BERT-Large sized model for 3M iterations is expected to take more than a month in our experiment environments, so we stick to BERT-Base size. All other hyperparameters except the learning rate during pre-training are the same as the original BERT. We found that LR 1.5e-4 results in slightly better compare to LR 1e-4 used in the original BERT.

Parameter	Pre-training	Fine-tuning
Encoder layers	12	12
Decoder layers	3	-
Attention heads	12	12
Hidden size	768	768
Sequence length	512	128 / 512
Sentence tokens	20	20
Vocab Size	30522	30522
Batch size	256	32
Step / Epoch	1M/3M	2 ∼ 15
Warm-up	10K	10%
Learning Rate	1.5e-4	1/3/5e-5/1e-4
Adam epsilon	1e-6	1e-6
Dropout	0.1	0.1
Attention Dropout	0.1	0.1
Precision	Float16	Float16

Table 7: Training Hyperparameters.

We use English Wikipedia and Bookcorpus(Zhu et al., 2015) for pre-training. Since Bookcorpus is no longer available online, we collected our own version of BookCorpus using publicly available crawling code (`https://github.com/soskek/bookcorpus`). Texts are extracted from Wikipedia dumps using WikiExtractor (`https://github.com/attardi/wikiextractor`). Simple heuristic preprocesses are applied to clean the corpus which removed sentences that do not contain enough words. The final size of processed corpus are 9.2GB and 5.7 GB for Wikipedia and BookCorpus respectively. The total size is slightly smaller compare to the total corpus used to train the original BERT because some links are unavailable when we collected the BookCorpus. We used 8 NVIDIA v100 GPUs for pretraining and it took about 5 days to train for 1M iteration. We tokenize the corpus with WordPiece (Wu et al., 2016) tokenizer using uncased vocabulary of Google's official BERT release.

For all fine-tuning tasks, we use batch size 32 with 512 sequence length for SQuAD and 128 for GLUE tasks. Hyperparameter searches are mainly done for epoch {2, 3, 4, 5} and learning rate { 1e-5, 3e-5, 5e-5 }. We run 5 runs for each parameter combinations to get a stable dev set results. GLUE test set scores are achieved by submitting test set predictions of the best dev score models to the glue evaluation server. We report the best hyperparameters for each task in Table 8.

Task	Epoch	Learning Rate
SQuAD v1.1	2	5e-5
SQuAD v2.0	2	3e-5
CoLA	4	1e-5
SST-2	3	3e-5
MRPC	3	3e-5
STS-B	4	1e-5
QQP	4	3e-5

B Implementation Details

We use Tensorflow(Abadi et al., 2015) for all of our experiments. Our implementations are based on the NVIDIA's tensorflow implementation of BERT which supports multi GPU using Horovod (Sergeev and Balso, 2018) and half precision training (`https://github.com/NVIDIA/DeepLearningExamples/tree/master/TensorFlow/LanguageModeling/BERT`). We adapt an implementation of transformer decoder from official tensorflow's transformer implementation (`https://github.com/tensorflow/models/tree/master/official/transformer`)

Detecting Fine-Grained Cross-Lingual Semantic Divergences without Supervision by Learning to Rank

Abstract

Detecting fine-grained differences in content conveyed in different languages matters for cross-lingual NLP and multilingual corpora analysis, but it is a challenging machine learning problem since annotation is expensive and hard to scale. This work improves the prediction and annotation of fine-grained semantic divergences. We introduce a training strategy for multilingual BERT models by learning to rank synthetic divergent examples of varying granularity. We evaluate our models on the **R**ationalized **E**nglish-**Fre**nch **S**emantic **D**ivergences, a new dataset released with this work, consisting of English-French sentence-pairs annotated with semantic divergence classes and token-level rationales. Learning to rank helps detect fine-grained sentence-level divergences more accurately than a strong sentence-level similarity model, while token-level predictions have the potential of further distinguishing between coarse and fine-grained divergences.

1 Introduction

Comparing and contrasting the meaning of text conveyed in different languages is a fundamental NLP task. It can be used to curate clean parallel corpora for downstream tasks such as machine translation (Koehn et al., 2018), cross-lingual transfer learning, or semantic modeling (Ganitkevitch et al., 2013; Conneau and Lample, 2019), and it is also useful to directly analyze multilingual corpora. For instance, detecting the commonalities and divergences between sentences drawn from English and French Wikipedia articles about the same topic would help analyze language bias (Bao et al., 2012; Massa and Scrinzi, 2012), or mitigate differences in coverage and usage across languages (Yeung et al., 2011; Wulczyn et al., 2016; Lemmerich et al., 2019). This requires not only detecting coarse content mismatches, but also fine-grained differences in sentences that overlap in content. Consider the following English and French sentences, sampled from the WikiMatrix parallel corpus. While they share important content, highlighted words convey meaning missing from the other language:

> EN *Alexander Muir's "The Maple Leaf Forever"* ***served for many years*** *as an* ***unofficial*** *Canadian* ***national anthem****.*
> FR *Alexander Muir compose The Maple Leaf Forever (en) qui est un* ***chant patriotique*** *pro canadien* ***anglais****.*
> GLOSS *Alexander Muir composes The Maple Leaf Forever which is an English Canadian patriotic song.*

We show that explicitly considering diverse types of semantic divergences in bilingual text benefits both the annotation and prediction of cross-lingual semantic divergences. We create and release the **R**ationalized **E**nglish-**Fre**nch **S**emantic **D**ivergences corpus (REFRESD), based on a novel divergence annotation protocol that exploits rationales to improve annotator agreement. We introduce Divergent mBERT, a BERT-based model that detects fine-grained semantic divergences without supervision by learning to rank synthetic divergences of varying granularity. Experiments on REFRESD show that our model distinguishes semantically equivalent from divergent examples much better than a strong sentence similarity baseline and that unsupervised token-level divergence tagging offers promise to refine distinctions among divergent instances. We make our code and data publicly available.[1]

---

November 16–20, 2020.

2 Background

Following Vyas et al. (2018), we use the term **cross-lingual semantic divergences** to refer to differences in meaning between sentences written in two languages. Semantic divergences differ from typological divergences that reflect different ways of encoding the same information across languages (Dorr, 1994). In sentence pairs drawn from comparable documents—written independently in each language but sharing a topic—sentences that contain translated fragments are rarely exactly equivalent (Fung and Cheung, 2004; Munteanu and Marcu, 2005), and sentence alignment errors yield coarse mismatches in meaning (Goutte et al., 2012). In translated sentence pairs, differences in discourse structure across languages (Li et al., 2014) can lead to sentence-level divergences or discrepancies in translation of pronouns (Lapshinova-Koltunski and Hardmeier, 2017; Šoštarić et al., 2018); translation lexical choice requires selecting between near synonyms that introduce language-specific nuances (Hirst, 1995); typological divergences lead to structural mismatches (Dorr, 1994), and non-literal translation processes can lead to semantic drifts (Zhai et al., 2018).

Despite this broad spectrum of phenomena, recent work has effectively focused on coarse-grained divergences: Vyas et al. (2018) work on subtitles and Common Crawl corpora where sentence alignment errors abound, and Pham et al. (2018) focus on fixing divergences where content is appended to one side of a translation pair. By contrast, Zhai et al. (2018, 2019) introduce token-level annotations that capture the meaning changes introduced by human translators during the translation process (Molina and Hurtado Albir, 2002). However, this expensive annotation process does not scale easily.

When processing bilingual corpora, any meaning mismatches between the two languages are primarily viewed as noise for the downstream task. In shared tasks for filtering web-crawled parallel corpora (Koehn et al., 2018, 2019), the best performing systems rely on translation models, or cross-lingual sentence embeddings to place bilingual sentences on a clean to noisy scale (Junczys-Dowmunt, 2018; Sánchez-Cartagena et al., 2018; Lu et al., 2018; Chaudhary et al., 2019). When mining parallel segments in Wikipedia for the WikiMatrix corpus (Schwenk et al., 2019), examples are ranked using the LASER score (Artetxe and Schwenk, 2019), which computes cross-lingual similarity in a language-agnostic sentence embedding space. While this approach yields a very useful corpus of 135M parallel sentences in 1,620 language pairs, we show that LASER fails to detect many semantic divergences in WikiMatrix.

3 Unsupervised Divergence Detection

We introduce a model based on multilingual BERT (mBERT) to distinguish divergent from equivalent sentence-pairs (Section 3.1). In the absence of annotated training data, we derive synthetic divergent samples from parallel corpora (Section 3.2) and train via learning to rank to exploit the diversity and varying granularity of the resulting samples (Section 3.3). We also show how our model can be extended to label tokens within sentences (Section 3.4).

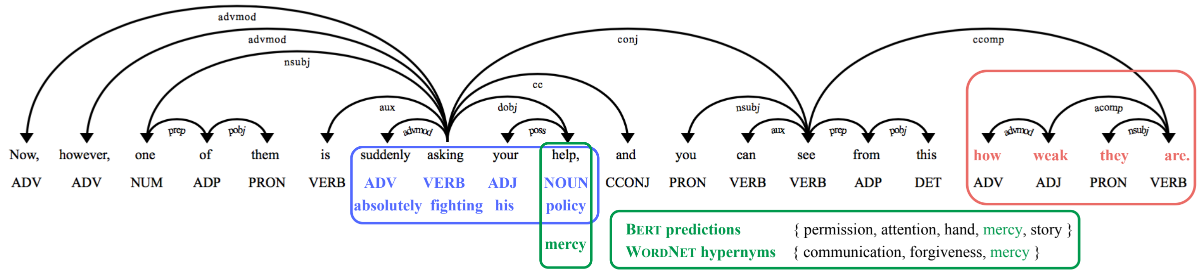
3.1 Divergent mBERT Model

Following prior work (Vyas et al., 2018), we frame divergence detection as binary classification (equivalence vs. divergence) given two inputs: an English sentence $\mathbf{x_e}$ and a French sentence $\mathbf{x_f}$. Given the success of multilingual masked language models like mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), and XLM-R (Conneau et al., 2020) on cross-lingual understanding tasks, we build our classifier on top of multilingual BERT in a standard fashion: we create a sequence $\mathbf{x}$ by concatenating $\mathbf{x_e}$ and $\mathbf{x_f}$ with helper delimiter tokens: $\mathbf{x} = ([\text{CLS}], \mathbf{x_e}, [\text{SEP}], \mathbf{x_f}, [\text{SEP}])$. The [CLS] token encoding serves as the representation for the sentence-pair $\mathbf{x}$, passed through a feed-forward layer network F to get the score $F(\mathbf{x})$. Finally, we convert the score $F(\mathbf{x})$ into the probability of $\mathbf{x}$ belonging to the equivalent class.

3.2 Generating Synthetic Divergences

We devise three ways of creating training instances that mimic divergences of varying granularity by perturbing seed equivalent samples from parallel corpora (Table 1):

Subtree Deletion We mimic semantic divergences due to content included only in one language by deleting a randomly selected subtree in the dependency parse of the English sentence, or French words aligned to English words in that subtree. We use subtrees that are not leaves, and that cover less than half of the sentence length. Durán et al. (2014); Cardon and Grabar (2020) success-



Seed Equivalent Sample

Now, however, one of them is suddenly asking your help, and you can see from this how weak they are.

Maintenant, cependant, l'un d'eux vient soudainement demander votre aide et vous pouvez voir à quel point ils sont faibles.

Subtree Deletion

Now, however, one of them is suddenly asking your help, and you can see from this.

Maintenant, cependant, l'un d'eux vient soudainement demander votre aide et vous pouvez voir à quel point ils sont faibles .

Phrase Replacement

Now, however, one of them is absolutely fighting his policy , and you can see from this how weak they are.

Maintenant, cependant, l'un d'eux vient soudainement demander votre aide et vous pouvez voir à quel point ils sont faibles.

Lexical Substitution

Now, however, one of them is suddenly asking your mercy , and you can see from this.

Maintenant, cependant, l'un d'eux vient soudainement demander votre aide et vous pouvez voir à quel point ils sont faibles.

Table 1: Starting from a seed equivalent parallel sentence-pair, we create three types of divergent samples of varying granularity by introducing the highlighted edits.

fully use this approach to compare sentences in the same language.

Phrase Replacement Following Pham et al. (2018), we introduce divergences that mimic phrasal edits or mistranslations by substituting random source or target sequences by another sequence of words with matching POS tags (to keep generated sentences as grammatical as possible).

Lexical Substitution We mimic *particularization* and *generalization* translation operations (Zhai et al., 2019) by substituting English words with hypernyms or hyponyms from WordNet. The replacement word is the highest scoring WordNet candidate in context, according to a BERT language model (Zhou et al., 2019; Qiang et al., 2019).

We call all these divergent examples **contrastive** because each divergent example contrasts with a specific equivalent sample from the seed set. The three sets of transformation rules above create divergences of varying granularity and create an **implicit ranking over divergent examples** based on the range of edit operations, starting from a single token with lexical substitution, to local short phrases for phrase replacement, and up to half the words in a sentence when deleting subtrees.

3.3 Learning to Rank Contrastive Samples

We train the Divergent mBERT model by learning to rank synthetic divergences. Instead of treating equivalent and divergent samples independently, we exploit their contrastive nature by explicitly pairing divergent samples with their seed equivalent sample when computing the loss. Intuitively, *lexical substitution* samples should rank higher than *phrase replacement* and *subtree deletion* and lower than seed *equivalents*: we exploit this intuition by enforcing a margin between the scores of increasingly divergent samples.

Formally, let $\mathbf{x}$ denote an English-French sentence-pair and $\mathbf{y}$ a contrastive pair, with $\mathbf{x} > \mathbf{y}$ indicating that the divergence in $\mathbf{x}$ is finer-grained than in $\mathbf{y}$. For instance, we assume that $\mathbf{x} > \mathbf{y}$ if $\mathbf{x}$ is generated by lexical substitution and $\mathbf{y}$ by subtree deletion.

At training time, given a set of contrastive pairs $\mathcal{D} = \{(\mathbf{x}, \mathbf{y})\}$, the model is trained to rank the score of the first instance higher than the latter by minimizing the following margin-based loss

$$\mathcal{L}_{\text{sent}} = \frac{1}{|\mathcal{D}|}\Big(\sum_{(\mathbf{x},\mathbf{y})\in\mathcal{D}} \max\{0, \xi - F(\mathbf{x}) + F(\mathbf{y})\}\Big) \quad (1)$$

where ξ is a hyperparameter margin that controls the score difference between the sentence-pairs $\mathbf{x}$

and $\mathbf{y}$. This ranking loss has proved useful in supervised English semantic analysis tasks (Li et al., 2019), and we show that it also helps with our cross-lingual synthetic data.

3.4 Divergent mBERT for Token Tagging

We introduce an extension of Divergent mBERT which, given a bilingual sentence pair, produces a) a sentence-level prediction of equivalence vs. divergence and b) a sequence of EQ/DIV labels for each input token. EQ and DIV refer to token-level tags of equivalence and divergence, respectively.

Motivated by annotation rationales, we adopt a multi-task framework to train our model on a set of triplets $\mathcal{D}' = \{(\mathbf{x}, \mathbf{y}, \mathbf{z})\}$, still using only synthetic supervision (Figure 1). As in Section 3.3, we assume $\mathbf{x} > \mathbf{y}$, while $\mathbf{z}$ is the sequence of labels for the second encoded sentence pair $\mathbf{y}$, such that, at time t, $z_t \in \{\text{EQ},\text{DIV}\}$ is the label of y_t. Since Divergent mBERT operates on sequences of subwords, we assign an EQ or DIV label to a word token if at leat one of its subword units is assigned that label.

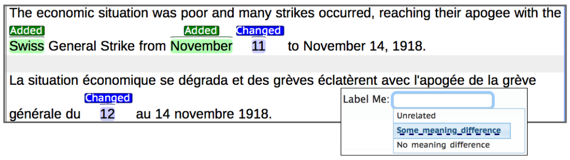
For the token prediction task, the final hidden state h_t of each y_t token is passed through a feed-forward layer and a softmax layer to produce the probability P_{y_t} of the y_t token belonging to the EQ class. For the sentence task, the model learns to rank $\mathbf{x} > \mathbf{y}$, as in Section 3.3. We then minimize the sum of the sentence-level margin-loss and the average token-level cross-entropy loss ($\mathcal{L}_{\text{CE}}$) across all tokens of $\mathbf{y}$, as defined in Equation 2.

$$\mathcal{L} = \frac{1}{|\mathcal{D}'|}\Big(\sum_{(\mathbf{x},\mathbf{y},\mathbf{z})\in\mathcal{D}'} \big(\max\{0, \xi - F(\mathbf{x}) + F(\mathbf{y})\} + \frac{1}{|\mathbf{y}|}\sum_{t=1}^{|\mathbf{y}|} \mathcal{L}_{\text{CE}}(\mathrm{P}_{y_t}, z_t)\big)\Big) \tag{2}$$

Similar multi-task models have been used for Machine Translation Quality Estimation (Kim et al., 2019a,b), albeit with human-annotated training samples and a standard cross-entropy loss for both word-level and sentence-level sub-tasks.

4 Rationalized English-French Semantic Divergences

We introduce the **R**ationalized **E**nglish-**Fr**ench **S**emantic **D**ivergences (REFRESD) dataset, which consists of 1,039 English-French sentence-pairs annotated with sentence-level divergence judgments and token-level rationales. Figure 2 shows an example drawn from our corpus.



The economic situation was poor and many strikes occurred, reaching their apogee with the Swiss General Strike from November 11 to November 14, 1918.

La situation économique se dégrada et des grèves éclatèrent avec l'apogée de la grève générale du 12 au 14 novembre 1918.

Figure 2: Screenshot of an example annotated instance.

Our annotation protocol is designed to encourage annotators' sensitivity to semantic divergences other than misalignments, without requiring expert knowledge beyond competence in the languages of interest. We use two strategies for this purpose: (1) we explicitly introduce distinct divergence categories for unrelated sentences and sentences that overlap in meaning; and (2) we ask for annotation rationales (Zaidan et al., 2007) by requiring annotators to highlight tokens indicative of meaning differences in each sentence-pair. Thus, our approach strikes a balance between coarsely annotating sentences with binary distinctions that are fully based on annotators' intuitions (Vyas et al., 2018), and exhaustively annotating all spans of a sentence-pair with fine-grained labels of translation processes (Zhai et al., 2018). We describe the annotation process and analysis of the collected instances based on data statements protocols described in Bender and Friedman (2018); Gebru et al. (2018). We include more information in A.4.

Task Description An annotation instance consists of an English-French sentence-pair. Bilingual participants are asked to read them both and highlight tokens in each sentence that convey meaning not found in the other language. For each highlighted span, they pick whether this span conveys added information ("Added"), information that is present in the other language but not an exact match ("Changed"), or some other type ("Other"). Those fine-grained classes are added to improve consistency across annotators and encourage them to read and compare the text closely. Finally, participants are asked to make a sentence-level judgment by selecting one of the following classes: "No meaning difference", "Some meaning difference", "Unrelated". Participants are not given specific instructions on how to use span annotations to make sentence-level decisions. Furthermore, participants have the option of using a text box to provide any comments or feedback on the example and their decisions. A summary of the different span and sentence labels along with the instructions given to participants can be found in A.3.

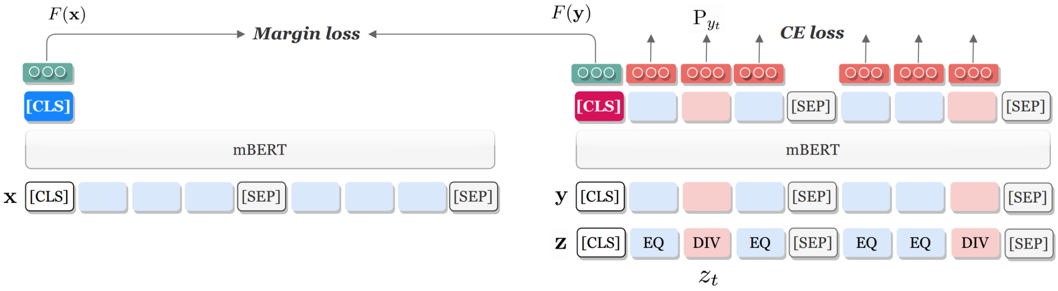


Figure 1: Divergent mBERT training strategy: given a triplet ($\mathbf{x}$,$\mathbf{y}$,$\mathbf{z}$), the model minimizes the sum of a margin-based loss via ranking a contrastive pair $\mathbf{x} > \mathbf{y}$ and a token-level cross-entropy loss on sequence labels $\mathbf{z}$.

Curation rationale Examples are drawn from the English-French section of the WikiMatrix corpus (Schwenk et al., 2019). We choose this resource because (1) it is likely to contain diverse, interesting divergence types, since it consists of mined parallel sentences of diverse topics which are not necessarily generated by (human) translations, and (2) Wikipedia and WikiMatrix are widely used resources to train semantic representations and perform cross-lingual transfer in NLP. We exclude obviously noisy samples by filtering out sentence-pairs that a) are too short or too long, b) consist mostly of numbers, c) have a small token-level edit difference. The filtered version of the corpus consists of 2,437,108 sentence-pairs.

Quality Control We implement quality control strategies at every step. We build a dedicated task interface using the BRAT annotation toolkit (Stenetorp et al., 2012) (Figure 2). We recruit participants from an educational institution and ensure they are proficient in both languages of interest. Specifically, participants are either bilingual speakers or graduate students pursuing a Translation Studies degree. We run a pilot study were participants annotate a sample containing both duplicated and reference sentence-pairs previously annotated by one of the authors. All annotators are found to be internally consistent on duplicated instances and agree with the reference annotations more than 60% of the time. We solicit feedback from participants to finalize the instructions.

Inter-annotator Agreement (IAA) We compute IAA for sentence-level annotations, as well as for the token and span-level rationales (Table 2). We report 0.60 Krippendorf's α coefficient for sentence classes, which indicates a "moderate" agreement between annotators (Landis and Koch, 1977). This constitutes a significant improvement over the 0.41 and 0.49 reported agreement coefficients on crowdsourced annotations of equivalence vs. divergence English-French parallel sentences drawn from OpenSubtitles and CommonCrawl corpora by prior work (Vyas et al., 2018).

Disagreements mainly occur between the "No meaning difference" and "Some meaning difference" classes, which we expect as different annotators might draw the line between which differences matter differently. We only observed 3 examples where all 3 annotators disagreed (tridisagreements), which indicates that the "Unrelated" and "No meaning difference" categories are more clear-cut. The rare instances with tridisagreements and bidisagreements—where the disagreement spans the two extreme classes—were excluded from the final dataset. Examples of REFRESD corresponding to different levels of IAA are included in A.5.

Granularity	**Method**	**IAA**
Sentence	Krippendorf's α	0.60
Span	macro F1	45.56 ± 7.60
Token	macro F1	33.94 ± 8.24

Table 2: Inter-annotator agreement measured at different levels of granularities for the REFRESD dataset.

Quantifying agreement between rationales requires different metrics. At the span-level, we compute macro F1 score for each sentence-pair following DeYoung et al. (2020), where we treat one set of annotations as the reference standard and the other set as predictions. We count a prediction as a match if its token-level Intersection Over Union (IOU) with any of the reference spans overlaps by more than some threshold (here, 0.5). We report average span-level and token-level macro F1 scores, computed across all different pairs of annotators. Average statistics indicate that our annotation protocol enabled the collection of a high-quality dataset.

Dataset Statistics Sentence-level annotations were aggregated by majority vote, yielding 252, 418, and 369 instances for the "Unrelated", "Some meaning difference", and "No meaning difference" classes, respectively. In other words, 64% of samples are divergent and 40% of samples contain fine-grained meaning divergences, confirming that divergences vary in granularity and are too frequent to be ignored even in a corpus viewed as parallel.

5 Experimental Setup

Data We normalize English and French text in WikiMatrix consistently using the Moses toolkit (Koehn et al., 2007), and tokenize into subword units using the "BertTokenizer". Specifically, our pre-processing pipeline consists of a) replacement of Unicode punctuation, b) normalization of punctuation, c) removing of non-printing characters, and d) tokenization.[2] We align English to French bitext using the Berkeley word aligner.[3] We filter out obviously noisy parallel sentences, as described in Section 4, Curation Rationale. The top 5,500 samples ranked by LASER similarity score are treated as (noisy) equivalent samples and seed the generation of synthetic divergent examples.[4] We split the seed set into 5,000 training instances and 500 development instances consistently across experiments. Results on development sets for each experiment are included in A.7.

Models Our models are based on the HuggingFace transformer library (Wolf et al., 2019).[5] We fine-tune the "BERT-Base Multilingual Cased" model (Devlin et al., 2019),[6] and perform a grid search on the margin hyperparameter, using the synthetic development set. Further details on model and training settings can be found in A.1.

Evaluation We evaluate all models on our new REFRESD dataset using Precision, Recall, F1 for each class, and Weighted overall F1 score as computed by *scikit-learn* (Pedregosa et al., 2011).[7]

6 Binary Divergence Detection

We evaluate Divergent mBERT's ability to detect divergent sentence pairs in REFRESD.

6.1 Experimental Conditions

LASER baseline This baseline distinguishes equivalent from divergent samples via a threshold on the LASER score. We use the same threshold as Schwenk et al. (2019), who show that training Neural Machine Translation systems on WikiMatrix samples with LASER scores higher than 1.04 improves BLEU. Preliminary experiments suggest that tuning the LASER threshold does not improve classification and that more complex models such as the VDPWI model used by Vyas et al. (2018) underperform Divergent mBERT, as discussed in A.2.

Divergent mBERT We compare Divergent mBERT trained by learning to rank contrastive samples (Section 3.3) with ablation variants.

To test the impact of contrastive training samples, we fine-tune Divergent mBERT using 1. the Cross-Entropy (**CE**) loss on randomly selected synthetic divergences; 2. the **CE** loss on paired equivalent and divergent samples, treated as independent; 3. the proposed training strategy with a **Margin** loss to explicitly compare contrastive pairs.

Given the fixed set of seed equivalent samples (Section 5, Data), we vary the combinations of divergent samples: 1. **Single divergence type** we pair each seed equivalent with its corresponding divergent of that type, yielding a single contrastive pair; 2. **Balanced sampling** we randomly pair each seed equivalent with one of its corresponding divergent types, yielding a single contrastive pair; 3. **Concatenation** we pair each seed equivalent with one of each synthetic divergence type, yielding four contrastive pairs; 4. **Divergence ranking** we learn to rank pairs of close divergence types: equivalent vs. lexical substitution, lexical substitution vs. phrase replacement, or subtree deletion yielding four contrastive pairs.[8]

6.2 Results

All Divergent mBERT models outperform the LASER baseline by a large margin (Table 3). The proposed training strategy performs best, improving over LASER by 31 F1 points. Ablation experiments and analysis further show the benefits of diverse contrastive samples and learning to rank.

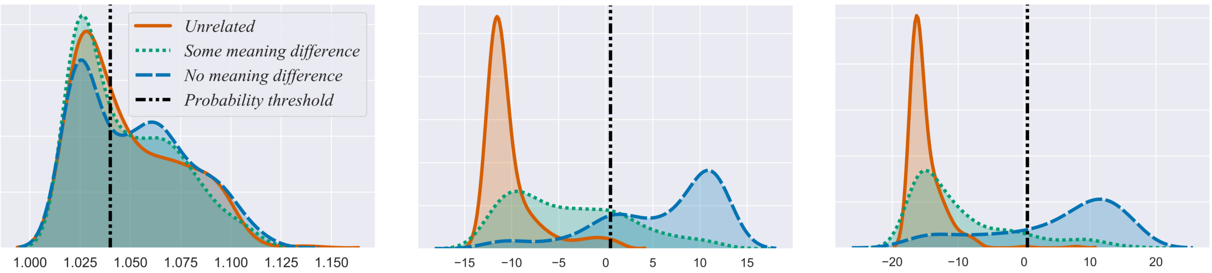
Table 3: Intrinsic evaluation of Divergent mBERT and its ablation variants on the REFRESD dataset. We report Precision (P), Recall (R), and F1 for the equivalent (+) and divergent (-) classes separately, as well as for both classes (*All*). *Divergence Ranking* yields the best F1 scores across the board.



(a) LASER (b) *Subtree Deletion* (c) *Divergence Ranking*

Figure 3: Score distributions assigned by different models to sentence-pairs of REFRESD. *Divergence Ranking* scores for the “Some meaning difference” class are correctly skewed more toward negative values.

Contrastive Samples With the CE loss, independent contrastive samples improve over randomly sampled synthetic instances overall (+8.7 F1+ points on average), at the cost of a smaller drop for the divergent class (−5.3 F1- points) for models trained on a single type of divergence. Using the margin loss helps models recover from this drop.

Divergence Types All types improve over the LASER baseline. When using a single divergence type, *Subtree Deletion* performs best, even matching the overall F1 score of a system trained on all types of divergences (*Balanced Sampling*). Training on the *Concatenation* of all divergence types yields poor performance. We suspect that the model is overwhelmed by negative instances at training time, which biases it toward predicting the divergent class too often and hurting F1+ score for the equivalent class.

Divergence Ranking How does divergence ranking improve predictions? Figure 3 shows model score distributions for the 3 classes annotated in REFRESD. *Divergence Ranking* particularly improves divergence predictions for the “Some meaning difference” class: the score distribution for this class is more skewed toward negative values than when training on contrastive *Subtree Deletion* samples.

		Union			Pair-wise Union			Intersection		
Model	Multi-task	F1-DIV	F1-EQ	F1-Mul	F1-DIV	F1-EQ	F1-Mul	F1-DIV	F1-EQ	F1-Mul
Random Baseline		0.21	0.62	0.13	0.33	0.59	0.20	0.21	0.62	0.13
Token-only		0.39	0.77	0.30	0.46	**0.88**	0.41	0.46	**0.92**	0.42
Balanced	✓	0.41	0.77	0.32	0.46	0.87	0.40	0.43	0.91	0.40
Concatenation	✓	0.41	**0.78**	0.32	0.48	**0.88**	0.42	0.46	**0.92**	0.42
Divergence Ranking	✓	**0.45**	**0.78**	**0.35**	**0.51**	**0.88**	**0.45**	**0.49**	**0.92**	**0.45**

Table 4: Evaluation of different models on the token-level prediction task for the **"Some meaning difference"** class of REFRESD. *Divergence Ranking* yields the best results across the board.

7 Finer-Grained Divergence Detection

While we cast divergence detection as binary classification in Section 6, human judges separated divergent samples into "Unrelated" and "Some meaning difference" classes in the REFRESD dataset. Can we predict this distinction automatically? In the absence of annotated training data, we cannot cast this problem as a 3-way classification, since it is not clear how the synthetic divergence types map to the 3 classes of interest. Instead, we test the hypothesis that token-level divergence predictions can help discriminate between divergence granularities at the sentence-level, inspired by humans' use of rationales to ground sentence-level judgments.

7.1 Experimental Conditions

Models We fine-tune the **multi-task** mBERT model that makes token and sentence predictions jointly, as described in Section 3.4. We contrast against a sequence labeling mBERT model trained independently with the CE loss (**Token-only**). Finally, we run a **random baseline** where each token is labeled EQ or DIV uniformly at random.

Training Data We tag tokens edited when generating synthetic divergences as DIV (e.g., highlighted tokens in Table 1), and others as EQ. Since edit operations are made on the English side, we tag aligned French tokens using the Berkeley aligner.

Evaluation We expect token-level annotations in REFRESD to be noisy since they are produced as rationales for sentence-level rather than token-level tags. We, therefore, consider three methods to aggregate rationales into token labels: a token is labeled as DIV if it is highlighted by at least one (**Union**), two (**Pair-wise Union**), or all three annotators (**Intersection**). We report F1 on the DIV and EQ class, and F1-Mul as their product for each of the three label aggregation methods.

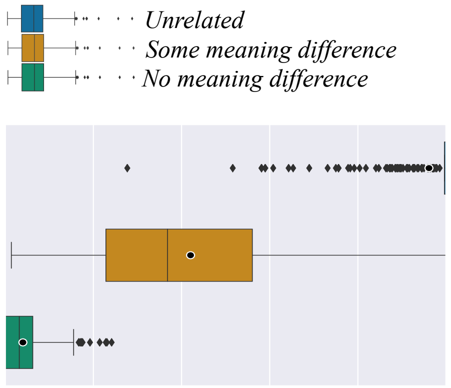
7.2 Results

Token Labeling We evaluate token labeling on REFRESD samples from the "Some meaning difference" class, where we expect the more subtle differences in meaning to be found, and the token-level annotation to be most challenging (Table 4). Examples of Divergent mBERT's token-level predictions are given in A.6. The *Token-only* model outperforms the *Random Baseline* across all metrics, showing the benefits of training even with noisy token labels derived from rationales. *Multi-task* training further improves over *Token-only* predictions for almost all different metrics. *Divergence Ranking* of contrastive instances yields the best results across the board. Also, on the auxiliary sentence-level task, the *Multi-task* model matches the F1 as the standalone *Divergence Ranking* model.

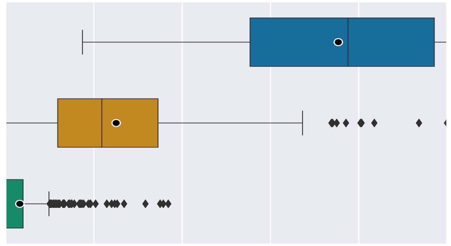
From Token to Sentence Predictions We compute the % of DIV predictions within a sentence-pair. The multi-task model makes more DIV predictions for the divergent classes as its % distribution is more skewed towards greater values (Figure 4 (d) vs. (e)). We then show that the % of DIV predictions of the *Divergence Ranking* model can be used as an indicator for distinguishing between divergences of different granularity: intuitively, a sentence pair with more DIV tokens should map to a coarse-grained divergence at a sentence-level. Table 5 shows that thresholding the % of DIV tokens could be an effective discrimination strategy, which we will explore further in future work.

	UN			SD			
DIV %	**P**	**R**	**F1**	**P**	**R**	**F1**	**F1-all**
10	48	**97**	64	66	51	57	59
20	69	84	**76**	**83**	79	81	80
30	82	63	71	81	**85**	**83**	**81**
40	**94**	35	51	73	84	78	75

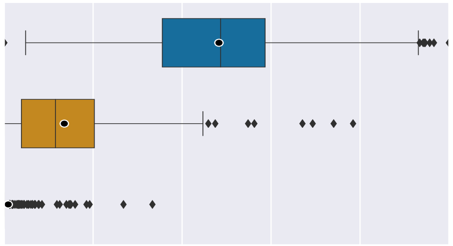
Table 5: "Some meaning difference" (SD) vs. "Unrelated" (UN) classification based on % of DIV labels.



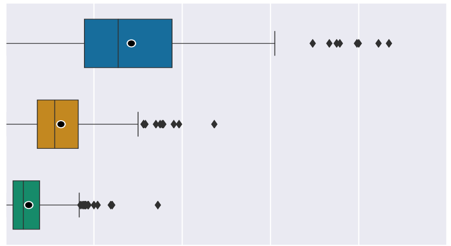
(a) *Union*



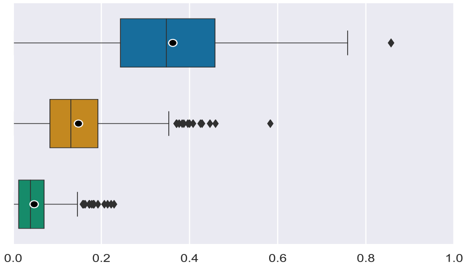
(b) *Pair-wise Union*



(c) *Intersection*



(d) *Token-only*



(e) *Divergence Ranking*

Figure 4: Percentage distributions of DIV tokens in REFRESD and DIV token predictions of two models: *Divergence Ranking* makes more DIV predictions compared to the *Token-only* model, enabling a better distinction between the divergent classes.

8 Related Work

Our work is closely related to but distinct from the Semantic Textual Similarity (STS) task that measures the **degree of equivalence** in the underlying semantics of paired snippets of text (Agirre et al., 2016; Cer et al., 2017). Most commonly, state-of-the-art models address the STS task via interaction models that use alignment mechanisms to integrate word-level interactions in their final predictions (He and Lin, 2016; Parikh et al., 2016) or via learning vector representations of sentences that are then compared using distance-based measures (Nie and Bansal, 2017; Conneau et al., 2017; Cer et al., 2018; Reimers and Gurevych, 2019; Yang et al., 2019).

9 Conclusion

We show that explicitly considering diverse semantic divergence types benefits both the annotation and prediction of divergences between texts in different languages.

We contribute REFRESD, a new dataset of WikiMatrix sentences-pairs in English and French, annotated with semantic divergence classes and token-level rationales that justify the sentence level annotation. 64% of samples are annotated as divergent, and 40% of samples contain fine-grained meaning divergences, confirming that divergences are too frequent to ignore even in parallel corpora. We show that these divergences can be detected by a mBERT model fine-tuned without annotated samples, by learning to rank synthetic divergences of varying granularity.

Inspired by the rationale-based annotation process, we show that predicting token-level and sentence-level divergences jointly is a promising direction for further distinguishing between coarser and finer-grained divergences.

A Appendices

A.1 Implementation Details

Training setup We employ the Adam optimizer with initial learning rate $\eta = 2\text{e}{-5}$, fine-tune for at most 5 epochs, and use early-stopping to select the best model. We use a batch size of 32 for experiments that do not use contrastive training and a batch size of 16 for those using contrastive training to establish a fair comparison.

Model setup All of our models are based on the "Multilingual BERT-base model" consisting of: 12-layers, 768-hidden size, 12-heads and 110M parameters.

Average Runtime & Computing Infrastructure Each experiment is run on a single GeForce GTX 1080 GPU. For experiments run on either a single type of divergence (e.g., *Subtree Deletion*) or using *Balanced* sampling, the average duration time is $\sim$ 0.4 hours. For *Divergence Ranking* and *Concatenation*, sampling methods, training takes $\sim$ 2 hours to complete.

Hyperparameter search on margin We perform a grid search on the margin parameter for each experiment that employs contrastive training. We experiment with values $\{3, 4, 5, 6, 7, 8\}$ and pick the one corresponding to the best Weighted-F1 score on a synthetic development set. Table 6 shows mean and variance results on both the development and the REFRESD dataset for different ξ values. In general, we observe that our model's performance on REFRESD is not sensitive to the margin's choice, as reflected by the small variances on the REFRESD Weighted-F1.

A.2 Very Deep Pair-Wise Interaction baseline

We compare against the Very Deep Pair-Wise Interaction (VDPWI) model repurposed by Vyas et al. (2018) to identify cross-lingual semantic divergence vs. equivalence. We fine-tune mBERT models on coarsely-defined semantic synthetic divergent pairs, similarly to the authors. We report results on two crowdsourced datasets, consisting of equivalence vs. divergence labels for 300 sentence-pairs, drawn from the noisy OpenSubtitles and CommonCrawl corpora. The two evaluation datasets are available at: `https://github.com/yogarshi/SemDiverge/tree/master/dataset`.

Synthetic	**Dev**	**REFRESD**	ξ*	**Dev***
Phrase replacement	$91.83_{\pm 1.14}$	$78.60_{\pm 1.84}$	7	93
Subtree Deletion	$93.67_{\pm 2.22}$	$82.67_{\pm 0.22}$	8	95
Lexical Substitution	$91.50_{\pm 0.25}$	$70.50_{\pm 1.58}$	5	92
Balanced	$87.67_{\pm 0.56}$	$80.33_{\pm 0.56}$	5	88
Concatenation	$89.03_{\pm 0.50}$	$79.51_{\pm 0.67}$	5	90
Divergence Ranking	$77.80_{\pm 1.36}$	$83.67_{\pm 0.22}$	5	79

Table 6: Average results of Divergent mBERT as a function of the number of hyperparameter trials for the margin value (ξ). The first row corresponds to the sampling method used for creating synthetic contrastive training examples. The second and third rows correspond to the mean/variance of Weighted-F1 results, measured on the development and the REFRESD dataset, respectively. The fourth row describes the best value of the margin hyperparameter (ξ*) for each experiment, while the last row denotes the corresponding Weighted-F1 score on the development set.

	OpenSubtitles			CommonCrawl		
Method	**F1-**	**F1+**	**F1**	**F1-**	**F1+**	**F1**
Vyas et al. (2018)	78	72	77	85	73	80
mBERT	**81**	**76**	**79**	**87**	**76**	**83**

Table 7: Performance comparison between mBERT and VDPWI trained on coarsely-generated semantic divergences. We report F1 overall results (F1) and F1+/F1-scores for the two classes, on the crowdsourced OpenSubtitles and CommonCrawl datasets.

Table 7 presents results on the OpenSubtitles and CommonCrawl testbeds. We observe that mBERT trained on similarly defined coarse divergences performs better than cross-lingual VDPWI.

A.3 REFRESD: Annotation Guidelines

Below we include the annotation guidelines given to participants:

"You are asked to compare the meaning of English and French text excerpts. You will be presented with one pair of texts at a time (about a sentence in English and a sentence in French). For each pair, you are asked to do the following:

1 Read the two sentences carefully. Since the sentences are provided out of context, your understanding of content should only rely on the information available in the sentences. There is no need to guess what additional information might be available in the documents the excerpts come from.

2 Highlight the text spans that convey different meaning in the two sentences. After highlighting a span of text, you will be asked to further characterize it as:

> **ADDED** *the highlighted span corresponds to a piece of information that* ***does not exist*** *in the other sentence*
> **CHANGED** *the highlighted span corresponds to a piece of information that exists in the other sentence, but* ***their meaning is not the exact same***
> **OTHER** *none of the above holds*

You can highlight as many spans as needed. You can **optionally** provide an explanation for your assessment in the text form under the Notes section (e.g., literal translation of idiom)

3 Compare the meaning of the two sentences by picking one of the three classes:

> **UNRELATED** *The two sentences are completely unrelated or have a few words in common but convey unrelated information about them*
> **SOME MEANING DIFFERENCE** *The two sentences convey* ***mostly the same information, except differences for some details or nuances*** *(e.g., some information is added and/or missing on either or both sides; some English words have a more general or specific translation in French)*

A.4 Annotation Procedures

We run 8 online annotation sessions. Each session consists of 120 instances, annotated by 3 participants, and lasts about 2 hours. Participants are allowed to take breaks during the process. Participants are rewarded with Amazon gift cards at a rate of $2 per 10 examples, with bonuses of $5 and $10 for completing the first and additional sessions, respectively.

A.5 Annotated examples in REFRESD

Table 8 includes examples of annotated instances drawn from REFRESD, corresponding to different levels of inter-annotator agreement.

A.6 Token predictions of Divergent mBERT

Table 9 shows randomly selected instances from REFRESD along with token tags predicted by our best performing system (*Divergence Ranking*).

A.7 Results on synthetic development sets

Tables 10 and 11 report results on development sets for each experiment included in Tables 3 and 4, respectively.

Abstract

Semantic sentence embedding models encode natural language sentences into vectors, such that closeness in embedding space indicates closeness in the semantics between the sentences. Bilingual data offers a useful signal for learning such embeddings: properties shared by both sentences in a translation pair are likely semantic, while divergent properties are likely stylistic or language-specific. We propose a deep latent variable model that attempts to perform source separation on parallel sentences, isolating what they have in common in a latent semantic vector, and explaining what is left over with language-specific latent vectors. Our proposed approach differs from past work on semantic sentence encoding in two ways. First, by using a variational probabilistic framework, we introduce priors that encourage source separation, and can use our model's posterior to predict sentence embeddings for monolingual data at test time. Second, we use high-capacity transformers as both data generating distributions and inference networks – contrasting with most past work on sentence embeddings. In experiments, our approach substantially outperforms the state-of-the-art on a standard suite of unsupervised semantic similarity evaluations. Further, we demonstrate that our approach yields the largest gains on more difficult subsets of these evaluations where simple word overlap is not a good indicator of similarity.[1]

1 Introduction

Learning useful representations of language has been a source of recent success in natural language processing (NLP). Much work has been done on learning representations for words (Mikolov et al., 2013; Pennington et al., 2014) and sentences (Kiros et al., 2015; Conneau et al., 2017). More recently, deep neural architectures have been used to learn contextualized word embeddings (Peters et al., 2018; Devlin et al., 2018) enabling state-of-the-art results on many tasks. We focus on learning semantic *sentence* embeddings in this paper, which play an important role in many downstream applications. Since they do not require any labelled data for fine-tuning, sentence embeddings are useful out-of-the-box for problems such as measurement of Semantic Textual Similarity (STS; Agirre et al. (2012)), mining bitext (Zweigenbaum et al., 2018), and paraphrase identification (Dolan et al., 2004). Semantic similarity measures also have downstream uses such as fine-tuning machine translation systems (Wieting et al., 2019a).

There are three main ingredients when designing a sentence embedding model: the architecture, the training data, and the objective function. Many architectures including LSTMs (Hill et al., 2016; Conneau et al., 2017; Schwenk and Douze, 2017; Subramanian et al., 2018), Transformers (Cer et al., 2018; Reimers and Gurevych, 2019), and averaging models (Wieting et al., 2016b; Arora et al., 2017) are capable of learning sentence embeddings. The choice of training data and objective are intimately intertwined, and there are a wide variety of options including next-sentence prediction (Kiros et al., 2015), machine translation (Espana-Bonet et al., 2017; Schwenk and Douze, 2017; Schwenk, 2018; Artetxe and Schwenk, 2018), natural language inference (NLI) (Conneau et al., 2017), and multi-task objectives which include some of the previously mentioned objectives (Cer et al., 2018) potentially combined with additional tasks like constituency parsing (Subramanian et al., 2018).

Surprisingly, despite ample testing of more powerful architectures, the best performing models for many sentence embedding tasks related to semantic similarity often use simple architectures that are mostly agnostic to the interactions between

words. For instance, some of the top performing techniques use word embedding averaging (Wieting et al., 2016b), character n-grams (Wieting et al., 2016a), and subword embedding averaging (Wieting et al., 2019b) to create representations. These simple approaches are competitive with much more complicated architectures on in-domain data and generalize well to unseen domains, but are fundamentally limited by their inability to capture word order. Training these approaches generally relies on discriminative objectives defined on paraphrase data (Ganitkevitch et al., 2013; Wieting and Gimpel, 2018) or bilingual data (Wieting et al., 2019b; Chidambaram et al., 2019; Yang et al., 2020). The inclusion of latent variables in these models has also been explored (Chen et al., 2019).

Intuitively, bilingual data in particular is promising because it potentially offers a useful signal for learning the underlying semantics of sentences. Within a translation pair, properties shared by both sentences are more likely semantic, while those that are divergent are more likely stylistic or language-specific. While previous work learning from bilingual data perhaps takes advantage of this fact *implicitly*, the focus of this paper is modelling this intuition *explicitly*, and to the best of our knowledge, this has not been explored in prior work. Specifically, we propose a deep generative model that is encouraged to perform *source separation* on parallel sentences, isolating what they have in common in a latent *semantic embedding* and explaining what is left over with *language-specific latent vectors*. At test time, we use inference networks (Kingma and Welling, 2013) for approximating the model's posterior on the semantic and source-separated latent variables to encode monolingual sentences. Finally, since our model and training objective are generative, our approach does not require knowledge of the distance metrics to be used during evaluation, and it has the additional property of being able to generate text.

In experiments, we evaluate our probabilistic source-separation approach on a standard suite of STS evaluations. We demonstrate that the proposed approach is effective, most notably allowing the learning of high-capacity deep Transformer architectures (Vaswani et al., 2017) while still generalizing to new domains, significantly outperforming a variety of state-of-the-art baselines. Further, we conduct a thorough analysis by identifying subsets of the STS evaluation where simple word overlap is not able to accurately assess semantic similarity. On these most difficult instances, we find that our approach yields the largest gains, indicating that our system is modeling interactions between words to good effect. We also find that our model better handles cross-lingual semantic similarity than multilingual translation baseline approaches, indicating that stripping away language-specific information allows for better comparisons between sentences from different languages.

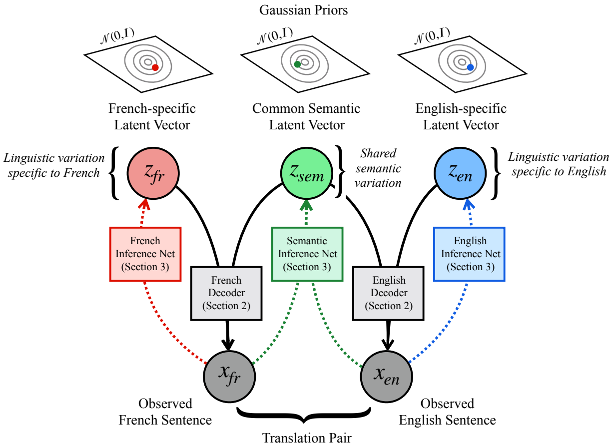

Figure 1: The generative process of our model. Latent variables modeling the linguistic variation in French and English, z_{fr} and z_{en}, as well as a latent variable modeling the common semantics, z_{sem}, are drawn from a multivariate Gaussian prior. The observed text in each language is then conditioned on its language-specific variable and z_{sem}.

Finally, we analyze our model to uncover what information was captured by the source separation into the semantic and language-specific variables and the relationship between this encoded information and language distance to English. We find that the language-specific variables tend to explain more superficial or language-specific properties such as overall sentence length, amount and location of punctuation, and the gender of articles (if gender is present in the language), but semantic and syntactic information is more concentrated in the shared semantic variables, matching our intuition. Language distance has an effect as well, where languages that share common structures with English put more information into the semantic variables, while more distant languages put more information into the language-specific variables. Lastly, we show outputs generated from our model that exhibit its ability to do a type of style transfer.

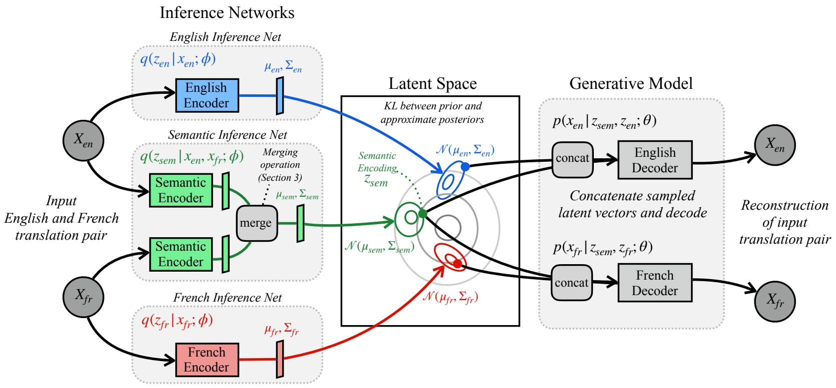

Figure 2: The computation graph for the variational lower bound used during training. The English and French text are fed into their respective inference networks and the semantic inference network to ultimately produce the language variables z_{fr} and z_{en} and semantic variable z_{sem}. Each language-specific variable is then concatenated to z_{sem} and used by the decoder to reconstruct the input sentence pair.

2 Model

Our proposed training objective leverages a generative model of parallel text in two languages. Our model is language agnostic, and applies to a wide variety of languages (see Section 5) but we will use the running example of English (`en`) and French (`fr`) pairs consisting of an English sentence x_{en} and a French sentence x_{fr}. Importantly, the generative process utilizes three underlying latent vectors: language-specific variation variables (language variables) z_{fr} and z_{en} for each side of the translation, as well as a shared semantic variation variable (semantic variable) z_{sem}. In this section we will first describe the generative model for the text and latent variables. In the following section we will describe the inference procedure of z_{sem} given an input sentence, which corresponds to our core task of obtaining sentence embeddings useful for downstream tasks such as semantic similarity.

The generative process of our model, the Bilingual Generative Transformer (BGT), is depicted in Figure 1 and the training computation graph is shown in Figure 2. First, we sample latent variables $\langle z_{fr}, z_{en}, z_{sem}\rangle$, where $z_i \in \mathbb{R}^k$, from a multivariate Gaussian prior $\mathcal{N}(0, I_k)$. These variables are then fed into a decoder that samples sentences; x_{en} is sampled conditioned on z_{sem} and z_{en}, while x_{fr} is sampled conditioned on z_{sem} and z_{fr}. Because sentences in both languages will use z_{sem} in generation, we expect that in a well-trained model this variable will encode semantic, syntactic, or stylistic information shared across both sentences, while z_{fr} and z_{en} will handle any language-specific peculiarities or specific stylistic decisions that are less central to the sentence meaning and thus do not translate across sentences. In the following section, we further discuss how this is explicitly encouraged by the learning process.

Decoder Architecture. Many latent variable models for text use LSTMs (Hochreiter and Schmidhuber, 1997) as their decoders (Yang et al., 2017; Ziegler and Rush, 2019; Ma et al., 2019). However, state-of-the-art models in neural machine translation have seen increased performance and speed using deep Transformer architectures. We also found in our experiments (see Appendix C for details) that Transformers led to increased performance in our setting, so they are used in our main model.

We use two decoders in our model, one for modelling $p(x_{fr}|z_{sem}, z_{fr};\theta)$ and one for modeling $p(x_{en}|z_{sem}, z_{en};\theta)$ (see right side of Figure 2). Each decoder takes in a language variable and a semantic variable, which are concatenated and used by the decoder for reconstruction. We explore four ways of using this latent vector: (1) Concatenate it to the word embeddings (Word) (2) Use it as the initial hidden state (Hidden, LSTM only) (3) Use it as you would the attention context vector in the traditional sequence-to-sequence framework (Attention) and (4) Concatenate it to the hidden state immediately prior to computing the logits (Logit). Unlike Attention, there is no additional feedforward layer in this setting. We experimented with these four approaches, as well as combinations thereof, and report this analysis in Appendix A. From these experiments, we see that the closer the sentence embedding is to the final word predictor, the better the performance on downstream tasks evaluating its semantic content. We hypothesise that this is due to better gradient propagation because the sentence embedding is now closer to the error signal. Since Attention and Logit performed best, we use these in our main experiments.

3 Learning and Inference

Our model is trained on a set of parallel sentences X consisting of N examples, $X = \{\langle x_{en}^1, x_{fr}^1\rangle, \dots, \langle x_{en}^N, x_{fr}^N\rangle\}$, and Z is our collection of latent variables $Z = (\langle z_{en}^1, z_{fr}^1, z_{sem}^1\rangle, \dots, \langle z_{en}^N, z_{fr}^N, z_{sem}^N\rangle)$. We wish to maximize the likelihood of the parameters of the two decoders θ with respect to the observed X, marginalizing over the latent variables Z.

$$p(X;\theta) = \int_Z p(X, Z;\theta) dZ$$

Unfortunately, this integral is intractable due to the complex relationship between X and Z. However, related latent variable models like variational autoencoders (VAEs; Kingma and Welling (2013)) learn by optimizing a variational lower bound on the log marginal likelihood. This surrogate objective is called the evidence lower bound (ELBO) and introduces a variational approximation, q to the true posterior of the model p. The q distribution is parameterized by a neural network with parameters ϕ. ELBO for our model is written as:

$$\begin{aligned}\text{ELBO} = &\mathbb{E}_{q(Z|X;\phi)}[\log p(X|Z;\theta)] - \\ &\text{KL}(q(Z|X;\phi)||p(Z;\theta))\end{aligned}$$

This lower bound on the marginal can be optimized by gradient ascent by using the reparameterization trick (Kingma and Welling, 2013). This trick allows for the expectation under q to be approximated through sampling in a way that preserves backpropagation. We make several independence assumptions for $q(z_{sem}, z_{en}, z_{fr}|x_{en}, x_{fr};\phi)$ to match our goal of source separation: we factor q as $q(z_{sem}|x_{en}, x_{fr};\phi)q(z_{en}|x_{en};\phi)q(z_{fr}|x_{fr};\phi)$. The parameters of the encoders that make up the inference networks, defined in the next paragraph, are denoted as ϕ.

Lastly, we note that the KL term in our ELBO equation *explicitly encourages* explaining variation that is shared by translations with the shared semantic variable, and explaining language-specific variation with the corresponding language-specific variables. Encoding information shared by the two sentences in the shared variable results in only a single penalty from the KL loss, while encoding the information separately in both language specific variables will cause unnecessary replication, doubling the overall cost incurred by the KL term.

Encoder Architecture. We use three inference networks as shown on the left side of Figure 2: an English inference network to produce the English language variable, a French inference network to produce the French language variable, and a semantic inference network to produce the semantic variable. Just as in the decoder architecture, we use a Transformer for the encoders.

The semantic inference network is a bilingual encoder that encodes each language. For each translation pair, we alternate which of the two parallel sentences is fed into the semantic encoder within a batch. Since the semantic encoder is meant to capture language agnostic semantic information, its outputs for a translation pair should be similar regardless of the language of the input sentence. We note that other operations are possible for combining the views each parallel sentence offers. For instance, we could feed both sentences into the semantic encoder and pool their representations. However, in practice we find that alternating works well and also can be used to obtain sentence embeddings for text that is not part of a translation pair. We leave further study of combining views to future work.

4 Experiments

4.1 Baseline Models

We experiment with fourteen baseline models, covering both the most effective approaches for learning sentence embeddings from the literature and ablations of our own BGT model. These baselines can be split into three groups as detailed below.

Models from the Literature (Trained on Different Data) We compare to well known sentence embedding models Infersent (Conneau et al., 2017), GenSen (Subramanian et al., 2018), the Universal Sentence Encoder (USE) (Cer et al., 2018), LASER (Artetxe and Schwenk, 2018), as well as BERT (Devlin et al., 2018).[2] We used the pretrained BERT model in two ways to create a sentence embedding. The first way is to concatenate the hidden states for the CLS token in the last four layers. The second way is to concatenate the hidden states of all word tokens in the last four layers and mean pool these representations. Both methods result in a 4096 dimension embedding. We also compare to the newly released model, Sentence-

---

[2] Note that in all experiments using BERT, including Sentence-BERT, the large, uncased version is used.

Bert (Reimers and Gurevych, 2019). This model is similar to Infersent (Conneau et al., 2017) in that it is trained on natural language inference data, SNLI (Bowman et al., 2015). However, instead of using pretrained word embeddings, they fine-tune BERT in a way to induce sentence embeddings.[3]

Models from the Literature (Trained on Our Data) These models are amenable to being trained in the exact same setting as our own models as they only require parallel text. These include the sentence piece averaging model, SP, from Wieting et al. (2019b), which is among the best of the averaging models (i.e. compared to averaging only words or character n-grams) as well the LSTM model, BiLSTM, from Wieting and Gimpel (2017). These models use a contrastive loss with a margin. Following their settings, we fix the margin to 0.4 and tune the number of batches to pool for selecting negative examples from $\{40, 60, 80, 100\}$. For both models, we set the dimension of the embeddings to 1024. For BiLSTM, we train a single layer bidirectional LSTM with hidden states of 512 dimensions. To create the sentence embedding, the forward and backward hidden states are concatenated and mean-pooled. Following Wieting and Gimpel (2017), we shuffle the inputs with probability p, tuning p from $\{0.3, 0.5\}$.

We also implicitly compare to previous machine translation approaches like Espana-Bonet et al. (2017); Schwenk and Douze (2017); Artetxe and Schwenk (2018) in Appendix A where we explore different variations of training LSTM sequence-to-sequence models. We find that our translation baselines reported in the tables below (both LSTM and Transformer) outperform the architectures from these works due to using the Attention and Logit methods mentioned in Section 2, demonstrating that our baselines represent, or even over-represent, the state-of-the-art for machine translation approaches.

BGT Ablations Lastly, we compare to ablations of our model to better understand the benefits of parallel data, language-specific variables, the KL loss term, and how much we gain from the more conventional translation baselines.

- ENGLISHAE: English autoencoder on the English side of our `en-fr` data.
- ENGLISHVAE: English variational autoencoder on the English side of our `en-fr` data.
- ENGLISHTRANS: Translation from `en` to `fr`.
- BILINGUALTRANS: Translation from both `en` to `fr` and `fr` to `en` where the encoding parameters are shared but each language has its own decoder.
- BGT W/O LANGVARS: A model similar to BILINGUALTRANS, but it includes a prior over the embedding space and therefore a KL loss term. This model differs from BGT since it does not have any language-specific variables.
- BGT W/O PRIOR: Follows the same architecture as BGT, but without the priors and KL loss term.

4.2 Experimental Settings

The training data for our models is a mixture of OpenSubtitles 2018[4] `en-fr` data and `en-fr` Gigaword[5] data. To create our dataset, we combined the complete corpora of each dataset and then randomly selected 1,000,000 sentence pairs to be used for training with 10,000 used for validation. We use `sentencepiece` (Kudo and Richardson, 2018) with a vocabulary size of 20,000 to segment the sentences, and we chose sentence pairs whose sentences are between 5 and 100 tokens each.

In designing the model architectures for the encoders and decoders, we experimented with Transformers and LSTMs. Due to better performance, we use a 5 layer Transformer for each of the encoders and a single layer decoder for each of the decoders. This design decision was empirically motivated as we found using a larger decoder was slower and worsened performance, but conversely, adding more encoder layers improved performance. More discussion of these trade-offs along with ablations and comparisons to LSTMs are included in Appendix C.

For all of our models, we set the dimension of the embeddings and hidden states for the encoders and decoders to 1024. Since we experiment with two different architectures,[6] we follow two different optimization strategies. For training models

---

[3] Most work evaluating accuracy on STS tasks has averaged the Pearson's r over each individual dataset for each year of the STS competition. However, Reimers and Gurevych (2019) computed Spearman's ρ over concatenated datasets for each year of the STS competition. To be consistent with previous work, we re-ran their model and calculated results using the standard method, and thus our results are not the same as those reported Reimers and Gurevych (2019).

[4] `http://opus.nlpl.eu/OpenSubtitles.php`

[5] `https://www.statmt.org/wmt10/training-giga-fren.tar`

[6] We use LSTMs in our ablations.

Data	Sentence 1	Sentence 2	Gold Score
Hard+	Other ways are needed.	It is necessary to find other means.	4.5
Hard-	How long can you keep chocolate in the freezer?	How long can I keep bread dough in the refrigerator?	1.0
Negation	It's not a good idea.	It's a good idea to do both.	1.0

Table 1: Examples from our *Hard STS* dataset and our negation split. The sentence pair in the first row has dissimilar structure and vocabulary yet a high gold score. The second sentence pair has similar structure and vocabulary and a low gold score. The last sentence pair contains negation, where there is a *not* in Sentence 1 that causes otherwise similar sentences to have low semantic similarity.

with Transformers, we use Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 10^{-8}$. We use the same learning rate schedule as Vaswani et al. (2017), i.e., the learning rate increases linearly for 4,000 steps to 5×10^{-4}, after which it is decayed proportionally to the inverse square root of the number of steps. For training the LSTM models, we use Adam with a fixed learning rate of 0.001. We train our models for 20 epochs.

For models incorporating a translation loss, we used label smoothed cross entropy (Szegedy et al., 2016; Pereyra et al., 2017) with $\epsilon = 0.1$. For ENGLISHVAE, BGT and BILINGUALTRANS, we anneal the KL term so that it increased linearly for 2^{16} updates, which robustly gave good results in preliminary experiments. We also found that in training BGT, combining its loss with the BILINGUALTRANS objective during training of both models increased performance, and so this loss was summed with the BGT loss in all of our experiments. We note that this does not affect our claim of BGT being a generative model, as this loss is only used in a multi-task objective at training time, and we calculate the generation probabilities according to standard BGT at test time.

Lastly, in Appendix B, we illustrate that it is crucial to train the Transformers with large batch sizes. Without this, the model can learn the goal task (such as translation) with reasonable accuracy, but the learned semantic embeddings are of poor quality until batch sizes approximately reach 25,000 tokens. Therefore, we use a maximum batch size of 50,000 tokens in our ENGLISHTRANS, BILINGUALTRANS, and BGT W/O PRIOR, experiments and 25,000 tokens in our BGT W/O LANGVARS and BGT experiments.

4.3 Evaluation

Our primary evaluation are the 2012-2016 SemEval Semantic Textual Similarity (STS) shared tasks (Agirre et al., 2012, 2013, 2014, 2015, 2016), where the goal is to accurately predict the degree to which two sentences have the same meaning as measured by human judges. The evaluation metric is Pearson's r with the gold labels.

Secondly, we evaluate on *Hard STS*, where we combine and filter the STS datasets in order to make a more difficult evaluation. We hypothesize that these datasets contain many examples where their gold scores are easy to predict by either having similar structure and word choice and a high score or dissimilar structure and word choice and a low score. Therefore, we split the data using symmetric word error rate (SWER),[7] finding sentence pairs with low SWER and low gold scores as well as sentence pairs with high SWER and high gold scores. This results in two datasets, Hard+ which have SWERs in the bottom 20% of all STS pairs and whose gold label is between 0 and 1,[8] and Hard- where the SWERs are in the top 20% of the gold scores are between 4 and 5. We also evaluate on a split where negation was likely present in the example.[9] Examples are shown in Table 1.

Lastly, we evaluate on STS in `es` and `ar` as well as cross-lingual evaluations for `en-es`, `en-ar`, and `en-tr`. We use the datasets from SemEval 2017 (Cer et al., 2017). For this setting, we train BILINGUALTRANS and BGT on 1 million examples from `en-es`, `en-ar`, and `en-tr` OpenSubtitles 2018 data.

4.4 Results

The results on the STS and *Hard STS* are shown in Table 3.[10] From the results, we see that BGT has the highest overall performance. It does especially well compared to prior work on the two *Hard STS* datasets. We used paired bootstrap resampling to check whether BGT significantly outperforms SentenceBert, SP, BILINGUALTRANS, and BGT W/O PRIOR on the STS task. We found all gains to be

---

[7] We define symmetric word error rate for sentences s_1 and s_2 as $\frac{1}{2}WER(s_1, s_2) + \frac{1}{2}WER(s_2, s_1)$, since word error rate (WER) is an asymmetric measure.

[8] STS scores are between 0 and 5.

[9] We selected examples for the negation split where one sentence contained *not* or *'t* and the other did not.

[10] We obtained values for STS 2012-2016 from prior works using SentEval (Conneau and Kiela, 2018). Note that we include all datasets for the 2013 competition, including SMT, which is not included in SentEval.

Model	Semantic Textual Similarity (STS)								
	2012	2013	2014	2015	2016	**Avg.**	Hard+	Hard-	**Avg.**

BGT	**85.7**	**74.9**	**75.6**	**73.5**	**74.9**

Figure 4: Performance measured in Pearson's $r \times 100$, on the SemEval 2017 STS task on the `es-es`, `ar-ar`, `en-es`, `en-ar`, and `en-tr` datasets.

significant with $p < 0.01$. [11]

From these results, we see that both positive examples that have little shared vocabulary and structure and negative examples with significant shared vocabulary and structure benefit significantly from using a deeper architecture. Similarly, examples where negation occurs also benefit from our deeper model. These examples are difficult because more than just the identity of the words is needed to determine the relationship of the two sentences, and this is something that SP is not equipped for since it is unable to model word order. The bottom two rows show *easier* examples where positive examples have high overlap and low SWER and vice versa for negative examples. Both models perform similarly on this data, with the BGT model having a small edge consistent with the overall gap between these two models.

Lastly, in Table 4, we show the results of STS evaluations in `es` and `ar` and cross-lingual evaluations for `en-es`, `en-ar`, and `en-tr`. We also include a comparison to LASER, which is a multilingual model.[12] From these results, we see that BGT has the best performance across all datasets, however the performance is significantly stronger than the BilingualTrans and BGT w/o Prior baselines in the cross-lingual setting. Since BGT w/o LangVars also has significantly better performance on these tasks, most of this gain seems to be due to the prior having a regularizing effect. However, BGT outperforms BGT w/o LangVars overall, and we hypothesize that the gap in performance between these two models is due to BGT being able to strip away the language-specific information in the representations with its language-specific variables, allowing for the semantics of the sentences to be more directly compared.

5 Analysis

We next analyze our BGT model by examining what elements of syntax and semantics the language and semantic variables capture relative both to each-other and to the sentence embeddings from the BilingualTrans models. We also analyze how the choice of language and its lexical and syntactic distance from English affects the semantic and syntactic information captured by the semantic and language-specific encoders. Finally, we also show that our model is capable of sentence generation in a type of *style transfer*, demonstrating its capabilities as a generative model.

---

[11] We show further difficult splits in Appendix D, including a negation split, beyond those used in *Hard STS* and compare the top two performing models in the STS task from Table 3. We also show easier splits of the data to illustrate that the difference between these models is smaller on these splits.

[12] We note that this is not a fair comparison for a variety of reasons. For instance, our models are just trained on two languages at a time, but are only trained on 1M translation pairs from OpenSubtitles. LASER, in turn, is trained on 223M translation pairs covering more domains, but is also trained on 93 languages simultaneously.

Model	Semantic Textual Similarity (STS)						
	2012	2013	2014	2015	2016	Hard+	Hard-

Table 3: Average STS performance for the 2012-2016 datasets, measured in Pearson's $r \times 100$, followed by probing results on predicting number of subjects, number of objects, constituent tree depth, top constituent, word content, length, number of punctuation marks, the first punctuation mark, and whether the articles in the sentence are the correct gender. All probing results are measured in accuracy $\times 100$.

5.1 STS

We first show that the language variables are capturing little semantic information by evaluating the learned English language-specific variable from our BGT model on our suite of semantic tasks. The results in Table 2 show that these encoders perform closer to a random encoder than the semantic encoder from BGT. This is consistent with what we would expect to see if they are capturing extraneous language-specific information.

5.2 Probing

We probe our BGT semantic and language-specific encoders, along with our BILINGUALTRANS encoders as a baseline, to compare and contrast what aspects of syntax and semantics they are learning relative to each other across five languages with various degrees of similarity with English. All models are trained on the OpenSubtitles 2018 corpus. We use the datasets from Conneau et al. (2018) for semantic tasks like number of subjects and number of objects, and syntactic tasks like tree depth, and top constituent. Additionally, we include predicting the word content and sentence length. We also add our own tasks to validate our intuitions about punctuation and language-specific information. In the first of these, *punctuation number*, we train a classifier to predict the number of punctuation marks[13] in a sentence. To make the task more challenging, we limit each label to have at most 20,000 examples split among training, validation, and testing data.[14] In the second task, *punctuation first*, we train a classifier to predict the identity of the first punctuation mark in the sentence. In our last task, *gender*, we detect examples where the gender of the articles in the sentence is incorrect in French or Spanish. To create an incorrect example, we switch articles from {le, la, un, une} for French and {el, la, los, las} for Spanish, with their (indefinite or definite for French and singular or plural for Spanish) counterpart with the opposite gender. This dataset was balanced so random chance gives 50% on the testing data. All tasks use 100,000 examples for training and 10,000 examples for validation and testing. The results of these experiments are shown in Table 3.

These results show that the source separation is effective - stylistic and language-specific information like length, punctuation and language-specific

---

[13] Punctuation were taken from the set { ’ ! ” # $ % & \’ ( ) * + , − . / : ; < = > ? @ [ ] ^_ ‘ { — } ˜ . }.

[14] The labels are from 1 punctuation mark up to 10 marks with an additional label consolidating 11 or more marks.

gender information are more concentrated in the language variables, while word content, semantic and syntactic information are more concentrated in the semantic encoder. The choice of language is also seen to be influential on what these encoders are capturing. When the languages are closely related to English, like in French and Spanish, the performance difference between the semantic and English language encoder is larger for word content, subject number, object number than for more distantly related languages like Arabic and Turkish. In fact, word content performance is directly tied to how well the alphabets of the two languages overlap. This relationship matches our intuition, because lexical information will be cheaper to encode in the semantic variable when it is shared between the languages. Similarly for the tasks of length, punctuation first, and punctuation number, the gap in performance between the two encoders also grows as the languages become more distant from English. Lastly, the gap on STS performance between the two encoders shrinks as the languages become more distant, which again is what we would expect, as the language-specific encoders are forced to capture more information.

Japanese is an interesting case in these experiments, where the English language-specific encoder outperforms the semantic encoder on the semantic and syntactic probing tasks. Japanese is a very distant language to English both in its writing system and in its sentence structure (it is an SOV language, where English is an SVO language). However, despite these difference, the semantic encoder strongly outperforms the English language-specific encoder, suggesting that the underlying meaning of the sentence is much better captured by the semantic encoder.

5.3 Generation and Style Transfer

In this section, we qualitatively demonstrate the ability of our model to generate sentences. We focus on a *style-transfer* task where we have original seed sentences from which we calculate our semantic vector z_{sem} and language specific vector z_{en}. Specifically, we feed in a *Source* sentence into the semantic encoder to obtain z_{sem}, and another *Style* sentence into the English language-specific encoder to obtain z_{en}. We then generate a new sentence using these two latent variables. This can be seen as a type of style transfer where we expect the model to generate a sentence that has the semantics of the *Source* sentence and the style of the *Style* sentence. We use our `en-fr` BGT model from Table 3 and show some examples in Table 4. All input sentences are from held-out `en-fr` OpenSubtitles data. From these examples, we see further evidence of the role of the semantic and language-specific encoders, where most of the semantics (e.g. topical word such as *seen* and *tech* in the *Source* sentence) are reflected in the output, but length and structure are more strongly influenced by the language-specific encoder.

Source	you know what i've seen?
Style	he said, "since when is going fishing" had anything to do with fish?"
Output	he said, "what is going to do with me since i saw you?"
Source	guys, that was the tech unit.
Style	is well, "capicci" ...
Output	is that what, "technician"?
Source	the pay is no good, but it's money.
Style	do we know cause of death?
Output	do we have any money?
Source	we're always doing stupid things.
Style	all right listen, i like being exactly where i am,
Output	all right, i like being stupid, but i am always here.

Table 4: *Style transfer* generations from our learned BGT model. *Source* refers to the sentence fed into the semantic encoder, *Style* refers to the sentence fed into the English language-specific encoder, and *Output* refers to the text generated by our model.

6 Conclusion

We propose Bilingual Generative Transformers, a model that uses parallel data to learn to perform *source separation* of common semantic information between two languages from language-specific information. We show that the model is able to accomplish this source separation through probing tasks and text generation in a style-transfer setting. We find that our model bests all baselines on unsupervised semantic similarity tasks, with the largest gains coming from a new challenge we propose as *Hard STS*, designed to foil methods approximating semantic similarity as word overlap. We also find our model to be especially effective on unsupervised cross-lingual semantic similarity, due to its stripping away of language-specific information allowing for the underlying semantics to be more directly compared. In future work, we will explore generalizing this approach to the multilingual setting, or applying it to the pre-train and fine-tune paradigm used widely in other models such as BERT.

A Location of Sentence Embedding in Decoder for Learning Representations

As mentioned in Section 2, we experimented with 4 ways to incorporate the sentence embedding into the decoder: Word, Hidden, Attention, and Logit. We also experimented with combinations of these 4 approaches. We evaluate these embeddings on the STS tasks and show the results, along with the time to train the models 1 epoch in Table 5.

For these experiments, we train a single layer bidirectional LSTM (BiLSTM) ENGLISHTRANS model with embedding size set to 1024 and hidden states set to 512 dimensions (in order to be roughly equivalent to our Transformer models). To form the sentence embedding in this variant, we mean pool the hidden states for each time step. The cell states of the decoder are initialized to the zero vector.

Architecture	STS	Time (s)
BiLSTM (Hidden)	54.3	1226
BiLSTM (Word)	67.2	1341
BiLSTM (Attention)	68.8	1481
BiLSTM (Logit)	69.4	1603
BiLSTM (Wd. + Hd.)	67.3	1377
BiLSTM (Wd. + Hd. + Att.)	68.3	1669
BiLSTM (Wd. + Hd. + Log.)	69.1	1655
BiLSTM (Wd. + Hd. + Att. + Log.)	68.9	1856

Table 5: Results for different ways of incorporating the sentence embedding in the decoder for a BiLSTM on the Semantic Textual Similarity (STS) datasets, along with the time taken to train the model for 1 epoch. Performance is measured in Pearson's $r \times 100$.

From this analysis, we see that the best performance is achieved with Logit, when the sentence embedding is place just prior to the softmax. The performance is much better than Hidden or Hidden+Word used in prior work. For instance, recently (Artetxe and Schwenk, 2018) used the Hidden+Word strategy in learning multilingual sentence embeddings.

A.1 VAE Training

We also found that incorporating the latent code of a VAE into the decoder using the Logit strategy increases the mutual information while having little effect on the log likelihood. We trained two LSTM VAE models following the settings and aggressive training strategy in (He et al., 2019), where one LSTM model used the Hidden strategy and the other used the Hidden + Logit strategy. We trained the models on the `en` side of our `en-fr` data. We found that the mutual information increased form 0.89 to 2.46, while the approximate negative log likelihood, estimated by importance weighting, increased slightly from 53.3 to 54.0 when using Logit.

B Relationship Between Batch Size and Performance for Transformer and LSTM

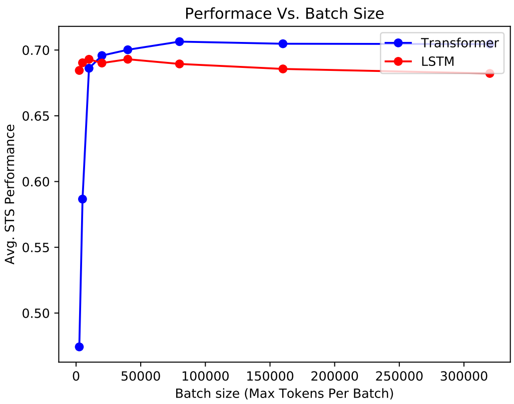

Figure 5: The relationship between average performance for each year of the STS tasks 2012-2016 (Pearson's $r \times 100$) and batch size (maximum number of words per batch).

It has been observed previously that the performance of Transformer models is sensitive to batch size (Popel and Bojar, 2018) . We found this to be especially true when training sequence-to-sequence models to learn sentence embeddings. Figure 5 shows plots of the average 2012-2016 STS performance of the learned sentence embedding as batch size increases for both the BiLSTM and Transformer. Initially, at a batch size of 2500 tokens, sentence embeddings learned are worse than random, even though validation perplexity does decrease during this time. Performance rises as batch size increases up to around 100,000 tokens. In contrast, the BiLSTM is more robust to batch size, peaking much earlier around 25,000 tokens, and even degrading at higher batch sizes.

C Model Ablations

In this section, we vary the number of layers in the encoder and decoder in BGT W/O PRIOR. We see that performance increases as the number of encoder layers increases, and also that a large decoder hurts performance, allowing us to save training time by using a single layer. These results can be compared to those in Table 7 showing that

Data Split	n	BGT	SP
All	13,023	**75.3**	74.1
Negation	705	**73.1**	68.7
Bottom 20% SWER, label $\in [0, 2]$	404	**63.6**	54.9
Bottom 10% SWER, label $\in [0, 1]$	72	**47.1**	22.5
Top 20% SWER, label $\in [3, 5]$	937	**20.0**	14.4
Top 10% SWER, label $\in [4, 5]$	159	**18.1**	10.8
Top 20% SWER, label $\in [0, 2]$	1380	**51.5**	49.9
Bottom 20% SWER, label $\in [3, 5]$	2079	**43.0**	42.2

Table 6: Performance, measured in Pearson's $r \times 100$, for different data splits of the STS data. The first row shows performance across all unique examples, the next row shows the negation split, and the last four rows show difficult examples filtered symmetric word error rate (SWER). The last two rows show relatively easy examples according to SWER.

Architecture	STS	Time (s)
Transformer (5L/1L)	70.3	1767
Transformer (3L/1L)	70.1	1548
Transformer (1L/1L)	70.0	1244
Transformer (5L/5L)	69.8	2799

Table 7: Results on the Semantic Textual Similarity (STS) datasets for different configurations of ENGLISH-TRANS, along with the time taken to train the model for 1 epoch. (XL/YL) means X layers were used in the encoder and Y layers in the decoder. Performance is measured in Pearson's $r \times 100$.

Transformers outperform BiLSTMS in these experiments.

D Hard STS

We show further difficult splits in Table 6, including a negation split, beyond those used in *Hard STS* and compare the top two performing models in the STS task from Table 3. We also show easier splits in the bottom of the table.

Semantically Inspired AMR Alignment for the Portuguese Language

Abstract

Abstract Meaning Representation (AMR) is a graph-based semantic formalism where the nodes are concepts and edges are relations among them. Most of AMR parsing methods require alignment between the nodes of the graph and the words of the sentence. However, this alignment is not provided by manual annotations and available automatic aligners focus only on the English language, not performing well for other languages. Aiming to fulfill this gap, we developed an alignment method for the Portuguese language based on a more semantically matched word-concept pair. We performed both intrinsic and extrinsic evaluations and showed that our alignment approach outperforms the alignment strategies developed for English, improving AMR parsers, and achieving competitive results with a parser designed for the Portuguese language.

1 Introduction

According to Banarescu et al. (2013), Abstract Meaning Representation (AMR) is a semantic meaning representation, which may be encoded as a rooted Direct Acyclic Graph (DAG) where the nodes are concepts, and the edges are relations among them. This representation explicitly details semantics information, as depicted in Figure 1. In this figure, the `live-01` node is the root of the graph and `city` node introduces a named entity. Moreover, `:ARGx` relations are predicates from the PropBank lexicon (Kingsbury and Palmer, 2002), which encode semantic information according to each PropBank sense.

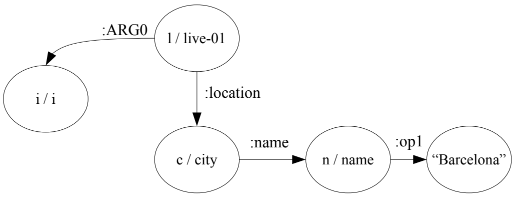

Figure 1: An example of AMR graph for the sentence "I live in Barcelona".

To parse a text into an AMR graph, most of the AMR parsers require alignment between the word (tokens) of the sentence and the nodes of the corresponding graph (see, for instance, (Flanigan et al., 2014; Wang et al., 2015; Zhou et al., 2016; Damonte et al., 2017). However, this anchoring is not provided by manual annotations. Also, the available automatic aligners focus only on the English language (Pourdamghani et al., 2014; Flanigan et al., 2014; Liu et al., 2018), and they do not perform well for other languages. For Portuguese, for instance, the sentence "*Não era surpresa para mim*" (It was no surprise to me), the `JAMR` aligner (Flanigan et al., 2014) produces alignment only between the token *surpresa* (surprise) and the node `surpresa`, as shown in Figure 2.

```
# ::snt Não era surpresa para mim
# ::alignments 2-3|0

(s / surpresa
   :polarity -
   :domain (e / eu))
```

Figure 2: Alignment produced by JAMR aligner for the sentence "*Não era surpresa para mim*" (It was no surprise to me).

The `JAMR` aligned only the span `2-3`, which is the token *surpresa* (surprise), with node `0`, which is the root of the graph; `-` and `eu` nodes were not aligned. This wrong or bad alignments occur because of the `JAMR` aligner adopts a string-match strategy that is focused on the English language. Besides, these issues contribute to a decrease in the performance of AMR parsers. As a result, recent AMR parsing methods have focused on alignment-free approaches (Lyu and Titov, 2018; Zhang et al., 2019a,b). However, they require a large annotated

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1595–1600,
November 16–20, 2020.

corpus, which is available only for English.

In this context, aiming to bridge this lack of resources and tools for other languages, we propose an AMR aligner for Portuguese that focuses on a more semantically matched word-concept pair. For that, we use pre-trained word embeddings and the Word Mover's Distance (WMD) function (Kusner et al., 2015) to match span tokens in the sentence with nodes in the graph. Word embeddings capture some semantics information about a corpus, and WMD measures the dissimilarity between two documents even if they have no words in common. With this, it is possible to produce semantically inspired matches instead of only string-match.

To evaluate our approach, we carry out both intrinsic and extrinsic experiments on an annotated corpus from Portuguese. Our aligner produced better alignments than alignment strategies proposed for English and improved AMR parsing for Portuguese, reaching competitive results with an AMR parser designed for that language.

The remaining of this paper is organized as follows. In Section 2, we briefly introduce the related work. Section 3 describes our proposed aligner. In Section 4, we conduct some experiments and evaluations and show our results. Finally, Section 5 concludes the paper indicating future research.

2 Related Work

Flanigan et al. (2014) developed the first AMR aligner, named `JAMR`. The authors created a rule-based aligner with fourteen heuristic rules to greedily align concepts in the nodes of the graph with tokens in the sentence. The alignment format is a space-separated list of spans with their graph fragments, where each a descriptor specifies each node (e.g. (Gorn, 1965)): `0` for the root node, `0.0` for the first child of the root node, `0.1` for the second child of the root node and so forth. For example, for the sentence, "The boy wants to go.", the `JAMR` generates alignments according to Figure 3. The `JAMR` aligned the spans `2-3`, `4-5`, and `1-2` (that refer to `wants`, `go`, and `boy`, respectively) with the nodes `0`, `0.1`, and `0.0` (that are the root of the graph, the second child of the root, and the first child of the root, respectively).

Pourdamghani et al. (2014) adopted an unsupervised word alignment technique with machine learning. The authors followed a syntax-based Statistical Machine Translation (SMT) according to the IBM word alignment model (Brown et al., 1993) to align linearized AMR graphs with English sentences. For the sentence "The boy wants to go", this approach produces alignments, as shown in Figure 4, where '∼ n' specifies a link to the nth English word. As we can see, the third token (`wants`) was aligned with the concept `want-01`, the second token (`boy`) with the concept `boy`, and the fifth token (`go`) with the concept `go-01`.

```
# ::snt The boy wants to go
# ::alignments 2-3|0 4-5|0.1 1-2|0.0

(w / want-01
   :ARG0 (b / boy)
   :ARG1 (g / go-01
      :ARG0 b))
```

Figure 3: An example of the `JAMR` aligner for the sentence "The boy wants to go".

```
The boy wants to go

(w / want-01 ~ 3
   :ARG0 (b / boy ~ 2)
   :ARG1 (g / go-01 ~ 5
      :ARG0 b))
```

Figure 4: Alignments produced for the sentence "The boy wants to go".

Liu et al. (2018) extended and improved the `JAMR` aligner by adding semantic resources into the rules, such as GloVe embeddings (Pennington et al., 2014) and the Morphosemantic database (Fellbaum et al., 2009). Besides, they noted that the `JAMR` aligner requires that words have at least a common longest prefix of four characters, omitting the shorter cases (as word `actions` aligned with the concept `act-01`). Thus, their method improved the `JAMR` aligner in a 4.6% f-score on the LDC2014T2 corpus. The authors also showed that their aligner improved the `JAMR` (Flanigan et al., 2014) and `CAMR` (Wang et al., 2015) parsers.

3 Our Aligner

In order to properly adapt AMR parsers from English to Portuguese, we developed an alignment strategy based on document similarity for the Portuguese language. Our method produces alignments in the `JAMR` aligner format since most of the AMR parsers adopt this alignment type. To support our method, we used the pre-trained GloVe[1] embeddings of 100 dimensions for the Portuguese

---

[1] We also experimented other pre-trained models with dimensions of 50, 100, and 300.

language (Hartmann et al., 2017) and some lexical resources. We organized our method into three phases over input annotated sentences: preprocessing, mapping, and aligning.

In the first step, we tokenize the sentences and lemmatize each token, applying the Stanza tool (Qi et al., 2020) trained for Portuguese. The Portuguese tokenization is slightly different from English. For example, some hyphenated words, as "*via-me*" and "*ouvi-la*" (translated for "saw me" and "hear her"), should be separated by the hyphen, whereas other words, as "*segunda-feira*" and "*recém-casados*" (translated for "Monday" and "newly married"), should not be separated. To detail the next steps, we will use Figure 5 as an example.

```
# ::snt Mas Pedro não respondeu
# ::alignments 0-1|0 3-4|0.0 2-3|0.0.0
1-2|0.0.1+0.0.1.0+0.0.1.0.0 5-6|0.0.2 6-7|0.0.2.0

(c / contrast-01                    0
   :ARG2 (r / responder-01          0.0
      :polarity -                   0.0.0
      :ARG0 (p / person             0.0.1
         :name (n / name            0.0.1.0
            :op1 "Pedro"))))        0.0.1.0.0
```

Figure 5: An example of AMR for the sentence "*Mas Pedro não respondeu*"(But Peter did not answer).

In the next step, we mapped each concept to its respective position in the graph. One can see that we mapped the `contrast-01` concept to the root of the graph `0`, its child `responder-01` to `0.0`, and their children `-` and `person` to their respective positions `0.0.0` and `0.0.1`. To do this, we used the Penman tool (Goodman, 2020).

In the last step, we align the word tokens of the sentence with the concepts of the graph. The AMR language has two concept types: concrete and abstract (or special keywords) ones. The former are those that are explicitly present in the sentence, while the latter are not. In Figure 5, we can see that the `responder-01` is a concrete concept, since it is in the sentence, while the `contrast-01`, `person`, and `name` concepts are abstract[2].

To align concrete concepts, we use the Word Mover's Distance (WMD)[3] (Kusner et al., 2015) and the pre-trained GloVe embeddings of 100 dimensions. The WMD is a distance function where the lower distance value indicates a higher similarity to the documents. It measures the minimum amount of distance that embedded words of one document need to "travel" to reach the embedded words of another document.

We used this distance function to evaluate a distance between the embedded word tokens in the sentence and the embedded concepts in the graph to produce alignments with more semantics information than string-match. Furthermore, we empirically defined a maximum distance (threshold) of 1.5 to match a token with a concept, i.e., our strategy maps a word with a concept only if the distance between them is less than the defined threshold. Figure 6 shows this strategy to align the words of the sentence with concrete concepts of the graph.

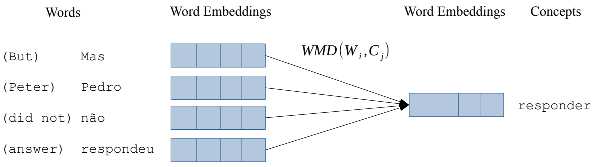

Figure 6: Aligning word tokens with concrete concepts

From this figure, $W = \{w_1, ..., w_n\}$ is the set of words of a sentence and $C = \{c_1, ..., c_n\}$ is the set of concrete concepts of the graph. Our method aligns a w_i with a c_j if and only if the WMD value between w_i and c_j is lower than 1.5, and that value is the lowest among the other delta values.

To align abstract concepts, we use some lexical resources (list of words) to aid and get a higher recall in the alignment. At this time, the AMR formalism has 44 abstract concepts[4] and 110 concepts that represent named entities[5]. For instance, in Figure 5, the `person` is a concept that produces a named entity and, as this concept is in the resource, our alignment strategy aligns this concept and its children with the *Pedro* (Peter) token, which is the span `1-2`, generating the alignment `1-2|0.0.1+0.0.1.0+0.0.1.0.0`, which means that the span `1-2` is aligned with the concept `person` (`0.0.1`) plus `name` (`0.0.1.0`) plus "`Pedro`" (`0.0.1.0.0`).

In addition to named entities and abstract concepts, AMR concepts encompass contrastive conjunctions and negations. To align these concepts, we also created two more lexical resources [6,7] (list of words) for these concepts. Likewise, as ab-

---

[2] "`Pedro`" and `-` are constants, as they get no variable.

[3] We also tested other similarity metrics.

[4] https://amr.isi.edu/doc/amr-dict.html

[5] https://www.isi.edu/~ulf/amr/lib/ne-types.html

[6] https://www.isi.edu/~ulf/amr/lib/popup/contrast.html

[7] https://www.enchantedlearning.com/wordlist/negativewords.shtml

stract concepts and named entities, as the words *Mas* (But) and *não* (not) are in the resources, our alignment method aligns the spans `0-1` and `2-3`, which are the words *Mas* (But) and *não* (not), respectively, with nodes `0` and `0.0.0`, which are `contrast-01` and `-`, respectively (see Figure 5). Our alignment tool is available at `http://github.com/rafaelanchieta/amr-aligner`. In what follows, we detail our experiments with the aligner and the obtained results.

4 Experiments and Results

We performed two experiments, one intrinsic and another extrinsic. In the first, we randomly chose and manually aligned one hundred sentences with their respective AMRs from the Little Prince corpus (Anchiêta and Pardo, 2018a). Then, we compared the manual alignment with the alignments produced by Flanigan et al. (2014) (JAMR), Pourdamghani et al. (2014) (henceforth, we refer to it as UNSU), Liu et al. (2018) (TAMR), and our proposed aligner. We converted the alignment format of the UNSU aligner to produce alignments in the JAMR aligner format. In Table 1, we show the obtained results in the intrinsic evaluation.

Aligner	Precision	Recall	F-score
JAMR	0.71	0.86	0.78
UNSU	0.48	0.58	0.53
TAMR	0.70	0.88	0.78
OURS	**0.86**	**0.91**	**0.89**

Table 1: Results in the intrinsic evaluation

As we can see, our aligner outperformed those developed for English, which means that our alignment strategy produced alignments more consistent with those manually produced. To get these values, we followed the evaluation method of Flanigan et al. (2014).

In order to confirm the intrinsic evaluation results, we performed an extrinsic evaluation. Thus, we adapted the AMR parsers of Damonte et al. (2017) (henceforth, we refer to it as AMREager) and Wang et al. (2015) (henceforth, we refer to it as CAMR) for the Portuguese language. We chose these parsers because they use alignments, are open source, need only minor modifications for reuse with other languages, and have a good performance on small corpora.

We trained these parsers on The Little Prince corpus of the Portuguese language (Anchiêta and Pardo, 2018a), which contains 1,274, 145, and 143 sentences for training, development, and testing, respectively. To compare the results of the parsers, we used the traditional Smatch metric (Cai and Knight, 2013) and the more recently proposed SEMA metric (Anchiêta et al., 2019). SEMA is a more robust metric that considers the parent of the nodes in the graph, producing fairer results than the Smatch metric. Table 2 shows the obtained results in the extrinsic evaluation.

Parser	Aligner	Smatch			SEMA		
		P	R	F1	P	R	F1
CAMR	JAMR	0.46	0.34	0.39	0.20	0.14	0.16
	UNSU	0.35	0.29	0.32	0.15	0.10	0.12
	TAMR	0.47	0.36	0.41	0.24	0.18	0.20
	OURS	**0.54**	**0.47**	**0.50**	**0.32**	**0.27**	**0.29**
AMREager	JAMR	0.44	0.33	0.38	0.18	0.13	0.15
	UNSU	0.34	0.27	0.30	0.14	0.09	0.11
	TAMR	0.38	0.34	0.36	0.17	0.15	0.16
	OURS	**0.51**	**0.45**	**0.48**	**0.30**	**0.26**	**0.28**

Table 2: Results in the extrinsic evaluation

From this table, one realizes that our aligner improved the adapted AMR parsers for Portuguese in both metrics, confirming the results of the intrinsic evaluation. Moreover, the CAMR parser achieved a competitive result (50% f-score) compared to the RBAMR parser (53% f-score over the same corpus) (Anchiêta and Pardo, 2018b), a rule-based AMR parser designed for the Portuguese language.

We also performed a fine-grained error analysis to identify the weaknesses of our aligner. For that, we used the evaluation tool of Damonte et al. (2017) to compare the CAMR parser, as it achieved the best results, with the best aligners JAMR, TAMR, and OURS. We present the results in Table 3.

CAMR	JAMR	TAMR	OURS
Metric	**F-score**		
Unlabeled	0.46	0.48	**0.58**
No WSD	0.41	0.42	**0.52**
NER	0.00	**0.13**	0.00
Wiki	0.00	0.00	0.00
Negations	0.00	0.00	**0.61**
Concepts	0.52	0.53	**0.58**
Reetrancies	0.05	0.06	**0.07**
SRL	0.32	0.37	**0.52**

Table 3: Fine-grained results

We can see that the CAMR parser + our aligner outperformed the other aligners in most metrics.

The models tied for the Wiki metric due to the corpus not having wiki annotation. In the NER metric, the `TAMR` aligner performed better than the other aligners. This result is because of the specific rules used to align named entities and the Morphosemantic database that this aligner makes use of. Besides, our aligner achieved only 0.07 of reentrancies, as the aligner is not prepared to align reentrancies. One solution could be to model reentrancies as a tree, according to Zhang et al. (2019a).

Another issue is the occurrence of hidden subjects in Portuguese, i.e., sentences where the subject 'I' is in the graph, but it is not in the sentence (it is implicit). Our aligner tool also ignores this phenomenon. One solution could be to apply a preprocessing to identify and include the hidden subjects in the sentences.

Treating these issues remain for future work. We also intend to investigate the Morphosemantic database, aiming to improve the accuracy in the alignment of named entities.

The adapted AMR parsers are available at `http://github.com/rafaelanchieta/CAMR-PT` and `http://github.com/rafaelanchieta/amr-eager-pt`.

5 Conclusion

In this paper, we presented an AMR alignment method designed for the Portuguese language. It is based on pre-trained word embeddings and Word Mover's Distance to match word tokens in the sentences and nodes in the corresponding AMR graphs. This simple approach may be adopted for other languages with few resources, aiming to get tools for natural language understanding tasks. Furthermore, this aligner may help to build or increase semantic resources, using a promising approach as back-translation (Sobrevilla Cabezudo et al., 2019). Future work includes adopting multilingual word embeddings (Lample et al., 2018) to produce alignments for other languages. More details about AMR resources and tools for the Portuguese language may be found at the OPINANDO project webpage [8].

Abstract

BERT is inefficient for sentence-pair tasks such as clustering or semantic search as it needs to evaluate combinatorially many sentence pairs which is very time-consuming. Sentence BERT (SBERT) attempted to solve this challenge by learning semantically meaningful representations of single sentences, such that similarity comparison can be easily accessed. However, SBERT is trained on corpus with high-quality labeled sentence pairs, which limits its application to tasks where labeled data is extremely scarce. In this paper, we propose a lightweight extension on top of BERT and a novel self-supervised learning objective based on mutual information maximization strategies to derive meaningful sentence embeddings in an unsupervised manner. Unlike SBERT, our method is not restricted by the availability of labeled data, such that it can be applied on different domain-specific corpus. Experimental results show that the proposed method significantly outperforms other unsupervised sentence embedding baselines on common semantic textual similarity (STS) tasks and downstream supervised tasks. It also outperforms SBERT in a setting where in-domain labeled data is not available, and achieves performance competitive with supervised methods on various tasks.

1 Introduction

BERT-based pretrained language models (Devlin et al.; Liu et al., 2019) have set new state-of-the-art performance on various downstream NLP tasks. However, they are inefficient for sentence-pair regression tasks such as clustering or semantic search because they need to evaluate combinatorially many sentence pairs during inference, which will result in a massive computational overhead. For example, finding the most similar pair in a collection of 10k sentences requires about 50 million ($\binom{10k}{2}$) inference computations with BERT, which requires about 65 hours on a V100 GPU (Reimers and Gurevych, 2019).

Much previous work attempted to address this problem by learning semantically meaningful representations for each sentence, such that similarity measures like cosine distance can be easily evaluated for sentence-pair regression tasks. The straightforward way to derive a fixed-size sentence embedding from BERT-based models is to average the token representations at the last layer or using the output of the [CLS] token. Reimers and Gurevych (2019) showed that both approaches yield rather unsatisfactory sentence embeddings. They proposed a model, Sentence-BERT (SBERT), to further fine-tune BERT on natural language inference (NLI) tasks with labeled sentence pairs and achieved state-of-the-art performance on many semantic textual similarity tasks. However, such improvements are induced by high-quality supervision, and we find that their performance is degraded where labeled data of the target task is extremely scarce or the distribution of test set differs significantly from the NLI dataset used for training.

Learning sentence representations in an unsupervised manner is a critical step to work with unlabeled or partially labeled dataset to address the aforementioned challenge (Kiros et al., 2015; Gan et al., 2017; Hill et al., 2016; Pagliardini et al., 2017; Yang et al., 2018). A common approach for unsupervised sentence representation learning is to leverage on self-supervision with large unlabeled corpus. For example, early methods explored various auto-encoders for sentence embedding (Socher et al., 2011; Hill et al., 2016). Recent work such as skip-thought (Kiros et al., 2015) and FastSent (Hill et al., 2016) assumed that a sentence is likely to have similar semantics to its context, and designed

self-supervised objectives that encourage models to learn sentence representations by predicting contextual information. However, the performance of these models is far behind that of supervised learning ones on many tasks, which unveils an urgent need of better unsupervised sentence embedding methods.

In this work, we propose a novel unsupervised sentence embedding model with light-weight feature extractor on top of BERT for sentence encoding, and train it with a novel self-supervised learning objective. Our model is not restricted by the availability of labeled data and can be applied to any domain of interest. Instead of simply averaging BERT token embeddings, we use convolutional neural network (CNN) layers with mean-over-time pooling that transform BERT token embeddings to a global sentence embedding (Kim, 2014). Moreover, we propose a novel self-supervised learning objective that maximises the mutual information (MI) between the global sentence embedding and all its local contexts embeddings, inspired by recent advances on unsupervised representation learning for images and graphs (Hjelm et al., 2019; Velickovic et al., 2019). Our model is named Info-Sentence BERT (IS-BERT). In IS-BERT, the representation of a specific sentence is encouraged to encode all aspects of its local context information, using local contexts derived from other input sentences as negative examples for contrastive learning. This learning procedure encourages the encoder to capture the unique information that is shared across all local segments of the specific input sentence while different from other inputs, leading to more expressive and semantically meaningful sentence embeddings.

We evaluate our method on two groups of tasks – Semantic Textual Similarity (STS) and SentEval (Conneau and Kiela, 2018). Empirical results show that IS-BERT significantly outperforms other unsupervised baselines on STS and SentEval tasks. In addition, we show that IS-BERT substantially outperforms SBERT in a setting where task-specific labeled data is not available. This demonstrates that IS-BERT has the flexibility to be applied to new domains without label restriction. Finally, IS-BERT can achieve performance competitive with or even better than supervised learning methods in certain scenarios.

2 Related Work

2.1 Sentence Representation Learning

Prior approaches for sentence embedding include two main categories: (1) unsupervised sentence embedding with unlabeled sentences, and (2) supervised learning with labeled sentences, while a few methods might leverage on both of them.

Unsupervised Sentence Embedding. There are two main directions to work with unlabeled corpus, according to whether the input sentences are ordered or not. In the scenario with unordered sentences, the input is usually a single sentence and models are designated to learn sentence representations base on the internal structures within each sentence, such as recursive auto-encoders (Socher et al., 2011), denoising auto-encoders (Hill et al., 2016), and the paragraph vector model (Le and Mikolov, 2014). Our model follows this setting as well but benefits from the model capacity of BERT and knowledge in large pretraining corpus.

Methods working with ordered sentences utilize the distributional hypothesis which assumes that a sentence is likely to have similar semantics to its context. Under this assumption, they formulate generative or discriminative tasks that require the models to correctly predict the contextual information , such as skip-thought (Kiros et al., 2015) and FastSent (Hill et al., 2016), or to distinguish target sentences from contrastive ones (Jernite et al., 2017; Logeswaran and Lee, 2018) for sentence embedding (Jernite et al., 2017; Logeswaran and Lee, 2018). These methods require ordered sentences or corpus with inter-sentential coherence for training, which limits their applications to domains with only short texts.

Supervised Sentence Embedding. There have also been attempts to use labeled data for sentence embedding. Conneau et al. (2017) proposed the InferSent model that uses labeled data of the Stanford Natural Language Inference dataset (SNLI) (Bowman et al., 2015) and the Multi-Genre NLI dataset (Williams et al., 2018) to train a BiLSTM siamese network for sentence embedding. Universal Sentence Encoder (Cer et al., 2018) utilized supervised training with SNLI to augment the unsupervised training of a transformer network. SBERT (Reimers and Gurevych, 2019) also trained a siamese network on NLI to encode sentences, but it further benefits from the pretraining procedure of BERT. Though effective, those models could be problematic to port to new domains where high-quality labeled data is not available, or the text distribution is significantly different from the NLI dataset such that knowledge learned from NLI cannot be successfully transferred. Addressing this limitation requires unsupervised methods.

2.2 Representation Learning with MI

Unsupervised representation learning with mutual information has a long history, such as the informax principle and ICA algorithms (Bell and Sejnowski, 1995; Hyvärinen and Oja, 2000). Theoretically, many generative models for representation learning based on reconstruction such as auto-encoders or GANs (Nowozin et al., 2016) are closely related to the idea of maximizing the MI between the model inputs and outputs. Despite the pivotal role in machine learning, MI is historically hard to compute, especially in high-dimensional and continuous settings such as neural networks. Recently, multiple estimators were proposed as lower bounds for mutual information estimation (Belghazi et al., 2018; van den Oord et al., 2018), which were demonstrated to be effective for unsupervised representation learning in various scenarios (Hjelm et al., 2019; Ji et al., 2019; Sun et al., 2020; Kong et al., 2020). Our model is mainly inspired by the DIM model (Hjelm et al., 2019) for vision tasks, associated with a novel self-supervised learning objective to maximize the MI between the global sentence embedding and the representations of all its local contexts. Different from (Hjelm et al., 2019), we mainly work with sequential sentence data with the pretrainted BERT model and further investigate the generalization ability of the learned representation across different domains. Kong et al. (2020) also used MI with BERT, but their objective is for language modeling while our focus is on sentence representation learning. The corresponding downstream tasks are completely different as well.

3 Model

In this section, we outline a general model, the Info-Sentence BERT (IS-BERT), for unsupervised sentence representation learning. We first give the problem formulation, then we present the details of our method and the corresponding neural network architecture.

3.1 Problem Formulation

Given a set of input sentences $\mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_n\}$, our goal is to learn a representation $\mathbf{y}_i \in R^d$ in $\mathcal{Y}$ for each sentence $\mathbf{x}_i$ in an unsupervised manner. For simplicity, we denote this process with a parameterized function $\mathcal{E}_\Theta : \mathcal{X} \longrightarrow \mathcal{Y}$, and denote the empirical distribution of the input set $\mathcal{X}$ as $\mathbb{P}$.

We aim to acquire sentence representations by maximizing the mutual information between the sentence-level global representation and the token-level local representations. This idea was inspired by recent advances on unsupervised representation learning for images and graphs (Hjelm et al., 2019; Sun et al., 2020). The motivation behind such learning strategy is to encourage sentence representations to encode multiple aspects shared by the local information of tokens such as n-gram contextual dependencies.

3.2 Model Architecture

Our model architecture is illustrated in Figure 1. We first use BERT to encode an input sentence $\mathbf{x}$ to a length-l sequence of token embeddings $\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_l$. Then we apply 1-D convolutional neural network (CNN) layers with different window (kernel) sizes on top of these token embeddings to capture the n-gram local contextual dependencies of the input sentence. Formally, an n-gram embedding $\mathbf{c}_i$ generated by a CNN with window size k is computed as

$$\mathbf{c}_i = f(\mathbf{w} \cdot \mathbf{h}_{i:i+k-1} + \mathbf{b}), \tag{1}$$

where $\mathbf{h}_{i:i+k-1}$ is the concatenation of the token embeddings within a window. $\mathbf{w}$ and $\mathbf{b}$ are learnable parameters of the CNN layer shared across all windows over the sequence, and f is the ReLU activation. We use padding to keep the sequence length of outputs the same as inputs.

To better capture contextual information with various ranges, we apply several CNNs with different window sizes (e.g. 1, 3, 5) to the input sentences. The final local representation of a token is the concatenation of its representations obtained with different window sizes, as shown in Figure 1. We denote the length-l local token representations sequence for a sentence $\mathbf{x}$ as $\mathcal{F}_\theta(\mathbf{x}) := \{\mathcal{F}_\theta^{(i)}(\mathbf{x}) \in \mathbb{R}^d\}_{i=1}^{l}$, where $\mathcal{F}_\theta$ is the encoding function consisting of BERT and CNNs with trainable parameters θ, and i is the token index. The global sentence

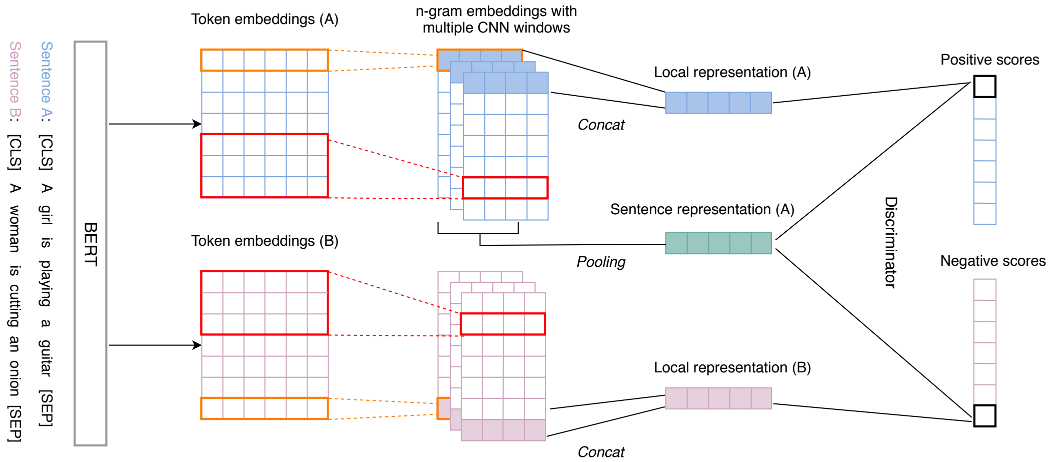

Figure 1: Model Architecture. Two sentences are encoded by BERT and multiple CNNs with different window sizes to get concatenated local n-gram token embeddings. A discriminator T takes all pairs of $\{$sentence representation, token representation$\}$ as input and decides whether they are from the same sentence. In this example, we treat sentence "A" as the positive sample and "B" as negative, then n-gram embeddings of "A" will be summarized to a global sentence embedding via pooling. The discriminator produces scores for all token representations from both "A" and "B" to maximize the MI estimator in Eq.2.

representation of $\mathbf{x}$ denoted as $\mathcal{E}_\theta(\mathbf{x}) \in \mathbb{R}^d$ is computed by applying a mean-over-time pooling layer on the token representations $\mathcal{F}_\theta(\mathbf{x})$. Both sentence and token representations are parameterized by θ as pooling does not introduce additional parameters. The induction of the these representations is different from the previous sentence-BERT model (Reimers and Gurevych, 2019). While Reimers and Gurevych (2019) simply used mean- or max-pooling strategies over the token representations from BERT outputs which can be regard as 1-gram embeddings, we use a set of parallel CNN layers with various window sizes to capture n-gram contextual dependencies. Both the sentence representation and token representations will be fed into a discriminator network to produce scores for MI estimation as presented in 3.3.

3.3 MI Maximization Learning

The learning objective is to maximize the mutual information (MI) between the global sentence representation $\mathcal{E}_\theta(\mathbf{x})$ and each of its local token representation $\mathcal{F}^{(i)}_\theta(\mathbf{x})$. As MI estimation is generally intractable for continuous and high-dimensional random variables, we usually maximizing over lower bound estimators of MI, such as the Noise-Contrastive estimator (Gutmann and Hyvärinen, 2012) and Jensen-Shannon estimator (Nowozin et al., 2016; Hjelm et al., 2019). In this paper, we use the Jensen-Shannon estimator. Mathematically, the Jensen-Shannon estimator $\mathcal{I}^{JSD}_\omega(\mathcal{F}^{(i)}_\theta(\mathbf{x}); \mathcal{E}_\theta(\mathbf{x}))$ is defined as

$$\begin{aligned}\widehat{\mathcal{I}}^{JSD}_\omega(\mathcal{F}^{(i)}_\theta(\mathbf{x}); \mathcal{E}_\theta(\mathbf{x})) :=&\\ &E_{\mathbb{P}}[-sp(-T_\omega(\mathcal{F}^{(i)}_\theta(\mathbf{x}), \mathcal{E}_\theta(\mathbf{x})))]\\ &- E_{\mathbb{P}\times\tilde{\mathbb{P}}}[sp(T_\omega(\mathcal{F}^{(i)}_\theta(\mathbf{x}'), \mathcal{E}_\theta(\mathbf{x})))],\end{aligned} \tag{2}$$

where $T_\omega : \mathcal{F} \times \mathcal{E} \to \mathbb{R}$ is a discriminator parameterized by a neural network with learnable parameters ω. It takes all the pairs of a global sentence embedding and local token embeddings as input and generates corresponding scores to estimate $\widehat{\mathcal{I}}^{JSD}_\omega$, see Figure 1. $\mathbf{x}'$ is the negative sample drawn from distribution $\tilde{\mathbb{P}} = \mathbb{P}$, and $sp(z) = \log(1 + e^z)$ is the softplus activation function. The end-goal learning objective over the whole dataset $\mathcal{X}$ is defined as:

$$\begin{aligned}\omega^*, \theta^* = \operatorname*{argmax}_{\omega,\theta} \frac{1}{|\mathcal{X}|}\Bigg(&\\ \sum_{\mathbf{x}\in\mathcal{X}} \sum_{i=1}^{l_x} &\widehat{\mathcal{I}}^{JSD}_\omega(\mathcal{F}^{(i)}_\theta(\mathbf{x}); \mathcal{E}_\theta(\mathbf{x}))\Bigg),\end{aligned} \tag{3}$$

where $|\mathcal{X}|$ is the size of the dataset, l_x is the length of sentence $\mathbf{x}$, and ω^*, θ^* denote the optimum.

In Eq. 2, $\mathcal{F}^{(i)}_\theta(\mathbf{x}')$ corresponds to a local representation of the negative sample $\mathbf{x}'$ drawn from $\tilde{\mathbb{P}} = \mathbb{P}$. In practice, given a batch of sentences, we can treat each sentence and its local context representations as positive examples, and treat all the local context representations from other sentences in this batch as negative examples. Through maximizing $\widehat{\mathcal{I}}^{JSD}$, $\mathcal{E}_\theta(\mathbf{x})$ is encouraged to have high

MI with its local context representations. This will push the encoder to capture the unique information that is shared across all local segments of the input sentence while different from other sentences, which leads to expressive sentence representation.

4 Experiment

Following previous works (Reimers and Gurevych, 2019; Hill et al., 2016), we conduct evaluation on two kinds of tasks:

- Unsupervised Semantic Textual Similarity (STS): These tasks measure a model's performance on sentence similarity prediction. The results are good indicators of effectiveness on unsupervised tasks such as clustering and semantic search.
- Supervised downstream tasks: These tasks measure the effectiveness of sentence embeddings on downstream supervised tasks.

We consider two groups of baselines. The first group corresponds to models trained with unlabeled sentences. This includes the **unigram-TFIDF** mdoel, the **Paragraph Vector** model (Le and Mikolov, 2014), the Sequential Denoising Auto-Encoder (**SDAE**) (Hill et al., 2016), the **Skipthought** (Kiros et al., 2015) model and the **FastSent** (Hill et al., 2016) model, all trained on the Toronto book corpus (Zhu et al., 2015) consisted of 70M sentences. We also consider representing sentence with the average of Glove embeddings, the average of the last layer representations of BERT, and the [CLS] embedding of BERT, respectively. The second group consists of models trained on labeled NLI data including **InferSent** (Conneau et al., 2017), Universal Sentence Encoder (**USE**) (Cer et al., 2018), and sentence BERT (**SBERT-NLI**) (Reimers and Gurevych, 2019). uncased-BERT-base is used for all BERT-related models including IS-BERT.

4.1 Unsupervised Evaluations

For STS tasks, we conduct evaluations on two types of datasets. 4.1.1 shows the results on seven STS benchmarks, which include texts from various domains and are commonly used for evaluating general-purpose sentence representations. 4.1.2 further shows the results on the challenging Argument Facet Similarity (AFS) dataset (Misra et al., 2016), which is more suitable for evaluating model's performance in domain-specific scenarios. For all methods compared in this subsection, cosine-similarity of the obtained sentence embeddings is used to compute their similarity, avoiding the time-consuming regression evaluation as with original BERT-based models.

4.1.1 Unsupervised STS

Experimental Details: We evaluate our model on the STS tasks 2012-2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), the STS benchmark (STSb for short) (Cer et al., 2017), and the SICK-Relatedness dataset (Marelli et al., 2014). The corresponding datasets consist of sentence pairs with labels from 0 to 5 indicating the semantic relatedness. As pointed out in Reimers et al. (2016) that Pearson correlation is badly suited for STS, Spearman's rank correlation between the cosine-similarity of the sentence embeddings and the gold labels is instead used as the evaluation metric.

Following SBERT which was trained on the combination of the SNLI (Bowman et al., 2015) and the Multi-Genre NLI (MultiNLI) (Williams et al., 2018) datasets with gold labels, we train IS-BERT on the same collection of sentences, but without using the label information. We denote our model in this setting as **IS-BERT-NLI**. SNLI contains 570,000 sentence pairs annotated with the labels *contradiction*, *entailment*, and *neutral*. MultiNLI contains 430,000 sentence pairs which are from a wider range of genres of spoken and written texts. Note that IS-BERT-NLI was only trained on the 1 million pairs with the labels excluded.

We strictly follow the evaluation process of Reimers and Gurevych (2019) to make our results comparable to theirs. The development set of STSb is used for hyperparameter tuning. On all datasets, we apply three CNNs with window sizes 1, 3, and 5. Each CNN has 256 filters, making the final concatenated token representations of size 256*3. The learning rate is set to 1e-6 and the batch size is 32.

Results: Table 1 presents the results. Models are grouped into two sets by the nature of the data on which they were trained. We make the following observations. First, BERT out-of-the-box gives surely poor results on STS tasks. Both the [CLS] and averaging BERT embeddings perform worse than averaging GloVe embeddings. Second, all supervised methods outperform other unsupervised baselines, which suggests that the knowledge obtained from supervised learning on NLI can be well transfered to these STS tasks. This is also indicated in previous works (Hill et al., 2016; Cer et al., 2018)

Table 1: Spearman rank correlation ρ between the cosine similarity of sentence representations and the gold labels for various Semantic Textual Similarity (STS) tasks. $\rho * 100$ is reported in this paper. All BERT-based models use uncased-BERT-base as the transformer encoder. Results of baselines marked with [†] are extracted from (Hill et al., 2016) (with a different number of decimal places). Results of baselines marked with [‡] are extracted from (Reimers and Gurevych, 2019).

that the dataset on which sentence embeddings are trained significantly impacts their performance on STS benchmarks and they found NLI datasets are particularly useful.

On average, IS-BERT-NLI significantly outperforms other unsupervised baselines. It even outperforms InferSent trained on labeled SNLI and MultiNLI datasets in 5 out of 7 tasks. This demonstrates the effectiveness of the proposed training strategy. USE and SBERT are the top two performers. As expected, IS-BERT-NLI is in general inferior to these two supervised baselines because they are trained with the particularly useful labeled NLI data as well as large unlabeled data, but IS-BERT-NLI also achieves performance comparable to them in certain scenarios, e.g., STS13 and STS15, even it was only trained on the NLI unlabeled data.

4.1.2 Argument Facet Similarity

We have shown in Section 4.1.1 that the proposed model substantially outperforms other unsupervised methods. However, the STS benchmarks in Section 4.1.1 are not domain or task specific, and it has been shown that they favor the supervised methods trained on NLI more (Hill et al., 2016; Cer et al., 2018). In this subsection, we further conduct evaluation on an Argument Facet Similarity (AFS) dataset (Misra et al., 2016) which is more task-specific. Models are compared in a setting without task or domain-specific labeled data. In this setting, SBERT needs to be trained on NLI and transferred to the AFS dataset for evaluation. Since IS-BERT does not require labeled data, it can be directly trained on the task-specific raw texts. We denote our model in this setting as **IS-BERT-AFS**.

Experimental Details: The AFS corpus annotated 6,000 sentential argument pairs from social media dialogs on three controversial topics: *gun control*, *gay marriage*, and *death penalty*. Each argument pair was annotated on a scale from 0 (different) to 5 (equivalent). To be considered similar, argument must not only make similar claims, but also provide a similar reasoning. In addition, the lexical gap between the sentences in AFS is much larger, making it a more challenging task compared to STS tasks. The proposed IS-BERT-AFS is trained on sentences from all three domains. It uses CNNs with window size set to 3, 5, and 7, as the average sentence length is longer in AFS. Other hyperparameters are the same as in Section 4.1.1.

Results: Table 2 presents the results. We also provide the Pearson correlation r to make the results comparable to (Reimers and Gurevych, 2019). The models in the top group are trained without task-specific labeled data. IS-BERT-AFS clearly outperforms other models in this setting. One major finding is that SBERT-NLI and InferSent, the models trained on the labeled NLI data, perform the worst on this task. We believe this is due to the fact that the NLI corpus significantly differs from the AFS dataset. An improper training set could lead to extremely bad performance in the unsupervised transfer learning setting, which supports our claim that supervised sentence embedding methods are problematic to port to new domains when the distribution of target data (i.e. AFS) differs significantly from the pretraining one (i.e. NLI).

We also show results of BERT and SBERT in another two settings when trained with task-specific labeled data as in (Reimers and Gurevych, 2019). When trained on all topics (10-fold cross-validation), both BERT and SBERT easily achieve scores above 70, while we observe large performance drop when they are trained in a cross-topic setting (i.e. train on two topics of AFS and evaluate on the third topic). The even larger performance drop of SBERT when trained on NLI (ρ from 74.13 to 15.84) again demonstrates that the domain-relatedness between the training set and the target test set has a huge impact on supervised sentence embedding learning, as a result, the supervised methods are problematic to be applied to downstream tasks of domains without labeled data.

Model	r	ρ
Without task-specific labeled data

4.2 Supervised Evaluations

4.2.1 SentEval

Experimental Details: Here we evaluate the sentence representations in IS-BERT on a set of supervised tasks. Following Reimers and Gurevych (2019), we use a set of classification tasks that covers various types of sentence classification, including sentiment analysis (**CR** (Hu and Liu, 2004), **MR** (Pang and Lee, 2005) and **SST** (Socher et al., 2013)), question-type classification (**TREC** (Li and Roth, 2002)), subjectivity classification (**SUBJ** (Pang and Lee, 2004)), opinion polarity classification (**MPQA** (Wiebe et al., 2005)) and paraphrase identification (**MRPC** (Dolan et al., 2004)).

Since these tasks are more domain-specific, we train IS-BERT on each of the task-specific dataset (without label) to produce sentence embeddings, which are then used for training downstream classifiers. We denote this setting as **IS-BERT-task**. SentEval (Conneau and Kiela, 2018) toolkit is used to automate the evaluation process. It takes sentence embeddings as fixed input features to a logistic regression classifier, which is trained in a 10-fold cross-validation setup and the prediction accuracy is computed for the test-fold.

Results: Table 3 presents the results. Overall, supervised methods outperform unsupervised baselines. This indicates that pretraining sentence encoder with high-quality labeled data such as NLI is helpful in a supervised transfer learning setting. Note that in this task, SentEval fits a logistic regression classifier to the sentence embeddings with labels of the downstream tasks. Thus, the models that achieve good results on this task do not necessarily work well on unsupervised tasks such as clustering. As shown in Section 4.1.2, training on NLI could lead to extremely bad performance on downstream unsupervised tasks when the domain data significantly differs from NLI.

IS-BERT-task is able to outperform other unsupervised baselines on 6 out of 7 tasks, and it is on par with InferSent and USE which are strong supervised baselines trained on NLI task. This demonstrates the effectiveness of the proposed model in learning domain-specific sentence embeddings.

4.2.2 Supervised STS

Experimental Details: Following Reimers and Gurevych (2019), we use the STSb (Cer et al., 2017) dataset to evaluate models' performance on the supervised STS task. This dataset includes 8,628 sentence pairs from the three categories *cap-*

tions, *news*, and *forums*. It is divided into train (5,749), dev (1,500) and test (1,379).

We compare IS-BERT to the state-of-the-art BERT and SBERT methods on this task. BERT is trained with a regression head on the training set with both sentences passed to the network (BERT-STSb). SBERT is trained on the training set by encoding each sentence separately and using a regression objective function.

We experiment with two setups: 1) Without self-supervised learning with the max-MI objective in Eq.3, IS-BERT is directly used for encoding each sentence and fine-tuned on the training set with a regression objective. We denote this setting as **IS-BERT-STSb (ft)**. 2) IS-BERT is first trained on the training set without label using the self-supervised learning objective. Then, it is fine-tuned on the labeled data with a regression objective. We denote this setting as **IS-BERT-STSb (ssl+ft)**. At the prediction time, cosine similarity is computed between each pair of sentences.

Results: The results are depicted in Table 4. BERT and SBERT performs similarly on this task. IS-BERT-STSb (ssl+ft) outperforms both baselines. Another interesting finding is that when directly fine-tuning IS-BERT on the labeled data, it performs much worse than SBERT. The only difference between them is that IS-BERT-STSb(ft) uses CNN layers with mean pooling to obtain sentence embeddings while SBERT simply uses a pooling layer to do so. This suggests that a more complex sentence encoder does not automatically lead to better sentence embeddings. However, when comparing IS-BERT-STSb(ft) with IS-BERT-STSb(ssl+ft), we observe that adding self-supervised learning before fine-tuning leads to more than 10% performance improvements. This indicates that the our self-supervise learning method can also be used as an effective domain-adaptation approach before fine-tuning the network.

5 Conclusions

In this paper, we proposed the IS-BERT model for unsupervised sentence representation learning with a novel MI maximization objective. IS-BERT outperforms all unsupervised sentence embedding baselines on various tasks and is competitive with supervised sentence embedding methods in certain scenarios. In addition, we show that sentence

BERT (SBERT), the state-of-the-art supervised method, is problematic to apply to certain unsupervised tasks when the target domain significantly differs from the dataset it was trained on. IS-BERT achieves substantially better results in this scenario as it has the flexibility to be trained on the task-specific corpus without label restriction. In the future, we want to explore semi-supervised methods for sentence embedding and its transferability across domains.

Abstract

Phrase alignment is the basis for modelling sentence pair interactions, such as paraphrase and textual entailment recognition. Most phrase alignments are compositional processes such that an alignment of a phrase pair is constructed based on the alignments of their child phrases. Nonetheless, studies have revealed that non-compositional alignments involving long-distance phrase reordering are prevalent in practice. We address the phrase alignment problem by combining an unordered tree mapping algorithm and phrase representation modelling that explicitly embeds the similarity distribution in the sentences onto powerful contextualized representations. Experimental results demonstrate that our method effectively handles compositional and non-compositional global phrase alignments. Our method significantly outperforms that used in a previous study and achieves a performance competitive with that of experienced human annotators.

1 Introduction

Phrase alignment is a fundamental problem in modelling the interactions between a pair of sentences, such as paraphrase identification, textual entailment recognition, and question answering (Das and Smith, 2009; Heilman and Smith, 2010; Wang and Manning, 2010). Phrase alignment generally adheres to compositionality, in which a phrase pair is aligned based on the alignments of their child phrases. Nonetheless, non-compositional alignments involving long-distance phrase reordering are prevalent in practice (Burkett et al., 2010; Heilman and Smith, 2010; Arase and Tsujii, 2017). Figure 1 shows an example of phrase alignment in which phrases of the same colours are alignable, *i.e.* they are phrasal paraphrases. The alignment of 'antivirus vaccines' and 'vaccines against the virus' is compositional, as supported by alignments of their child nodes although their orderings are reversed. Similarly, the alignment of their parents τ_2^s and τ_2^t is compositional. By contrast, the alignment of τ_1^s and τ_1^t is non-compositional in relation to the alignment of τ_2^s and τ_2^t; although τ_1^t and τ_2^t are siblings, τ_1^s is not a sibling of τ_2^s, *i.e.* not in the scope of the parent node of τ_2^s. To treat such a long-distance correspondence in non-compositional alignment, one has to consider candidate phrases outside the local scope and potentially the entire sentence.

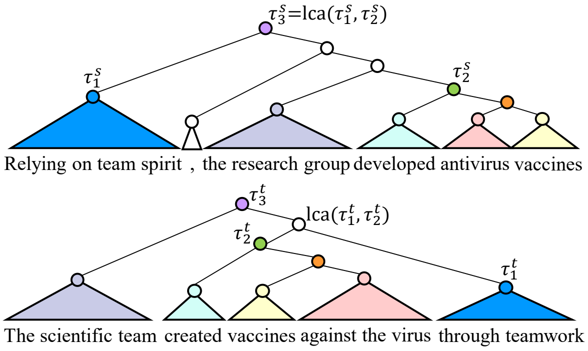

Figure 1: Phrase alignments by the proposed method (phrases of the same colour are paraphrases)

In this study, we address the phrase alignment problem by combining a tree mapping algorithm with phrase representation modelling. We treat compositional alignment by an algorithm for an *unordered* tree mapping (Zhang, 1996). For the algorithm to work, definition of the edit cost (*i.e.* dissimilarity between phrases) is crucial. We propose a novel phrase representation, by which the edit cost is defined, based on contextualized representations by the bidirectional encoder representations from transformers (BERT) (Devlin et al., 2019). The proposed phrase representation models the similarity distribution in the entire sentence, thereby allowing the algorithm to be extended to treat non-compositional global alignments.

Phrase alignment can be difficult even for humans because there is unavoidable subjectivity in

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1611–1623,
November 16–20, 2020. ©2020 Association for Computational Linguistics

acceptable semantic discrepancies between paraphrases. Our experimental results indicate that the proposed method achieves 95.7% of the alignment quality of trained human annotators for phrase alignment in paraphrase sentence pairs.

The contributions of this study are twofold. First, we formalise the compositional phrase alignment problem as an unordered tree mapping. Second, we propose a phrase representation model that allows non-compositional global alignments.

2 Related Work

2.1 Tree Mapping and Phrase Alignment

Ordered tree mapping has been employed to estimate the similarity of a pair of sentences for its ability to align syntactic trees (Punyakanok et al., 2004; Alabbas and Ramsay, 2013; Yao et al., 2013; McCaffery and Nederhof, 2016). However, it is too restrictive in that the order of the aligned phrases in the sentences must be the same. Previous studies extended the algorithm to adapt the edit costs (Bernard et al., 2008; Mehdad, 2009; Alabbas and Ramsay, 2013) and edit operations (Heilman and Smith, 2010; Wang and Manning, 2010) to specific tasks. In contrast, the unordered tree mapping that we employ in this study is sufficiently flexible to assure identification of optimal compositional phrase alignments.

Parallel parsing also involves phrase alignment in its parsing process. As the tree isomorphism assumption is too restrictive, previous studies have employed various relaxation techniques that prefer but do not force synchronisation. Burkett et al. (2010) used weakly synchronised grammar, and Das and Smith (2009) used quasi-synchronous grammars (Smith and Eisner, 2006). Choe and McClosky (2015) used dual decomposition to encourage agreement between two parse trees. All of these methods allow excess flexibility beyond compositionality in alignment. Rule extraction for tree transducers also involves phrase alignments (Martínez-Gómez and Miyao, 2016) but disregards phrase boundaries to maximise the coverage of extracted rules. In contrast, the phrase alignment problem addressed in our study adheres to syntactic structures.

2.2 Phrase Representation Generation

Researchers have proposed specialised phrase representations for specific tasks (Arase and Tsujii, 2019; Yin et al., 2020) on top of contextualised representations. In this study, we propose dedicated phrase representations for the alignment problem. Before contextualised representation, studies considered word alignment distributions for modelling semantic interactions between a pair of sentences (He and Lin, 2016; Parikh et al., 2016; Chen et al., 2017). We agree with their intuition that the pairwise similarities alone are not good enough to define the cost of alignment. In case there are other similar phrases, their pairwise similarities have to be properly adjusted. This adjustment is crucial for treating non-compositional global alignment.

3 Phrase Alignment Method

3.1 Preliminaries and Notation

We refer to one of the paraphrasal sentences as the *source*, s, and the other as the *target*, t. Superscripts s and t represent source and target, respectively. The syntactic trees of the source and target, $T^s = \{\tau_i^s\}_i$ and $T^t = \{\tau_j^t\}_j$, determine the phrase structures; τ_i^s and τ_j^t are the source and target phrases. The alignments of their phrases are $\mathbb{H} = \{\mathbb{h}_i = \langle \tau_i^s, \tau_i^t \rangle\}_i$. We interchangeably use the subscript of a node as the index of the alignment or the index of the node in a tree whenever the meaning is apparent from the context. A phrase can align to an empty node $\tau_\emptyset$ ($\tau_\emptyset \notin T$), which is called the *null* alignment.

We define functions to traverse a tree: $\mathrm{ds}(\tau)$ derives descendant nodes of τ, and $\mathrm{lca}(\tau_i, \tau_j)$ derives the lowest common ancestor of τ_i and τ_j. Additionally, function $\deg(T)$ computes the maximum depth of T, and $|\cdot|$ counts the number of elements in a set; *e.g.* $|T|$ is the number of nodes in T.

3.2 Problem Definition

Based on Arase and Tsujii (2017), we reformalise conditions of legitimacy as a set of compositional phrase alignments $\mathbb{H}_L$.

Definition 3.1. *Legitimacy conditions consist of the following:*

Consistency *In $\mathbb{H}_L$, a phrase ($\neq \tau_\emptyset$) in the source tree is aligned with at most one phrase ($\neq \tau_\emptyset$) in the target tree, and vice versa.*

Monotonicity *For $\langle \tau_i^s, \tau_i^t \rangle, \langle \tau_j^s, \tau_j^t \rangle \in \mathbb{H}_L$, $\tau_i^s \in ds(\tau_j^s)$ iff $\tau_i^t \in ds(\tau_j^t)$.*

Familiness *For $\langle \tau_1^s, \tau_1^t \rangle$, $\langle \tau_2^s, \tau_2^t \rangle$, $\langle \tau_3^s, \tau_3^t \rangle$ in $\mathbb{H}_L$,* *lca*(τ_1^s, τ_2^s) *is a proper ancestor*[1] *of* τ_3^s *iff* *lca*(τ_1^t, τ_2^t) *is a proper ancestor of* τ_3^t.

The consistency condition ensures one-to-one alignment. The monotonicity condition regulates the retainment of the ancestor-descendant relation in the source and target sides. The familiness condition realises compositionality in the language, which constrains such that two separate subtrees of T^s should be aligned to two separate subtrees of T^t.[2] In other words, the familiness condition prohibits a node in the source subtree to align to a node outside that target subtree. In Figure 1, $\langle\tau_1^s, \tau_1^t\rangle$ violates the familiness condition in relation to $\langle\tau_2^s, \tau_2^t\rangle$ and $\langle\tau_3^s, \tau_3^t\rangle$ because τ_3^s is not a proper ancestor of $\text{lca}(\tau_1^s, \tau_2^s)$, whereas τ_3^t is a proper ancestor of $\text{lca}(\tau_1^t, \tau_2^t)$.

We define non-compositional alignments $\mathbb{H}_{\text{nc}}$ as alignments that satisfy the legitimacy conditions internally but do not satisfy them against $\mathbb{H}_L$. For example, the alignment $\langle\tau_1^s, \tau_1^t\rangle$ in Figure 1 is compositionally composed and satisfies the legitimacy conditions for its internal alignments. However, it does not satisfy the legitimacy conditions against alignments of $\langle\tau_2^s, \tau_2^t\rangle$ and $\langle\tau_3^s, \tau_3^t\rangle$ for violation of the familinesss condition. We allow $\mathbb{H}_{\text{nc}}$ to be added into $\mathbb{H}_L$ if it is compatible;

Definition 3.2. $\mathbb{H}_{nc}$ *is compatible with* $\mathbb{H}_L$ *iff for all* $\langle\tau_i^s, \tau_i^t\rangle \in \mathbb{H}_{nc}$ $(\tau_i^s, \tau_i^t \neq \tau_\emptyset)$*, both* $\langle\tau_i^s, \tau_\emptyset\rangle$ *and* $\langle\tau_\emptyset, \tau_i^t\rangle$ *are in* $\mathbb{H}_L$.

When the compatibility condition is met, $\mathbb{H}_{\text{nc}}$ can be safely added to $\mathbb{H}_L$ by complementing null alignments without violating the consistency condition. We implement this process by a simple post-processing step (Section 3.4).

3.3 Compositional Alignment

Finding the optimal set of legitimate compositional alignments (Definition 3.1) is equivalent to finding the minimum cost of constrained tree mapping (Zhang, 1996), which belongs to the problem of *unordered* tree mapping (Bille, 2005). The edit operations of re-labelling, deletion, and insertion correspond to alignment of two nodes, null alignment of a source node, and null alignment of a target node, respectively. Although the unordered tree mapping problem is in general MAX SNP-hard (Zhang and Jiang, 1994), the constrained tree edit distance (CTED) algorithm (Zhang, 1996) achieves polynomial time complexity using the familiness condition. In essence, the CTED algorithm reduces the unordered tree mapping problem to a maximum matching problem by the familiness condition. The reduction enables faster dynamic programming of $\mathcal{O}(|T^s||T^t|(\deg(T^s) + \deg(T^t))\log(\deg(T^s) + \deg(T^t)))$. Details of the CTED algorithm are described in detail in Appendix B.

To apply CTED for phrase alignment, the edit cost function $\gamma(\cdot) \to \mathbb{R}$ is the key, which should satisfy the properties of a proper distance metric. This function evaluates the *dissimilarity* of a phrase pair, for which we propose a phrase representation model (Section 4). We use cosine distance as $\gamma(\cdot) \in [0, 2.0]$ because of its prevalence in measuring dissimilarity between representations. However, it is not a proper distance metric because it does not satisfy the triangle inequality property. In future work, we will investigate alternative distance metrics.

We also need to estimate the cost of a null alignment. It is not trivial to generate representation of such an empty phrase; hence, we decided to use a constant cost $\lambda_\emptyset$, *i.e.*,

$$\gamma(\langle\tau^s, \tau_\emptyset\rangle) = \gamma(\langle\tau_\emptyset, \tau^t\rangle) = \lambda_\emptyset \in [0, 2.0].$$

The appropriate value of $\lambda_\emptyset$ is determined using a development set.

3.4 Non-compositional Alignment

We designed top-down post-processing for non-compositional alignment so that the legitimacy conditions (Definition 3.1) will be maximally satisfied in the final alignments. As Algorithm 3.1 shows, we add a set of alignments $\mathbb{H}_{\text{nc}}$ that compose the non-compositional alignments into $\mathbb{H}_L$ when they are compatible. Our post-processing aligns all the coloured phrase pairs in Figure 1 by allowing $\langle\tau_1^s, \tau_1^t\rangle$ and its descendant alignments.

Algorithm 3.1 takes matrices of edit distance and corresponding operations D and A as input, which are obtained by CTED. $D[i+1][j+1]$ and $A[i+1][j+1]$ store the total cost and operations, respectively, to compose alignment of $\langle\tau_i^s, \tau_j^t\rangle$. Note that index 0 is reserved for null alignments. The algorithm sorts null alignments in $\mathbb{H}_L$ in descending order of the span covering the source and target phrases (line 2). For each null alignment, the algorithm finds candidates of non-compositional

---

[1] A proper ancestor of a node i is any node j such that node j is an ancestor of node i and j is not the same node as i.

[2] Our definition is less constrained than that in Arase and Tsujii (2017) as discussed in Appendix A.

Algorithm 3.1 Non-compositional alignment

```
Input: Legitimate alignments $\mathbb{H}_L$ and matrices of tree edit distance and corresponding operations $D$ and $A$
 1: $\mathbb{H}_\emptyset \leftarrow \{\langle \tau^s, \tau_\emptyset \rangle, \langle \tau_\emptyset, \tau^t \rangle | \mathbb{H}_L\}$
 2: Sort $\mathbb{H}_\emptyset$ by descending order of phrase span
 3: for all $\langle \tau_i^s, \tau_j^t \rangle \in \mathbb{H}_\emptyset$ do
 4:   if $\tau_j^t = \tau_\emptyset$ then                ▷ target side is $\tau_\emptyset$
 5:     for all $k \in \underset{\ell}{\operatorname{argmin}}\, D[i+1][\ell]$ do
 6:       if IsCompatible($A[i+1][k], \mathbb{H}_L$) then UpdateAlignments($A[i+1][k], \mathbb{H}_L, \mathbb{H}_\emptyset$)
 7:   else
 8:     Do the same for the source side
 9: function IsCompatible($\hat{A}, \mathbb{H}_L$)
10:   for all $\langle \tau_i^s, \tau_j^t \rangle \in \hat{A}$ where $\tau_i^s, \tau_j^t \neq \tau_\emptyset$ do
11:     if $\langle \tau_i^s, \tau_k^t \rangle \in \mathbb{H}_L$ or $\langle \tau_l^s, \tau_j^t \rangle \in \mathbb{H}_L$ where $\tau_k^t, \tau_l^s \neq \tau_\emptyset$ then return False
12:   return True
13: function UpdateAlignments($\hat{A}, \mathbb{H}_L, \mathbb{H}_\emptyset$)
14:   for all $\langle \tau_i^s, \tau_j^t \rangle \in \hat{A}$ where $\tau_i^s, \tau_j^t \neq \tau_\emptyset$ do
15:     $\mathbb{H}_L \leftarrow \mathbb{H}_L \cup \{\langle \tau_i^s, \tau_j^t \rangle\}$
16:     Remove $\langle \tau_i^s, \tau_\emptyset \rangle$ from $\mathbb{H}_L$ and $\mathbb{H}_\emptyset$
17:     Remove $\langle \tau_\emptyset, \tau_j^t \rangle$ from $\mathbb{H}_L$ and $\mathbb{H}_\emptyset$
```

alignments achieving the minimum cost (line 5). Then, using the IsCompatible function, it checks whether a non-compositional alignment and its descendant alignments are compatible with the current set of alignments. If so, they are added to $\mathbb{H}_L$ by the UpdateAlignments function, replacing null alignments $\langle \tau_i^s, \tau_\emptyset \rangle$ and $\langle \tau_\emptyset, \tau_j^t \rangle$ in $\mathbb{H}_L$ with non-compositional alignment $\langle \tau_i^s, \tau_j^t \rangle$.

Our post-processing is a heuristic to maximally satisfy the legitimacy conditions, as finding the best combination of non-compositional alignments is computationally intractable.[3] Our method ensures that non-compositional alignments improve the alignment cost by only allowing those with minimum cost.

4 Phrase Representation for Alignment

We propose a phrase representation model on top of the pre-trained BERT. One of the most common methods for obtaining a phrase representation from BERT is pooling outputs corresponding to tokens in the phrase. However, as we empirically show in Section 6, this method exhibits an unsatisfactory ability for modelling the similarity distribution in a sentence pair. Hence, we propose a novel method for generating phrase representations suitable for the phrase alignment problem.

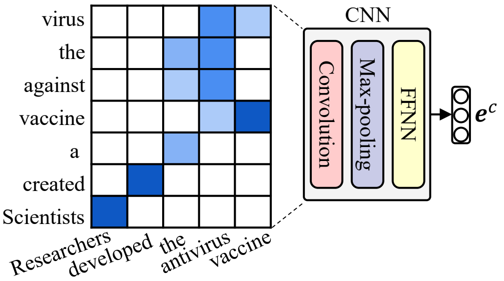

Figure 2: Modelling similarity distribution (shades of the matrix represent word similarities)

Problem Statement and Approach The estimate of a phrase pair's similarity for alignment is unique, because their similarity should depend on similarities of other phrases in the sentence pair. That is, even if the pairwise similarity of τ_i^s and τ_j^t is high, the similarity score should be lowered if there is a phrase in the source sentence that is more similar to τ_j^t. Hence, we generate a phrase representation that reflects the similarity distribution within the sentence pair; this is particularly important for non-compositional alignments to find a globally plausible alignment pair.

We first generate a representation of the similarity distribution within the sentence pair. We then transform the phrase representation obtained from BERT, referring to the representation of the similarity distribution using an attention mechanism.

Similarity Distribution Modelling We regard outputs of the last layer $\boldsymbol{h} \in \mathbb{R}^b$ of BERT as token representations, where b is the hidden size determined by the BERT pre-training settings. Using the token representations, we generate a representation of similarity distribution $\boldsymbol{e}^c \in \mathbb{R}^b$ (Figure 2).

We first compute cosine similarities between token representations of the sentence pair and obtain the similarity matrix. We then encode the similarity matrix using a convolutional neural network (CNN) and obtain $\boldsymbol{e}^c$, called the *SimMatrix* representation. Our CNN is shallow, under the assumption that a shallow model is sufficient to capture latent features in SimMatrix. A shallow model also allows training with a smaller corpus while fine-tuning BERT. The CNN consists of a one-channel convolution layer activated by the rectified linear unit function, a max-pooling layer, and a fully connected feed-

---

[3] Arase and Tsujii (2017) do not assure maximal satisfaction of the legitimacy conditions.

forward neural network (FFNN).

Representation Generation We obtain a basic representation of τ^s for span i to j by simply pooling the token representations obtained from BERT: $\boldsymbol{e}^s = \text{pool}(\boldsymbol{h}_i, \dots, \boldsymbol{h}_j) \in \mathbb{R}^b$. Similarly, a basic representation $\boldsymbol{e}^t$ of target phrase τ^t is obtained. We then transform $\boldsymbol{e}^t$ to reflect the SimMatrix representation $\boldsymbol{e}^c$. For this, we use an attention mechanism as shown in Figure 3, which has the same architecture as the Transformer (Vaswani et al., 2017). The attention layer consists of multi-head attention and FFNNs. Our model takes $\boldsymbol{e}^c$, $\boldsymbol{e}^s$, and $\boldsymbol{e}^t$, and transforms $\boldsymbol{e}^t$ into $\hat{\boldsymbol{e}}^t \in \mathbb{R}^b$.

Loss Function To train the phrase representation model, we use a triplet margin loss:

$$\mathcal{L}(\boldsymbol{e}^s, \hat{\boldsymbol{e}}^t_p, \hat{\boldsymbol{e}}^t_n) = \max\{\|\boldsymbol{e}^s - \hat{\boldsymbol{e}}^t_p\|_2 - \|\boldsymbol{e}^s - \hat{\boldsymbol{e}}^t_n\|_2 + \delta, 0\}, \quad (1)$$

where $\hat{\boldsymbol{e}}^t_p$ and $\hat{\boldsymbol{e}}^t_n$ are transformed representations of positive (alignable) and negative (unalignable) pairs, respectively, and δ is a margin. Intuitively, the loss function makes representations of paraphrase pairs closer, whereas those of non-paraphrase pairs are more distant. For negative examples, we randomly sample phrases that are separated by more than one hop from the alignable pair in T^t. At an inference, we transform the basic representation of a target phrase by our model and compute the cost $\gamma(\boldsymbol{e}^s, \hat{\boldsymbol{e}}^t)$.

We also tried models that discriminate alignable phrases or minimise the cosine similarity of an alignable pair. However, they were all inferior to the triplet margin loss.

5 Experiment Setting

5.1 Creation of ESPADA

To train our phrase representation model, we need a corpus with phrase alignments annotated on sentence pairs. We extended the Syntactic Phrase Alignment Dataset for Evaluation (SPADE) (Arase and Tsujii, 2018), creating the Extended Syntactic Phrase Alignment DAtaset (ESPADA). Following the same annotation scheme, we annotated $1,916$ sentence pairs sampled from NIST OpenMT[4] corpora. ESPADA is now the largest annotation corpus for this problem and will be released by the Linguistic Data Consortium (LDC) soon.

A linguist first annotated gold-standard syntactic trees on paraphrases based on the head-driven phrase structure grammar. Then, three native or near-native English speakers annotated the $1,916$ paraphrases in parallel to identify phrasal paraphrases; *i.e.* the total number of annotated sentences is $5,748$. Before the formal annotation, there was a training phase to improve annotation agreement; all annotators annotated trial samples.[5] One of the authors inspected the results and gave advice on any misunderstandings of the annotation guidelines. Appendix C provides further details of the annotation process.

Table 1 shows the statistics for ESPADA and SPADE; $\sim$ 252k phrasal paraphrases were identified, among which $\sim$ 81k unique pairs were agreed upon by at least two annotators and $\sim$ 66k unique pairs were agreed upon by all annotators. The last two rows show, in ESPADA and SPADE, 3.2% to 4.7% of pairs did not satisfy the monotonicity condition, and 1.1% to 1.4% of triplets did not satisfy

---

[5] excluded from the formal annotation set

	ALIR (%)	ALIP (%)	ALIF (%)
ESPADA	93.3	90.2	91.7
SPADE (dev)	93.5	91.4	92.4
SPADE (test)	92.3	90.3	91.3

Table 2: Human performance

the familiness condition in alignments agreed upon by at least two annotators. Note that the monotonicity and familiness conditions are defined on relations of alignment pairs and triples, respectively; hence, these percentages do not mean that these percentages of alignments are non-compositional.

5.2 Evaluation Metrics and Upper Bounds

We used SPADE as an evaluation corpus; Table 1 shows statistics for its development (dev) and test sets. As evaluation metrics, we used alignment recall (ALIR), alignment precision (ALIP), and alignment F-measure (ALIF) (Arase and Tsujii, 2017, 2018). ALIR evaluates how gold-standard alignments can be replicated by automatic alignments, and ALIP measures how automatic alignments overlap with alignments identified by at least one annotator:

$$\mathrm{ALIR} = \frac{|\{\mathbb{h} | \mathbb{h} \in \mathbb{H}_a \wedge \mathbb{h} \in \mathbb{G} \cap \mathbb{G}'\}|}{|\mathbb{G} \cap \mathbb{G}'|},$$

$$\mathrm{ALIP} = \frac{|\{\mathbb{h} | \mathbb{h} \in \mathbb{H}_a \wedge \mathbb{h} \in \mathbb{G} \cup \mathbb{G}'\}|}{|\mathbb{H}_a|},$$

where $\mathbb{H}_a$ is a set of automatic alignments, and $\mathbb{G}$ and $\mathbb{G}'$ are those obtained by two respective annotators. ALIF computes the harmonic mean of ALIR and ALIP. Because SPADE provides alignments by three annotators, there are three combinations for $\mathbb{G}$ and $\mathbb{G}'$. The final ALIR, ALIP, and ALIF values are calculated by taking the averages.

Note that these evaluation metrics count null alignments also; hence, ALIP performs differently from a general precision metric in that stricter models will have lower ALIP scores. This is because a stricter model aligning only a small number of phrases ($\neq \tau_\emptyset$) increases the number of null alignments, making $|\mathbb{H}_a|$ larger.

The agreement among the human annotators can also be measured using ALIR, ALIP, and ALIF by regarding one annotator as a test and the other two as gold-standard and then taking averages. The scores for the trained annotators were consistent between ESPADA and SPADE as shown in Table 2. This indicates that phrase alignment is difficult even for humans because acceptable levels of semantic divergence in paraphrases cannot be perfectly controlled. Hence, we regard these human scores as upper bounds for ALIR, ALIP, and ALIF.

5.3 Comparison Method

As the comparison state-of-the-art syntactic phrase alignment method, we used Arase and Tsujii (2017). We re-implemented this method and compared the performance on aligning gold parse trees.

Additionally, we compared variations of our method via ablation studies. We investigated the effect of CTED by comparing it with alignments by a naive thresholding, which aligns phrases having cosine similarities above a threshold. The threshold was set to maximise the ALIF score on the SPADE development set.

To investigate the effect of our phrase representation model, we compared it with a simply fine-tuned BERT using Equation (1) but directly inputting basic phrase representations of $\boldsymbol{e}_p^t$ and $\boldsymbol{e}_n^t$. To investigate the effect of SimMatrix representation, we compared it with the representation of the `[CLS]` symbol (denoted as BERT+`[CLS]`). BERT defines its input to begin with the special symbol `[CLS]`, whose representation has been commonly used as a representation of sentence pair (Devlin et al., 2019). The assumption here is that BERT may learn to embed information of similarity distribution into `[CLS]` representation.

As a pre-trained model for generating phrase representations, we compared the fine-tuning approach with the feature-based approach, *i.e*. FastText (Bojanowski et al., 2017) and embeddings from language models (ELMo) (Peters et al., 2018). For all pre-trained models, we used mean-pooling to generate a basic phrase representation, which consistently outperformed max-pooling in our preliminary experiments.

5.4 Model Settings

We used the following public pre-trained models: 'crawl-300d-2M-subword'[6] as FastText, 'Original (5.5B)'[7] as ELMo, and 'BERT-Base, Uncased'[8] as BERT. We implemented our method and its variations using PyTorch[9] with libraries Transformers,[10]

AllenNLP,[11] and NetworkX[12] for solving the minimum cost maximum flow problem in CTED.

Our attention mechanism had eight heads; the other settings were the same as those for Transformer (Vaswani et al., 2017). Dropouts of 10% and 50% were applied to the BERT and ELMo outputs, respectively, as recommended in their papers. The CNN had a kernel size of three in the convolution layer and two for the pooling layer. The SimMatrix was padded with zeros for sentences shorter than the maximum sequence length of 128.[13]

All models used AdamW (Loshchilov and Hutter, 2019) as an optimiser, using default settings except on the learning rate. We tuned a few hyperparameters in our models to maximise the ALIF score on the development set of SPADE by a grid search. The value of null alignment cost $\lambda_{\emptyset}$ was searched for in the range $[0.05, 0.95]$ by intervals of 0.05, the margin δ in the loss function was searched for in $[0.2, 1.0]$ by intervals of 0.2, and the learning rate was chosen from among $1.0\mathrm{e}-5$, $3.0\mathrm{e}-5$, and $5.0\mathrm{e}-5$.

5.5 Training Settings

All experiments were conducted on an NVIDIA Tesla V100 GPU. We trained our phrase representation model using ESPADA. We simply used all phrase alignments by the three annotators, regarding all of them as equally reliable, *i.e.* each sentence pair has three sets of phrase alignments. We split the entire dataset into training and validation sets (90% and 10%, respectively) after randomly shuffling the sentence pairs, which prevents the same sentence pair from appearing in both sets. The batch size was 16. Training was terminated by validation-based early-stopping with patience 5 and minimum delta 0.005.

To alleviate the randomness effects in initialising the neural networks, we trained and evaluated the models 10 times with random seeds and report means of the evaluation scores with 95% confidence intervals. Further, we tested the significance of differences in means of the evaluation scores by the randomised test (Efron and Tibshirani, 1994). Throughout the paper, we present the best scores with a significance level of $< 1\%$ using a bold font.

6 Experiment Results

6.1 Overall Results

Table 3 compares the methods' performance. BERT+SimMatrix+CTED (last row) includes the full feature set; it transforms the phrase representation using SimMatrix representation and aligns phrases using CTED. This method performed the best overall, achieving an ALIF score of 87.4% with post-processing. This ALIF score is 95.7% of that achieved by humans (Table 2).

We investigated non-compositional alignments produced by BERT+SimMatrix+CTED with post-processing. We found that 0.1% of alignment pairs did not satisfy the monotonicity condition and 1.2% of alignment triplets did not satisfy the familiness condition. These non-compositional alignments cover 3.5% and 23.2% of those of the gold standard that did not satisfy the monotonicity and familiness conditions, respectively (as shown in Table 1).

Effect of CTED Algorithm and Post-Processing The middle and last sets of rows compare CTED-based and thresholding-based alignments. Thresholding-based alignment greedily aligns phrases by disregarding compositionality. In contrast, the pure CTED-based alignment only allows compositional alignments and makes all non-compositional alignments null. Even though CTED is much stricter than thresholding, it achieved competitive ALIF scores. The scores of the CTED-based alignment further improves by allowing non-compositional alignments by post-processing; ALIR, ALIP, and ALIF improved by 2.2, 3.4, and 2.8 percentage points on average, respectively.

Effect of Phrase Representation Model The last set of rows shows the performance of alignments by CTED with different phrase representation approaches. BERT+SimMatrix+CTED significantly outperformed BERT+CTED and BERT+`[CLS]`+CTED. The superiority of SimMatrix representation over `[CLS]` was more pronounced on alignments with post-processing. Although ALIF of BERT+`[CLS]`+CTED with post-processing achieved 94.4% of the human score, SimMatrix representation further improved it by 1.2 percentage points.

These results indicate that a phrase representation that explicitly models the similarity distribution is crucial for handling non-compositional alignments. We conjecture that SimMatrix representation has two effects in phrase alignment.

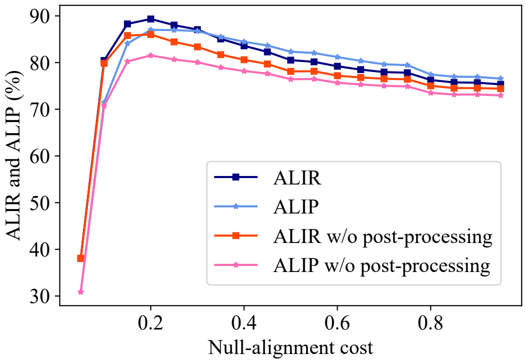

Figure 4: ALIR and ALIP on SPADE development set by null alignment cost

First, it encourages a null alignment in CTED when there is a more similar phrase beyond the local scope. *I.e.*, it implicitly relaxes the syntactic constraint when composing compositional alignments that could be too restrictive to handle non-compositional alignments. Second, the SimMatrix representation allows the post-processing to find a globally plausible alignment pair considering the entire similarity distribution.

Effect of Null-Alignment Cost Figure 4 presents ALIR and ALIP by the cost of null alignment $\lambda_\emptyset$ for BERT+SimMatrix+CTED with and without post-processing. A small $\lambda_\emptyset$ causes the method to align only a small number of phrases and produce a large number of null alignments. In contrast, a large $\lambda_\emptyset$ confuses the method by allowing a larger number of possible alignments. Both situations are harmful, but the former has a larger impact. This is because the constraint of CTED only allows a legitimate set of phrase alignments, which effectively prunes away incorrect alignments.

Figure 4 empirically confirms that the post-processing is effective in improving ALIR and ALIP scores; these scores with post-processing were always higher than those without. The same trend was also observed for BERT+CTED and for BERT+`[CLS]`+CTED. This occurs because our post-processing only allows non-compositional alignments of minimum cost. Hence, it also improves ALIR and ALIP scores when phrase representations are reliable.

6.2 Effects on Feature-Based Approaches

Table 4 shows the effect on performance when CTED is combined with the feature-based approaches: FastText, ELMo, and BERT without fine-tuning.[14] Specifically, we generated a phrase representation by simply mean-pooling token representations generated by these pre-trained models and aligned phrases by CTED or by thresholding. Note that these methods behave deterministically owing to the absence of neural network training.

BERT w/o fine-tuning+CTED achieved an ALIF score of 84.7% with post-processing, even though it only tunes the hyper-parameter $\lambda_\emptyset$. Although it scored lower than the proposed method (BERT+SimMatrix+CTED), the result is still encouraging for conducting phrase alignment in domains for which no corpora are available for training our phrase representation model.

Improvements in ALIR, ALIP, and ALIF scores by CTED over thresholding were much greater with FastText than with ELMo or BERT; it showed average gains of 6.0 to 8.6 percentage points. Improvements ranged from -0.8 to 2.7 for ELMo and from 0.2 to 1.3 percentage points for BERT. The CTED algorithm constrains alignments by the syntactic structures. FastText representations obviously do not retain such structural information. We conjecture that FastText-based alignment is com-

---

[14] Although we also applied our phrase representation model to feature-based approaches, the results were inferior to those given here, as discussed in Appendix D.

Method	$\lambda_\emptyset$	w/o post-processing ALIR (%)	w/o post-processing ALIP (%)	w/o post-processing ALIF (%)	w/ post-processing ALIR (%)	w/ post-processing ALIP (%)	w/ post-processing ALIF (%)
FastText+Thresh.	0.70	74.7	72.9	73.8	–	–	–
FastText+CTED	0.80	83.3	78.9	81.1	84.3	81.9	83.1
ELMo+Thresh.	0.50	81.7	80.7	81.2	–	–	–
ELMo+CTED	0.75	84.3	79.8	82.0	85.7	81.8	83.7
BERT w/o fine-tuning+Thresh.	0.80	82.3	79.6	80.9	–	–	–
BERT w/o fine-tuning+CTED	0.85	83.6	79.8	81.7	**85.9**	**83.5**	**84.7**

Table 4: ALIR, ALIP, and ALIF scores with feature-based approaches

pensated for by CTED. In contrast, the smaller improvements on ELMo and BERT imply that they obtain such structural information through their masked language model training. This result is consistent with previous studies (Hewitt and Manning, 2019; Jawahar et al., 2019; Reif et al., 2019) that confirmed that BERT learns syntactic structures.

7 Discussion and Future Work

In contrast to previous methods, ours can align phrases not only in paraphrasal sentence pairs but also in partially paraphrasal pairs. We plan to apply it to a comparable corpus of partial paraphrases and investigate the performance, with the aim of creating a large-scale syntactic and phrasal paraphrase dataset. We intend to expand our method to conduct forest alignments for making it robust against parsing errors, which are inevitable in handling large corpora. Further, as our method does not restrict input to syntactic trees but only assumes tree structures with arbitrary numbering (*e.g*. left-to-right post-order numbering) as input, we intend to try alignments of chunk-based trees, which is desirable for applications that process text fragments, *e.g*. those that perform information extraction.

Acknowledgments

Discussions on the tree mapping problem with Dr. Masakazu Ishihata and Mr. Taihei Oki have been illuminating. Dr. Joseph Tabolt, Mr. Michael Doerner, Ms. Tabatha Kobayashi, and Mr. Johannes Hoseth Klev made enormous contributions as annotators for creating ESPADA. We appreciate the anonymous reviewers for their insightful comments and suggestions to improve the paper. This work was supported by JST, ACT-I, Grant Number JPMJPR16U2, Japan.

Appendices

A Detailed Comparison with Previous Study

Arase and Tsujii (2017) include additional conditions that a legitimate set of compositional alignments should satisfy. One of these is called the root-pair containment condition, which requires the root nodes of trees to be aligned. This constraint firmly restricts their method such that it can only handle a paraphrasal sentence pair as input. Our method, by contrast, can align any pair of sentences, *i.e.* not only paraphrasal sentences but also sentences that are only partially paraphrasal.

Algorithm B.1 CTED algorithm (Zhang, 1996)

```
Input: Source and target trees $T^s$ and $T^t$
Output: Tree edit distance matrix $D[i][j]$, where
    $1 \leq i \leq |T^s|$ and $1 \leq j \leq |T^t|$
$D[0][0] = 0$, $F[0][0] = 0$
for all $i = 1$ to $|T^s|$ do          ▷ target side is $\tau_\emptyset$
    $F[i][0] = \sum_{k=1}^{n_i} D[i_k][0]$
    $D[i][0] = F[i][0] + \gamma(\langle \tau_i^s, \tau_\emptyset \rangle)$
for all $j = 1$ to $|T^t|$ do          ▷ source side is $\tau_\emptyset$
    $F[0][j] = \sum_{k=1}^{n_j} D[0][j_k]$
    $D[0][j] = F[0][j] + \gamma(\langle \tau_\emptyset, \tau_j^t \rangle)$
for all $i = 1$ to $|T^s|$ do
    for all $j = 1$ to $|T^t|$ do
        Compute $F[i][j]$ (Equation (2))
        Compute $D[i][j]$ (Equation (3))
```

Additionally, in their study, the familiness condition is replaced by the maximum set condition. The maximum set condition, together with the monotonicity condition, constrains all the lowest common ancestors (LCAs) of any pair of non-null alignments in $\mathbb{H}_L$ to ensure that they are aligned. That is, for all $\mathbb{h}_m, \mathbb{h}_n \in \mathbb{H}_L$ of non-null alignments, $\langle \tau_i^s, \tau_i^t \rangle \in \mathbb{H}_L$, where $\tau_i^s = \text{lca}(\tau_m^s, \tau_n^s)$ and $\tau_i^t = \text{lca}(\tau_m^t, \tau_n^t)$. Owing to this constraint, their method belongs to the class of LCA-preserving distance mappings (Zhang et al., 1995), whose constraint is tighter than the constraint edit distance mapping. In phrase alignment, this forces LCAs of two aligned nodes to be aligned as well, even though the majority of phrases under the LCAs are null alignments. By contrast, CTED allows such LCAs to have null alignments depending on the alignments of descendant nodes.

B CTED Algorithm

Algorithm B.1 shows the CTED algorithm. For brevity, we denote the ith node in a tree as i and its child nodes as $I = \{i_k | i_1, \ldots, i_{n_i}\}$, where n_i is the number of children. The input trees are numbered; the numbers are determined by an arbitrary ordering of the nodes in the tree, such as left-to-right post-order numbering or left-to-right pre-order numbering. The algorithm first computes the minimum cost of $\mathbb{H}_{i,j}$, which are alignments of forests rooted at nodes i and j (line 10):

$$F[i][j] = \min \begin{cases} F[0][j] + \min_{1 \le k \le n_j} \{F[i][j_k] - F[0][j_k]\}, \\ F[i][0] + \min_{1 \le l \le n_i} \{F[i_l][j] - F[i_l][0]\}, \\ \min_{\mathbb{H}_{i,j}} \gamma(\mathbb{H}_{i,j}). \end{cases} \tag{2}$$

Then (line 11), it computes the minimum cost of $\langle i, j \rangle$, $\langle i, \tau_\emptyset \rangle$, and $\langle \tau_\emptyset, j \rangle$ as

$$D[i][j] = \min \begin{cases} D[0][j] + \min_{1 \le k \le n_j} \{D[i][j_k] - D[0][j_k]\}, \\ D[i][0] + \min_{1 \le l \le n_i} \{D[i_l][j] - D[i_l][0]\}, \\ F[i][j] + \gamma(\langle \tau_i^s, \tau_j^t \rangle). \end{cases} \tag{3}$$

In Equation (2), $\gamma(\mathbb{H}_{i,j})$ is the summation of the alignment costs between the forests:

$$\gamma(\mathbb{H}_{i,j}) = \sum_{\langle u,v \rangle \in \mathbb{H}_{i,j}} \gamma(\langle u, v \rangle),$$

where u or v is $\tau_\emptyset$ for null alignments.

The algorithm searches for $\mathbb{H}_{i,j}$ that has the minimum cost by solving the minimum cost maximum flow problem on a graph $G(V, E)$, as shown in Figure 5. The vertex set consists of $V = \{s_0, s_t, \tau_\emptyset^i, \tau_\emptyset^j\} \cup I \cup J$, where s_0 and s_t are the start and sink nodes, respectively, and $\tau_\emptyset^i$ and $\tau_\emptyset^j$ are null nodes. Each edge in E has a cost and capacity: Edges (s_0, i_k), $(s_0, \tau_\emptyset^i)$, (j_l, s_t), and $(\tau_\emptyset^j, s_t)$ are cost zero; (i_k, j_l) is cost $D[i_k][j_l]$; $(\tau_\emptyset^i, j_t)$ is cost $D[0][j_l]$; $(i_k, \tau_\emptyset^j)$ is cost $D[i_k][0]$; and $(\tau_\emptyset^i, \tau_\emptyset^j)$ is cost zero. All the edges have capacity one except $(s_0, \tau_\emptyset^i)$, $(\tau_\emptyset^i, \tau_\emptyset^j)$, and $(\tau_\emptyset^j, s_t)$, whose capacities are n_j, $\min(n_i, n_j)$,[15] and n_i, respectively. Obviously, the maximum flow of G is $n_i + n_j$ and G is a network with integer capacities and non-negative costs. The minimum cost on the maximum flow of G is proven to be in agreement with $\min_{\mathbb{H}_{i,j}} \gamma(\mathbb{H}_{i,j})$ in (Zhang, 1996).

Algorithm B.1 only shows the computation of the alignment cost for brevity. However, the corresponding edit operations, *i.e.* alignments, can be computed simultaneously in the same manner as the edit cost.

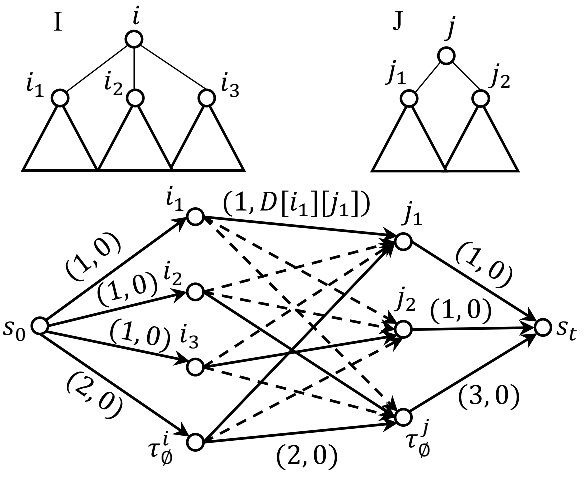

Figure 5: Minimum cost maximum flow problem (values in parentheses represent the (capacity, cost) of each edge)

C Details of ESPADA Creation

To obtain paraphrasal sentence pairs to annotate, we sampled paraphrases from reference translations in NIST OpenMT corpora[16] excluding sentences in SPADE. There are a variety of resources for constructing paraphrases, including reference translations (Weese et al., 2014), news texts (Dolan et al., 2004), and tweets (Lan et al., 2017). Arase and Tsujii (2018) discussed how paraphrases constructed from reference translations are authentic in the sense that they only pose paraphrastic phenomena because they are constrained by corresponding source sentences. By contrast, paraphrases extracted from other resources tend to have more diverse linguistic phenomena, such as additions and omissions of information and inferences requiring knowledge of the world.

First, we recruited a linguist who is also a native English speaker to annotate the gold-standard syntactic trees on paraphrases based on the grammar of the head-driven phrase structure. Through this process, the linguist identified and discarded ungrammatical and/or non-paraphrasal pairs. The annotated trees were checked automatically for formatting, and the linguist corrected the annotations of trees with errors, such as trees with inconsistent bracketing. We then had three native or near-native English speakers annotate the phrase alignments.

---

[15] The flows in a solution should pass through all the non-null nodes; hence, the capacity between empty trees should be $(n_i + n_j) - \max(n_i, n_j) = \min(n_i, n_j)$, which subtracts the minimum flows from/to non-null nodes from the maximum flow of G. Zhang (1996) set this capacity to $\max(n_i, n_j) - \min(n_i, n_j)$, but that produces a degenerate solution.

Method	$\lambda_\emptyset$	w/o post-processing ALIR (%)	 ALIP (%)	 ALIF (%)	w/ post-processing ALIR (%)	 ALIP (%)	 ALIF (%)
ELMo+SimMatrix+CTED	0.60	82.5 ± 0.1	79.9 ± 0.1	81.2 ± 0.1	83.5 ± 0.1	81.6 ± 0.1	82.5 ± 0.1

BERT w/o FT+SimMatrix+CTED	0.80	84.3 ± 0.1	80.4 ± 0.0	82.3 ± 0.0	85.3 ± 0.1	82.0 ± 0.1	83.6 ± 0.1

Table 5: ALIR, ALIP, and ALIF scores for our phrase representation model when applied to feature-based models ('BERT w/o FT' stands for 'BERT without fine-tuning')

D Phrase Representation with Feature-Based Approaches

We also applied our phrase representation model to ELMo and BERT, using them as feature generators. We trained only the attention and CNN models using ESPADA. For ELMo, we also trained the scalar weighting parameters.

Table 5 shows the results. Unfortunately, all of these methods are inferior to their counterparts that lack our phrase representation model: ELMo+CTED and BERT w/o fine-tuning+CTED, respectively. We conjecture that ESPADA may be insufficiently large for training our phrase representation model to adapt to a pre-trained model that behaves in a completely independent manner. BERT's ability to adapt quickly to a specific task by fine-tuning is a notable advantage.

Abstract

Verifying fact on semi-structured evidence like tables requires the ability to encode structural information and perform symbolic reasoning. Pre-trained language models trained on natural language could not be directly applied to encode tables, because simply linearizing tables into sequences will lose the cell alignment information. To better utilize pre-trained transformers for table representation, we propose a **S**tructure-**A**ware **T**ransformer (**SAT**), which injects the table structural information into the mask of the self-attention layer. A method to combine symbolic and linguistic reasoning is also explored for this task. Our method outperforms baseline with 4.93% on TabFact, a large scale table verification dataset.

1 Introduction

Table fact verification aims at classifying whether a textual hypothesis is entailed or refuted by the given table. It could benefit downstream tasks such as fake news detection, misinformation detection, etc. Compared to fact verification over textual evidence (Dagan et al., 2006; Bowman et al., 2015), verification on semi-structured data further requires 1) the ability to encode and understand structural information of tables, and 2) the ability to perform symbolic reasoning over structured data, such as counting, comparing, and numerical calculation. Although large-scale pre-trained language models (Devlin et al., 2019; Yang et al., 2019) achieved dominant results on textual entailment datasets (Wang et al., 2019), they could not be directly used to encode semi-structured data as they are pre-trained on unstructured natural language.

Wenhu et al. (2020) eliminate the discrepancy by serializing tables into word sequences, and then table fact verification could be processed as a natural language inference task. The most straightforward method for table serialization is linearizing the table contents via horizontal scan. However, this would destroy structural information within tables, i.e. the alignments between table cells. In Figure 1, the value "533" and "733" is meaningless digits without the column name "core clock", and it is hard for the model to recover the alignments from the flattened word sequence. Therefore, Table-BERT (Wenhu et al., 2020) includes the column name into cell representation using natural language templates during the linearization. However, comparing or counting column contents of different rows over the flattened word sequence remains a hard task, and simply duplicating the column name multiple times does not achieve satisfying results.

To better utilize the transformer architecture for table representation, we propose to inject the table's structural information into the mask of the self-attention layer. Figure 2 illustrates the pattern commonly adopted when human read or write a table. Usually, each table row describes a record, and cell $c_{1,2}$ describes a record property with the attribute name clarified in the corresponding column name $c_{0,2}$. Besides, values of the same column are usually compared or aggregated for analysis. So, the colored row and column are most crucial to the representation of cell $c_{1,2}$. In the long flattened sequence obtained by horizontal/vertical scan, the alignments between table cells would be disturbed by other unimportant words. To tackle this problem, we have the representation of cell $c_{1,2}$ only depend on the colored cells in Figure 2 by zeroing the attention weights to other ones. Figure 3 illustrates the representation of cell $c_{1,2}$ utilizing transformer. Through masking, only two pseudo sentences, i.e. the corresponding row and column, that share some common words are considered in the representation of each cell. That is, the flattened word sequence is implicitly decomposed into a series of small readable sentences so as to unleashes the power of large pre-trained language model.

Comparison of intel graphics processing units

cpu	market	core clock (mhz)	execution units	memory bandwidth
celeron g1101 pentiumg69xx	desktop	533	12	17 gb/s
core i3 - 5x0 core i5 - 655k	desktop	733	12	21.3 gb/s
core i7 - 620le core i7 - 6x0lm	mobile	266-566	12	17.1 gb/s

Entailed Statement

1. each cpu have 12 execution unit
2. core i3 – 5x0 have faster core clock than core i7 -620le

Refuted Statement

1. core i7 - 620le is designed for mobile market and its memory bandwidth is 21.3 gb/s.
2. There are three series of cpu designed for desktop market.

Figure 1: Examples of table fact verification, the right boxes provide entailed and refuted statements respectively.

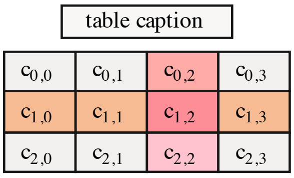

Figure 2: Illustration of table understanding. The colored row and column are crucial to understanding cell $c_{1,2}$.

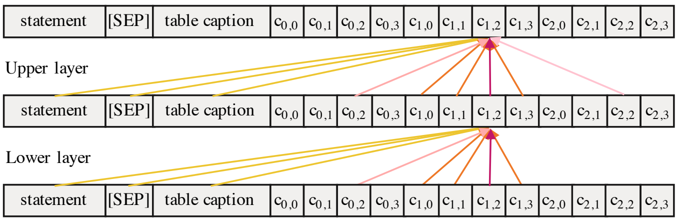

Figure 3: Illustration of masked self-attention for representation of cell $c_{1,2}$. Attentions among cells of the same column are enabled in upper layers to support cross-row reasoning, e.g. $c_{1,2} \sim c_{2,2}$.

Pre-trained transformers are good at semantic-level understanding, i.e. capturing the identical meaning between different expressions. However, one limitation is that they are not doing perfectly in symbolic reasoning (Asai and Hajishirzi, 2020). To tackle this, we perform first-order aggregation over each column and append the result as a special row into the table. An improvement of 1% is achieved, indicating that the ability of hard symbolic reasoning requires further studying.

Our contributions are summarized as follows:

- A **S**tructure-**A**ware **T**ransformer (**SAT**) is devised to better represent semi-structured tables, which injects structural information into attention mask of pre-trained transformers.
- For statements that require symbolic reasoning, we explore a method to combine symbolic reasoning and semantic matching.
- Experimental results show that our method outperforms the state-of-the-art method by 4.93%. Our code is available at `https://github.com/zhhongzhi/sat`.

2 Methodology

As the examples shown in Figure 1, given a statement S, table fact verification aims to classify whether the statement is entailed or refuted by the evidence table T. The table T consists of a caption t and cells $\{c_{i,j}\}$ of $m \times n$, where m and n are the numbers of rows and columns. Since pre-trained transformer could only take word sequences as input, we feed it with a concatenation of the statement S, the [SEP] token, the table caption t, and the flattened table T_f. The table could be serialized by the horizontal or vertical scan. Figure 3 shows an example of horizontal scanning.

The representation of the word sequence follows the general encoding procedure of the pre-trained transformers (Devlin et al., 2019), so we only describe the self-attention layer in which an attention mask is introduced for table representation. As illustrated in Figure 2, understanding the table requires both horizontal and vertical views. That is, if the table is flattened by a horizontal scan, the vertical alignment information will be lost, and vise versa. For example, the column name $c_{0,2}$ is crucial to the representation of $c_{1,2}$, but its signal could be perturbed by other cells in grey, since all $c_{0,*}$ and $c_{2,*}$ cells are far from $c_{1,2}$ in the flattened sequence and are processed equally.

Therefore, we propose to recover the alignment information by masking signals of unimportant cells during self-attention. The attention mask $\boldsymbol{M} \in \mathbf{R}^{L\times L}$ is defined as:

$$M_{i,j} = \begin{cases} 0 & w_i \sim w_j \\ -\infty & w_i \not\sim w_j \end{cases} \tag{1}$$

where L is the sequence length, and $w_i \sim w_j$ denotes that w_j is attended to when generating representation of w_i, while $w_j \not\sim w_i$ means the opposite. Denote the input of l-th self-attention layer as $\boldsymbol{H}^l \in \mathbf{R}^{L\times d}$, where d is the hidden size. The attention mask is then applied to the self-attention layer as follows:

$$\begin{aligned} \boldsymbol{Q}^l, \boldsymbol{K}^l, \boldsymbol{V}^l &= \boldsymbol{H}^l\boldsymbol{W}_q, \boldsymbol{H}^l\boldsymbol{W}_k, \boldsymbol{H}^l\boldsymbol{W}_v \\ \boldsymbol{A}^l &= \text{softmax}(\frac{\boldsymbol{Q}^l\boldsymbol{K}^{l^T} + \boldsymbol{M}}{\sqrt{d_k}}) \end{aligned} \tag{2}$$

where $\boldsymbol{W}_* \in \mathbf{R}^{d \times d_k}$ are trainable parameters. The output of self-attention layer is then calculated as:

$$\boldsymbol{H}^{l+1} = \boldsymbol{A}^l\boldsymbol{V}^l \tag{3}$$

It could be observed that if $w_j \not\sim w_i$, then $A_{i,j}$ is reset to zero and $\boldsymbol{H}_j^l$ will not contribute to the representation of w_i, i.e. $\boldsymbol{H}_i^{l+1}$.

Figure 3 sketches the representation learning of tokens in cell $c_{1,2}$ leveraging the masked self-attention. In the lower layers, the token representation of each cell considers information from four aspects: a) tokens of the same row that describe the same entry, b) its column title that clarifies the attribute name, c) the table caption which provides global background, and d) the statement for verification. In the upper layers, cross row attention among cells of the same column is further enabled. In this manner, lower layers focus on capturing low-level lexical information and upper layers are capable of simple cross-row reasoning. Note that tokens of the statement S and the table caption receive information from all cells.

Another preferred ability of SAT is to perform symbolic reasoning such as counting, comparing, and numerical calculation. Pre-trained models like BERT are good at semantic-level understanding, but not symbolic reasoning (Geva et al., 2020; Asai and Hajishirzi, 2020). We explore to enhance the performance of counting verification by converting the counting problem into a semantic matching problem. Specifically, for every column, the frequency of duplicate cell contents is counted as a summary cell, leading to a summary row which is then appended to the table. For example, the summary cell of the second column in Figure 1 is “count desktop:2”, so the second refuted statement could be verified via semantic matching.

3 Experiments

3.1 Dataset

Experiments are carried out using TabFact[1] (Wenhu et al., 2020), a large scale table fact verification dataset. The basic statistics of TabFact are listed in Table 1. The dataset contains both simple and complex statements. Simple statements only involve a single row/record, while the complex ones require higher-order semantics (argmax, count, etc.), and the statements are rephrased so more ability on linguistic reasoning is required.

Split	#Statement	#Table	Simple/Complex
Train	92,238	13,182	–
Val	12,792	1,696	–
Test	12,779	1,695	4,230/8,609

Table 1: Basic statistics of TabFact.

3.2 Experimental Settings

Model weights are initialized using BERT-base model trained on English corpus. The first 6 layers are regarded as lower layers, and the other 6 layers are taken as upper layers. We finetune the model with a batch size of 10 and a learning rate of 2e-5. It usually takes 15-18 epochs until convergence.

The flatten sequence is usually longer than the sequence limit of BERT, which requires more memory and training time. Hence, we only retain the top 5 table rows according to the number of words shared with the statement. During experiments, the maximum sequence length is set to 256.

3.3 Results and Ablation Study

The experimental results on TabFact are listed in Table 2. Our method achieves an accuracy of 73.23% on the test set and outperforms Table-BERT by 4.93%. The improvement on complex statements is even larger, which achieves 5.75%.

Effect of Attention Mask Without the attention mask, test accuracy is 67.67% and 64.27% for horizontal and vertical scans respectively, namely a decrease of 5.15% and 8.96% compared to the complete SAT. An interesting finding is that the horizontal scan outperforms the vertical scan when removing the mask, which is consistent with our intuition that each row describes an entry and thus horizontal alignment information is more important. With the cell alignment information recovered by the attention mask, the gap is rather small when using SAT, demonstrating its robustness towards different scan directions.

The last two rows of Table 2 present two variants of the masks, where we adopt an identical mask matrix for all transformer layers instead of using different ones for low/high layers. Results indicate

that designing different mask matrix for low/high layers, with the intention to model low-level lexical information and high-level cross-row reasoning, has indeed achieved better performance.

Essentially, by masking signals of unimportant cells, SAT implicitly segments the unnatural long sequence into a series of meaningful subsequences. Such sub-sequences are more friendly to pre-trained language models, so the power of large pre-trained transformer can be unleashed.

The Summary Row Appending a summary row to the table brings a stable improvement of 1%, which mainly contributes to the complex test set. This indicates that although pre-trained transformer is dominant on semantic understanding, its ability on symbolic reasoning is limited. With the counting problem in scope, experimental results show that it is promising to combine both symbolic reasoning and semantic understanding abilities by feeding symbolic reasoning results into SAT.

SAT vs Table Position Embeddings Experiments are further carried out to identify whether the table position encoding method introduced in TaPaS(Herzig et al., 2020) is better than the proposed SAT on table encoding. Row and column positional embeddings are added to the original positional embeddings of BERT to identify the table alignment information. The experimental results are listed in the fourth row of Table 2. An accuracy of 59.8% is observed while the accuracy of the BERT baseline is 68.30%. The results show that BERT is perturbed by the additional table positional embeddings and the model did not converge well. Though the table position information is appended to the inputs, the following transformer layers are not ready to accept and propagate the signal without pre-training. It is demonstrated that simply providing positional information without pre-training is not sufficient for Transformer to encode tables.

3.4 Case study

We analyzed samples that are fixed by SAT compared to baselines. It is observed that a large portion (43/80) of them are statements involve multiple facts/table cells that do not requires logic reasoning. Besides, several problems (9/80) that requires simple count and comparison are fixed. The model both fixed (the other 38) and failed on some samples that require complex symbolic logical reasoning, such as argument sort, conditional aggregation and then comparison. The behavior is most likely random guess for both SAT and baselines. The results show that SAT mainly contributes to the general table representation and enhance the linguistic reasoning, and the summary row appended helps to solve some count problems.

4 Related Work

To encourage the study on table fact verification, Wenhu et al. (2020) construct a large scale table fact checking dataset and study two promising approaches, Table-BERT and Latent Program Algorithm (LPA) respectively. Table-BERT transforms the problem into a natural language inference task to leverage the power of the pre-trained language models. LPA formulates the task as a program synthesis problem and it is good at symbolic reasoning. Our work aligns with the direction of Table-BERT. Inspired by existing work Weijie et al. (2020); Nguyen et al. (2020); Dong et al. (2019); Yang et al. (2019) that manipulates self-attention masks, we devise a structure-aware transformer to attain better table representation.

There are several recent works that table fact verification could benefit from. Geva et al. (2020) and Asai and Hajishirzi (2020) study to improve the pre-trained model in numerical reasoning and logical comparisons. The enhanced pre-trained model could be directly used in our approach. Herzig et al. (2020) extend BERT's architecture to encode tables for the table question answering task (Iyyer et al., 2017), where additional embeddings identifying the row and column number are added. The proposed architecture is potentially applicable to table fact checking but requires expensive pre-training.

5 Conclusion

We propose SAT to enhance the pre-trained transformer's ability on table representation by injecting structural information into the mask of self-attention layers. Significant improvements on TabFact demonstrate its effectiveness. We further enhance SAT by appending a summary row to the table, the results show that it is promising to solve the fact verification that requires both symbolic reasoning and semantic understanding by feeding symbolic reasoning results into SAT. Overall, an improvement of 4.93% is achieved compared to the state-of-the-art method. The proposed method can further contribute to other semi-structured data (table, graph, etc.) related tasks, e.g. WikiTableQuestions (Pasupat and Liang, 2015) and CommonsenseQA (Talmor et al., 2019). There still exists plenty of potentials that require future studies in this direction.

Abstract

Document-level relation extraction aims to extract relations among entities within a document. Different from sentence-level relation extraction, it requires reasoning over multiple sentences across paragraphs. In this paper, we propose **G**raph **A**ggregation-and-**I**nference **N**etwork (GAIN), a method to recognize such relations for long paragraphs. GAIN constructs two graphs, a heterogeneous *mention-level graph* (MG) and an *entity-level graph* (EG). The former captures complex interaction among different mentions and the latter aggregates mentions underlying for the same entities. Based on the graphs we propose a novel path reasoning mechanism to infer relations between entities. Experiments on the public dataset, DocRED, show GAIN achieves a significant performance improvement (2.85 on F1) over the previous state-of-the-art. Our code is available at https://github.com/PKUnlp-icler/GAIN.

1 Introduction

The task of identifying semantic relations between entities from text, namely relation extraction (RE), plays a crucial role in a variety of knowledge-based applications, such as question answering (Yu et al., 2017, Qiu et al., 2019) and large-scale knowledge graph construction. Previous methods (Zeng et al., 2014; Zeng et al., 2015; Xiao and Liu, 2016; Zhang et al., 2017; Zhang et al., 2018; Baldini Soares et al., 2019) focus on sentence-level RE, which predicts relations among entities in a single sentence. However, sentence-level RE models suffer from an inevitable limitation – they fail to recognize relations between entities across sentences. Hence, extracting relations at the document-level is necessary for a holistic understanding of knowledge in text.

Object: ***U.S.***
relation: **country**

Figure 1: An example document and its desired relations from DocRED (Yao et al., 2019). Entity mentions and relations involved in these relation instances are colored. Other mentions are underlined for clarity.

There are several major challenges in effective relation extraction at the document-level. Firstly, the subject and object entities involved in a relation may appear in different sentences. Therefore a relation cannot be identified based solely on a single sentence. Secondly, the same entity may be mentioned multiple times in different sentences. Cross-sentence context information has to be aggregated to represent the entity better. Thirdly, the identification of many relations requires techniques of logical reasoning. This means these relations can only be successfully extracted when other entities and relations, usually spread across sentences, are identified implicitly or explicitly. As Figure 1 shows, it is easy to recognize the intra-sentence relations (*Maryland*, country, *U.S.*), (*Baltimore*, located in the administrative territorial entity, *Maryland*), and (*Eldersburg*, located in the administrative territorial entity, *Maryland*), since the subject and object appear in the same sentence. However, it is non-trivial to predict the inter-sentence relations between *Baltimore* and *U.S.*, as well as *Eldersburg* and *U.S.*,

Error Type	Count
Intra-sentence	535
Inter-sentence	615
Logical Reasoning	242

Table 1: Statistics of bad cases in randomly sampled 100 documents from DocRED dev set for BiLSTM (Yao et al., 2019), with 1150 bad cases in total.

whose mentions do not appear in the same sentence and have long-distance dependencies. Besides, the identification of these two relation instances also requires logical reasoning. For example, *Eldersburg* belongs to *U.S.* because *Eldersburg* is located in *Maryland*, which belongs to *U.S.*.

Recently, Yao et al. (2019) proposed a large-scale human-annotated document-level RE dataset, DocRED, to push sentence-level RE forward to document-level and it contains massive relation facts. Figure 1 shows an example from DocRED. We randomly sample 100 documents from the DocRED dev set and manually analyze the bad cases predicted by a BiLSTM-based model proposed by Yao et al. (2019). As shown in Table 1, the error type of inter-sentence and that of logical reasoning take up a large proportion of all bad cases, with 53.5% and 21.0% respectively. Therefore, in this paper, we aim to tackle these problems to extract relations from documents better.

Previous work in document-level RE do not consider reasoning (Gupta et al., 2019; Jia et al., 2019; Yao et al., 2019), or only use graph-based or hierarchical neural network to conduct reasoning in an implicit way (Peng et al., 2017; Sahu et al., 2019; Nan et al., 2020). In this paper, we propose a **G**raph **A**ggregation-and-**I**nference **N**etwork (GAIN) for document-level relation extraction. It is designed to tackle the challenges mentioned above directly. GAIN constructs a heterogeneous **M**ention-level **G**raph (MG) with two types of nodes, namely mention node and document node, and three different types of edges, i.e., intra-entity edge, inter-entity edge and document edge, to capture the context information of entities in the document. Then, we apply Graph Convolutional Network (Kipf and Welling, 2017) on MG to get a document-aware representation for each mention. **E**ntity-level **G**raph (EG) is then constructed by merging mentions that refer to the same entity in MG, on top of which we propose a novel path reasoning mechanism. This reasoning mechanism allows our model to infer multi-hop relations between entities.

In summary, our main contributions are as follows:

- We propose a novel method, Graph Aggregation-and-Inference Network (GAIN), which features a double graph design, to better cope with document-level RE task.
- We introduce a heterogeneous Mention-level Graph (MG) with a graph-based neural network to model the interaction among different mentions across the document and offer document-aware mention representations.
- We introduce an Entity-level Graph (EG) and propose a novel path reasoning mechanism for relational reasoning among entities.

We evaluate GAIN on the public DocRED dataset. It significantly outperforms the previous state-of-the-art model by 2.85 F1 score. Further analysis demonstrates the capability of GAIN to aggregate document-aware context information and to infer logical relations over documents.

2 Task Formulation

We formulate the document-level relation extraction task as follows. Given a document comprised of N sentences $\mathcal{D} = \{s_i\}_{i=1}^{N}$ and a variety of entities $\mathcal{E} = \{e_i\}_{i=1}^{P}$, where $s_i = \{w_j\}_{j=1}^{M}$ refers to the i-th sentence consisting of M words, $e_i = \{m_j\}_{j=1}^{Q}$ and m_j refers to a span of words belonging to the j-th mention of the i-th entity, the task aims to extract the relations between different entities in $\mathcal{E}$, namely $\{(e_i, r_{ij}, e_j) | e_i, e_j \in \mathcal{E}, r_{ij} \in \mathcal{R}\}$, where $\mathcal{R}$ is a pre-defined relation type set.

In our paper, a relation r_{ij} between entity e_i and e_j is defined as inter-sentential, if and only if $S_{e_i} \cap S_{e_j} = \varnothing$, where S_{e_i} denotes those sentences containing mentions of e_i. Instead, a relation r_{ij} is defined as intra-sentential, if and only if $S_{e_i} \cap S_{e_j} \neq \varnothing$. We also define K-hop relational reasoning as predicting relation r_{ij} based on a K-length chain of existing relations, with e_i and e_j being the head and tail of the reasoning chain, i.e., $e_i \xrightarrow{r_1} e_m \xrightarrow{r_2} \dots e_n \xrightarrow{r_K} e_j \Rightarrow e_i \xrightarrow{r_{ij}} e_j$.

3 Graph Aggregation and Inference Network (GAIN)

GAIN mainly consists of 4 modules: encoding module (Sec. 3.1), mention-level graph aggrega-

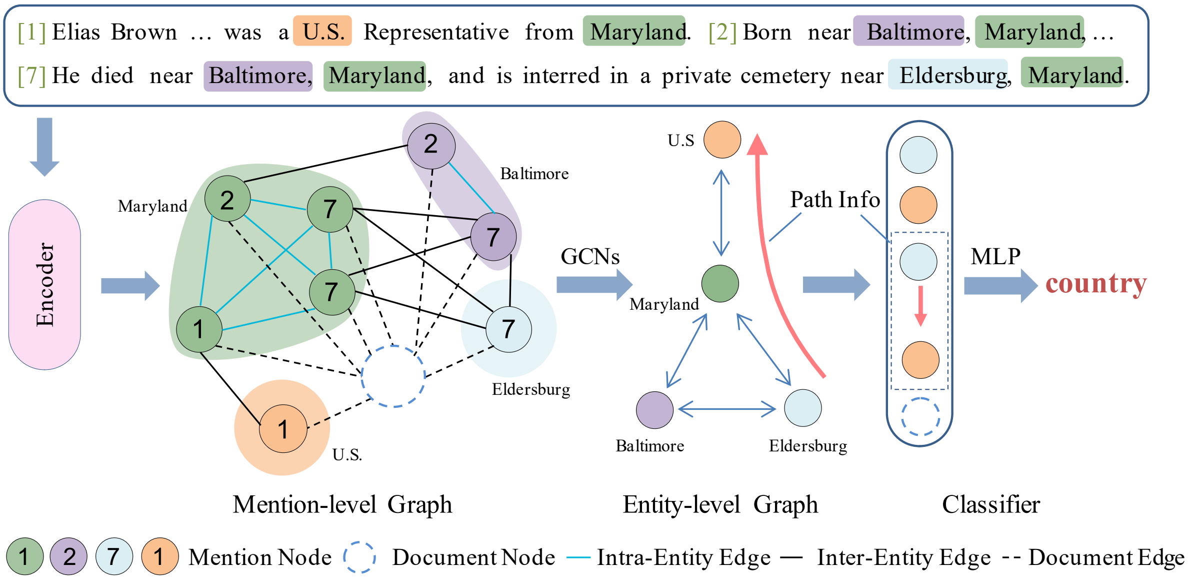

Figure 2: The overall architecture of GAIN. First, a context encoder consumes the input document to get a contextualized representation for each word. Then, the Mention-level Graph is constructed with mention nodes and a document node. After applying GCN, the graph is transformed into Entity-level Graph, where the paths between entities are identified for reasoning. Finally, the classification module predicts target relations based on the above information. Different entities are in different colors. The number i in the mention node denotes that it belongs to the i-th sentence.

tion module (Sec. 3.2), entity-level graph inference module (Sec. 3.3), classification module (Sec. 3.4), as is shown in Figure 2.

3.1 Encoding Module

In the encoding module, we convert a document $\mathcal{D} = \{w_i\}_{i=1}^{n}$ containing n words into a sequence of vectors $\{g_i\}_{i=1}^{n}$. Following Yao et al. (2019), for each word w_i in $\mathcal{D}$, we first concatenate its word embedding with entity type embedding and coreference embedding:

$$x_i = [E_w(w_i); E_t(t_i); E_c(c_i)] \tag{1}$$

where $E_w(\cdot)$, $E_t(\cdot)$ and $E_c(\cdot)$ denote the word embedding layer, entity type embedding layer and coreference embedding layer, respectively. t_i and c_i are named entity type and entity id. We introduce *None* entity type and id for those words not belonging to any entity.

Then the vectorized word representations are fed into an encoder to obtain the context sensitive representation for each word:

$$[g_1, g_2, \ldots, g_n] = Encoder([x_1, x_2, \ldots, x_n]) \tag{2}$$

where the $Encoder$ can be LSTM or other models.

3.2 Mention-level Graph Aggregation Module

To model the document-level information and interactions between mentions and entities, a heterogeneous Mention-level Graph (MG) is constructed.

MG has two different kinds of nodes: mention node and document node. Each mention node denotes one particular mention of an entity. And MG also has one document node that aims to model the overall document information. We argue that this node could serve as a pivot to interact with different mentions and thus reduce the long distance among them in the document.

There are three types of edges in MG:

- **Intra-Entity Edge:** Mentions referring to the same entity are fully connected with intra-entity edges. In this way, the interaction among different mentions of the same entity could be modeled.
- **Inter-Entity Edge:** Two mentions of different entities are connected with an inter-entity edge if they co-occur in a single sentence. In this way, interactions among entities could be modeled by co-occurrences of their mentions.
- **Document Edge:** All mentions are connected to the document node with the document edge.

With such connections, the document node can attend to all the mentions and enable interactions between document and mentions. Besides, the distance between two mention nodes is at most two with the document node as a pivot. Therefore long-distance dependency can be better modeled.

Next, we apply Graph Convolution Network (Kipf and Welling, 2017) on MG to aggregate the features from neighbors. Given node u at the l-th layer, the graph convolutional operation can be defined as:

$$h_u^{(l+1)} = \sigma\left(\sum_{k\in\mathcal{K}}\sum_{v\in\mathcal{N}_k(u)} W_k^{(l)} h_v^{(l)} + b_k^{(l)}\right) \quad (3)$$

where $\mathcal{K}$ are different types of edges, $W_k^{(l)} \in \mathbb{R}^{d\times d}$ and $b_k^{(l)} \in \mathbb{R}^d$ are trainable parameters. $\mathcal{N}_k(u)$ denotes neighbors for node u connected in k-th type edge. σ is an activation function (e.g., ReLU).

Different layers of GCN express features of different abstract levels, and therefore in order to cover features of all levels, we concatenate hidden states of each layer to form the final representation of node u:

$$\mathbf{m}_u = [h_u^{(0)}; h_u^{(1)}; \ldots; h_u^{(N)}] \quad (4)$$

where $h_u^{(0)}$ is the initial representation of node u. For a mention ranging from the s-th word to the t-th word in the document, $h_u^{(0)} = \frac{1}{t-s+1}\sum_{j=s}^{t} g_j$ and for document node, it is initialized with the document representation output from the encoding module.

3.3 Entity-level Graph Inference Module

In this subsection, we introduce Entity-level Graph (EG) and path reasoning mechanism. First, mentions that refer to the same entity are merged to entity node so as to get the nodes in EG. Note that we do not consider document node in EG. For i-th entity node $\mathbf{e}_i$ mentioned N times, it is represented by the average of its N mention representations:

$$\mathbf{e}_i = \frac{1}{N}\sum_n \mathbf{m}_n \quad (5)$$

Then, we merge all inter-entity edges that connect mentions of the same two entities so as to get the edges in EG. The representation of directed edge from $\mathbf{e}_i$ to $\mathbf{e}_j$ in the EG is defined as :

$$\mathbf{e}_{ij} = \sigma\left(W_q[\mathbf{e}_i; \mathbf{e}_j] + b_q\right) \quad (6)$$

where W_q and b_q are trainable parameters, and σ is an activation function (e.g., ReLU).

Based on the vectorized edge representation, the i-th path between head entity $\mathbf{e}_h$ and tail entity $\mathbf{e}_t$ passing through entity $\mathbf{e}_o$ is represented as:

$$\mathbf{p}_{h,t}^i = [\mathbf{e}_{ho}; \mathbf{e}_{ot}; \mathbf{e}_{to}; \mathbf{e}_{oh}] \quad (7)$$

Note that we only consider two-hop paths here, while it can easily extend to multi-hop paths.

We also introduce attention mechanism (Bahdanau et al., 2015), using the entity pair $(\mathbf{e}_h, \mathbf{e}_t)$ as query, to fuse the information of different paths between $\mathbf{e}_h$ and $\mathbf{e}_t$.

$$s_i = \sigma([\mathbf{e}_h; \mathbf{e}_t] \cdot W_l \cdot \mathbf{p}_{h,t}^i) \quad (8)$$

$$\alpha_i = \frac{e^{s_i}}{\sum_j e^{s_j}} \quad (9)$$

$$\mathbf{p}_{h,t} = \sum_i \alpha_i \mathbf{p}_{h,t}^i \quad (10)$$

where α_i is the normalized attention weight for i-th path. Consequently, the model will pay more attention to useful paths. σ is an activation function.

With this module, an entity can be represented by fusing information from its mentions, which usually spread in multiple sentences. Moreover, potential reasoning clues are modeled by different paths between entities. Then they can be integrated with the attention mechanism so that we will take into account latent logical reasoning chains to predict relations.

3.4 Classification Module

For each entity pair $(\mathbf{e}_h, \mathbf{e}_t)$, we concatenate the following representations: (1) the head and tail entity representation $\mathbf{e}_h$ and $\mathbf{e}_t$ derived in the Entity-level Graph, with the comparing operation (Mou et al., 2016) to strengthen features, i.e., absolute value of subtraction between the representation of two entities, $|\mathbf{e}_h - \mathbf{e}_t|$, and element-wise multiplication, $\mathbf{e}_h \odot \mathbf{e}_t$; (2) the representation of document node in Mention-level Graph, $\mathbf{m}_{doc}$, as it can help aggregate cross-sentence information and provide document-aware representation; (3) the comprehensive inferential path information $\mathbf{p}_{h,t}$.

$$I_{h,t} = [\mathbf{e}_h; \mathbf{e}_t; |\mathbf{e}_h - \mathbf{e}_t|; \mathbf{e}_h \odot \mathbf{e}_t; \mathbf{m}_{doc}; \mathbf{p}_{h,t}] \quad (11)$$

Finally, we formulate the task as multi-label classification task and predict relations between entities:

$$P(r|\mathbf{e}_h, \mathbf{e}_t) = sigmoid\left(W_b\sigma(W_a I_{h,t} + b_a) + b_b\right) \quad (12)$$

where W_a, W_b, b_a, b_b are trainable parameters, σ is an activation function (e.g., ReLU). We use binary cross entropy as the classification loss to train our model in an end-to-end way:

$$\mathcal{L} = -\sum_{\mathcal{D}\in\mathcal{S}}\sum_{h\neq t}\sum_{r_i\in\mathcal{R}} \mathbb{I}\left(r_i=1\right)\log P\left(r_i|\mathbf{e}_h,\mathbf{e}_t\right) + \mathbb{I}\left(r_i=0\right)\log\left(1-P\left(r_i|\mathbf{e}_h,\mathbf{e}_t\right)\right) \tag{13}$$

where $\mathcal{S}$ denotes the whole corpus, and $\mathbb{I}\left(\cdot\right)$ refers to indication function.

4 Experiments

4.1 Dataset

We evaluate our model on DocRED (Yao et al., 2019), a large-scale human-annotated dataset for document-level RE constructed from Wikipedia and Wikidata. DocRED has 96 relations types, $132,275$ entities, and $56,354$ relational facts in total. Documents in DocRED contain about 8 sentences on average, and more than 40.7% relation facts can only be extracted from multiple sentences. Moreover, 61.1% relation instances require various inference skills such as logical inference (Yao et al., 2019). we follow the standard split of the dataset, $3,053$ documents for training, $1,000$ for development and $1,000$ for test. For more detailed statistics about DocRED, we recommend readers to refer to the original paper (Yao et al., 2019).

4.2 Experimental Settings

In our GAIN implementation, we use 2 layers of GCN and set the dropout rate to 0.6, learning rate to 0.001. We train GAIN using AdamW (Loshchilov and Hutter, 2019) as optimizer with weight decay 0.0001 and implement GAIN under PyTorch (Paszke et al., 2017) and DGL (Wang et al., 2019b).

We implement three settings for our GAIN. **GAIN-GloVe** uses GloVe (100d) and BiLSTM (256d) as word embedding and encoder. **GAIN-BERT**$_{base}$ and **GAIN-BERT**$_{large}$ use BERT$_{base}$ and BERT$_{large}$ as encoder respectively and the learning rate is set to $1e^{-5}$.

4.3 Baselines and Evaluation Metrics

We use the following models as baselines.

Yao et al. (2019) proposed models to encode the document into a sequence of hidden state vector $\{\boldsymbol{h_i}\}_{i=1}^{n}$ using **CNN** (Fukushima, 1980), **LSTM** (Hochreiter and Schmidhuber, 1997), and **BiLSTM** (Schuster and Paliwal, 1997) as their encoder, and predict relations between entities with their representations. Other pre-trained models like **BERT** (Devlin et al., 2019), **RoBERTa** (Liu et al., 2019), and **CorefBERT** (Ye et al., 2020) are also used as encoder (Wang et al., 2019a; Ye et al., 2020) to document-level RE task.

Context-Aware, also proposed by Yao et al. (2019) on DocRED adapted from (Sorokin and Gurevych, 2017), uses an LSTM to encode the text, but further utilizes attention mechanism to absorb the context relational information for predicting.

BERT-Two-Step$_{base}$, proposed by Wang et al. (2019a) on DocRED. Though similar to BERT-RE$_{base}$, it first predicts whether two entities have a relationship and then predicts the specific target relation.

HIN-GloVe/HIN-BERT$_{base}$, proposed by Tang et al. (2020). Hierarchical Inference Network (HIN) aggregate information from entity-level, sentence-level, and document-level to predict target relations, and use GloVe (Pennington et al., 2014) or BERT$_{base}$ for word embedding.

LSR-GloVe/LSR-BERT$_{base}$, proposed by Nan et al. (2020) recently. They construct a graph based on the dependency tree and predict relations by latent structure induction and GCN. Nan et al. (2020) also adapted four graph-based state-of-the-art RE models to DocRED, including **GAT** (Velickovic et al., 2017), **GCNN** (Sahu et al., 2019), **EoG** (Christopoulou et al., 2019), and **AGGCN** (Guo et al., 2019). We also include their results.

Following Yao et al. (2019), we use the widely used metrics F1 and AUC in our experiment. We also use Ign F1 and Ign AUC, which calculate F1 and AUC excluding the common relation facts in the training and dev/test sets.

4.4 Results

We show GAIN's performance on the DocRED dataset in Table 2, in comparison with other baselines.

Among the models not using BERT or BERT variants, GAIN-GloVe consistently outperforms all sequential-based and graph-based strong baselines by $0.9 \sim 12.82$ F1 score on the test set. Among the models using BERT or BERT variants, GAIN-BERT$_{base}$ yields a great improvement of F1/Ign F1 on dev and test set by $2.22/6.71$ and $2.19/2.03$, respectively, in comparison with the strong baseline LSR-BERT$_{base}$. GAIN-BERT$_{large}$ also improves $2.85/2.63$ F1/Ign F1 on test set compared with

Table 2: Performance on DocRED. Models above the first double line do not use pre-trained model. Results with * are reported in their original papers. Results with ‡ are performances of graph-based state-of-the-art RE models implemented in (Nan et al., 2020). Results with † are based on our implementation.

previous state-of-the-art method, CorefRoBERTa-RE$_{large}$. It suggests that GAIN is more effective in document-level RE tasks. We can also observe that LSR-BERT$_{base}$ improves F1 by 3.83 and 4.87 on dev and test set with GloVe embedding replaced with BERT$_{base}$. In comparison, our GAIN-BERT$_{base}$ yields an improvement by 5.93 and 6.16, which indicates GAIN can better utilize BERT representation.

4.5 Ablation Study

To further analyze GAIN, we also conduct ablation studies to illustrate the effectiveness of different modules and mechanisms in GAIN. We show the results of the ablation study in Table 3.

First, we remove the heterogeneous Mention-level Graph (MG) of GAIN. In detail, we initialize an entity node in Entity-level Graph (EG) with Eq. 5 but replace $\mathbf{m}_n$ with $h_n^{(0)}$, and apply GCN to EG instead. Features in different layers of GCN are concatenated to obtain $\mathbf{e}_i$. Without MG, the performance of GAIN-GloVe/GAIN-BERT$_{base}$ sharply drops by 2.08/2.02 Ign F1 score on dev set. This drop shows that MG plays a vital role in capturing interactions among mentions belonging to the same and different entities and document-aware features.

Next, we remove the inference module. To be specific, the model abandon the path information between head and tail entity $\mathbf{p}_{h,t}$ obtained in Entity-level Graph, and predict relations only based on entity representation, $\mathbf{e}_h$ and $\mathbf{e}_t$, and document node representation, $\mathbf{m}_{doc}$. The inference module's removal results in poor performance across all metrics, for instance, 2.21/2.17 Ign F1 score decrease on the dev set for GAIN-GloVe/GAIN-BERT$_{base}$. It suggests that our path inference mechanism helps capture the potential K-hop inference paths to infer relations and, therefore, improve document-level RE performance.

Moreover, taking away the document node in MG leads to 2.19/1.88 Ign F1 decrease on the dev set for GAIN-GloVe/GAIN-BERT$_{base}$. It helps GAIN aggregate the document information and works as a pivot to facilitate the information exchange among different mentions, especially those far away from each other within the document.

4.6 Analysis & Discussion

In this subsection, we further analyze both inter-sentential and inferential performance on the development set. The same as Nan et al. (2020), we report Intra-F1/Inter-F1 scores in Table 4, which only consider either intra- or inter-sentence relations respectively. Similarly, in order to evaluate

Model	Dev				Test	
	Ign F1	Ign AUC	F1	AUC	Ign F1	F1

RoBERTa-RE$_{base}$	65.65	50.09
BERT-Two-Step$^*_{base}$	61.80	47.28
LSR-BERT$^*_{base}$	65.26	52.05
GAIN-BERT$_{base}$	**67.10**	**53.90**
- *MG*	66.15	51.42

Table 4: Intra- and Inter-F1 results on dev set of DocRED. Results with * are reported in (Nan et al., 2020).

the inference ability of the models, Infer-F1 scores are reported in Table 5, which only considers relations that engaged in the relational reasoning process . For example, we take into account the golden relation facts r_1, r_2, and r_3 if there exist $e_h \xrightarrow{r_1} e_o \xrightarrow{r_2} e_t$ and $e_h \xrightarrow{r_3} e_t$ when calculating Infer-F1.

As Table 4 shows, GAIN outperforms other baselines not only in Intra-F1 but also Inter-F1, and the removal of MG leads to a more considerable decrease in Inter-F1 than Intra-F1, which indicates our MG do help interactions among mentions, especially those distributed in different sentences with long-distance dependency.

Besides, Table 5 suggests GAIN can better handle relational inference. For example, GAIN-BERT$_{base}$ improves 5.11 Infer-F1 compared with RoBERTa-RE$_{base}$. The inference module also plays an important role in capturing potential inference chains between entities, without which GAIN-BERT$_{base}$ would drop by 1.78 Infer-F1.

Model	Infer-F1	P	R
CNN	37.11	32.81	42.72

- *Inference Module*	45.11	36.91	57.99

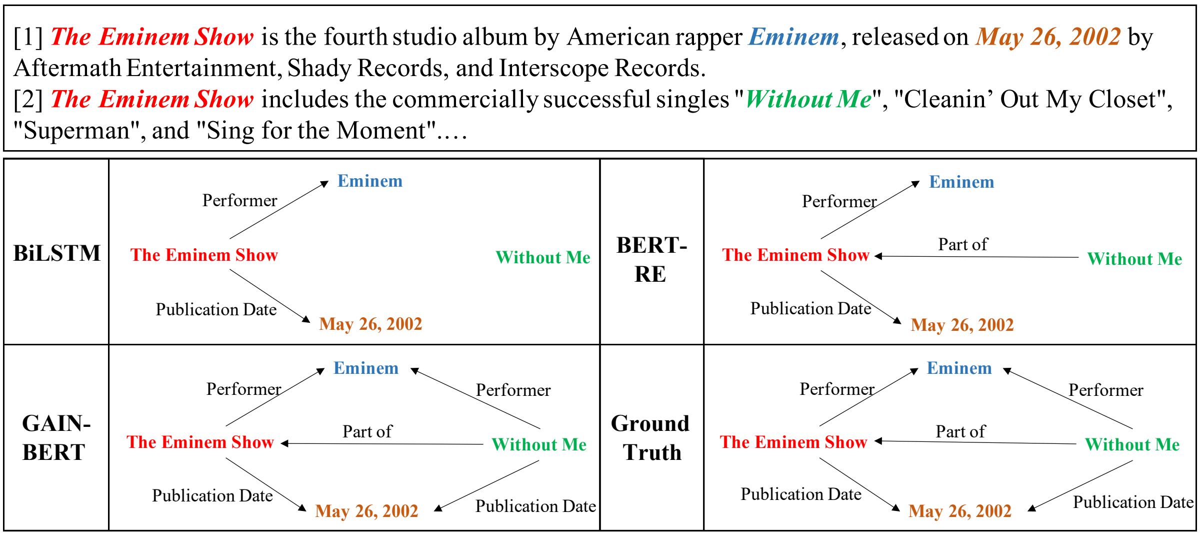
Table 5: Infer-F1 results on dev set of DocRED. P: Precision, R: Recall.

4.7 Case Study

Figure 3 also shows the case study of our proposed model GAIN, in comparison with other baselines. As is shown, BiLSTM can only identify two relations within the first sentence. Both BERT-RE$_{base}$ and GAIN-BERT$_{base}$ can successfully predict *Without Me* is part of *The Eminem Show*. But only GAIN-BERT$_{base}$ is able to deduce the performer and publication date of *Without Me* are the same as those of *The Eminem Show*, namely *Eminem* and *May 26, 2002*, where it requires logical inference across sentences.

5 Related Work

Previous approaches focus on sentence-level relation extraction (Zeng et al., 2014; Zeng et al., 2015; Wang et al., 2016; Zhou et al., 2016; Xiao and Liu, 2016; Zhang et al., 2017; Feng et al., 2018; Zhu et al., 2019). But sentence-level RE models face an



[1] ***The Eminem Show*** is the fourth studio album by American rapper ***Eminem***, released on ***May 26, 2002*** by Aftermath Entertainment, Shady Records, and Interscope Records.
[2] ***The Eminem Show*** includes the commercially successful singles "***Without Me***", "Cleanin' Out My Closet", "Superman", and "Sing for the Moment"....

Figure 3: The case study of our proposed GAIN and baseline models. The models take the document as input and predict relations among different entities in different colors. We only show a part of entities within the documents and the according sentences due to the space limitation.

inevitable restriction in practice, where many real-world relation facts can only be extracted across sentences. Therefore, many researchers gradually shift their attention into document-level relation extraction.

Several approaches (Quirk and Poon, 2017; Peng et al., 2017; Gupta et al., 2019; Song et al., 2018; Jia et al., 2019) leverage dependency graph to better capture document-specific features, but they ignore ubiquitous relational inference in document. Recently, many models are proposed to address this problem. Tang et al. (2020) proposed a hierarchical inference network by considering information from entity-level, sentence-level, and document-level. However, it conducts relational inference implicitly based on a hierarchical network while we adopt the path reasoning mechanism, which is a more explicit way.

(Christopoulou et al., 2019) is one of the most powerful systems on document-level RE tasks recently. Compared to (Christopoulou et al., 2019) and other graph-based approaches to relation extraction, our architecture features many different designs with different motivations behind them. First, the ways of graph construction are different. We create two separate graphs of different levels to capture long-distance document-aware interactions and entity path inference information, respectively. While Christopoulou et al. (2019) put mentions and entities in the same graph. Moreover, they do not conduct graph node representation learning like GCN to aggregate interactive information on the constructed graph, only using the features from BiLSTMs to represent nodes. Second, the processes of path inference are different. Christopoulou et al. (2019) use a walk-based method to iteratively generate a path for every entity pair, which requires the extra overhead of hyper-parameter tuning to control the process of inference. Instead, we use an attention mechanism to selectively fuse all possible path information for the entity pair while without extra overhead.

When we were writing this paper, (Nan et al., 2020) make their work public as preprints, which adopt the dependency tree to capture the semantic information in the document. They put mention and entity nodes in the same graph and conduct inference implicitly by using GCN. Unlike their work, our GAIN presents mention node and entity node in different graphs to better conduct inter-sentence information aggregation and infer relations more explicitly.

Some other attempts (Verga et al., 2018; Sahu et al., 2019; Christopoulou et al., 2019) study document-level RE in a specific domain like biomedical RE. However, the datasets they use usually contain very limited relation types and entity types. For instance, CDR (Li et al., 2016) only has one type of relation and two types of entities, which may not be the ideal testbed for relational reasoning.

6 Conclusion

Extracting inter-sentence relations and conducting relational reasoning are challenging in document-level relation extraction.

In this paper, we introduce Graph Aggregation-and-Inference Network (GAIN) to better cope with document-level relation extraction, which features double graphs in different granularity. GAIN utilizes a heterogeneous Mention-level Graph to model the interaction among different mentions across the document and capture document-aware features. It also uses an Entity-level Graph with a proposed path reasoning mechanism to infer relations more explicitly.

Experimental results on the large-scale human-annotated dataset, DocRED, show GAIN outperforms previous methods, especially in inter-sentence and inferential relations scenarios. The ablation study also confirms the effectiveness of different modules in our model.

Acknowledgments

The authors would like to thank Ying Zeng, Yuwen Wu, Zhenqiao Song, and the anonymous reviewers for their thoughtful and constructive comments and ByteDance AI Lab for providing the computational resources for this work. A Hyperparameter settings

We use development set to manually tune the optimal hyperparameters for GAIN, based on the Ign F1 score. Hyperparameter settings for GAIN-GloVe, GAIN-BERT$_{base}$ and GAIN-BERT$_{large}$ are listed in Table 6, 7 and 8, respectively. The value of hyperparameters we finally adopted are in bold. Note that we do not tune all the hyperparameters.

Hyperparameter	Value
Batch Size	16, **32**
Learning Rate	**0.001**
Activation Function	**ReLU**, Tanh
Positive v.s. Negative Ratio	1, 0.5, **0.25**
Word Embedding Size	**100**

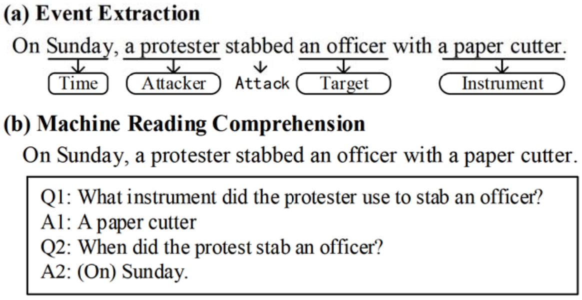
Abstract

Event extraction (EE) is a crucial information extraction task that aims to extract event information in texts. Previous methods for EE typically model it as a classification task, which are data-hungry and suffer from the data scarcity problem. In this paper, we propose a new learning paradigm of EE, by explicitly casting it as a machine reading comprehension problem (MRC). Our approach includes an unsupervised question generation process, which can transfer event schema into a set of natural questions, followed by a BERT-based question-answering process to retrieve answers as EE results. This learning paradigm enables us to strengthen the reasoning process of EE, by introducing sophisticated models in MRC, and relieve the data scarcity problem, by introducing the large-scale datasets in MRC. The empirical results show that: i) our approach attains state-of-the-art performance by considerable margins over previous methods. ii) Our model is excelled in the data-scarce scenario, for example, obtaining 49.8% in F1 for event argument extraction with only 1% data, compared with 2.2% of the previous method. iii) Our model also fits with zero-shot scenarios, achieving 37.0% and 16% in F1 on two datasets without using any EE training data.

1 Introduction



On Sunday, a protester stabbed an officer with a paper cutter.

On Sunday, a protester stabbed an officer with a paper cutter.

Q1: What instrument did the protester use to stab an officer?
A1: A paper cutter
Q2: When did the protest stab an officer?
A2: (On) Sunday.

Figure 1: Comparison of the event extraction task and machine reading comprehension task.

Event extraction (EE), a crucial information extraction (IE) task, aims to extract event information in texts. For example, in a sentence S1 (shown in Figure 1 (a)), an EE system should recognize an `Attack` event[1], expressed by an *event trigger* *stabbed* with four *event arguments* — *Sunday* (Role=`Time`), *a protester* (Role=`Attacker`), *an officer* (Role=`Target`), and *a paper cutter* (Role=`Instrument`). EE is shown to benefit a wide range of applications including knowledge base augmentation (Ji and Grishman, 2011), document summarization, question answering (Berant et al., 2014), and others.

In the current study, EE is mostly formulated as a *classification* problem, aiming to locate and categorize each event trigger/argument (Ahn, 2006; Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016). Despite many advances, classification based methods are data-hungry, which require a great deal of training data to ensure good performance (Chen et al., 2017; Li et al., 2013; Liu et al., 2018a). Moreover, such methods generally cannot deal with *new* event types never encountered during training time (Huang et al., 2018).

In this particular study, we introduce a new learning paradigm for EE, shedding lights on tackling the above problems simultaneously. Our major motivation is that, essentially EE may be viewed as a machine reading comprehension (MRC) problem (Hermann et al., 2015; Chen et al., 2016) involving text understanding and matching, aiming to find event-specific information in texts. For example, in S1, the extraction of role-filler of `Instrument` is semantically equivalent to the following question-answering process (as shown in Figure 1 (b)):

Q1: *What* `Instrument` *did the protester use*

---

[1] According to the ACE event ontology.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1641–1651,
November 16–20, 2020.

to stab the officer? **A1:** *a paper cutter*. [2]
This implies new ways to tackle EE, which come with two major advantages: First, by framing EE as MRC, we can leverage the recent advances in MRC (e.g., BERT (Devlin et al., 2019)) to boost EE task, which may greatly strengthen the reasoning process in the model. Second, we may directly leverage the abundant MRC datasets to boost EE, which may relieve the data scarcity problem (This is referred to as *cross-domain data augmentation*). The second advantage also opens a door for zero-shot EE: for unseen event types, we can list questions defining their schema and use an MRC model to retrieve answers as EE results, instead of obtaining training data for them in advance.

To bridge MRC and EE, the key challenge lies in generating *relevant* questions describing an event scheme (e.g., generating Q1 for `Instrument`). Note we cannot adopt supervised question generation methods (Duan et al., 2017; Yuan et al., 2017; Elsahar et al., 2018), owing to the lack of aligned question-event pairs. Previous works connecting MRC and other tasks usually adopt human-designed templates (Levy et al., 2017; FitzGerald et al., 2018; Li et al., 2019b,a; Gao et al., 2019; Wu et al., 2019). For example, in QA-SRL (FitzGerald et al., 2018), the question for a predicate `publish` is always "Who published something?", regardless of the contexts. Such questions may not expressive enough to instruct an MRC model to find answers.

We overcome the above challenge by proposing an unsupervised question generation process, which can generate questions that are both relevant and context-dependent. Specifically, in our approach, we assume that each question can be decomposed as two parts, reflecting query topic and context-related information respectively. For example, Q1 can be decomposed as "*What instrument*" and "*did the protester use to stab the officer?*". To generate the query topic expression, we design a template-based generation method, combining role categorization and interrogative words realization. To generate the more challenging context-dependent expression, we formulate it as an *unsupervised* translation task (Lample et al., 2018b) (or style transfer (Prabhumoye et al., 2018)), which transforms a descriptive statement into a question-style expression, based on in-domain de-noising auto-encoding (Vincent et al., 2008) and cross-domain back-translation (Sennrich et al., 2016). Note the training process only needs large volume of descriptive statements and *unaligned* question-style statements. Finally, after the questions are generated, we build a BERT based MRC model (Devlin et al., 2019) to answer each of question and synthesize all of the answers as the result of EE.

To evaluate our approach, we have conducted extensive experiments on the benchmark EE datasets, and the experimental results have justified the effectiveness of our approach. Specifically, 1) in the standard evolution, our method attains state-of-the-art performance and outperforms previous EE methods by a margin (§ 4.2). 2) In the data-low scenario, our approach demonstrates promising results, for example, achieving 49.8% in F1 using 1% of training data, compared with only 2.2% in F1 of the previous EE method (§ 4.3). 3) Our approach also fits with zero-shot scenarios, achieving 37.0% and 16.6% in F1 on two datasets without using any EE training data (§ 4.4).

To sum up, we make the following contributions:

- We investigate a new formulation of EE, by framing it as an MRC problem explicitly. We show this new formulation can boost EE by leveraging both model and data in the area of MRC. Our work may encourage more works studying transfer learning from MRC to boost information extraction.

- We propose an unsupervised question generation method to bridge MRC and EE. Compared with previous works using templates to generate questions, our method can generate questions that are both topic-relevant and context-dependent, which can better instruct an MRC model for question-answering.

- We report on state-of-the-art performance on the benchmark EE dataset. Our method also demonstrate promising results in addressing data-low and zero-shot scenarios.

2 Related Work

Event Extraction. EE is a crucial IE task that aims to extract event information in texts, which has attracted extensive attention among researchers. Traditional EE methods employ manual-designed features, such as the syntactic feature (Ahn, 2006), document-level feature (Ji and Grishman, 2008), entity-level feature (Hong et al., 2011) and other features (Liao and Grishman, 2010; Li et al., 2013)

---

[2] Figure 1 (b) gives another example.

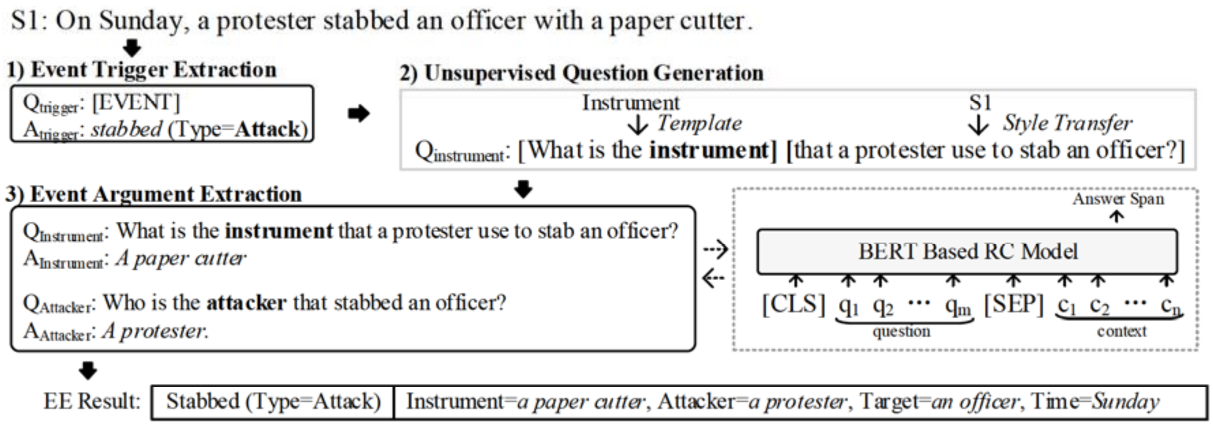


Figure 2: The overview of the proposed model RCEE. Given S1, RCEE first uses a special query [EVENT] to locate event trigger and predict the type. Then RCEE generates questions for each semantic role related to the predicted event type. Finally, RCEE answers each question and synthesizes all of the answers as the EE result.

for the task. Modern EE methods employ neural models, such as Convolutional Neural Networks (Chen et al., 2015), Recurrent Neural Networks (Nguyen et al., 2016; Sha et al., 2018), Graph Convolutional Neural Networks (Liu et al., 2018b, 2019b), and other advanced architectures (Yang and Mitchell, 2016; Liu et al., 2018a, 2019a; Nguyen and Nguyen, 2019; Zhang et al., 2019). Despite many advances, as mentioned in Introduction, most previous approaches formulate EE as a classification problem, which usually suffer from the data scarcity problem, and they generally cannot deal with new event types never seen at the training time.

MRC for Other Tasks. Our work also relates to works connecting MRC and other tasks, such as relation extraction (Levy et al., 2017; Li et al., 2019b), semantic role labeling (FitzGerald et al., 2018), named entity recognition (Li et al., 2019a), and others (Wu et al., 2019; Gao et al., 2019). Particularly, Du and Cardie (2020) adopt a similar idea to frames EE as MRC. But different from our work, most of the above methods (Levy et al., 2017; Li et al., 2019b; FitzGerald et al., 2018; Du and Cardie, 2020) adopt human-designed, context-independent questions, which may not provide enough contextual evidence for question-answering. Some works indeed do not adopt question-style queries (Li et al., 2019a; Gao et al., 2019). For example, Li et al. (2019a) use "Find organizations in the text" as a query command to find ORGANIZATION entity. The discrepancy between such non-natural "queries" and natural questions in MRC datasets may hinder effective transfer learning from MRC to the task. By contrast, our work aims to generate both relevant and context-related questions via an unsupervised question generation method.

3 The Approach

Our approach, denoted by RCEE (Reading Comprehension for Event Extraction), is visualized in Figure 2. Specifically, given a sentence S1, RCEE first identifies an event trigger "*stabbed*" and its event type `Attack`, on receiving a special query "[Event]". Secondly, RCEE generates a question for each semantic role corresponding to the event schema of `Attack`. Thirdly, RCEE builds an MRC model to answer each question as event argument extraction. Finally, RCEE synthesizes all of the answers as the final result of EE.

The technical details of RCEE are presented in the following. In the illustration, we denote a sentence as $c = \{c_1, \cdots, c_n\}$, and we structure the illustration as event trigger extraction, unsupervised question generation, event argument extraction, and the training procedure of RCEE.

3.1 Event Trigger Extraction

To extract event triggers, we use "[EVENT]" as a special query command, indicating finding all event triggers in texts[3]. The reason is that event triggers are usually verbs, and it is hard to design questions for them. Also note here this special query command enables event trigger and argument extraction share a same encoding model.

---

[3] We have also tried questions like "*What events are mentioned in texts?*" and type-related questions like "*Which are ATTACK/DIE events?*" but found no improvement.

Category	Role	Templs.
Time-related	`Time`	When
Place-related	`Place`	Where
Person-related	`Victim`, `Attacker`, ...	Who is the Role
General role	`Instrument`, `Target`, ...	What is the Role

Table 1: Role categorization and generation templates.

Next, we adopt classification-based (instead of span-based method) for trigger extraction, considering that most triggers (over 95% in ACE) are single words, and span-based answer generation may be too heavy. Specifically, we first jointly encode "[EVENT]" with the sentence c to compute an encoded representation (we refer to § 3.3 for details). Then for each word c_i in c, we take its encoded representation as the input of a logistic regression model, and compute a vector o_{c_i} containing probabilities of different event types. Finally, the probability of the lth event type for c_i is $p(l|c_i) = o_{c_i}^{(l)}$, which is the lth element of o_{c_i}.

3.2 Unsupervised Question Generation

After trigger extraction, RCEE generates a set of questions according to the predicted event type. Here we assume each question can be composited as: 1) *query topic*, which reflects the relevance of a question, and 2) *question-style event statement*, which encodes the context-related information.

Question Topic Generation. We devise template-based methods for query topic generation. Note to make a question natural enough, we should consider different interrogative words for different semantic roles. For example, the query topic for the semantic role `Time` might be "When [...]", but for `Attacker` might be "Who [...]". With the above motivation, we first group semantic roles into different categories, and then design different templates for each category. Table 1 shows our categorization (i.e., time-related, place-related, person-related and general roles) and templates for the ACE 2005 event ontology. According to the table, the generated query topic for `Victim` is "*Who is the Victim*".

Question Contextualization. Question contextualization aims to generate the remaining question-style event statement. Here formulate it as an unsupervised translation task (Lample et al., 2018a,b), with a goal to maps *descriptive statement* (such as the sentence) to a *question-style statement*, with no parallel resources. It can also be viewed as style transfer (Prabhumoye et al., 2018). To achieve the goal, we first build large corpora of descriptive statements (denoted as S) and *unaligned* natural questions (denoted as Q)[4], and we restrict each instance in S a window of words centered at a verb, and each instance of Q a question removing interrogative words such as When/Where/Who/What. Second, following Lample et al. (2018b), we build two MT models: $P_{S\to Q}(q_s|s)$, which maps a descriptive statement $s \in S$ as a question-style statement q_s, and $P_{Q\to S}(s_q|q)$, which conducts the translation reversely. Each MT model includes an encoder and a decoder in the source and target domains respectively. For example, $P_{S\to Q}(q_s|s)$ has an encoder E_S in S, and a decoder D_Q in Q. Third, We train $P_{S\to Q}(q_s|s)$ and $P_{Q\to S}(s_q|q)$ jointly via in-domain auto-encoding, de-noising auto-encoding (Vincent et al., 2008), and cross-domain online-back translation (Sennrich et al., 2016), as shown in Figure 3. Finally, at the inference time, a window of words centered at the predicted trigger (denoted by s_x) is considered as input of $P_{S\to Q}(q_s|s)$, and we compute the question-style statement q_{s_x} via:

$$q_{s_x} = \arg\max_{q_{s_x}} P_{S\to Q}(q_{s_x}|s_x) \qquad (1)$$

q_{s_x} is concatenated with the pre-generated query topic to generate the final question.

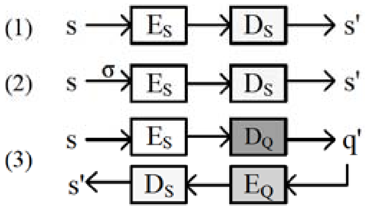

Figure 3: Illustration of (1) in-domain auto-encoding, (2) de-noising auto-encoding, and (3) cross-domain online-back translation. E_S (E_Q) and D_S (D_Q) are encoder and decoder in domain S (Q). σ denotes random noise such as word masking (Lample et al., 2018b).

3.3 Event Argument Extraction

RCEE then performs event argument extraction as question answering, by using a BERT based MRC model. Let a question be $q = \{q_1, \cdots, q_m\}$

---

[4] In our approach, S contains sentences extracted from Wikipedia, and Q contains user-generated questions from a QA site `https://question.com/`. After filtering, S and Q have a size of 70M and 43M respectively

Learning Input Representations. We first encode q and c jointly to learn the input representations, by constructing an sequence "[CLS] q [SEP] c" as input of BERT. To further enhance the representation, we devise a new embedding, *word sharing embedding*, as the input of BERT, with a motivation that shared words of q and c are more likely to convey event information. Specifically, the word sharing embedding of a word w_i (in q or c) is:

$$p_{w_i} = \begin{cases} p_{sh} \in \mathbb{R}^{d_1} & \text{if } w_i \text{ is shared by } q \text{ and } c \\ p_{no} \in \mathbb{R}^{d_1} & \text{otherwise} \end{cases} \tag{2}$$

where p_{sh} and p_{no} are two embedding vectors getting updated during training. After encoding, we take the last hidden layer of BERT, $H_c^q \in \mathbb{R}^{N \times d_2}$, as the final representation of q and c, where N = m + n + 2[5], and d_2 designates BERT's hidden dimension.

Adaptive Argument Generation. Different from triggers, event arguments generation is tackled by span-based algorithms (Hermann et al., 2015), as they are usually entities and contain multiple words. While we note over 14% of semantic roles have *zero* or *multiple* arguments, we revise the existing algorithm to tackle the issue (shown in Algorithm 1). Specifically, given the joint representation H_c^q of q and c, we fist compute two probability vectors containing the start and end positions of the answer over every position in c:

$$p_{start} = \text{softmax}(H_c^q W_{start}) \tag{3}$$

$$p_{end} = \text{softmax}(H_c^q W_{end}) \tag{4}$$

where W_{start} and $W_{end} \in \mathbb{R}^{2d_4 \times 1}$ are model parameters. Then, we regard the special token "[SEP]" as "no-answer" indicator, and we only use start/end positions whose probabilities are higher than that of "[SEP]" to construct candidate answers. We adopt several heuristics regarding i) relative position of start/end index, length constraint, and likelihood threshold δ to filter out illegal answers. The new algorithm can generate both zero or more than one answers for a question. Additionally, when entity information is known (this setting is adopted in many approaches (Chen et al., 2015; Nguyen et al., 2016)), we further adopt *golden entity refinement*, which enforces answers have the same boundaries as ground-truth entities.

Algorithm 1 Adaptive Argument Generation

```
procedure FUN(c, $p_{start}$, $p_{end}$)
    answer_list = []
    s_list ← filter_by_probability($p_{start}$)
    e_list ← filter_by_probability($p_{end}$)
    ▷ Construct candidate answers using s_list and e_list
    for each candidate (s_idx, e_idx) do
        ▷ s_idx should be ahead of e_idx
        ▷ length should less than 4
        if $p_{start}[s_{idx}] + p_{end}[e_{idx}] > \delta$ then
            ans = make_span(c, s_idx, e_idx)
            answer_list.add(ans)
        end if
    end for
    golden_entity_refinement(answer_list)
    return answer_list
end procedure
```

3.4 Training

To train RCEE, we adopt a pre-training followed by fine-tuning strategy, which can jointly train a model using datasets of MRC and EE.

Pre-training Stage. In the pre-training stage, we train RCEE on MRC datasets, with a loss:

$$\mathcal{L}_{rc}(\theta) = \sum\nolimits_{\langle c,q,a \rangle} \text{P}(a|c,q) \tag{5}$$

where $\langle c, q, a \rangle$ denotes an MRC example consisting of context c, query q, and answer a; $\text{P}(a|c,q)$ indicates the likelihood of the ground-truth answer a given c and q, which is defined as:

$$\text{P}(a|c,q) = \log p(g_s^a|c,q) + \log p(g_e^a|c,q) \tag{6}$$

where g_s^a and g_e^a are respectively the ground-truth start/end positions.

Fine-Tuning Stage. In the fine-tuning stage, we train RCEE on EE datasets with a loss:

$$\mathcal{L}_{ev}(\theta) = -\sum_e \left(\log p(g_e|w_e) + \sum_{r \in \mathcal{A}(g_e)} \text{P}(a_r|c_e, q_r) \right) \tag{7}$$

where e ranges over each event instance; w_e indicates the trigger of e; g_e indicates the event type of e; $Arg(e)$ designates the role set of g_e; r ranges over each rule. We adopt Adam (Kingma and Ba, 2014) to update parameters of RCEE.

---

[5] For simplicity of illustration, we assume the output of BERT has a same length of "[CLS] q [SEP] c". In fact, BERT may split a word based on byte pair encoding.

Table 2: Results of trigger extraction (TRIGGER EX.), argument extraction (ARGUMENT EX.), and argument extraction with golden triggers (ARGUMENT EX.(O)). P, R and F1 stand for precision, recall, and f1-score respectively; † denotes our re-implementation; * denotes a significance level of $p = 0.05$.

4 Experiments

4.1 Experimental Setups

Datasets and Evaluation. Our experiments are conducted on the widely-used ACE 2005 benchmark[6], which defines 33 different event types and 35 semantic roles. We split the dataset as training, validating, and testing sets according to previous works (Li et al., 2013; Chen et al., 2015; Yang and Mitchell, 2016), and we also adopt precision (P), recall (R), and F1-score (F1) as evaluation metrics to ensure comparability. Significance tests are conducted using methods proposed by Yeh (2000) with a significance level of $p = 0.05$.

Implementation Details. We adopt BERT-Large, which has 24 layers, 1024 hidden units, and 16 attention heads, as our MRC model. Other hyper-parameters are tuned on the validating set via a grid search. Specifically, the dimension of word sharing embedding is set as 100 (from 10, 50, 100, 200, to 500). The answer prediction threshold δ is set as 0.3 (from [0.1, 0.2, .., 0.9]). The batch size is set as 10 (from 2, 5, 10, 15). The dropout rate is set as 0.5. We adopt SQuAD 2.0 (Rajpurkar et al., 2018) for cross-domain data argumentation (Our MRC model achieves 83.9% in F1). Implementations of unsupervised question generation are in supplement materials. Our code will be released at `https://github.com/jianliu-ml/EEasMRC`.

Baseline Models. We compare our model with: 1) JointBeam (Li et al., 2013), a state-of-the-art feature-based method for EE; 2) DMCNN (Chen et al., 2015) and 3) JRNN (Nguyen et al., 2016), two models adopting Convolution Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) respectively for EE; 4) dbRNN (Sha et al., 2018) and 5) JMEE (Liu et al., 2018b) two models exploring syntax information via RNNs and Graph Convolotional Neural Networks (GCNs) for EE. Joint EE models are also considered, including: 6) Joint3EE (Nguyen and Nguyen, 2019), which uses a unified architecture to predict entities and events; 7) JointTrans (Zhang et al., 2019), which adopts a left-to-right transaction-based method for EE. To further investigate whether the improvement are introduced by BERT representation, we also consider: 8) BERTEE, which adopts BERT representations but uses classification strategy for EE. Our model is denoted as RCEE and RCEE_ER ("ER" denotes with golden entity refinement). We use DA to indicate cross-domain data augmentation.

4.2 Standard Evaluation

In the standard evaluation, we consider two settings with 1) known entities, which is considered by many previous methods, and 2) unknown entities, which is a more realistic setting.

Results with Known Entities. Table 2 gives the results of trigger (Trigger Ex.) and argument extraction (Argument Ex.) with known entities. We also report on results of argument extraction with oracle triggers (Argument Ex.(O)), to exclude the potential error propagation from trigger extraction results. From the results, 1) RCEE_ER attains state-of-the-art performance, outperforming all baselines by considerable margins (+0.6% in trigger extraction; (+3.6% (5.4%)) in argument ex-

---

METHOD	G_E	P_E	ΔF1
JointBeam (2013)	52.7	41.8	↓10.9
DMCNN (2015)	56.8	48.0†	↓8.8
JMEE (2018b)	60.3	50.4†	↓9.9
BERTEE	60.6†	51.9†	↓8.7
Joint3EE (2019)	-	52.1	-
JointTrans (2019)	-	53.3	-
RCEE	63.6	**59.3***	↓4.3
RCEE *w/o* DA	62.7	58.7	↓4.0

Table 3: Results of argument extraction with unknown entities (P_E). ΔF1 indicates the performance gap compared with results with known entities (G_E).

traction). 2) Especially, RCEE_ER outperforms BERTEE (which also use BERT representations) with over 5% in argument extraction, which indicates that the improvements are mainly from problem reformulation, rather than introducing BERT representations. 3) The high recall of RCEE_ER indicates that it can predict more examples than baselines, which may imply that RCEE_ER can tackle difficult cases that fail baseline models.

Results with Unknown Entities. Table 3 gives results with unknown entities. In this setting, classification-based methods need to identify entities first, thus we implement a BERT-base one for them[7]. Joint EE methods are also compared, which do not require entity information. We use RCEE for comparison, which excludes entity refinement. From the results, RCEE still demonstrates the best performance — it beats both classification based methods (over 9.3% in F1) and joint models (over 6.0%). By checking $\Delta F1$, we note RCEE relies relatively less on golden entities (-4.3% in F1 without them), but classification-based methods depend heavily on them, suffering from a drop of over 8% in F1 with the predicted entities.

4.3 Results in Data-Scarce Scenarios

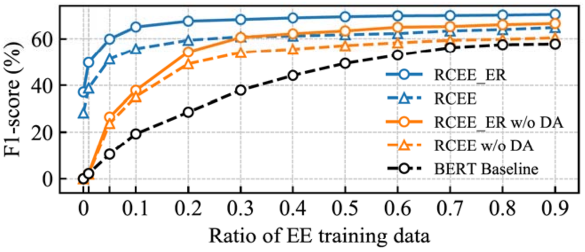

Figure 4: Results on different ratios of EE training data.

METHOD	1%	5%	10%	20%
DMCNN	-	8.7	16.6	23.7
dbRNN	-	8.1	17.2	24.1
BERTEE	2.20	10.5	19.3	28.6
RCEE	38.8	51.3	55.7	59.4
RCEE *w/o* DA	2.00	23.8	35.2	49.2
RCEE_ER	**49.8**	**59.9**	**65.1**	**67.6**
RCEE_ER *w/o* DA	2.20	26.5	37.8	54.1

Table 4: F1 score (%) on exploring the extremely data-scarce scenarios.

Figure 4 compares models and BERTEE in data-scarce scenarios, and Table 4 gives results in the *extremely* data-low scenario ($\leq$ 20% training data)[8]. From the results, our model demonstrates superior performance, for example, obtaining 49.8% in F1 with only 1% of EE training data, in comparison to 2.2% in F1 of BERTEE. We note the improvement comes from two aspects: 1) Data augmentation (DA). For example, DA improves +47.6% and +33.4% for RCEE_ER in experiments with 1% and %5 data according to Table 4. 2) Answer generation algorithm. Note RCEE_ER without DA still consistently outperforms BERTEE in data-low scenarios. This implies the answer generation algorithm is *data-efficient* than classification method. The reason might be that, the answer generation algorithm in our approach is position-based, which might be robust for unseen words. While the classification method in previous EE methods are largely word-based, which requires more labeled data.

4.4 Results in Zero-Shot Scenarios

Table 5 shows the results regarding zero-shot EE, where EE data is completely banned for training (Only using DA for model pre-training). To increase the persuasiveness of results, we adopt another dataset, FrameNet (Baker, 2014) (where frames are treated as meta event type) for evaluation. From the results: without any EE data, our model achieves 37% and 16.6% in F1 on ACE and FrameNet. This illustrates the effectiveness of our model handling unseen types.

---

[7] One tagger reaches 85.4%/85.9%/85.6% in P/R/F1, matching the state-of-the-art (Yang and Mitchell, 2016).

[8] To simplicity discussion, we assume golden triggers in the following experiments.

DATASET	MODEL	P	R	F1
ACE2005	RCEE	25.5	26.0	25.8
	RCEE_ER	38.2	35.8	37.0
FrameNet	RCEE	18.2	15.3	16.6

Table 5: F1 score (%) on exploring the zero-shot scenarios on ACE 2005 and FrameNet.

5 Further Discussion

5.1 Impact of Question Generation

We compare different question generation strategies: 1) QRole, which uses a role's name as query; 2) QCommand, which uses "Find the #Role" as query (Li et al., 2019a), and 3) QTemplate, which uses a template "What is the #ROLE in the #event_trigger event?" as query (FitzGerald et al., 2018). From the results, QRole, QCommand, and QTemplate achieve 60.1%, 64.9%, and 68.%5 in F1 in argument extraction; compared with 70.1% of our approach. We note the inferiority of those methods may lay in their poor expression ability. For example, in a sentence "The pair *flew* to Singapore last year after ...", QNAME uses "Time" as query; QCommand uses "Find the Time" as query; QTemplate uses "What is the Time in the flew event?" as query. While our approach directly generates a nearly perfect question "[When] do the pair fly to Singapore?" We provide more examples in supplement materials.

5.2 Performance on Different Roles

Figure 5 shows the performance of RCEE on different semantic roles, regarding four randomly selected roles with 1) plenty data, e.g. `Defendant` with 359 training examples; 2) medium-sized data, e.g. `Money` with 75 examples; and 3) limited data, e.g. `Seller` and `Price` with only 32 and 9 examples (rare roles). From the results, classification based methods, e.g. BERTEE, can achieve a good result for roles with plenty data, but their performance deteriorates seriously when a role has insufficient data. By comparison, our approach RCEE demonstrates excellent performance in handling rare roles, for example, obtaining 61.5% and 78.2% in F1 for `Seller` and `Price` (note `Price` has only 9 examples), in compared with 8.9% and 1.7% of BERTEE.

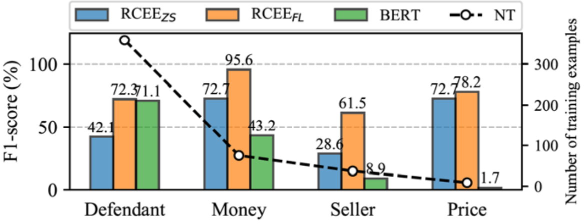

Figure 5: Performance on different roles. RCEE$_{ZS}$ and RCEE$_{FL}$ indicate zero-shot and full-training scenarios. NT denotes number of training data of a role.

(a) Putin were scheduled to **leave** ... *16 words omit* ... nations in Evian, France.
Role=`Destination` | G="Evian, France" | P=NONE

(b) Attempts by Laleh and Ladan to have ... *14 words omit* ... both of them could **die**.
Role=`Victim` | G="Laleh and Ladan" | P="them"

Table 6: Example error cases. Bold denotes trigger; G and P denote the ground-truth and predicted argument.

5.3 Error Analysis

We conduct error analysis in this section. One typical error is related to long-range dependency, accounting for 23.4% (here "long-range" denotes the distance between a trigger and an argument is $\geq$ 10). Table 6 (a) shows a case, where the argument *Evian, France* is about 20 words away from the trigger **leave**, making it difficult to identify the argument. 2) The second error relates to roles whose meaning are general, e.g., `Entity`, `Agent` — it is usually difficult to generate meaningful questions for these roles, causing 32.7% errors among all cases. 3) The third error relates to co-reference, which accounts for 17.2%. Considering the example in Table 6 (b), where **die** evokes a `Die` event with "Laleh" and "Ladan" fulfilling a semantic role `Victim`. Our model predicts "them" (two words ahead of **die**) as answer — though "them" is a reference of "Laleh and Ladan", it considered as an error according to current evaluations. This also raises the question of whether we should consider co-reference when we evaluate EE systems.

6 Conclusion and Future Work

In this paper, we take a fresh look at EE by casting it as an MRC problem. Our method includes an unsupervised question generation process which can generate both relevant and context-related questions, whose effectiveness is verified by empirical results. In the future, we would adapt our method to other IE tasks to study its application scope.

A Implementation Details of Unsupervised Question Generation

Following Lample et al. (2018b), we use FastBPE to split each example into sub-word units, with a vocabulary size of $60k$. We implement both encoders and decoders as 4-layer transformers, where one layer is domain-specific for both the encoder and decoder and the rest are shared. Moreover, we use the standard hyper-parameter settings recommended by (Lample et al., 2018b). The input word embeddings are initialized as FastText vectors trained on the concatenation of the S and Q. During training, we reduce the coefficient of auto-encoding loss from 1.0 to 0.5 by 100K steps and to 0 by 300K steps. We cease training when the BLEU scores between back-translated and input questions stop improving, usually around 800K steps. For inference, we use a beam size of 5 and a language model to evaluate all the candidates to yield the best one.

Negotiations between Washington and Pyongyang on Role = `Time/Place` (When/Where) did the negotiations between Washington and Pyongyang begin ?

Abstract

Event detection (ED), which means identifying event trigger words and classifying event types, is the first and most fundamental step for extracting event knowledge from plain text. Most existing datasets exhibit the following issues that limit further development of ED: (1) **Data scarcity**. Existing small-scale datasets are not sufficient for training and stably benchmarking increasingly sophisticated modern neural methods. (2) **Low coverage**. Limited event types of existing datasets cannot well cover general-domain events, which restricts the applications of ED models. To alleviate these problems, we present a MAssive eVENt detection dataset (MAVEN), which contains $4,480$ Wikipedia documents, $118,732$ event mention instances, and 168 event types. MAVEN alleviates the data scarcity problem and covers much more general event types. We reproduce the recent state-of-the-art ED models and conduct a thorough evaluation on MAVEN. The experimental results show that existing ED methods cannot achieve promising results on MAVEN as on the small datasets, which suggests that ED in the real world remains a challenging task and requires further research efforts. We also discuss further directions for general domain ED with empirical analyses. The source code and dataset can be obtained from `https://github.com/THU-KEG/MAVEN-dataset`.

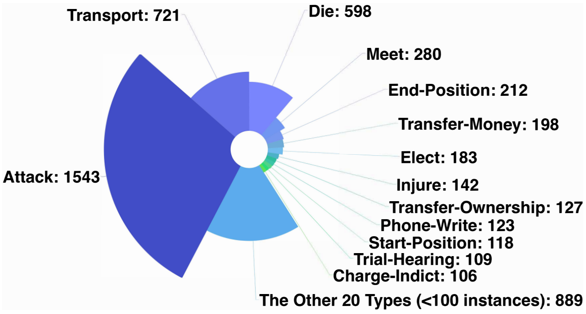

Figure 1: Data distribution of the most widely-used ACE 2005 English dataset. It contains 33 event types, 599 documents and $5,349$ instances in total.

1 Introduction

Event detection (ED) is an important task of information extraction, which aims to identify event triggers (the words or phrases evoking events in text) and classify event types. For instance, in the sentence "*Bill Gates* `founded` *Microsoft in 1975*", an ED model should recognize that the word "`founded`" is the trigger of a `Found` event. ED is the first stage to extract event knowledge from text (Ahn, 2006) and also fundamental to various NLP applications (Yang et al., 2003; Basile et al., 2014; Cheng and Erk, 2018; Yang et al., 2019).

Due to the rising requirement of event understanding, many efforts have been devoted to ED in recent years. The advanced models have been continuously proposed, including the feature-based models (Ji and Grishman, 2008; Gupta and Ji, 2009; Li et al., 2013; Araki and Mitamura, 2015) and advanced neural models (Chen et al., 2015; Nguyen and Grishman, 2015; Nguyen et al., 2016; Feng et al., 2016; Ghaeini et al., 2016; Liu et al., 2017; Zhao et al., 2018; Chen et al., 2018; Ding et al., 2019; Yan et al., 2019). Nevertheless, the benchmark datasets for ED are upgraded slowly. As event annotation is complex and expensive, the existing datasets are mostly small-scale. As shown in Figure 1, the most widely-used ACE 2005 English dataset (Walker et al., 2006) only contains 599 documents and $5,349$ annotated instances. Due to the inherent data imbalance problem, 20 of its 33 event types only have fewer than 100 annotated instances. As recent neural methods are typically data-hungry, these small-scale datasets are not sufficient for training and stably benchmarking mod-

ern sophisticated models. Moreover, the covered event types in existing datasets are limited. The ACE 2005 English dataset only contains 8 event types and 33 specific subtypes. The Rich ERE ontology (Song et al., 2015) used by TAC KBP challenges (Ellis et al., 2015, 2016) covers 9 event types and 38 subtypes. The coverage of these datasets is low for general domain events, which results in the models trained on these datasets cannot be easily transferred and applied on general applications.

Recent research (Huang et al., 2016; Chen et al., 2017) has shown that the existing datasets suffering from the data scarcity and low coverage problems are now inadequate for benchmarking emerging methods, i.e., the evaluation results are difficult to reflect the effectiveness of novel methods. To tackle these issues, some works adopt the distantly supervised methods (Mintz et al., 2009) to automatically annotate data with existing event facts in knowledge bases (Chen et al., 2017; Zeng et al., 2018; Araki and Mitamura, 2018) or use bootstrapping methods to generate new data (Ferguson et al., 2018; Wang et al., 2019b). However, the generated data are inevitably noisy and homogeneous due to the limited number and low diversity of event facts and seed data instances.

In this paper, we present MAVEN, a human-annotated massive general domain event detection dataset constructed from English Wikipedia and FrameNet (Baker et al., 1998), which can alleviate the data scarcity and low coverage problems:

(1) Our MAVEN dataset contains $111,611$ different events, $118,732$ event mentions, which is twenty times larger than the most widely-used ACE 2005 dataset, and $4,480$ annotated documents in total. To the best of our knowledge, this is the largest human-annotated event detection dataset until now.

(2) MAVEN contains 168 event types, which covers a much broader range of general domain events. These event types are manually derived from the frames defined in the linguistic resource FrameNet (Baker et al., 1998), which has been shown to have good coverage of general event semantics (Aguilar et al., 2014; Huang et al., 2018). Furthermore, we construct a tree-structure hierarchical event type schema, which not only maintains the good coverage of FrameNet but also avoids the difficulty of crowd-sourced annotation caused by the original sophisticated schema, and may help future ED models with the hierarchy information.

We reproduce some recent state-of-the-art ED models and conduct a thorough evaluation of these models on MAVEN. From the experimental results, we observe significant performance drops of these models as compared with on existing ED benchmarks. It indicates that detecting general-domain events is still challenging and the existing datasets are difficult to support further explorations. We also explore some promising directions with empirical analyses, including modeling the multiple events shown in one sentence, using the hierarchical event schema to handle long-tail types and distinguish close types, and improving low-resource ED tasks with transfer learning. We hope that all contents of MAVEN could encourage the community to make further breakthroughs.

2 Event Detection Definition

In our dataset, we mostly follow the settings and terminologies defined in the ACE 2005 program (Doddington et al., 2004). We specify the vital terminologies as follows:

An **event** is a specific occurrence involving participants (Consortium, 2005). In MAVEN, we mainly focus on extracting the basic events that can be specified in one or a few sentences. Each event will be labeled with a certain **event type**. An **event mention** is a sentence within which the event is described. As the same event may be mentioned multiple times in a document, there are typically more event mentions than events. An **event trigger** is the key word or phrase in an event mention that most clearly expresses the event occurrence.

The ED task is to identify event triggers and classify event types for given sentences. Accordingly, ED is conventionally divided into two subtasks: Trigger Identification and Trigger Classification (Ahn, 2006). **Trigger identification** is to identify the annotated triggers from all possible candidates. **Trigger classification** is to classify the corresponding event types for the identified triggers. Both the subtasks are evaluated with micro precision, recall, and F-1 scores. Recent neural methods typically formulate ED as a token-level multi-class classification task (Chen et al., 2015; Nguyen et al., 2016) or a sequence labeling task (Chen et al., 2018; Zeng et al., 2018), and only report the trigger classification results (add an additional type `N/A` to be classified at the same time, indicating that the candidate is not a trigger). In MAVEN, we inherit all the above-mentioned settings in both dataset construction and model evaluation.

3 Data Collection of MAVEN

3.1 Event Schema Construction

The event schema used by the existing ED datasets like ACE (Doddington et al., 2004), Light ERE (Aguilar et al., 2014) and Rich ERE (Song et al., 2015) only includes limited event types (e.g. `Movement`, `Contact`, etc). Hence, we need to construct a new event schema with a good coverage of general-domain events for our dataset.

Inspired by Aguilar et al. (2014), we mostly use the frames in FrameNet (Baker et al., 1998) as our event types for a good coverage. FrameNet follows the frame semantic theory (Fillmore, 1976, 2006) and defines over 1,200 semantic frames along with corresponding frame elements, frame relations, and lexical units. From the ED perspective, some frames and lexical units can be used as event types and triggers respectively.

Considering FrameNet is primarily a linguistic resource constructed by linguistic experts, it prioritizes lexicographic and linguistic completeness over ease of annotation (Aguilar et al., 2014). To facilitate the crowd-sourced annotation with large numbers of annotators, we simplify the original frame schema into our event schema. We collect 598 event-related frames from FrameNet by recursively selecting the frames having "Inheritance", "Subframe" or "Using" relations with the `Event` frame like Li et al. (2019). Then we manually filter out abstractive frames (e.g. `Process_resume`), merge similar frames (e.g. `Choosing` and `Adopt_selection`), and assemble too fine-grained frames into more generalized frames (e.g. `Visitor_arrival` and `Drop_in_on` into `Arriving`). We finally get 168 event types to annotate, covering 74.4% (selected or inherit from the selected frames) of the 598 event-related frames, and the mapping between event types and frames are shown in Appendix D.

Based on the FrameNet inheritance relation and the HowNet event schema (Dong and Dong, 2003), we organize the event types into a tree-structure **hierarchical event type schema**. During annotation, we ask the annotators to label the triggers with the most fine-grained type (e.g. `Theft` and `Robbery`). The coarse-grained types (e.g. `Committing_crime`) are only used for those rare events without appropriate fine-grained types so that to recall more events with fewer labels. Appendix C shows the overall hierarchical schema.

Topic	#Documents	Percentage
Military conflict	1,458	32.5%
Hurricane	480	10.7%
Civilian attack	287	6.4%
Concert tour	255	5.7%
Music festival	170	3.8%
Total	2,650	59.2%

Table 1: Count and % of MAVEN documents in Top-5 EventWiki (Ge et al., 2018) topics.

3.2 Document Selection

To support the annotation, we need a large number of informative documents as our basic corpus. We adopt English Wikipedia as our data source considering it is informative and widely-used (Rajpurkar et al., 2016; Yang et al., 2018). Meanwhile, Wikipedia articles contain rich entities, which will benefit event argument annotation in the future.

To effectively select the articles containing enough events, we follow a simple intuition that the articles describing grand "topic events" may contain much more basic events than the articles about specific entity definitions. We adopt EventWiki (Ge et al., 2018) to help select the event-related articles. It is a knowledge base for major events and each major event is described with a Wikipedia article. We thus utilize the articles indexed by EventWiki as the base and manually select some articles to annotate their basic events covered by our event schema. To ensure the quality of articles, we follow the previous settings (Yao et al., 2019) to use the introductory sections for annotation. Moreover, we filter out the articles with fewer than 5 sentences or fewer than 10 event-related frames labeled by a semantic labeling tool (Swayamdipta et al., 2017).

Finally, we select 4,480 documents in total, covering 90 of the 95 major event topics defined in EventWiki. Table 1 shows the top 5 EventWiki topics of our selected documents.

3.3 Candidate Selection and Automatic Labeling

We have massive data to be annotated with 168 event types. To facilitate efficiency and improve consistency of our annotators, who are not all linguistic experts, we adopt some heuristic methods to narrow down trigger candidates and the corresponding event type candidates, and automatically label some triggers to provide information.

	Dataset	#Documents	#Tokens	#Sentences	#Event Types	#Events	#Event Mentions
	ACE 2005	599	303k	$15,789$	33	$4,090$	$5,349$
Rich ERE	LDC2015E29	91	43k	$1,903$	38	$1,439$	$2,196$
	LDC2015E68	197	164k	$8,711$	37	$2,650$	$3,567$
	LDC2015E78	171	114k	$4,979$	31	$2,285$	$2,933$
	TAC KBP 2014	351	282k	$14,852$	34	$10,719$	$10,719$
	TAC KBP 2015	360	238k	$11,535$	38	$7,460$	$12,976$
	TAC KBP 2016	169	109k	$5,295$	18	$3,191$	$4,155$
	TAC KBP 2017	167	99k	$4,839$	18	$2,963$	$4,375$
	Total	$1,272$	854k	$41,708$	38	$29,293$	$38,853$
	MAVEN	**$4,480$**	**$1,276$k**	**$49,873$**	**168**	**$111,611$**	**$118,732$**

Table 2: Statistics of MAVEN compared with existing widely-used ED datasets. The #Event Type shows the number of the most fine-grained types (i.e. the "subtype" of ACE and ERE). For the multilingual datasets, we report the statistics of the English subset (typically the largest subset) for direct comparisons to MAVEN. We merge all the Rich ERE datasets and remove the duplicate documents to get the "Total" statistics.

Candidate selection We first do POS tagging with the NLTK toolkit (Bird, 2006), and select the content words (nouns, verbs, adjectives, and adverbs) as the trigger candidates to be annotated. As event triggers can also be phrases, the phrases in documents that can be matched with the phrases provided in FrameNet are also selected as trigger candidates. For each trigger candidate, we provide 15 event types as label candidates. The 15 type candidates are automatically recommended with the cosine similarities between trigger word embeddings and the average of the word embeddings of event types' corresponding lexical units in FrameNet. The word embeddings we used here are the pre-trained Glove (Pennington et al., 2014) word vectors. To verify the effectiveness of these candidate selection methods, we randomly choose 50 documents and invite an expert to directly label all the words with the 168 event types. The results show that 100% of the expert-provided labeled triggers appeared among the automatically listed trigger candidates provided to annotators. Furthermore, the results also show that 96.8% of the expert-provided event types appeared among the 15 event type candidates automatically recommended to the annotators.

Automatic labeling We label some trigger candidates with a state-of-the-art frame semantic parser (Swayamdipta et al., 2017) and use the corresponding event types of the predicted frames as the default event types. The annotators can replace them with more appropriate event types or just keep them to save time and effort. Evaluated on the final dataset, the frame semantic parser can achieve 52.4% precision and 49.7% recall, which indicates that the automatic labeling process can help to save about a half of the overall annotation effort.

3.4 Human Annotation

The final step requires the annotators to label the trigger candidates with appropriate event types and merge the event mentions (annotate which mentions are expressing the same event).

Annotation process As the event annotation is complicated, to ensure the accuracy and consistency of our annotation, we follow the ACE 2005 annotation process (Consortium, 2005) to organize a two-stage iterative annotation. In the first stage, 121 crowd-source annotators are invited to annotate the documents given the default results and candidate sets described in the last section. Each document is annotated twice by two independent annotators in this stage. In the second stage, 17 experienced annotators and experts will give the final results on top of the annotation results of the two first-stage annotators. Each document will be annotated only once in the second stage.

Data quality To evaluate the dataset quality, we randomly sample 1,000 documents and invite different second-stage annotators to independently annotate these documents for one more time. We measure the inter-annotator agreements of the event type annotation between two annotators with Cohen's Kappa (Cohen, 1960). The results for the first stage trigger and type annotation are 38.2% and 42.7%, respectively. And the results for the second stage trigger and type annotation are 64.1% and 73.7%. One of the authors also manually examined

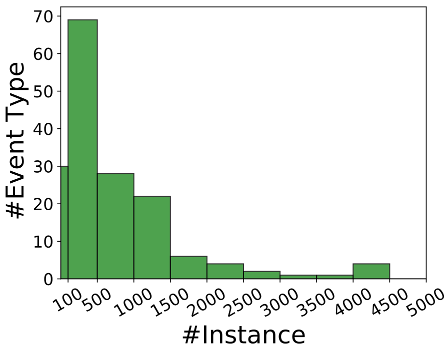

Figure 2: Distribution of MAVEN event types by their instance numbers.

Top-level Event Type	Subtype Examples	Percentage
`Action`	`Telling`, `Attack`, `Building`	46.9%
`Change`	`Change_event_time`, `Change_of_leadership`	27.5%
`Scenario`	`Emergency`, `Catastrophe`, `Incident`	13.4%
`Sentiment`	`Supporting`, `Convincing`, `Quarreling`	6.4%
`Possession`	`Commerce_buy`, `Giving`, `Renting`	5.7%

Table 3: Five top-level event types and their percentages of MAVEN. Appendix C shows more details.

50 random documents. The estimated accuracies of event type annotation and event mention merging are 90.1% and 86.0% respectively. These results show that although the general domain event annotation is difficult (the first-stage inter-agreement is low), MAVEN's quality is satisfactory.

4 Data Analysis of MAVEN

4.1 Data Size

We show the main statistics of MAVEN and compare them with some existing widely-used ED datasets in Table 2, including the most widely-used ACE 2005 dataset (Walker et al., 2006) and a series of Rich ERE annotation datasets provided by TAC KBP competition, which are DEFT Rich ERE English Training Annotation V2 (LDC2015E29), DEFT Rich ERE English Training Annotation R2 V2 (LDC2015E68), DEFT Rich ERE Chinese and English Parallel Annotation V2 (LDC2015E78), TAC KBP Event Nugget Data 2014-2016 (LDC2017E02) (Ellis et al., 2014, 2015, 2016) and TAC KBP 2017 (LDC2017E55) (Getman et al., 2017). The Rich ERE datasets can be combined as used in Lin et al. (2019) and Lu et al. (2019), but the combined dataset is still much smaller than MAVEN. MAVEN is larger than all existing ED datasets, especially in the number of events. Hopefully, the large-scale dataset can accelerate the research on general domain ED.

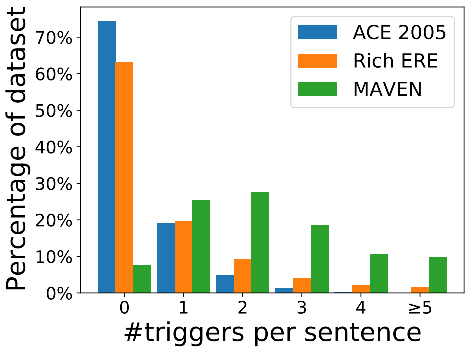

Figure 3: Distribution of sentences containing different numbers of (golden) triggers of three datasets.

4.2 Data Distribution

Figure 2 shows the histogram of MAVEN event types by their instance numbers. We can observe that the inherent data imbalance problem also exists in MAVEN. However, as MAVEN is large-scale, 41% and 82% event types have more than 500 and 100 instances respectively. Compared with existing datasets like ACE 2005 (only 39% event types have more than 100 instances), MAVEN significantly alleviates the data scarcity problem, which will benefit developing strong ED models and various event-related downstream applications.

We want MAVEN to serve as a real-world ED dataset, and the distribution of real-world data is inherently long-tail. To evaluate the ED ability on the long-tail scenario is also our goal. Hence, we do not apply data augmentation or balancing during dataset construction and maintain the real-world distribution in MAVEN. To support future exploration of handling the long-tail problem, we design a hierarchical event type schema, which may help transfer knowledge from the coarse-grained event types to the long-tail fine-grained types. We show the five top-level (most coarse-grained) types and their proportions in Table 3 and the detailed hierarchical schema in Appendix C.

4.3 Multiple Events in One Sentence

A key phenomenon of ED datasets is that a sentence can express multiple events at the same time, and ED models will better classify the event types with the help of correlations between multiple events. Although the multiple event phenomenon has been investigated by existing works (Li et al., 2013;

Subset	#Document	#Event	#Mention	#Negative.
Train	2,913	73,496	77,993	323,992
Dev	710	17,726	18,904	79,699
Test	857	20,389	21,835	93,570

Table 4: The statistics of splitting MAVEN. "#Negative." is the number of negative instances.

Chen et al., 2018; Liu et al., 2018) on ACE 2005 dataset, we observe that this phenomenon is much more common and complex on MAVEN.

In Figure 3, we compare MAVEN's percentages of sentences containing different numbers of triggers with ACE 2005 and the combined Rich ERE dataset (corresponding to the "Total" row in Table 2). We can observe that because MAVEN's coverage on general domain events is much higher, the multiple events in one sentence phenomenon is much more common in MAVEN than existing datasets. Moreover, as more event types are defined in MAVEN, the association relations between event types will be much more complex than on ACE 2005. We hope MAVEN can facilitate ED research on modeling multiple event correlations.

5 Experiments

Our experiments and analyses will show the challenges of MAVEN and promising ED directions.

5.1 Benchmark Setting

We firstly introduce the MAVEN benchmark setting here. MAVEN is randomly split into training, development, and test sets and the statistics of the three sets are shown in Table 4. After splitting, there are 32% and 71% of event types that have more than 500 and 100 training instances respectively, which ensures the models can be well-trained.

Conventionally, the existing ED datasets only provide the standard annotation of positive instances (the annotated event triggers) and researchers will sample the negative instances (non-trigger words or phrases) by themselves, which may lead to potential unfair comparisons between different methods. In MAVEN, we provide official negative instances to ensure fair comparisons. As described in Section 3.3, the negative instances are the content words labeled by the NLTK POS tagger or the phrases which can be matched with the FrameNet lexical units. In other words, we only filter out those empty words, which will not influence the application of models developed on MAVEN.

5.2 Experimental Setting

Models Recently, various neural models have been developed for ED and achieved superior performances compared with traditional feature-based models. Hence, we reproduce six representative state-of-the-art neural models and report their performances on both MAVEN and widely-used ACE 2005 to assess the challenges of MAVEN, including: (1) **DMCNN** (Chen et al., 2015) is a convolutional neural network (CNN) model, which leverages a CNN to automatically learn sequence representations and a dynamic multi-pooling mechanism to aggregate learned features into trigger-specific representations for classification. (2) **BiLSTM** (Hochreiter and Schmidhuber, 1997) is a vanilla recurrent neural network baseline, which adopts the widely-used bi-directional long short-term memory network to learn textual representations, and then uses the hidden states at the positions of trigger candidates for classifying event types. (3) **MOGANED** (Yan et al., 2019) is an advanced graph neural network (GNN) model. It proposes a multi-order graph attention network to effectively model the multi-order syntactic relations in dependency trees and improve ED. (4) **DMBERT** (Wang et al., 2019b) is a vanilla BERT-based model. It takes advantage of the effective pre-trained language representation model BERT (Devlin et al., 2019) and also adopts the dynamic multi-pooling mechanism to aggregate features for ED. We use the $\text{BERT}_{\text{BASE}}$ architecture in our experiments. (5) Different from the above token-level classification models, **BiLSTM+CRF** and **BERT+CRF** are sequence labeling models. To verify the effectiveness of modeling multiple event correlations, the two models both adopt the conditional random field (CRF) (Lafferty et al., 2001) as their output layers, which can model structured output dependencies. And they use BiLSTM and $\text{BERT}_{\text{BASE}}$ as their feature extractors respectively.

As we manually tune hyperparameters and some training details, the results of reproduced models may be different from the original papers. Please refer to Appendix A for reproduction details.

Evaluation Following the widely-used setting introduced in Section 2, we report the micro precision, recall, and F-1 scores for trigger classification as our evaluation metrics. For direct comparisons with the token-level classification models, we use span-based metrics for the sequence labeling base-

Method	ACE 2005			MAVEN		
	P	R	F-1	P	R	F-1
DMCNN	73.7 ± 2.42	63.3 ± 3.30	68.0 ± 1.95	**66.3 ± 0.89**	55.9 ± 0.50	60.6 ± 0.20
BiLSTM	71.7 ± 1.70	**82.8 ± 1.00**	**76.8 ± 1.01**	59.8 ± 0.81	67.0 ± 0.76	62.8 ± 0.82
BiLSTM+CRF	**77.2 ± 2.08**	74.9 ± 2.62	75.4 ± 1.64	63.4 ± 0.70	64.8 ± 0.69	64.1 ± 0.13
MOGANED	70.4 ± 1.38	73.9 ± 2.24	72.1 ± 0.39	63.4 ± 0.88	64.1 ± 0.90	63.8 ± 0.18
DMBERT	70.2 ± 1.71	78.9 ± 1.64	74.3 ± 0.81	62.7 ± 1.01	**72.3 ± 1.03**	67.1 ± 0.41
BERT+CRF	71.3 ± 1.77	77.1 ± 1.99	74.1 ± 1.56	65.0 ± 0.84	70.9 ± 0.94	**67.8 ± 0.15**

Table 5: The overall trigger classification performance of various models on ACE 2005 and MAVEN.

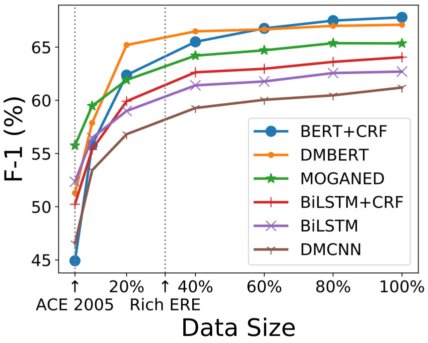

Figure 4: Model performance (F-1) change along with the training data size.

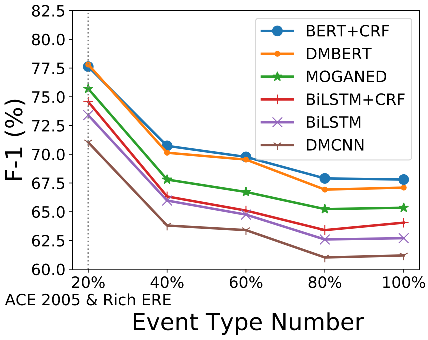

Figure 5: Model performance (F-1) change along with the number of event types.

lines. On ACE 2005[1], we use 40 newswire articles for test, 30 random documents for development, and 529 documents for training following previous work (Chen et al., 2015; Wang et al., 2019c), and sample all the unlabeled words as negative instances. To get stable results, we run each model 10 times on both datasets and report the averages and standard deviations for each metric.

5.3 Overall Experimental Results

The overall experimental results are in Table 5, from which we have the following observations:

(1) Although the models perform well on ACE 2005, their performances are significantly lower and not satisfying on MAVEN. It indicates that our MAVEN is challenging and the general domain ED still needs more research efforts. (2) The result deviations of various models on MAVEN are typically significantly lower than on the small-scale ACE 2005, which suggests that the small-scale datasets cannot stably benchmark sophisticated ED methods, while MAVEN alleviates this problem with its massive annotated data. (3) It is surprising to find that the BiLSTM-based models achieve remarkably high performance on ACE 2005, even outperform the BERT models. We guess this is because the small-scale dataset cannot stably train and benchmark large models. The results on MAVEN are intuitive. (4) From the comparison between the **BiLSTM+CRF** and **BiLSTM**, we can observe that the CRF-based method achieves obvious improvement on MAVEN, but cannot outperform the vanilla **BiLSTM** on ACE 2005. **BERT+CRF** also outperforms **DMBERT** on MAVEN even without the effective dynamic multi-pooling mechanism. Considering the key advantage of the CRF output layer in ED is to model multiple event correlations, the results are consistent with our observations in Section 4.3 that the multiple events in one sentence phenomenon is much more common in MAVEN. This suggests how to better modeling multiple events is worth exploring.

5.4 Analyses on Data Size and #Event Types

MAVEN contains more data and covers more event types compared with existing benchmarks. In this section, we analyze the benefits of a larger data scale and the challenge of more event types.

We randomly choose different proportions of documents from the MAVEN training set and compare the model performances trained with different sizes of data in Figure 4. We can observe that

---

[1] `catalog.ldc.upenn.edu/LDC2006T06`

Method	ACE 2005 Trigger Classification		
	P	R	F-1
DMBERT	70.2 ± 1.71	$\mathbf{78.9 \pm 1.64}$	74.3 ± 0.81
+aug	68.7 ± 1.21	76.4 ± 1.16	72.4 ± 0.75
+pretrain	$\mathbf{71.9 \pm 1.12}$	78.7 ± 1.44	$\mathbf{75.1 \pm 0.56}$

Table 6: The performance of DMBERT with two simple knowledge transfer methods on ACE 2005.

MAVEN can sufficiently train the models and stably benchmark them, and we will get unreliable comparison results at the existing datasets' scale.

We also randomly choose different proportions of event types and train the models to only classify the chosen types. The model performances are shown in Figure 5. With the increase in the number of event types, we can observe significant performance drops, which demonstrates the challenge brought by the high coverage of MAVEN.

5.5 Analyses on Transferability

As MAVEN annotates a large range of general domain events, an intuitive question is whether the general ED knowledge learned on MAVEN can transfer to other ED tasks that do not have sufficient data. We examine the transferability of MAVEN with experiments on ACE 2005.

We explore two simple transfer learning methods on **DMBERT** model. (1) Data augmentation (**+aug**) is to add $18,729$ MAVEN instances into ACE 2005 training set and directly train the model. As the event schema of ACE 2005 and MAVEN is different, we manually build an incomplete mapping of event types, which is shown in Appendix B. (2) Intermediate pre-training (**+pretrain**), which is to first train the model on MAVEN and then fine-tune it on ACE 2005. This method has been shown to be effective on some natural language inference tasks (Wang et al., 2019a).

The results are shown in Table 6, from which we can observe that as MAVEN focuses on different event types and a different text domain (Wikipedia), direct data augmentation harms ED performances while tested on ACE 2005 (newswire data). However, intermediate pre-training can improve ED on ACE 2005 with the general event knowledge learned on MAVEN, which indicates MAVEN's high coverage of event types can benefit other ED tasks. It is worth to explore how to apply more advanced transfer learning methods to improve the performance on low-resource ED scenarios.

Method	Identification Mistakes		Event Type Mistakes		
	FP	FN	Parent -Children	Between Siblings	Into Top 50%
DMCNN	27.3%	55.9%	15.5%	19.8%	89.2%
BiLSTM	26.9%	52.9%	14.5%	14.6%	90.3%
MOGANED	44.5%	31.3%	15.5%	17.8%	86.8%
DMBERT	48.5%	27.2%	13.1%	19.0%	87.0%

Table 7: The proportions of different kinds of mistakes in various models' predictions on MAVEN dev set. The numbers of positive and negative instances are $18,904$ and $79,699$, respectively.

5.6 Error Analysis

To analyze the abilities required by MAVEN, we conduct error analyses on the prediction results of various token-level classification ED models (the sequence labeling methods have span prediction errors, hence cannot be analyzed with misclassifying types as here). The results are shown in Table 7, from which we can observe:

(1) "Identification Mistakes" indicates misclassifying negative instances into positive types (FP) or misclassifying positive instances into `N/A` (FN), which is the most common mistake. It indicates that identifying event semantics from various and complicated language expressions is still challenging and needs further efforts.

(2) "Event Type Mistakes" indicates misclassifying between the 168 event types. The percentages of the three subtype mistakes are all calculated within "Event Type Mistakes". "Parent-Children" indicates misclassifying instances into their parent or children types in the tree-structure hierarchical event type schema, and "Between Siblings" indicates misclassifying instances into their sibling types. Considering each event type only has one parent type and 9.96 sibling types on average, the percentages of these two kinds of mistakes are significantly higher than misclassifying into other distant types. It suggests that existing models typically cannot well distinguish subtle differences between event types, and our hierarchical event type schema may help models to this point.

(3) "Into Top 50%" indicates misclassifying into event types with top 50% amounts of data. It shows that ED models should develop the ability to resist the influence of the inherent data imbalance problem. Hence, further explorations on handling these problems may bring more effective ED models. To this end, our hierarchical event schema may also be helpful in developing data balancing and data augmentation methods.

6 Related Work

As stated in Section 2, we follow the ED task definition specified in the ACE challenges, especially the ACE 2005 dataset (Doddington et al., 2004) in this paper, which requires ED models to generally detect the event triggers and classify them into specific event types. The ACE event schema is simplified into Light ERE and further extended to Rich ERE (Song et al., 2015) to cover more but still a limited number of event types. Rich ERE is used to create various datasets and the TAC KBP challenges (Ellis et al., 2014, 2015, 2016; Getman et al., 2017). Nowadays, the majority of ED and event extraction models (Ji and Grishman, 2008; Li et al., 2013; Chen et al., 2015; Feng et al., 2016; Liu et al., 2017; Zhao et al., 2018; Yan et al., 2019) are developed on these datasets. Our MAVEN follows the effective framework and extends it to numerous general domain event types and data instances.

There are also various datasets defining the ED task in different ways. The early MUC series datasets (Grishman and Sundheim, 1996) define event extraction as a slot-filling task. The TDT corpus (Allan, 2012) and some recent datasets (Minard et al., 2016; Araki and Mitamura, 2018; Sims et al., 2019; Liu et al., 2019) follow the open-domain paradigm, which does not require models to classify events into pre-defined event types for better coverage but limits the downstream application of the extracted events. Some datasets are developed for ED on specific domains, like the biomedical domain (Pyysalo et al., 2007; Kim et al., 2008; Thompson et al., 2009; Buyko et al., 2010; Nédellec et al., 2013), literature (Sims et al., 2019), Twitter (Ritter et al., 2012; Guo et al., 2013) and breaking news (Pustejovsky et al., 2003). These datasets are also typically small-scale due to the inherent complexity of event annotation, but their different settings are complementary to our work.

7 Conclusion and Future work

In this paper, we present a massive general domain event detection dataset (MAVEN), which significantly alleviates the data scarcity and low coverage problems of existing datasets. We conduct a thorough evaluation of the state-of-the-art ED models on MAVEN. The results indicate that general domain ED is still challenging and MAVEN may facilitate further research. We also explore some promising directions with analytic experiments, including modeling multiple event correlations (Section 5.3), utilizing the hierarchical event schema to distinguish close types (Section 5.6), and improving other ED tasks with transfer learning (Section 5.5). In the future, we will extend MAVEN to more event-related tasks like event argument extraction, event sequencing, etc.

A Hyperparameter Settings and Training Details

In this section, we introduce the hyperparameter settings and training details of various ED models that we implemented for experiments.

A.1 BERT-based Models

For both **DMBERT** and **BERT-CRF**, we use the $\text{BERT}_{\texttt{BASE}}$ model and the released pre-trained checkpoints[2], and implement them with HuggingFace's Transformers library (Wolf et al., 2019). The two models are both trained with the AdamW[3] optimizer and share most of the hyperparameters. Their hyperparameters are shown in Table 8.

For the **DMBERT** model, we insert special tokens (`[unused0]` and `[unused1]`) around the trigger candidates to indicate their positions and use a much larger batch size, hence the results are higher than the original implementation (Wang et al., 2019b).

For the **BERT+CRF** model, we use the widely-used "BIO" tagging schema, where "B-EventType", "I-EventType" and "O" stand for "Begin Event Type", "Inside Event Type" and "Others" respectively.

Learning Rate	5×10^{-5}
Adam ϵ	1×10^{-8}
Warmup Rate	0.0
DMBERT Batch Size	336
BERT-CRF Batch Size	256
DMBERT Validation Steps	500
BERT-CRF Validation Steps on MAVEN	100
BERT-CRF Validation Steps on ACE 2005	50

Table 8: Hyperparameter settings for the BERT-based models.

A.2 MOGANED Model

MOGANED model is implemented by ourselves since the official codes are not released. Compared with the original paper, our reproduction

---

[2] https://github.com/google-research/bert

[3] https://www.fast.ai/2018/07/02/adam-weight-decay/#adamw

uses Adam optimizer and does not use the L2 norm, while other model details are the same as Yan et al. (2019). We set most hyperparameters same as Yan et al. (2019) but the hyperparameter λ to be 1 rather than 5 since we find it can achieve better performances on both datasets. For the hyperparameters not mentioned in the original paper, we tune them manually. All hyperparameters are shown in Table 9.

K	3
λ	1
Batch Size	30
Leaky Alpha	0.2
Dropout Rate	0.3
Learning Rate	1×10^{-3}
Dimension of Pos-Tag Feature	50
Dimension of NER-Tag Feature	50
Dimension of Word Embedding	100
Dimension of Position Embedding	50
Dimension of Hidden Feature	100
Dimension of Graph Feature	150
Dimension of W_{att} Feature	100
Dimension of Aggregation Feature	100

Table 9: Hyperparameter settings for MOGANED.

A.3 DMCNN model

DMCNN model is implemented by ourselves since the official codes are not released. Compared with Chen et al. (2015), we use Adam optimizer instead of the ADADELTA (Zeiler, 2012) optimizer. We set all the hyperparameters the same as Chen et al. (2015) except the word embedding dimension and learning rate, which are not mentioned in the original paper. As the pre-trained word embeddings used in the original paper are not publicly released, we use the pre-trained word embeddings released by Chen et al. (2018) instead. The hyperparameters are shown in Table 10.

Batch Size	170
Dropout Rate	0.5
Learning Rate	1×10^{-3}
Adam ϵ	1×10^{-8}
Kernel Size	3
Dimension of PF	5
Number of Feature Map	200
Dimension of Word Embedding	100

Table 10: Hyperparameter settings for DMCNN.

A.4 BiLSTM-based Models

For both **BiLSTM** and **BiLSTM-CRF**, we use the pre-trained word embeddings released by Chen et al. (2018) and train them with the Adam (Kingma and Ba, 2014) optimizer. Similar with **BERT-CRF**, we use "BIO" tagging schema in **BiLSTM-CRF**. Their hyperparameters are shown in Table 11.

Batch Size	200
Dropout Rate	0.3
Learning Rate	1×10^{-3}
Adam ϵ	1×10^{-8}
Dimension of Hidden Layers	200
Dimension of Word Embedding	100

Table 11: Hyperparameter settings for the BiLSTM-based models.

A.5 Overall Training Details

For reproducibility, we report the training details of various models in this section. Table 12 shows the used computing infrastructures, the numbers of model parameters as well as the average running time of various models.

We mostly follow the original hyperparameter settings but also manually tune some hyperparameters. We select the models with the F-1 scores on the development sets of the both datasets. The validation performances of various models are shown in Table 13.

Method	**Computing Infrastructure**	**#para.**	**Runtime**	
			ACE 2005	**MAVEN**
DMCNN	1× RTX 2080 Ti	2M	3 min	5.5 min
BiLSTM	1× RTX 2080 Ti	2M	18 min	29 min
BiLSTM+CRF	1× RTX 2080 Ti	3M	21 min	67 min
MOGANED	1× RTX 2080 Ti	40M	55 min	90 min
DMBERT	8× RTX 2080 Ti	110M	110 min	201 min
BERT+CRF	1× RTX 2080 Ti	110M	32 min	97 min

Table 12: Training details of various models, including the computing infrastructures, the numbers of parameters, and the average runtimes.

Method	**ACE 2005**			**MAVEN**		
	P	**R**	**F-1**	**P**	**R**	**F-1**
DMCNN	73.3	53.5	61.8	66.5	55.5	60.5
BiLSTM	72.3	67.6	69.8	60.3	66.9	63.4
BiLSTM+CRF	75.9	60.8	67.5	64.1	64.6	64.3
MOGANED	72.4	66.2	69.1	63.7	63.7	63.7
DMBERT	71.4	72.4	71.9	64.6	70.1	67.2
BERT+CRF	75.4	76.8	76.1	65.7	68.8	67.2

Table 13: Validation performance of various models.

B Event Type Mapping for ACE and MAVEN

In Table 14, we present the event type mapping between parts of ACE 2005 and MAVEN event types, which is used in the data augmentation experiments in Section 5.5.

C Hierarchical Event Type Schema

We present the tree-structure hierarchical event type schema used by MAVEN in Figure 6. The eight red types are virtual types without annotated

ACE Types	MAVEN Types
Injure	Bodily_harm
Die	Death
Transport	Traveling
Transfer-Ownership	Getting,Receving, Commerce_buy, Giving, Submitting_documents, Supply, Commerce_sell, Renting, Exchange
Transfer-Money	Commerce_pay, Expensiveness, Earnings_and_losses
Attack	Attack
Demonstrate	Protest
Meet	Come_together, Social_event
Phone-Write	Communication, Telling
Arrest-Jail	Arrest, Prison
Extradite	Extradition
Trial-Hearing	Justifying

Table 14: Mapping between parts of ACE 2005 event types and MAVEN event types.

instances, which are only used for organizing similar event types together. The virtual types do not participate in classification for all the models and when we say we have 168 event types we do not take them into account.

D Event Types and their corresponding frames

As stated in Section 3.1, we manually induce 168 event types from the 598 FrameNet event-related frames. We present the mapping between the event types and frames in Table 15 to help understand our event schema construction process. Note that the shown mapping is not a strict mapping, i.e., the semantic coverage of a MAVEN event type may be larger than the union of its corresponding frames.

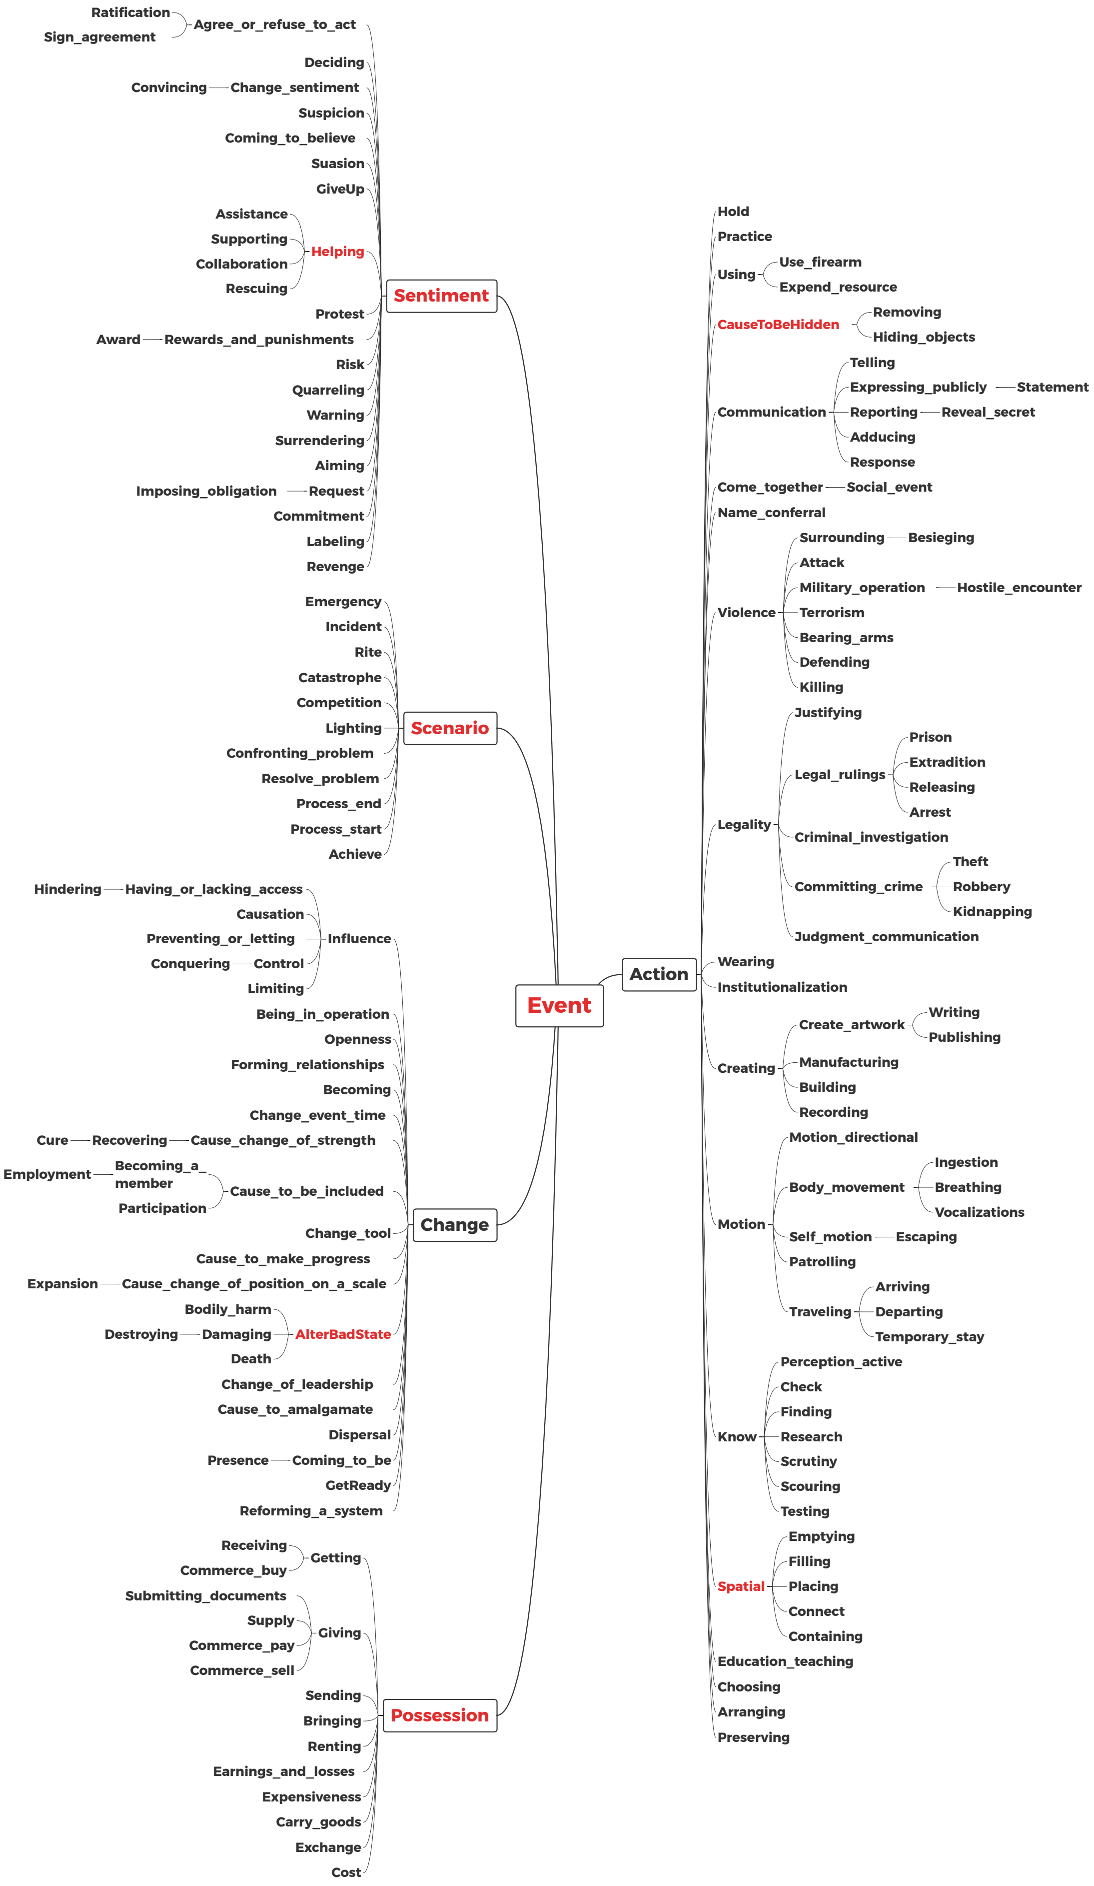

Figure 6: The hierarchical event type schema used in MAVEN. The red labels are virtual event types without annotated instances.

Event Type	**Corresponding Frame(s)**
Know	Becoming_aware
Warning	Warning
Catastrophe	Catastrophe
Placing	Placing_scenario, Placing, Being_located
Causation	Cause_to_start, Causation
Arriving	Drop_in_on, Visitor_arrival, Access_scenario, Visit_host_arrival, Arriving, Visiting_scenario_arrival
Sending	Commerce_money-transfer, Sending, Delivery, Product_delivery, Commerce_goods-transfer,Transfer, Post_transfer
Protest	Reasoning
Preventing_or_letting	Avoiding, Preventing, Prevent_from_having, Preventing_or_letting
Motion	Motion_scenario, Temporary_leave, Cause_motion, Cause_to_move_in_place, Motion, Cause_fluidic_motion, Fluidic_motion, Mass_motion
Damaging	Damaging
Destroying	Destroying, Cause_to_fragment, Render_nonfunctional
Death	Death, Losing_someone
Perception_active	Perception_active
Presence	Circumscribed_existence, Presence, Existence
Influence	Subjective_influence, Eventive_cognizer_affecting
Receiving	Post_receiving, Receiving
Check	Verification
Hostile_encounter	Hostile_encounter
Killing	Killing
Conquering	Conquering
Releasing	Releasing_from_custody, Bail_decision, Releasing, Freeing_from_confinement, Breaking_out_captive
Attack	Counterattack, Attack, Invading, Suicide_attack
Earnings_and_losses	Earnings_and_losses
Choosing	Adopt_selection, Choosing
Traveling	Visiting, Touring, Travel
Recovering	Rejuvenation
Using	Using
Coming_to_be	Coming_to_be
Cause_to_be_included	Cause_to_be_included
Process_start	Process_start, Activity_start
Change_event_time	Holding_off_on, Change_event_time, Change_event_duration
Reporting	Reporting

Bodily_harm	Cause_harm, Experience_bodily_harm
Suspicion	Suspicion
Statement	Statement, Claim_ownership
Cause_change_of_position_on_a_scale	Cause_change_of_position_on_a_scale
Coming_to_believe	Coming_to_believe
Expressing_publicly	Speak_on_topic, Expressing_publicly
Request	Request
Control	Being_in_control, Domination, Control, Self_control
Supporting	Supporting
Defending	Repel, Defending
Building	Building
Military_operation	Military_operation
Self_motion	Self_motion
GetReady	Activity_ready_state
Forming_relationships	Forming_relationships
Becoming_a_member	Becoming_a_member
Action	Enforcing, Execute_plan, Conduct, Intentionally_act
Removing	Removing, Removing_scenario

Abstract

Knowledge Graph (KG) alignment is to match entities in different KGs, which is important to knowledge fusion and integration. Recently, a number of embedding-based approaches for KG alignment have been proposed and achieved promising results. These approaches first embed entities in low-dimensional vector spaces, and then obtain entity alignments by computations on their vector representations. Although continuous improvements have been achieved by recent work, the performances of existing approaches are still not satisfactory. In this work, we present a new approach that directly learns embeddings of entity-pairs for KG alignment. Our approach first generates a pair-wise connectivity graph (PCG) of two KGs, whose nodes are entity-pairs and edges correspond to relation-pairs; it then learns node (entity-pair) embeddings of the PCG, which are used to predict equivalent relations of entities. To get desirable embeddings, a convolutional neural network is used to generate similarity features of entity-pairs from their attributes; and a graph neural network is employed to propagate the similarity features and get the final embeddings of entity-pairs. Experiments on five real-world datasets show that our approach can achieve the state-of-the-art KG alignment results.

1 Introduction

Knowledge graphs (KGs) have been built and applied in several domains, including question answering (Zhang et al., 2018), recommendation (Sun et al., 2018b), and information extraction (Yang and Mitchell, 2017). Most existing KGs are built separately by different organizations, using different data sources and languages. Therefore, KGs are heterogeneous that the same entity may exist in different KGs in different surface forms. On the other hand, KGs can be complementary to each other; knowledge about the same entity may distribute in several KGs. To handle the heterogeneity problem and integrate knowledge in different KGs, it is essential to perform KG alignment, i.e. matching entities in separate KGs.

Recently, KG embedding models have been explored in solving the problem of KG alignment. A number of embedding-based approaches have been proposed, including MTransE (Chen et al., 2017), JAPE (Sun et al., 2017), IPTransE (Zhu et al., 2017), GCN-Align (Wang et al., 2018), RDGCN (Wu et al., 2019), and MultiKE (Zhang et al., 2019), etc. These approaches first embed entities in low-dimensional vector spaces, and then obtain the entity alignments by computations on their vector representations. Comparing with traditional similarity-based approaches, embedding-based ones can effectively model different kinds of information in KGs, which align entities without manually designed similarity features. Most recently, continuous improvements have been achieved by combining multiple kinds of information in KGs or using more sophisticated embedding models. However, the performances of most approaches are still not satisfactory. According to the results in a recent work (Zhang et al., 2019), a traditional unsupervised alignment approach, Logmap (Jiménez-Ruiz and Cuenca Grau, 2011), outperforms most existing embedding-based approaches. To get more accurate alignment results, we propose an entity-pair embedding approach for KG alignment (EPEA). Instead of learning embeddings of single entities, our approach directly learns representations of entity-pairs. Similarity features of entities' attribute information are automatically extracted, which are then propagated using structure information of entities. Equivalent relations of entities can be accurately predicted based on the learned embeddings of entity-pairs.

Specifically, our work has the following contri-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1672–1680,
November 16–20, 2020.

butions:

- We introduce the definition of pairwise connectivity graph (PCG) of KGs, whose nodes are entity-pairs and edges correspond to relation-pairs. We solve the KG alignment problem via node embedding of the PCG.
- We propose a similarity feature extraction method based on convolutional neural network (CNN), which automatically generates feature vectors of entity-pairs encoding their attribute similarities.
- We propose a graph neural network (GNN) with edge-aware attentions to propagate similarity features in the PCG. Similarity features are propagated among the neighbors of entity-pairs, which incorporate structure similarity into the embeddings of entity-pairs.
- In the experiments on aligning real-world KGs, our approach outperforms the compared approaches, and achieves the state-of-the-art results.

The rest of this paper is organized as follows: Section 2 formalizes the entity alignment problem, Section 3 describes our proposed approach, Section 4 presents the evaluation results, Section 5 discusses some related work, and Section 6 is the conclusion.

2 Problem Formulation

2.1 KG and KG Alignment

KGs represent structural information about entities in real-world as triples having the form of $\langle s, p, o\rangle$. In this work, our KG alignment model considers both relational and attributional triples in KGs. The relational triples describe relations between entities, and the attributional triples describe attributes of entities. We formally represent a KG as $G = (E, R, A, L, T)$, where E, R, A and L are sets of entities, relations, attributes, and literals; $T \subseteq (E \times R \times E) \cup (E \times A \times L)$ is the sets of triples. Given two KGs $G = (E, R, A, L, T)$ and $G' = (E', R', A', L', T')$, the task of KG alignment is to find, for each entity in E, the equivalent entity in E'.

2.2 Pair-wise Connectivity Graph

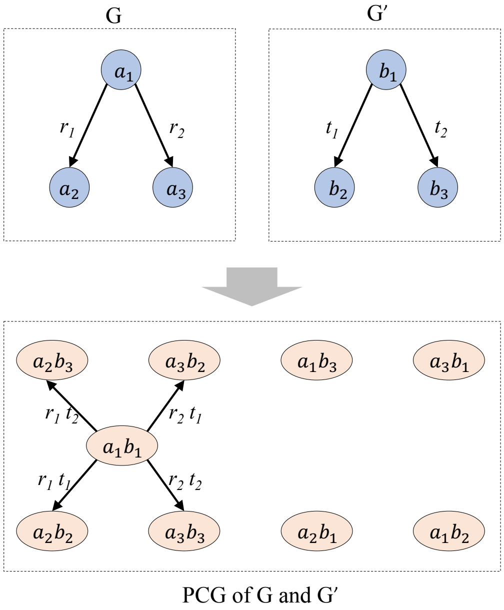

Figure 1: Pair-wise connectivity graph.

Pair-wise connectivity graph (PCG) can capture interactions of node-pairs of two directed graphs (Wang et al., 2012; Melnik et al., 2002). In this work, we define the PCG of KGs. For two KGs, each node in their PCG corresponds to an entity-pair from two KGs, and each edge connecting two nodes reflects the correlation between two entity-pairs. By generating the PCG of two KGs, the problem of KG alignment is then transformed to node embedding and classification (i.e. equivalent or nonequivalent) in the PCG. For two KGs $G = (E, R, A, L, T)$ and $G' = (E', R', A', L', T')$, the PCG of them is $\mathcal{G}(G, G') = (\mathcal{E}, \mathcal{R}, \mathcal{T})$, where $\mathcal{E}$, $\mathcal{R}$ and $\mathcal{T}$ are sets of nodes, edge types and edges. Each element in $\mathcal{E}$ corresponds to an entity-pair between G and G', and each element in $\mathcal{R}$ corresponds to an relation-pair. $\mathcal{T}$ is a set of typed edges between nodes, each edge is established as follows:

$$\begin{aligned} &\langle a, r, b\rangle \in T \wedge \langle a', r', b'\rangle \in T' \\ &\iff \langle (a, a'), (r, r'), (b, b')\rangle \in \mathcal{T} \end{aligned} \tag{1}$$

Figure 1 shows an example of PCG of two KGs. There are two KGs, each of them has three entities. The PCG of them contains nine nodes representing all the possible entity-pairs of two KGs; and there are four typed edges in the PCG. PCG can represent the connections of entity-pairs between two KGs, we use PCG to capture the interaction of possible entity alignments between two KGs. In our approach, the problem of KG alignment will be solved via node embedding of the PCG. Equivalent relations of entities are predicted based on the learned embeddings.

3 The Proposed Approach

Figure 2 shows the framework of our approach. Given two KGs, our approach first generates the PCG of them. Then, a CNN-based feature extraction method is used to generate node representations from the attribute information of entities. At last, an attention-based feature propagation is performed over the PCG to incorporate structure information into the node representations. Entity alignments are predicted based on the learned embeddings of entity-pairs. In the following, we present our approach in detail.

3.1 Generating the PCG

To generate the PCG of two KGs, we can first pair all the entities from two KGs as nodes, and then use Equation 1 to generate edges between nodes. However, KGs usually contain large number of entities, the PCG of two large-scale KGs will contain huge number of nodes. To avoid pairing all the entities from two KGs and control the size of the PCG, our approach selects entity-pairs having high equivalent possibilities as nodes in the PCG. Specifically, Locality-Sensitive Hashing (LSH) is employed in our approach to efficiently find similar entities between two KGs. LSH hashes similar items more likely into the same bucket than dissimilar items. Before using LSH, our approach first uses one of the following methods to generate set-representations of entities, which are used in the hashing process.

- **N-grams of Names.** If entity names are available and in the same language, this method generates a set of character-level n-grams of entities' names as the set-representations of entities.
- **N-grams of Attributes.** This method treats attribute values of an entity as text strings, and generates character-level n-grams of all the attribute values for each entity. All the n-grams are then merged into a set as the representation of the entity.
- **Seeding alignments.** If seeding alignments between two KGs are available, a set of aligned entities in an entity's neighborhood will be taken as the set-representation.

After being represented as sets of elements (n-grams or neighboring entities) by one of the above methods, all the entities in two KGs are hashed using LSH. To select entity-pairs as nodes in the PCG of G and G', our approach efficiently finds, for each entity $e \in G$, a set of entities $C_e = \{e'|e' \in G', J(e,e') > \delta\}$ as its alignment candidates, where $J(e,e')$ is the Jaccard similarity of two entities, δ is a predefined threshold. Entity e is then paired with all the entities in C_e to form the nodes in the PCG.

3.2 Attribute Feature Generation

Entities having the same or similar attribute values tend to be equivalent. Therefore, comparing attribute values of two entities are important for discovering entity alignments. In traditional approaches, attributes have to be first matched manually, then the values of corresponding attributes can be compared to get similarities between entities. In some of the embedding-based approaches, attribute types or values are utilized to generate attribute embeddings, which are integrated with structure embeddings of entities to get more accurate entity alignments. In this work, we extract similarity features from entities' attributes in an automatic way.

CNN-based Feature Extraction

We propose an attribute feature extraction method based on Convolutional Neural Network (CNN). Our method can automatically obtain useful similarity features of entity-pairs without any human effort. It generates a vector representation of each entity-pair in the PCG, which captures attribute similarities of two entities.

Given an entity-pair (e,e'), where $e \in G$ and $e' \in G'$. Let $A = \{A_1, ..., A_n\}$ and $A' = \{A'_1, ..., A'_m\}$ be two sets of all the attributes in G and G', respectively. Let $A_i(e)$ denotes the value of the i-th attribute of e, $A'_j(e')$ denotes the value of the j-th attribute of e'. To capture various similarities between two entities e and e', a similarity matrix $\mathbf{M}_{m\times n}$ is computed by comparing values of every attribute pair of two entities. Each element m_{ij} in $\mathbf{M}$ is the similarity of $A_i(e)$ and $A'_j(e')$. Attribute values in KGs may have various types, for example data, time, float, integer and string. To keep simplicity and effectiveness, our approach treats all the attribute values as strings. Similarities of attribute values are computed as N-gram-based Jaccard similarities of strings:

$$Jaccard(s,t) = \frac{|NG(s) \cap NG(t)|}{|NG(s) \cup NG(t)|} \qquad (2)$$

where $NG(s)$ and $NG(t)$ are n-grams of strings s

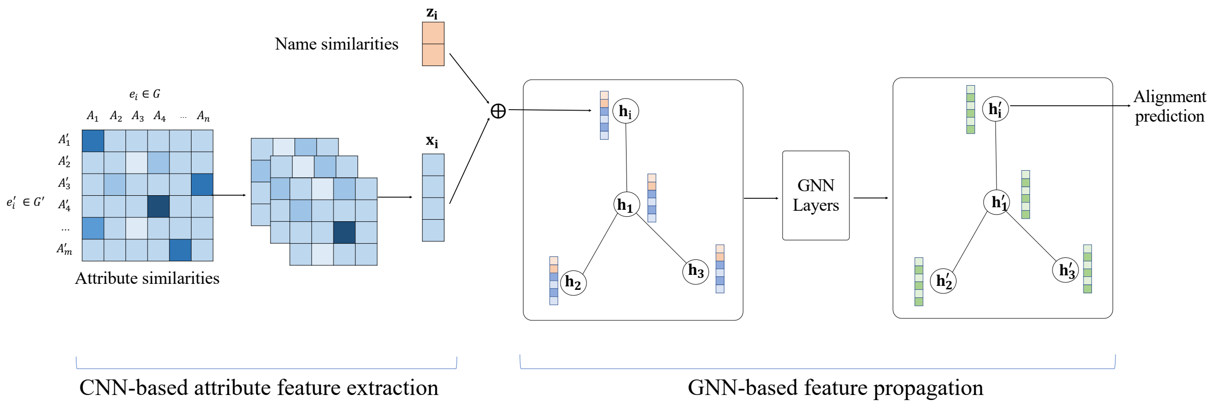

Figure 2: Framework.

and t.

Usually, one entity is only described by a small number of attributes in a KG. Therefore, for an entity, the values of many attributes are empty. The similarity matrix of two entities is usually a sparse one, with a large proportion of 0s in it. Meanwhile, similarities between some attributes may be useless for detecting alignments. To automatically find useful similarity patterns of attribute values, we use a CNN model to encode the sparse similarity matrix into a short and dense vector.

The input of the CNN is the similarity matrix $\mathbf{M}$ of two entities, two convolution layers are used to generate a dense similarity vector from $\mathbf{M}$. For the l-th convolution layer, its output is computed as follows:

$$\mathbf{X}_k^{(l)} = \mathrm{ReLU}\left(\mathbf{W}_k^{(l)} \otimes \mathbf{X}^{(l-1)} + \mathbf{b}_k^{(l)}\right) \tag{3}$$

where $\mathbf{X}^{(l-1)}$ is the input of l-th layer; for the first layer, $\mathbf{X}^{(0)} = \mathbf{M}$; we use multiple filters to extract useful similarity features from the input, $\mathbf{W}_k^{(l)}$ is the k-th filter of l-th layer, $\mathbf{b}_k^{(l)}$ is the bias of the k-th filter in l-th layer; $\otimes$ is the convolution operator. There is a max pooling layer after each convolution layer. The output features of last max pooling layer is the similarity vector of the entity-pair.

Name Similarity Features

In this work, name or label of an entity is considered as a special attribute, which is an important clue for determining whether two entities are equivalent. If entities' names are available in KGs, our approach computes a name similarity vector for each entity-pair, which will be concatenated with the similarity vector generated by the CNN model. To capture similarity features of entities' names from different aspects, we use multiple string-based similarity metrics, which are widely used in traditional similarity-based alignment approaches. If entities' names are in different languages in two KGs, machine translation tool will be used to translate names in one language to the other language. Let s and t be names of two entities, the following similarity measures are used in our approach.

- **String equality.** It measures whether two strings are the same:

$$z_1(s,t) = \begin{cases} 1 & \text{if } s = t, \\ 0 & else. \end{cases} \tag{4}$$

- **Edit Distance.** It evaluates the minimal cost of operations which have to applied to one of the strings to obtain the other string:

$$z_2(s,t) = 1 - \frac{|\{ops\}|}{max(len(s), len(t))}, \tag{5}$$

  where $\{ops\}$ denotes the set of operations, $len(\cdot)$ is the string length.

- **Jaccard Similarity.** It computes the Jaccard Similarity of the character-level n-grams of two strings, as defined in Equation 2, we denote this similarity as $z_4(s,t)$.

- **Substring Similarity.** It is computed by finding the longest common substring of two strings.

$$z_4(s,t) = \frac{2|LCS(s,t)|}{|s| + |t|}, \tag{6}$$

  where $LCS(s,t)$ is the longest common substring of s and t.

Let $\mathbf{z} = [z_1, z_2, z_3, z_4]$ denote name similarities of an entity-pair, it will be concatenated with the similarity vector $\mathbf{x}$ generated by CNN to form the initial feature vector of the entity-pair. The feature vectors of all the entity-pairs will be passed to an attention-based propagation process, to generate the final embeddings.

3.3 Attention-based Feature Propagation

Equivalent entities in two KGs are usually neighbored by some other equivalent entities. Therefore, structure information in KGs are very important for discovering entity alignments. In our work, edges between nodes in the PCG reflect the neighboring information of entity-pairs. To obtain feature representations of entity-pairs containing their neighbors' information, our approach propagates attribute features of entity-pairs following these edges. Specifically, our approach uses a Graph Neural Network (GNN) to propagate the attribute features of entity-pairs over the PCG. GNNs learn node representations in a graph by recursively aggregating the feature vectors of its neighbors, which are able to combine the node features and structure information in the graph. Several approaches have exploited GNNs for embedding-based KG alignment, which achieved promising results. In the previous approaches, GNNs are used for learning representations of entities. While in this work, we design a new GNN model for learning vector representations of entity-pairs.

Our model is a residual GNN with edge-aware attentions, which is built by modifying the attention mechanism of the GAT model (Velickovic et al., 2017). Our GNN model has two layers, each layer takes a set of node features $\mathbf{H} = \{\mathbf{h_1}, \mathbf{h_2}, ..., \mathbf{h_N}\}$ as inputs, where $\mathbf{h_i} \in \mathbb{R}^F$ and N is the number of nodes in the PCG, F is the dimension of the input features. Each layer generates a new set of node representations $\mathbf{H'} = \{\mathbf{h'_1}, \mathbf{h'_2}, ..., \mathbf{h'_N}\}$, $\mathbf{h'_i} \in \mathbb{R}^{F'}$ and it is computed as:

$$\mathbf{h'_i} = \sigma\left(\sum_{j \in \mathcal{N}_i} \alpha_{ij} \mathbf{W}\mathbf{h_j}\right), \tag{7}$$

where $\mathcal{N}_i$ is the set of neighboring nodes of the i-th node (ignoring the edge directions in the PCG), $\mathbf{W} \in \mathbb{R}^{F \times F'}$ is a shared matrix, α_{ij} is a learnable attention indicating the importance of the j-th node to the i-th node.

Edge-aware Attention Mechanism

In the GAT model, the attention α_{ij} is computed based on the features of node i and j. In the task of KG alignment, we consider that the type of edge between two nodes is important and should not be ignored. Therefore, we use an edge-aware attention mechanism to compute the attention α_{ij}. A shared attentional mechanism $\mathbb{R}^{F'} \times \mathbb{R}^{F'} \times \mathbb{R}^{F'} \to \mathbb{R}$ is used to computes attention coefficients:

$$e_{ij} = \text{LeakyReLU}\left(\mathbf{a}^\top \left[\mathbf{W}\mathbf{h_i} \| \mathbf{W}\mathbf{h_j} \| \mathbf{t_{(i \to j)}}\right]\right) \tag{8}$$

where $(i \to j)$ denotes the index of edge-type linking the i-th node to the j-th node, $\mathbf{t_{(i\to j)}} \in \mathbb{R}^{F'}$ is the vector representation of the edge-type; $\mathbf{a} \in \mathbb{R}^{3F'}$ is a weight vector of a single-layer feed-forward neural network for computing the attention coefficients; $\|$ represents concatenation of vectors. Here the vector of an edge-type is computed based on the nodes' vectors connected by it. For an edge-type t_k, let S_k and T_k be the sets of nodes' indices having outgoing edges and incoming edges of the type in the PCG respectively, the vector representation of t_k is computed as:

$$\mathbf{t_k} = \left|\frac{1}{|S_k|}\sum_{i \in S_k} \mathbf{W}\mathbf{h_i} - \frac{1}{|T_k|}\sum_{j \in T_k} \mathbf{W}\mathbf{h_j}\right|, \tag{9}$$

which is the element-wise absolute difference between the mean vectors of source and target nodes connected by t_k.

When the attention coefficients are obtained following Equation 8, normalized attentions are then computed using a softmax function over all the coefficients of its neighboring nodes:

$$a_{ij} = \text{softmax}_j(e_{ij}) = \frac{\exp(e_{ij})}{\sum_{k \in \mathcal{N}_i} \exp(e_{ik})} \tag{10}$$

where $\mathcal{N}_i$ is the set of neighboring nodes of the i-th node.

Residual Connections in GNN

To let the entity-pair embeddings memorize the original attribute features, we add residual connections from the input features to the output layer of the GNN model. We let $F = F'$, i.e. the sizes of input and output node vectors of each GNN layer are the same. A shortcut connection between the input and output layers is added, and the final representation of a node is computed by element-wise addition of $\mathbf{h_i^0}$ and $\mathbf{h_i^L}$, where $\mathbf{h_i^0} = [\mathbf{x_i} || \mathbf{z_i}]$ and $\mathbf{h_i^L}$ are the input and output features of the i-th node.

3.4 Model Training

There are two neural network models in our approach, i.e. the CNN model for attribute feature extraction and the GNN model for feature propagation. These two separate models are trained sequentially, using the same training data. For two KGs G and G', let $A = \{(e_i, v_i) | e_i \in G, v_i \in G'\}_{i=1}^{K}$ be a set of known entity alignments, they will be used as training data for both models.

For the CNN model, let $\mathbf{x_i}$ be the attribute feature vector of entity-pair (e_i, v_i) generated by the model. We use one fully-connected layer to generate a score for each entity-pair, taking $\mathbf{x_i}$ as the input:

$$S_{CNN}(e_i, v_i) = \sigma(\mathbf{c}^\top \mathbf{x_i} + \alpha) \tag{11}$$

where $\mathbf{c} \in \mathbb{R}^d$ and $\alpha \in \mathbb{R}$ are parameters, σ is the Sigmoid function.

For the GNN model, let $\mathbf{h_i}$ be the feature vector of entity-pair (e_i, v_i) after the feature propagation with the model. A similar score function is also defined as:

$$S_{GNN}(e_i, v_i) = \sigma(\mathbf{g}^\top \mathbf{h_i} + \beta) \tag{12}$$

where $\mathbf{g} \in \mathbb{R}^d$ and $\beta \in \mathbb{R}$ are parameters, σ is also the Sigmoid function.

For both models, we want the aligned entity-pairs having higher scores than the non-aligned entity-pairs. Therefore, two models are both trained by minimizing the following margin-based ranking loss function:

$$\mathcal{L} = \sum_{(e,v)\in A} \sum_{(e',v')\in A'_{(e,v)}} [\gamma - S(e,v) + S((e',v'))]_+ \tag{13}$$

where $[x]_+ = max\{0, x\}$, $\gamma > 0$ is a margin hyper-parameter, $A'_{(e,v)}$ denotes the set of non-aligned entity-pairs in the PCG containing entity e or v. The score S is either S_{CNN} or S_{GNN}, depending on which model is trained.

4 Experiments

4.1 Datasets

Five datasets are used to evaluate our approach, each dataset contains two knowledge graphs to be aligned. Table 1 outlines the detail information of these datasets. $\mathrm{DBP15K_{ZH-EN}}$, $\mathrm{DBP15K_{JA-EN}}$ and $\mathrm{DBP15K_{FR-EN}}$ were built by (Sun et al., 2017). They are generated from DBpedia and each dataset contains 15 thousand aligned entity pairs in two language versions of DBpedia. DBP-WD and DBP-YG were first used in (Sun et al., 2018a), which are generated from DBpedia, Wikidata and YAGO3. Each dataset contains 100 thousand aligned entity pairs. For all the datasets, we use the same training/testing split of aligned entity pairs with previous work (Sun et al., 2017, 2018a), 30% for training and 70% for testing.

Table 1: Details of the datasets

Datasets		# Entities	# Relations	# Attributes
$\mathrm{DBP_{ZH-EN}}$	Chinese	66,469	2,830	8,113
	English	98,125	2,317	7,173
$\mathrm{DBP_{JA-EN}}$	Japanese	65,744	2,043	5,882
	English	95,680	2,096	6,066
$\mathrm{DBP_{FR-EN}}$	French	66,858	1,379	4,547
	English	105,889	2,209	6,422
DBP-WD	DBpedia	100,000	330	351
	Wikidata	100,000	220	729
DBP-YG	DBpedia	100,000	302	334
	YAGO3	100,000	31	23

4.2 Experiment Settings

We implement our approach by using TensorFlow[1], and run experiments on a workstation with Intel Xeon 2.1GHz CPU, an NVIDIA Tesla P100 GPU and 64 GB memory. We use Hits@k and MRR(Mean reciprocal ranking) as the evaluation metrics, which are popular and widely used in other KG alignment work. Hits@k measures the percentage of correctly alignments ranked in the top k candidates. MRR is the average of the reciprocal ranks of the results. The higher Hits@k and MRR, the better is the performance. The dimensions of similarity features and final embeddings of entity-pairs are set to the same value, which is among {30, 60, 100, 120}, we consider the learning rate in two models among {0.1, 0.01, 0.002, 0.001}, the margin γ in loss functions among {1, 2, 4, 10}. Best configurations for two models in our approach are selected based on the MRR.

We compare our approach EPEA with recent KG alignment models, which can be divided into two groups. Models in the first group only use structure information in KGs, including MTransE (Chen et al., 2017), IPTransE (Zhu et al., 2017), BootEA (Sun et al., 2018a), MuGNN (Cao et al., 2019), RDGCN (Wu et al., 2019), AliNet (Zequn Sun, 2020), and NAEA (Zhu et al., 2019). other group of models use attribute or name information in KGs, including JAPE (Sun et al., 2017), GCN-Align (Wang et al., 2018), MultiKE (Zhang et al., 2019), and CEA (Zeng et al., 2020).

4.3 Results

Overall Comparisons. Table 2 shows the results of all approaches. Because all the approaches use the same sets of seeding and testing alignments in each dataset, the results of the compared approaches are obtained from their original papers. It shows that our approach EPEA achieves promising improvements compared with the previous approaches. Our approach outperforms all the compared approaches other than CEA on five datasets, in terms of Hits@1, Hits@10 and MRR. Taking no account of CEA, RDGCN achieved the state-of-the-art results on three cross-lingual datasets. Compared with RDGCN, our approach gets improvements of 17.7%, 15.7%, and 6.9% of Hits@1 on these datasets. MultiKE performed the best on DBP-WD and DBP-YG among the compared approaches excluding CEA, our approach outperforms MultiKE by 6.1% and 12.0% of Hits@1 on the two datasets, respectively. CEA is a strong approach which uses a collective alignment framework with adaptive feature fusion mechanism; only results of Hits@1 (i.e. accuracy) are reported by its authors. In terms of Hits@1, CEA performs better than RDGCN and MultiKE on cross-lingual and monolingual datasets, respectively. Compared with CEA, our approach gets higher Hits@1 on $\mathrm{DBP}_{\mathrm{ZH-EN}}$ and $\mathrm{DBP}_{\mathrm{JA-EN}}$, and gets better results than CEA on DBP-YG. CEA performs better than EPEA on $\mathrm{DBP}_{\mathrm{FR-EN}}$ and DBP-WD, but the results of two approaches are close, with small differences of 1.7% and 2.3%.

Contributions of component models. To analyze the contributions of component models in our approach, we build two variations of EPEA by removing or replacing GNN model. The first variation of EPEA is represented as CNN, which only uses the CNN model to predict alignments based on attribute features. The second variation of EPEA is represented as CNN+GAT, which replaces the edge-aware attentional GNN with GAT (Velickovic et al., 2017) in EPEA. The results of CNN and CNN+GAT are also outlined in Table 2. It shows that two sub-models of EPEA are both effective and important for the promising performance of EPEA. First, the CNN model can extract useful similarity features for predicting entity alignments, which gets better results than half of the comparison approaches, including MTransE, MuGNN, AliNet, JAPE, et al. Second, GNN-based feature propagation improves the results significantly, and the new designed GNN model edge-aware attention in EPEA works better than GAT. There is 11.9% improvements of Hits@1 on average when GAT is used to propagate the similarity features, while our new GNN model gets even bigger improvements, average 24.9% of Hits@1.

Impact of Seed Alignments. To investigate how the size of seed alignments (pre-aligned entity pairs for training) affects the results of our approach, we run our approach with different number of seed alignments. The proportions of seed alignments ranges from 5% to 30% with step of 5%. Figure 3 shows the $Hits@1$ and $Hits@10$ of EPEA on two datasets, DBP-YG and DBP$_{FR-EN}$. It shows that EPEA gets nearly optimal Hits on DBP-YG using 10% seed alignments, both Hits@1 and Hits@10 are 100% when more than 15% seed alignments are used. This is because DBP-YG contains rich attribute information of entities including entities' names, our approach can fully utilize attribute and structure information to accurately predict entity alignments even with small number of seed alignments. On the DBP$_{FR-EN}$ dataset, our approach gets >70% Hits@1 and >95% Hits@10 when only 10% seed alignments are used; it outperforms most of the compared approaches in Table 2 which use 30% seed alignments. As the number of seed alignments increases, our approach steadily improves the alignment results.

5 Related Work

A number of embedding-based entity alignment approaches have been proposed recently. Some approaches mainly rely on the structure information in KGs to find alignments, including MTransE (Chen et al., 2017), IPTransE (Zhu et al., 2017), BootEA (Sun et al., 2018a), MuGNN (Cao et al., 2019), NAEA (Zhu et al., 2019), RDGCN (Wu et al., 2019) and AliNet (Zequn Sun, 2020). Entity embeddings are learned by using information of entity and their relations. MTransE encodes structure information of KGs in separate spaces, and then performs transitions from one space to the other. TPTransE and BootEA both are iterative alignment approaches, which use new discovered alignments to expand the seeding alignments. MuGNN employs a multi-channel GNN to learn alignment-oriented KG embeddings. NAEA enhances the TransE model by learning embeddings by a neighborhood-aware attentional representation method. RDGCN uses a relation-aware dual-graph convolutional network to incorporate relation information via attentive interactions between KG and its dual relation counterpart. AliNet is a GNN-based model which aggregates both direct and distant neighborhood information.

To get improved results, some approaches utilize entity attributes or names in KGs. JAPE (Sun et al., 2017) performs attribute embedding by Skip-Gram model which captures the correlations of attributes in KGs. GCN-Align (Wang et al., 2018) encodes attribute information of entities into their embeddings by using GCNs. MultiKE (Zhang et al., 2019) uses a framework unifying the views of entity names, relations and attributes to learn embeddings for aligning entities. CEA (Zeng et al., 2020) combines structural, semantic and string features of entities, which are integrated with dynamically assigned weights.

Compared with the previous approaches, ours directly learns embeddings of entity-pairs, instead of entities. Attribute and structure information are encoded in the embeddings sequentially, and experiments validate the effectiveness of our approach.

6 Conclusion

This paper presents a new entity-pair embedding approach for KG alignment. Our approach first extracts useful attribute features of entity-pairs by using a convolutional neural network, and then propagates the features among the neighbors of entity-pairs, by using a graph neural network with edge-aware attentions. The embeddings are learned with the object of separating equivalent and nonequivalent entity-pairs. Experiments on five real-world datasets show that our approach achieves the state-of-the-art results.

Abstract

Few-shot Knowledge Graph (KG) completion is a focus of current research, where each task aims at querying unseen facts of a relation given its few-shot reference entity pairs. Recent attempts solve this problem by learning static representations of entities and references, ignoring their dynamic properties, i.e., entities may exhibit diverse roles within task relations, and references may make different contributions to queries. This work proposes an adaptive attentional network for few-shot KG completion by learning adaptive entity and reference representations. Specifically, entities are modeled by an adaptive neighbor encoder to discern their task-oriented roles, while references are modeled by an adaptive query-aware aggregator to differentiate their contributions. Through the attention mechanism, both entities and references can capture their fine-grained semantic meanings, and thus render more expressive representations. This will be more predictive for knowledge acquisition in the few-shot scenario. Evaluation in link prediction on two public datasets shows that our approach achieves new state-of-the-art results with different few-shot sizes. The source code is available at `https://github.com/JiaweiSheng/FAAN`.

1 Introduction

Knowledge Graphs (KGs) like Freebase (Bollacker et al., 2008), NELL (Carlson et al., 2010) and Wikidata (Vrandecic and Krötzsch, 2014) are extremely useful resources for NLP tasks, such as information extraction (Liu et al., 2018), machine reading (Yang and Mitchell, 2017), and relation extraction (Ren et al., 2017). A typical KG is a multi-relational graph, represented as triples of the form (h, r, t), indicating that two entities are connected by relation r. Although a KG contains a great number of triples, it is also known to suffer from incompleteness problem. KG completion, which aims at automatically inferring missing facts by examining existing ones, has thus attracted broad attention. A promising approach, namely KG embedding, has been proposed and successfully applied to this task. The key idea is to embed KG components, including entities and relations, into a continuous vector space and make predictions with their embeddings.

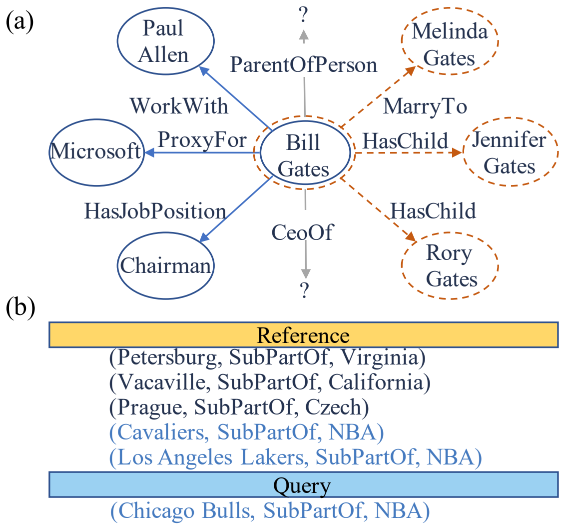

Figure 1: Illustration of dynamic properties in few-shot KG completion: (a) An entity has diverse roles in different tasks; and (b) References show distinct contributions to a particular query.

Current KG embedding methods mostly require sufficient training triples for all relations to learn expressive representations (*i.e.,* embeddings). In real KGs, a large portion of KG relations is actually long-tail, having only a limited (few-shot) number of relational triples (Xiong et al., 2018). This may lead to low performance of embedding models on KG completion for those long-tail relations.

Recently, several studies (Chen et al., 2019; Xiong et al., 2018; Zhang et al., 2020) have pro-

posed to address the few-shot issue of KG completion, where one task is to predict tail entity t in a query $(h, r, ?)$ given only a few entity pairs of the task relation r. These known few-shot entity pairs associated with r are called references. To improve semantical representations of the references, Xiong et al. (2018) and Zhang et al. (2020) devise modules to enhance entity embeddings with their local graph neighbors. The former simply assumes that all neighbors contribute equally to the entity embedding, and in this way the neighbors are always weighted identically. The latter develops the idea by employing an attention mechanism to assign different weights to neighbors, but the weights do not change throughout all task relations. Therefore, both works assign static weights to neighbors, leading to static entity representations when involved in different task relations. We argue that entity neighbors could have varied impacts associated with different task relations. Figure 1(a) gives an example of head entity `BillGates` associated with two task relations. The left neighbors show his business role, while the right ones show his family role, which reveals quite different meanings. Intuitively, the task relation `CeoOf` is supposed to pay more attention to the business role of entity `BillGates` than the other one.

In addition, task relations can be polysemous, also showing different meanings when involved in different entity pairs. Therefore, the reference triples could also make different contributions to a particular query. Take a task relation `SubPartOf` as an example. As shown in Figure 1(b), `SubPartOf` associates with different meanings, *e.g.*, organization-related as (`Cavaliers`, `SubPartOf`, `NBA`) and location-related as (`Petersburg`, `SubPartOf`, `Virginia`). Obviously, for query (`ChicagoBulls`, `SubPartOf`, `?`), referring to the organization-related references would be more beneficial.

To address the above issues, we propose an Adaptive Attentional Network for Few-Shot KG completion (FAAN), a novel paradigm that takes dynamic properties into account for both entities and references. Specifically, given a task relation with its reference/query triples, FAAN proposes an adaptive attentional neighbor encoder to model entity representations with one-hop entity neighbors. Unlike the previous neighbor encoder with a fixed attention map in (Zhang et al., 2020), we allow attention scores dynamically adaptive to the task relation under the translation assumption. This will capture the diverse roles of entities through varied impacts of neighbors. Given the enhanced entity representations, FAAN further adopts a stack of Transformer blocks for reference/query triples to capture multi-meanings of the task relation. Then, FAAN obtains a general reference representation by adaptively aggregating the references, further differentiating their contributions to different queries. As such, both entities and references can capture their fine-grained meanings, and render richer representations to be more predictive for knowledge acquisition in the few-shot scenario.

The contributions of this paper are three-fold:

(1) We propose the notion of dynamic properties in few-shot KG completion, which differs from previous paradigms by studying the dynamic nature of entities and references in the few-shot scenario.

(2) We devise a novel adaptive attentional network FAAN to learn dynamic representations. An adaptive neighbor encoder is used to adapt entity representations to different tasks. A Transformer encoder and an attention-based aggregator are used to adapt reference representations to different queries.

(3) We evaluate FAAN in few-shot link prediction on benchmark KGs of NELL and Wikidata. Experimental results reveal that FAAN could achieve new state-of-the-art results with different few-shot sizes.

2 Related Work

Recent years have seen increasing interest in learning representations for entities and relations in KGs, *a.k.a* KG embedding. Various methods have been devised, and roughly fall into three groups: 1) translation-based models which interpret relations as translating operations between head-tail entity pairs (Bordes et al., 2013; Yang et al., 2019); 2) simple semantic matching models which compute composite representations over entities and relations using linear mapping operations (Yang et al., 2015; Trouillon et al., 2016; Liu et al., 2017; Sun et al., 2019); and 3) (deep) neural network models which obtain composite representations using more complex operations (Schlichtkrull et al., 2018; Dettmers et al., 2018). Please refer to (Nickel et al., 2016; Wang et al., 2017; Ji et al., 2020) for a thorough review of KG embedding techniques. Traditional embedding models always require sufficient training triples for all relations, thus are limited when solving the few-shot problem.

Previous few-shot learning studies mainly focus on computer vision (Sung et al., 2018), imitation learning (Duan et al., 2017) and sentiment analysis (Li et al., 2019). Recent attempts (Xiong et al., 2018; Chen et al., 2019; Zhang et al., 2020) tried to perform few-shot relational learning for long-tail relations. Xiong et al. (2018) proposed a matching network GMatching, which is the first research on one-shot learning for KGs as far as we know. GMatching exploits a neighbor encoder to enhance entity embeddings from their one-hop neighbors, and uses a LSTM matching processor to perform a multi-step matching by a LSTM block. FSRL (Zhang et al., 2020) extends GMatching to few-shot cases, further capturing local graph structures with an attention mechanism. Chen et al. (2019) proposed a novel meta relational learning framework MetaR by extracting and transferring shared knowledge across tasks from a few existing facts to incomplete ones. However, previous studies learn static representations of entities or references, ignoring their dynamic properties. This work attempts to learn dynamic entity and reference representations by an adaptive attentional network.

Dynamic properties have also been explored in other contexts outside few-shot relational learning. Ji et al. (2015); Wang et al. (2019) performed KG completion by learning dynamic entity and relation representations, but their methods are specially devised for traditional KG completion. Lu et al. (2017) adopted an adaptive attentional model for image captioning. Luo et al. (2019) tried to model dynamic user preference using a recurrent network with adaptive attention for the sequential recommendation. All these studies demonstrate the capability of modeling dynamic properties to enhance learning algorithms.

3 Background

Gonsider a KG $\mathcal{G}$ containing a set of triples $\mathcal{T} = \{(h, r, t) \in \mathcal{E} \times \mathcal{R} \times \mathcal{E}\}$, where $\mathcal{E}$ and $\mathcal{R}$ denotes the entity set and relation set, respectively. This work focuses on a challenging link prediction scenario, *i.e.*, few-shot KG completion. We follow the standard definition of this task (Zhang et al., 2020):

Definition 1 (Few-shot KG Completion) *Given a relation* $r \in \mathcal{R}$ *and its reference set* $\mathcal{S}_r = \{(h_k, t_k) | (h_k, r, t_k) \in \mathcal{T}\}$, *one task is to complete triple* (h, r, t) *with tail entity* $t \in \mathcal{E}$ *missing, i.e., to predict t from a candidate entity set* $\mathcal{C}$ *given* $(h, r, ?)$. *When* $|\mathcal{S}_r| = K$ *and* K *is very small, the task is called* K*-shot KG completion.*

For this task, the goal of a few-shot learning method is to rank the true tail entity higher than false candidate entities, given few-shot reference entity pairs $\mathcal{S}_r$. To imitate such a link prediction task, each training task corresponds to a relation $r \in \mathcal{R}$ with its own reference/query entity pairs, *i.e.*, $\mathcal{D}_r = \{\mathcal{S}_r, \mathcal{Q}_r\}$, where $\mathcal{S}_r$ only consists of K-shot reference entity pairs (h_k, t_k). Additionally, $\mathcal{Q}_r = \{(h_m, t_m/\mathcal{C}_{h_m,r})\}$ contains all queries with ground-truth tail entity t_m and the corresponding candidates $\mathcal{C}_{h_m,r}$, where each candidate is an entity in $\mathcal{E}$ selected based on the entity type constraint (Xiong et al., 2018). The few-shot learning method thus could be trained on the task set by ranking the candidates in $\mathcal{C}_{h_m,r}$ given the query $(h_m, r, ?)$ and its references $\mathcal{S}_r$. All tasks in training form the *meta-training* set, denoted as $\mathcal{T}_{mtr} = \{\mathcal{D}_r\}$. Here, we only consider a closed set of entities appearing in $\mathcal{E}$.

After suffcient training with meta-training set, the learned model can be used to predict facts of new relation $r' \in \mathcal{R}'$ in testing. The relations used for testing are $unseen$ from meta-training, *i.e.*, $\mathcal{R}' \cup \mathcal{R} = \phi$. Each testing relation r' also has its own few-shot references and queries, *i.e.*, $\mathcal{D}_{r'} = \{\mathcal{S}_{r'}, \mathcal{Q}_{r'}\}$, defined in the same way as in meta-training. All tasks in testing form the *meta-testing* set, denoted as $\mathcal{T}_{mte} = \{\mathcal{D}_{r'}\}$. In addition, we also suppose that the model has access to a background KG $\mathcal{G}'$, which is a subset of $\mathcal{G}$ with all the relations excluded from $\mathcal{T}_{mtr}$ and $\mathcal{T}_{mte}$.

4 Our Approach

This section introduces our approach FAAN. Given a meta-training set $\mathcal{T}_{mtr}$, the purpose of FAAN is to learn a metric function for predictions by comparing the input query to the given references. To achieve this goal, FAAN consists of three major parts: (1) Adaptive neighbor encoder to learn adaptive entity representations; (2) Transformer encoder to learn relational representations for entity pairs; (3) Adaptive matching processor to compare the query to the given references. Finally, we present the detailed training objective of our model. Figure 2 shows the overall framework of FAAN for a task relation `CeoOf`.

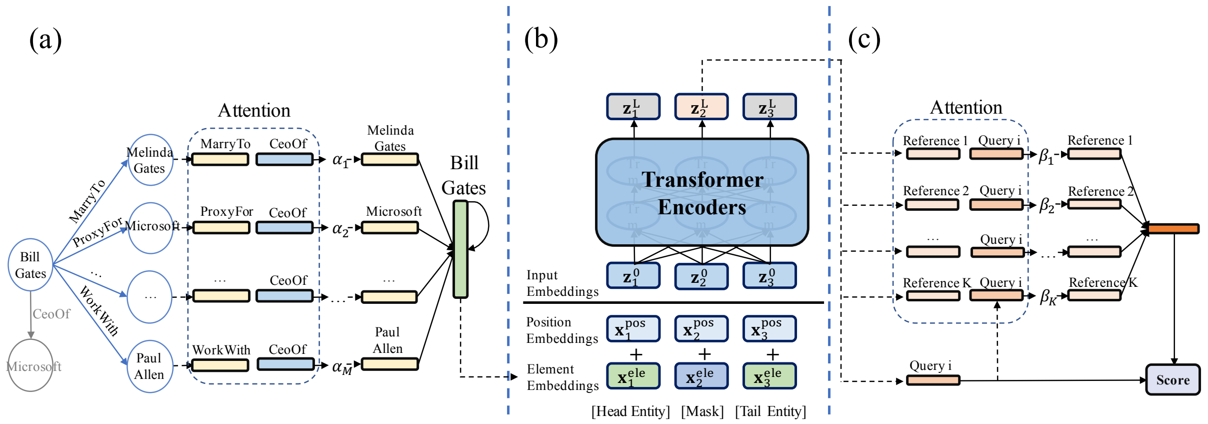

Figure 2: The framework of FAAN: (a) Adaptive neighbor encoder for entities; (b) Transformer encoder for entity pairs; (c) Adaptive matching processor to match K-shot references and the query.

4.1 Adaptive Neighbor Encoder for Entities

Previous works on embeddings (Schlichtkrull et al., 2018; Shang et al., 2019) have demonstrated that explicitly modeling graph contexts benefits KG completion. Recent few-shot relational learning methods encode one-hop neighbors to enhance entity embeddings with equal or fixed attentions (Xiong et al., 2018; Zhang et al., 2020), ignoring the dynamic properties of entities. To tackle this issue, we devise an adaptive neighbor encoder for entities discerning their entity roles associated with task relations. Specifically, we are given a triple of a few-shot task for relation r, *e.g.*, (h, r, t). Take the head entity h as a target, and we denote its one-hop neighbors as $\mathcal{N}_h = \{(r_{nbr}, e_{nbr}) | (h, r_{nbr}, e_{nbr}) \in \mathcal{G}'\}$. Here, $\mathcal{G}'$ is the background KG; r_{nbr}, e_{nbr} represent the neighboring relation and entity of h respectively. The aim of the proposed neighbor encoder is to obtain varied entity representations with $\mathcal{N}_h$ to exhibit their different roles when involved in different task relations. Figure 2(a) gives the details of the adaptive neighbor encoder, where `CeoOf` is the few-shot task relation and the other relations such as `MarryTo`, `ProxyFor` and `WorksWith` are the neighboring relations of the head entity `BillGates`.

As claimed in the introduction, the role of entity h can be varied with respect to the few-shot task relation r. However, few-shot task relations are always hard to obtain effective representations by existing embedding models that always require sufficient training data for the relations. Inspired by TransE (Bordes et al., 2013), we model the task relation embedding $\mathbf{r}$ as a translation between the entity embeddings $\mathbf{h}$ and $\mathbf{t}$, *i.e.*, we want $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ when the triple holds. The intuition here originates from linguistic regularities such as `Italy`$-$`Rome` $=$ `France`$-$`Paris`, and such analogy holds because of the certain relation `CapitalOf`. Under the translation assumption, we can obtain the embedding of few-shot task relation r given its entity pair (h, t):

$$\mathbf{r} = \mathbf{t} - \mathbf{h} \tag{1}$$

where $\mathbf{r}, \mathbf{t}, \mathbf{h} \in \mathbb{R}^d$; $\mathbf{t}$ and $\mathbf{h}$ are embeddings pre-trained on $\mathcal{G}'$ with current embedding model such as TransE; d denotes the pre-trained embedding dimension. Actually, the translation mechanism is not the only way to model the task relations. We leave the investigation of other KG embedding methods (Trouillon et al., 2016; Sun et al., 2019) to future work.

Intuitively, relations can reflect roles of an entity. As shown in Figure 1(a), the task relation `CeoOf` may be more related to `WorkWith` than `MarryTo`, since the first two exhibit a business role. That is to say, we can discern the roles of h according to the relevance between the task relation r and the neighboring relation r_{nbr}. Hence, we first define a metric function ψ to calculate their relevance score by a bilinear dot product:

$$\psi(r, r_{nbr}) = \mathbf{r}^\top \mathbf{W} \mathbf{r}_{nbr} + b \tag{2}$$

where $\mathbf{r}$ and $\mathbf{r}_{nbr}$ can be obtained by Eq. (1); both $\mathbf{W} \in \mathbb{R}^{d \times d}$ and $b \in \mathbb{R}$ are learnable parameters. Then, we obtain a role-aware neighbor embedding $\mathbf{c}_{nbr}$ for h by considering its diverse roles:

$$\mathbf{c}_{nbr} = \sum\nolimits_{e_{nbr} \in \mathcal{N}_h} \alpha_{nbr} \mathbf{e}_{nbr} \tag{3}$$

$$\alpha_{nbr} = \frac{\exp(\psi(r, r_{nbr}))}{\sum_{r_{nbr'} \in \mathcal{N}_h} \exp(\psi(r, r_{nbr'}))} \tag{4}$$

That means, when neighboring relations are more related to the task relation, $\psi(\cdot,\cdot)$ will be higher and the corresponding neighboring entities would play a more important role in neighbor embeddings.

In order to enhance entity embeddings, we simultaneously couple the pre-trained entity embedding $\mathbf{h}$ and its role-aware neighbor embedding $\mathbf{c}_{nbr}$. Then, h can be formulated as:

$$f(h) = \sigma(\mathbf{W}_1\mathbf{h} + \mathbf{W}_2\mathbf{c}_{nbr}), \tag{5}$$

where $\sigma(\cdot)$ denotes activation function, and we use Relu; $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{d\times d}$ are learnable parameters. Entity representations obtained in this way shall 1) preserve individual properties made by the current embedding model, and 2) possess diverse roles adaptive to different tasks. The above procedure also holds for the candidate tail entity t.

4.2 Transformer Encoder for Entity Pairs

Based on enhanced entity embeddings, we are going to derive embeddings of entity pairs. Figure 2(b) gives the details of Transformer encoder for entity pairs. FAAN borrows ideas from recent techniques for learning dynamic KG embeddings (Wang et al., 2019). Given an entity pair in a task of r, *i.e*, $(h, t) \in \mathcal{D}_r$, we take each entity pair with its task relation as a sequence $X = (x_1, x_2, x_3)$, where the first/last element is head/tail entity, and the middle is the task relation. For each element x_i in X, we construct its input representation as:

$$\mathbf{z}_i^0 = \mathbf{x}_i^{\text{ele}} + \mathbf{x}_i^{\text{pos}} \tag{6}$$

where $\mathbf{x}_i^{\text{ele}}$ denotes the element embedding, and $\mathbf{x_i}^{\text{pos}}$ the position embedding. Both $\mathbf{x_1}^{\text{ele}}$ and $\mathbf{x_3}^{\text{ele}}$ are obtained from the adaptive neighbor encoder. We allow a position embedding for each position within length 3. After constructing all input representations, we feed them into a stack of L Transformer blocks (Vaswani et al., 2017) to encode X and obtain:

$$\mathbf{z}_i^l = \text{Transformer}(\mathbf{z}_i^{l-1}), l = 1, 2, \cdots, L. \tag{7}$$

where $\mathbf{z}_i^l$ is the hidden state of x_i after the l-th layer. Transformer adopts a multi-head self-attention mechanism, with each block allowing each element to attend to all elements with different weights in the sequence.

To perform the few-shot KG completion task, we restrict the mask solely to the task relation r (*i.e.* x_2), so as to obtain meaningful entity pair embeddings. The final hidden state $\mathbf{z}_2^L$ is taken as the desired representation for the entity pair in $\mathcal{D}_r$. Such representation encodes semantic roles of each entity, and thus helps discern fine-grained meanings of task relations associated with different entity pairs. For more details about Transformer, please refer to Vaswani et al. (2017).

4.3 Adaptive Matching Processor

To make predictions by comparing the query to references, we devise an adaptive matching processor considering different semantic meanings of the task relation. Figure 2(c) gives the details of adaptive matching processor.

In order to compare one query to K-shot references, we are going to obtain a general reference representation for the given reference set $\mathcal{S}_r$. Considering the various meanings of the task relation, we define a metric function $\delta(q_r, s_{rk})$ that measures the semantic similarity of the query q_r and the reference triple s_{rk}. For simplicity, we achieve $\delta(q_r, s_{rk})$ with simple but effective dot product:

$$\delta\left(q_r, s_{rk}\right) = \mathbf{q}_r \cdot \mathbf{s}_{rk} \tag{8}$$

Unlike current few-shot relational learning models that learn static representations when predicting different queries, we adopt attention mechanism to obtain a general reference representation $g\left(\mathcal{S}_r\right)$ adaptive to the query. This can be formulated as:

$$g\left(\mathcal{S}_r\right) = \sum\nolimits_{s_{rk}\in\mathcal{S}_r} \beta_k \mathbf{s}_{rk} \tag{9}$$

$$\beta_k = \frac{\exp(\delta\left(q_r, s_{rk}\right))}{\sum\nolimits_{s_{rj}\in\mathcal{S}_r} \exp(\delta\left(q_r, s_{rj}\right))} \tag{10}$$

Here, β_k denotes the attention score of a reference; $s_{rk} \triangleq (h_k, t_k) \in \mathcal{S}_r$ denotes the k-th reference in the task of r, and $\mathbf{s}_{rk}$ is its embedding; $\mathbf{q}_r$ is the embedding of a query q_r in $\mathcal{Q}_r$. Both $\mathbf{s}_{rk}$ and $\mathbf{q}_r$ are obtained by Eq. (7), to capture their fine-grained meanings. Eq. (9) leads to the fact that references having similar meanings to the query would be more referential, making reference set $\mathcal{S}_r$ have an adaptive representation to different queries.

To make predictions, we define a metric function $\phi\left(q_r, \mathcal{S}_r\right)$ to measure the semantic similarity of the query q_r and the reference representation $\mathcal{S}_r$:

$$\phi\left(q_r, \mathcal{S}_r\right) = \mathbf{q}_r \cdot g\left(\mathcal{S}_r\right). \tag{11}$$

$\phi(\cdot)$ is expected to be large if the query holds, and small otherwise. Here, $\phi\left(\cdot,\cdot\right)$ can also be implemented with alternative metrics such as cosine similarity or Euclidean distance.

4.4 Model Training

With the adaptive neighbor encoder, the Transformer encoder and the adaptive matching processor, the overall model of FAAN is then trained on meta-training set $\mathcal{T}_{mtr}$. $\mathcal{T}_{mtr}$ is obtained by the following way. For each few-shot relation r, we randomly sample K-shot positive entity pairs from $\mathcal{T}$ as the reference set $\mathcal{S}_r$. The remaining entity pairs are utilized as positive query set $Q_r = \{(h_m, t_m)\}$. Then we construct a set of negative queries $Q_r^- = \{(h_m, t_m^-)\}$ by randomly corrupting the tail entity of (h_m, t_m), where $t_m^- \in \mathcal{E} \setminus \{t_m\}$. Then, the overall loss is formulated as:

$$\mathcal{L} = \sum_{r} \sum_{q_r \in Q_r} \sum_{q_r^- \in Q_r^-} \left[\gamma + \phi(q_r^-, \mathcal{S}_r) - \phi(q_r, \mathcal{S}_r)\right]_+ \tag{12}$$

where $[x]_+ = \max(0, x)$ is standard hinge loss, and γ is a margin separating positive and negative queries. To minimize $\mathcal{L}$, we take each relation in $\mathcal{T}_{mtr}$ as a task, and adopt a batch sampling based meta-training procedure proposed in (Zhang et al., 2020). To optimize model parameters in Θ and Transformer, we use Adam optimizer (Kingma and Ba, 2015), and further impose L_2 regularization on the parameters to avoid over-fitting.

5 Experiments

In this section, we conduct link prediction experiments to evaluate the performance of FAAN.

5.1 Datasets

We conduct experiments on two public benchmark datasets: NELL and Wiki[1]. In both datasets, relations that have less than 500 but more than 50 triples are selected to construct few-shot tasks. There are 67 and 183 tasks in NELL and Wiki, respectively. We use original 51/5/11 and 133/16/34 relations in NELL and Wiki, respectively, for training/validation/testing as defined in Section 3. Moreover, for each task relation, both datasets also provide candidate entities, which are constructed based on the entity type constraint (Xiong et al., 2018). More details are shown in Table 1.

5.2 Comparision Methods

In order to evaluate the effectiveness of our method, we compare our method against the following two groups of baselines:

Dateset	# Ent.	# Rel.	# Triples	# Tasks
NELL	68,545	358	181,109	67
Wiki	4,838,244	822	5,859,240	183

Table 1: Statistics of datasets. Each column represents the number of entities, relations, triples and tasks.

KG embedding method. This kind of method learns entity/relation embeddings by modeling relational structures in KG. We adopt five widely used methods as baselines: TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016), SimplE (Kazemi and Poole, 2018) and RotatE (Sun et al., 2019). All KG embedding methods require sufficient training triples for each relation, and learn static representations of KG.

Few-shot relational learning method. This kind of method achieves state-of-the-art performance of few-shot KG completion on NELL and Wiki datasets. GMatching (Xiong et al., 2018) adopts a neighbor encoder and a matching network, but assumes that all neighbors contribute equally. FSRL (Zhang et al., 2020) encodes neighbors with a fixed attention mechanism, and applies a recurrent autoencoder to aggregate references. MetaR (Chen et al., 2019) makes predictions by transferring shared knowledge from the references to the queries based on a novel optimization strategy. All the above methods learn static representations of entities or references, ignoring their dynamic properties.

5.3 Implementation Details

We perform 5-shot KG completion task for all the methods. Our implementation for KG embedding baselines is based on OpenKE[2] (Han et al., 2018) with their best hyperparameters reported in the original literature. During training, all triples in background KG $\mathcal{G}'$ and training set, as well as few-shot reference triples of validation and testing set are used to train models. For few-shot relational learning baselines, we extend GMatching from original one-shot scenario to few-shot scenario by three settings: obtaining general reference representation by mean/max pooling (denoted as MeanP/MaxP) over references, or taking the reference that leads to the maximal similarity score to the query (denoted as Max). Because FSRL was reported in completely different experimental settings, we reimplement the

model to make a fair comparison. We directly report the original results of MetaR with pre-trained embeddings to avoid re-implementation bias.

For all implemented few-shot learning methods, we initialize entity embeddings by TransE. The entity neighbors are randomly sampled and fixed before model training, and the maximum number of neighbors M is fixed to 50 on both datasets. The embedding dimensionality is set to 50 and 100 for NELL and Wiki, respectively. For FAAN, we further set the number of Transformer layers to 3 and 4, and the number of Transformer heads to 4 and 8, respectively. To avoid over-fitting, we also apply dropout to the neighbor encoder and the Transformer layer with the rate tuned in $\{0.1, 0.3\}$. The L_2 regularization coefficient is tuned in $\{0, 1e^{-4}\}$. The margin γ is fixed to 5.0. The optimal initial learning rate η for Adam optimizer is $5e^{-5}$ and $6e^{-5}$ for NELL and Wiki respectively, which is warmed up over the first 10k training steps, and then linearly decayed. We evaluate all methods for every 10k training steps, and select the best models leading to the highest MRR (described later) on the validation set within 300k steps. The optimal hyperparameters are tuned by grid search on the validation set.

5.4 Evaluation Metrics

To evaluate the performance of all methods, we measure the quality of the ranking of each test triple among all tail substitutions in the candidates: (h_m, r', t'_m), $t'_k \in \mathcal{C}_{h_m,r'}$. We report two standard evaluation metrics on both datasets: MRR and Hits@N. MRR is the mean reciprocal rank and Hits@N is the proportion of correct entities ranked in the top N, with $N = 1, 5, 10$.

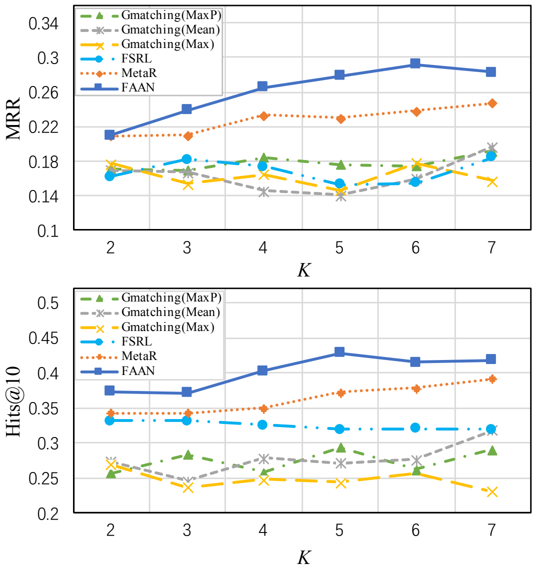

Figure 3: Impact of few-shot size K on NELL dataset.

5.5 Main Results in Link Prediction

The performance of all models on NELL and Wiki are shown in Table 2. The table reveals that:

(1) Compared to the traditional KG embedding methods, our model achieves better performance on both datasets. The experimental results indicate that our few-shot learning method is more suitable for solving few-shot issues.

(2) Compared to the few-shot learning baselines, our model also consistently outperforms them on both datasets in all metrics. Compared to the best performing baseline MetaR, FAAN achieves an improvement of 33.5%/20.6% in MRR/Hits@10 on NELL test data, and an improvement of 5.6%/10.8% on Wiki test data, respectively. It demonstrates that exploiting the dynamic properties of KG can indeed improve the

performance of few-shot KG completion.

5.6 Impact of Few-Shot Size

We conduct experiments to analyze the impact of few-shot size K. Figure 3 reports the performance of models on NELL data in different settings of K. The figure shows that:

(1) Our model outperforms all baselines by a large margin under different K, showing the effectiveness of our model in the few-shot scenario.

(2) An interesting observation is that a larger reference set does not always achieve better performance in the few-shot scenario. The reason is probably that few-shot scenario makes the performance sensitive to available references. Take the task relation `SubPartOf` in Figure 1(b) as an example. When making predictions for organization-related queries, injecting more location-related references is not necessarily useful. Even so, FAAN still gets relatively stable improvements compared to most baselines like GMatching and FSRL. The robustness to few-shot size comes from better reference embeddings generated by the adaptive aggregator.

5.7 Discussion for Model Variants

To inspect the effectiveness of the model components, we show results of experiments for model variants in Table 3:

(A) **Neighbor Encoder Variants:** In A1, we replace the encoder by mean pooling module used in GMatching. In A2, we aggregate neighbors with a fixed attention map as used in FSRL. In A3, we remove the embeddings of entities' own and encode them with only their neighbors. Experiments show that aggregating entity neighbors in an adaptive way and considering self-embedding can benefit the model performance.

(B) **Transformer Encoder Variants:** In B1, we replace the encoder by a concatenate operation on entity pairs as used in both GMatching and FSRL. In B2, we remove position embeddings in the Transformer encoder. Experiments indicate that the Transformer can effectively model few-shot relations, and position embeddings are also essential.

(C) **Matching Processor Variants:** In C1, we just obtain the embedding of reference set by averaging all reference representations. In C2, we only take the reference that is the most relevant to the query. In C3, we adopt the LSTM matching network as used in GMatching. Experiments indicate that our adaptive matching processor has superior capability in computing relevance between references and queries.

Table 5: Attention weights of 5-shot references, given two queries: Query 1 `(C. Bulls, NBA)` and Query 2 `(Astana, Kazakhstan)`. The task relation of all entity pairs is `SubPartOf`. The references that are more related to the query achieve higher attention weights.

5.8 Case Study for Adaptive Attentions

To better understand the effects of adaptive attentions in the neighbor encoder and the matching processor, we conduct a case study. Table 4 provides the most contributive relation neighbors with the highest attention weights in different tasks. We can see that the contributive neighbors for each entity in both tasks are different. The entities tend to focus more on the neighbors that are related to the task. Table 5 shows attention weights of references given different queries. The attention map of references is varied for each query, and the queries focus more on the related references. We can see that the attention weights are higher for location-related ref-

erences when the query is location-related, while those are higher for organization-related references when the query is organization-related. This further indicates that our adaptive matching processor can aggregate references dynamically adaptive to the query, and benefits the matching process. All the above results further confirm our intuition described in the introduction.

5.9 Results on Different Relations

Besides the overall performance reported in the main results, we also conduct experiments to evaluate the performance of each task relation in NELL testing data. Table 6 reports the results of the best baseline model MetaR and our model FAAN. According to the table, we find that the results of both models on different task relations are of high variance. The reason may be that the number of candidate entities is different, and the relations with large candidate set are usually hard to make predictions. Even so, our model FAAN has better performance in most cases, which indicates that our model is robust for different task relations.

6 Conclusion

This paper proposes an adaptive attentional network for few-shot KG completion, termed as FAAN. Previous studies solve this problem by learning static representations of entities or references, ignoring their dynamic properties. FAAN proposes to encode entity pairs adaptively, and predict facts by adaptively matching references with queries. Experiments on two public datasets demonstrate that our model outperforms current state-of-art methods with different few-shot sizes. Our future work might consider other advanced methods to model few-shot relations, and exploiting more contextual information like textual description to enhance entity embeddings.

Abstract

In this paper, we integrate span-related information into pre-trained encoder for entity relation extraction task. Instead of using general-purpose sentence encoder (e.g., existing universal pre-trained models), we introduce a span encoder and a span pair encoder to the pre-training network, which makes it easier to import intra-span and inter-span information into the pre-trained model. To learn the encoders, we devise three customized pre-training objectives from different perspectives, which target on tokens, spans, and span pairs. In particular, a span encoder is trained to recover a random shuffling of tokens in a span, and a span pair encoder is trained to predict positive pairs that are from the same sentences and negative pairs that are from different sentences using contrastive loss. Experimental results show that the proposed pre-training method outperforms distantly supervised pre-training, and achieves promising performance on two entity relation extraction benchmark datasets (ACE05, SciERC).

1 Introduction

Extraction of entities and relations from free texts is an important task in NLP. Its goal is to recognize text spans with specific types (*entities*) and semantic relations among those entities (*relations*). Current state-of-the-art systems usually employ the supervised joint learning algorithm (Miwa and Bansal, 2016; Sun et al., 2018, 2019a), which can alleviate error propagation caused by the pipeline method. In this paper, we focus on joint entity relation extraction.

Recently, pre-trained models (Devlin et al., 2018; Dong et al., 2019) have substantially advanced a variety of NLP tasks, including entity relation extraction (Li et al., 2019; Wadden et al., 2019). (Wadden et al., 2019) adopt BERT as a sentence encoder and build a multi-task framework for information extraction. However, universal pre-trained models are usually trained without explicitly handling text spans and relation among text span pairs. For example, the objectives of BERT are masked language model and next sentence prediction, which are defined at the token level and sentence level, respectively. It rarely considers incorporating span-related knowledge, which can provide rich information for better extracting entities and relations (Table 1).

	BERT	SpanBERT	ERNIE	Ours
Token Level	✓	✓	✓	✓
Span Level		✓	✓̲	✓
Span Pair Level				✓
Sentence Level	✓		✓	

Table 1: Comparison between pre-training objectives. ✓̲ means that additional annotations (entities) are used.

The traditional way to introduce more entity relation related information is through distant supervision, which aligns triples in knowledge bases and free texts. However, the distantly supervised dataset contains lots of noise samples, which may have a negative impact on other datasets as prior works (Sun and Wu, 2019). Besides, the distantly supervised dataset's annotated labels are usually inconsistent with that of the target dataset. As expected, in the preliminary experiment, we observe that the performance of the model directly pre-trained with annotated data provided by distantly supervised dataset (such as NYT) is not improved or even gets worse when it is fine-tuned on other entity relation dataset (such as ACE05). In addition, there are several existing works for incorporating entity information into pre-training objectives (Zhang et al., 2019; Sun et al., 2019b). However, these methods rely on entity annotations, which brings additional cost.

In this work, we focus on the unsupervised pre-training objectives. We present a novel pre-training

November 16–20, 2020. ©2020 Association for Computational Linguistics

network architecture customized for entity relation extraction. In addition to the default sentence encoder in existing pre-trained models (e.g., the Transformer encoder of BERT), we also pre-train *a span encoder* and *a span pair encoder*. To learn the two encoders, we propose three pre-training objectives corresponding to three levels: token boundary objective (token level), span permutation objective (span level), and contrastive span pair objective (span pair level). Token boundary objective can help to enhance the representation of the first subtoken of each token. Span encoder is trained by recovering the correct order of span tokens from its random shufflings. Span pair encoder is trained by the contrastive loss. Specifically, the predictions are made discriminatively with a sampled-softmax that contrasts positive pairs against negative pairs. Positive pairs are from the same sentences, while negative pairs are from different sentences. These three objectives share parameters and will be trained jointly.

A closely related work to span level pre-training objective is SpanBERT (Joshi et al., 2020), which adopts the span boundary objective to incorporate the span information. Different from (Joshi et al., 2020), we introduce not only a new objective at the span level but also a new objective at the span pair level (Table 1). Inspired by the recently proposed InfoWord (Kong et al., 2019), we use the contrastive loss to learn a better span pair representation. To utilize a large set of negative pairs without requiring large training batches, we extend the MoCo (He et al., 2019) framework to the proposed span pair objective. In summary, our main contributions are in the following [1]:

- We introduce a span encoder and a span pair encoder to incorporate intra-span and inter-span information in the pre-training network architecture, which is ignored in universal pre-trained models.

- We devise three novel objectives, token boundary objective, span permutation objective, and contrastive span pair objective, to learn the better encoders.

- The experimental results demonstrate that the proposed method not only exceeds the strong BERT baseline in entity relation extraction task but also achieves significant improvements (3% absolute) on the ACE05 dataset, and is comparable with the state-of-the-art on the SciERC dataset.

2 Background of Contrastive Learning

InfoNCE Contrastive learning is a framework that builds representations by learning to encode what makes two things similar or dissimilar [2]. Recently, (He et al., 2019) regrad contrastive learning as a *dictionary look-up* task. An effective contrastive loss function, called InfoNCE (Oord et al., 2018), is as follows. Formally, for any data point X, to learn a query encoder f_q and a key encoder f_k (the two encoders can be different, partially shared, or identical, we adopt two identical encoders), InfoNCE is to minimize the following loss function [3]

$$-\mathop{\mathbb{E}}_{X,X^+}\left[f_q(X)\cdot f_k(X^+) - \log Z\right]$$

$$Z = \exp(f_q(X)\cdot f_k(X^+)) + \sum_{X^-}\exp(f_q(X)\cdot f_k(X^-))$$

where X is a query sample and $\{X^+, X^-\}$ are key samples. X^+ is a similar key to query X and X^- is presumably dissimilar to X. Thus, X, X^+, X^- are referred to as *anchor*, *positive*, *negative* respectively in the parlance of contrastive learning.

Momentum Contrast (MoCo) Contrastive learning tends to work better with more negative examples, since presumably negative examples can decide the quality of the underlying representations learned. In the usual formulation of contrastive learning, the gradients flow back through both the query encoder and the key encoder, which means that the number of negative samples is restricted to the mini-batch size. Thus, the MoCo framework (He et al., 2019) is devised to process a large set of negative samples without requiring large training batches. Specifically, Instead of updating the key encoder with gradients back-propagation, MoCo periodically updates the key encoder using a momentum update:

$$\theta_k = m\theta_k + (1-m)\theta_q$$

Here, θ_k denotes the parameters of the key encoder (also called momentum encoder), and θ_q denotes the parameters of the query encoder (Figure 1). $m \in [0, 1)$ is a momentum coefficient (e.g.,

---

[1] Source code and pre-trained models are available at https://github.com/Receiling/PSPE.

[2] For more theoretical understanding, please refer to (Arora et al., 2019).

[3] Minimizing the InfoNCE loss maximizes a lower bound on the mutual information between $f_q(X)$ and $f_k(X^+)$ (Kong et al., 2019).

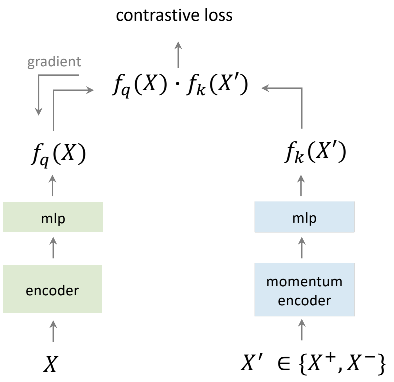

Figure 1: Framework of MoCo with an MLP projection.

$m = 0.999$, our default). MoCo only updates parameters θ_q with back-propagation, and decouples the size of key samples from the mini-batch size. Thus, MoCo can maintain a large queue of key samples, which contains one positive key sample and lots of negative key samples to one query. In addition, introducing an MLP (multi-layer perceptron) head projection between the representation and the contrastive loss substantially improves the quality of the learned representations (Chen et al., 2020a,b).

3 Approach

Given an input sentence $x = x_1, \ldots, x_{|x|}$ and a set of spans $\mathcal{S}$ (randomly sampling) in x, the target of our pre-training model is to obtain a contextualized vector representation for each span $s \in \mathcal{S}$, and a contextualized vector representation for each span pair (s_1, s_2). As shown in Figure 2, the pre-training task optimizes a shared Transformer (Vaswani et al., 2017) network, a span level CNN and attention parameters with respect to a token boundary objective, a span permutation objective, and a contrastive span pair objective. Different from universal pre-trained language models (Devlin et al., 2018; Peters et al., 2018), the proposed network incorporates rich intra-span and inter-span information [4]. Once our network is pre-trained, we can fine-tune it for entity relation extraction task.

3.1 Pre-training Network Architecture

This section presents the overall pre-training network architecture for sentence encoder, span encoder, and span pair encoder. The next section will describe the objectives for training the three components.

Sentence Encoder To obtain the contextual representations $\mathbf{h}_i$ for each token in the sentence x, we use multi-layer Transformer (Vaswani et al., 2017) as basic encoder like previous pre-training models, such as UniLM, BERT, and XLM. The output of the multi-layer Transformer is computed via:

$$\{\mathbf{h}_1, \ldots, \mathbf{h}_{|x|}\} = \mathtt{Transformer}(\{\mathbf{x}_1, \ldots, \mathbf{x}_{|x|}\})$$

The word representation $\mathbf{x}_i$ of x_i follows that of BERT (Devlin et al., 2018), which sums the corresponding token, segment and position embeddings.

Span Encoder Given a span $s \in \mathcal{S}$ in the sentence x, to compute the corresponding contextual span representation $\mathbf{h}_s$, we employ a CNN (a single convolution layer with a max-pooling layer) followed by an MLP on vectors $\{\mathbf{h}_i | x_i \in s\}$, as shown in the right part of Figure 2.

Span Pair Encoder Given a span pair $p = (s_1, s_2)$ in the sentence x, the sentence x is split into five spans, namely, *left context (L)*, s_1, *middle context (M)*, s_2 and *right context (R)*. To obtain the corresponding contextual span pair representation $\mathbf{h}_{s_1,s_2}$, we first employ the span encoder to extract five feature vectors regarding the five spans. Let $\mathbf{h}_L, \mathbf{h}_{s_1}, \mathbf{h}_M, \mathbf{h}_{s_2}, \mathbf{h}_R$ be the corresponding representations computed by span encoder. To allow the model to focus on more informative spans, we then represent the span pair p as a weighted sum of its contextualized span representations with a position-aware attention mechanism as

$$\mathbf{h}_p = \sum_{j \in \{L, s_1, M, s_2, R\}} a_j \mathbf{h}_j,$$

where the attention score a_j is computed as

$$\begin{aligned} a_j &= \text{Softmax}(e_j), \\ e_j &= \mathbf{v}^T \tanh(\mathbf{W}_h \mathbf{h}_j + \mathbf{W}_{\text{cls}} \mathbf{h}_{\text{cls}} + \\ &\quad \mathbf{W}_{s_1} \mathbf{p}_j^{s_1} + \mathbf{W}_{s_2} \mathbf{p}_j^{s_2}), \end{aligned}$$

where $\mathbf{W}_*$ and $\mathbf{v}$ are parameters and $\mathbf{h}_{\text{cls}}$ is the output of the first token ([CLS]). Following (Zhang et al., 2017), $\mathbf{p}_j^{s_1}$ and $\mathbf{p}_j^{s_2}$ are the relative position embedding with repsect to s_1 and s_2.

3.2 Pre-training Objectives

Learning powerful representations of span and span pair is crucial for the entity relation extraction task,

---

[4] We extract entities and relations for each sentence, so we omit the next sentence prediction in BERT, which is a sentence level objective.

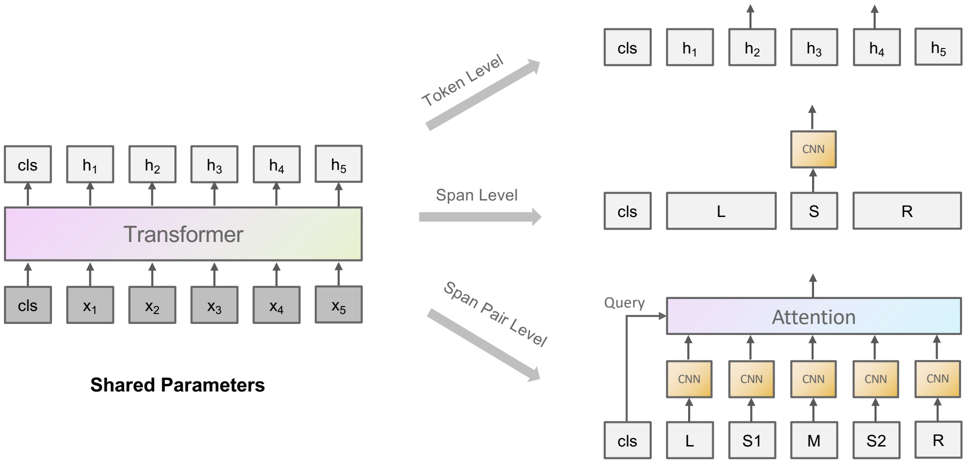

Figure 2: Overview of our pre-training. The Transformer parameters are shared across three objectives (i.e., token level, span level and span pair level).

which is not explicitly considered in the universal pre-trained models such as BERT. Here, we aim to design several tailored pre-training objectives that can guide the model to learn more powerful representations of spans and span pairs. The three tasks share parameters and are trained jointly (weighted sum of the objective functions).

Token Boundary Objective (TBO) In practice, masked language modeling (MLM) is usually applied at the sub-token level. Given the input sub-token sequence, a certain portion of sub-tokens are replaced by a special symbol `[M]`. The model is trained to recover the original sub-tokens from the corrupted version. In the downstream tasks, we simply take the first sub-token representation as the token representation. To enhance the first sub-token representation and maintain the token level information, we propose a variant MLM. Specifically, for each token, we mask the sub-tokens except the first sub-token, and then predict the masked sub-tokens with the first sub-token representation and corresponding position embedding. In experiments, for each sentence, we randomly select 15% of the sub-tokens to perform this objective.

Span Permutation Objective (SPO) Inspired by the recent SpanBERT (Joshi et al., 2020), we propose a different strategy to incorporate the intra-span information into our pre-training model. SpanBERT still focuses on enhancing single token representation, while we emphasize the contextual representation of the whole span. Instead of predicting each token of a masked span in SpanBERT, we shuffle the tokens in the span and then expect the model can recognize the disruption. Correctly, let $s = (x_{start}, x_{middle}, x_{end})$ be a span in the sentence x, where $start, end$ indicates its start and end position, and $middle$ indicates its middle positions (may contain multiple tokens). Let $\mathcal{P}$ be the set of all possible permutation of the three parts. Obviously, the number of all possible permutations is 3! ($|\mathcal{P}| = 6$). For each permutation $p \in \mathcal{P}$, we first assign it a unique permutation class $N_p (1 \leq N_p \leq |\mathcal{P}|)$, and then extract feature vectors regarding span s with the span encoder to predict the permutation class. The objective is to optimize the cross-entropy loss computed using the predicted permutation class and the gold permutation class. In the implementation, we sample n_p permutations (we always include the correct permutation).

Contrastive Span Pair Objective (CSPO) Previous pre-trained models only consider a single token or single span in the pre-training objective, and ignore the role of span pairs. For entity relation extraction task, it often involves predicting whether a relation exists on an entity pair. Thus, if we have a better-pre-trained span pair encoder, we may get a better entity relation extraction performance in the fine-tuning step. To this end, we propose a novel span pair level objective based on the contrastive learning framework. Inspired by InfoWord (Kong et al., 2019), it views spans and their matching contexts (i.e., contexts in the same sentences) as positive pairs, otherwise as negatives pairs. We extend this idea to the span pair level.

Formally, given a span pair $p = (s_1, s_2)$ in the sentence x, we consider the sentence with masked p (denoted by x_p^{context}) and the sentence with masked context of p (denoted by x_p^{target}) to be a positive pair (Figure 3). If both come from

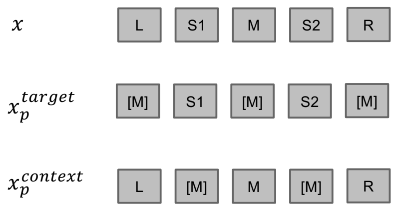

Figure 3: Examples of x_p^{target} and x_p^{context}.

two different sentences, it is a negative pair. In other words, $(x_p^{\text{context}}, x_p^{\text{target}})$ is a positive pair, and $(x_p^{\text{context}}, \hat{x}_{p'}^{\text{target}})$, $(\hat{x}_{p'}^{\text{context}}, x_p^{\text{target}})$ are negative pair, where p' is a span pair in another sentence $\hat{x}$. Next, we describe how to adapt the MoCo framework to achieve our span pair level objective.

To obtain the representations of x_p^{context} and x_p^{target}, we can apply the span pair encoder on the masked sentence. In expectation, the span pair encoder will learn a better representation from contrastive loss. We adopt the span pair encoder followed by an MLP as the two identical encoders f_q and f_k of the MoCo.

$$f_q(X) = f_k(X) = \texttt{MLP}(\texttt{SpanPairEncoder}(X))$$

We think of two situations for (X, X^+, X^-) as follows:

- We first consider x_p^{context} as the *anchor* data point X, i.e., $X = x_p^{\text{context}}$, then $X^+ = x_p^{\text{target}}$ and $X^- = \hat{x}_{p'}^{\text{target}}$;
- We can also consider x_p^{target} as the *anchor* data point X, i.e., $X = x_p^{\text{target}}$, then $X^+ = x_p^{\text{context}}$ and $X^- = \hat{x}_{p'}^{\text{context}}$.

where x and $\hat{x}$ are two different sentences. Given the input (X, X^+, X^-), the training objective is to minimize

$$- \sum_{(X,X^+,X^-)\in\mathcal{X}} \left\{ \mathop{\mathbb{E}}_{X,X^+} \left[f_q(X) \cdot f_k(X^+) - \log Z \right] \right\}$$

$$Z = \exp(f_q(X) \cdot f_k(X^+)) + \sum_{X^-} \exp(f_q(X) \cdot f_k(X^-))$$

$$\mathcal{X} = \{(x_p^{\text{context}}, x_p^{\text{target}}, \hat{x}_{p'}^{\text{target}}), (x_p^{\text{target}}, x_p^{\text{context}}, \hat{x}_{p'}^{\text{context}})\}$$

Appendix D provides the PyTorch-like pseudocode of MoCo for our proposed span pair task. For the current mini-batch, we encode the X and X^+, which form the positive sample pairs. The negative samples are from the queue (we maintain the two queues).

3.3 Pre-training Setup

Within one training batch, we optimize the weighted sum of three objectives. We use GELU as the activation function. The sentence encoder is initialized by $\text{BERT}_{\text{BASE}}$. We generate spans similar to (Joshi et al., 2020). For distantly supervised pre-training, we train our model for ten epochs with linear warm up rate over the first 20% steps and linear decay. For our unsupervised pre-training on the distantly supervised corpus (NYT), we train our model for ten epochs with linear warm up rate over the first 10% steps and linear decay. In order to achieve more training data, we sample sentences from English Wikipedia [5] and BooksCorpus, which has been processed similarly as (Devlin et al., 2018), and construct a dataset (4.8M sentences total) with 70M words. So the total iterations of pre-training are smaller than $\text{BERT}_{\text{BASE}}$. The vocabulary size is 28996. The maximum length of the input sequence is 128. We train our model for 40,000 steps with linear warm up rate over the first 18,000 steps and linear decay. Adam (Kingma and Ba, 2014) with $\beta_1 = 0.9, \beta_2 = 0.999$ is used for optimization. The learning rates of NYT and WikiBook are 5e-5 and 1e-4, respectively. The dropout rate is 0.1. The weight decay is 0.01. The batch size is 256 with gradient accumulation. It takes about 22 hours for 10, 000 steps using 1 Nvidia Tesla T4 16GB GPU.

3.4 Fine-tuning for Entity Relation Extraction

We define the entity relation extraction task as (Sun et al., 2019a) [6]. First, we perform entity span detection, which is tackled using the sequence labeling framework. We use the sentence encoder's output as the representation of words and feed it to a randomly initialized softmax classifier. We adopt cross-entropy loss for training the entity span detector. Then, for each detected entity span, we predict its entity type using a softmax classifier. The classifier takes its input from the pre-trained span encoder. Similarly, we predict its relation type for each detected entity span pair using a softmax classifier, which takes its input from the span pair encoder. We also adopt cross-entropy loss in these two tasks. Overall, three objectives are optimized simultaneously in the fine-tuning step.

---

[5] Wikipedia version: enwiki-20190301.

[6] The neural architecture for fine-tuning is provided in Appendix A.

Scheduled sampling was used for the entity model similar to (Miwa and Bansal, 2016). We adopt the discriminative fine-tuning strategy as (Howard and Ruder, 2018). We employ the early stop strategy and select models based on performances on the development set.

4 Experiments

We conduct experiments on two benchmark entity relation extraction datasets: ACE05 and SciERC. For the distantly supervised dataset, we choose the NYT dataset.

ACE05 The ACE05 dataset [7] annotates entity and relation types for a collection of documents. It is a standard corpus for entity relation extraction task. There are 7 entity types and 6 relation types in the corpus. We use the same data split of the ACE05 dataset (351 training, 80 validating, and 80 testing) as (Miwa and Bansal, 2016).

SciERC The SciERC dataset [8] provides entity, coreference and relation annotations for 500 scientific abstracts, which are taken from AI conference/workshop proceedings. We only use the annotations of entities and relations. The corpus contains 6 scientific entity types and 7 relation types. We use the same data split of SciERC dataset (350 training, 50 validating, and 100 testing) as (Luan et al., 2019).

NYT The NYT dataset[9] is a large-scale corpus which annotates 3 types of entities and 12 types of relations for New York Times news articles. The training set is automatically generated by distant supervision. (Jia et al., 2019) provides validation and testing data that are manually labeled. We do not use the testing data for pre-training. We choose the latest version NYT released by (Jia et al., 2019).

Evaluation. We evaluate F1 score as previous works (Miwa and Bansal, 2016; Sun et al., 2019a). Specifically, an output entity is correct if its type and boundary are correct, and an output relation is correct if its type and its two-argument entities are correct (i.e., exactly match). Some previous works (Luan et al., 2019; Wadden et al., 2019; Sanh et al., 2019) do not consider entity type for relation evaluation. We also report this result for comparison.

Table 3: Results on the ACE05 test data. "BERT" is our method without pre-training, which is initialized by $\text{BERT}_{\text{BASE}}$ and fine-tuned on ACE05 dataset. "SpanBERT" is similar to "BERT" and is initialized by $\text{SpanBERT}_{\text{BASE}}$. "SPE(NYT)" is the proposed model pre-trained on NYT dataset. "SPE-DS" is the proposed model pre-trained on NYT dataset with distantly supervised objectives.

4.1 Results on ACE05

First, we compare our methods with previous works in Table 2. In general, our proposed pre-training method "SPE " [10] achieves significant improvements over all the existing models in two ways of relation evaluation. Particularly, it achieves an improvement of 4.1 units (exactly match) over the LSTM-based GCN joint model (Sun et al., 2019a) and outperforms 3.0 percent (exactly match) comparing with the BERT-based QA model (Li et al., 2019). Comparing with multi-task learning based on ELMo and BERT (Sanh et al., 2019; Luan et al., 2019; Wadden et al., 2019), it also achieves a significant improvement. It is worth noting that our entity detection result underperforms (Luan et al., 2019; Wadden et al., 2019). The major reason is that we do not introduce additional supervision signals in the fine-tuning step, such as coreference resolution and event extraction. However, even without additional multi-task training data, we still achieve the best relation performance, demonstrating the effectiveness of the proposed pre-training method for the entity relation extraction task.

Table 6: Results on the ACE05 test data in different settings of MoCo framework.

Next, we compare our method with different pre-training in Table 3. "BERT" and "SpanBERT" have similar relation performances, and "SpanBERT" gets a better entity performance. Our "SPE" outperforms both in terms of relation performance, showing the contribution of the span and span pair representations learned by the proposed objectives. Comparing with distantly supervised per-training, for a fair comparison, we also use the NYT dataset as our pre-training corpus (line 4). In fact, we observe that pre-training results on Wiki and NYT are similar although the NYT data size is smaller (line 3 and line 4). Surprisingly, the distantly supervised pre-training (initialized by BERT$_{\text{BASE}}$) performs poorly even worse than the "BERT" baseline (line 1 and line 5). Our explanation of this phenomenon is that distant supervision introduces larger noisy samples, which results in a negative transfer. Comparing with distantly supervised pre-training, our method does not access any supervised signals that may be noisy, and achieves larger improvement in relation performance over the "BERT" baseline.

Thirdly, we analyze the contributions and effects on different settings (Table 4). We have several observations.

- Comparing with "BERT", "SPE" achieves comparable entity performance and outperforms it with 1.3 points in relation performance. This observation indicates the proposed pre-training objectives can help better learning span-related information, which is crucial for the entity relation extraction task. In addition, entity performance is insensitive to all models (all lines). They fluctuate at 0.4 points.

- When one of the pre-training objectives (line 3-5) is removed, we find the relation performance declines with varying degrees. In particular, the relation performance of "- SPO" drops largely (2.3 points and 2.1 points for both relation evaluations respectively). It demonstrates that the span encoder is quite effective for relation extraction.

- Comparing with "SPE", the relation performance of the "- CNN" decreases sharply (line 6). It shows that, with automatically annotated entities in free texts, the pre-training objectives are able to grasp some useful context information for identifying entities and relations.

Fourthly, we study the influences of fine-tuning data size. In Table 5, we can see that increasing the size of training data, in general, improve the performances of the entity relation extraction task. When the training data in the fine-tuning step is very small (10%, 20%), our pre-trained model is obviously better than the "BERT" baseline. We attribute these results to the powerful representations learned by our pre-training objectives. In addition, distantly supervised pre-training also have poor performances.

Finally, we test the influences of the component of the MoCo (Table 6) [11]. If we remove the last MLP head projection, the relation performance drops largely, which shows that MLP head pro-

---

Table 7: Results on the SciERC test data.

jection substantially improves the quality of the learned span and spar pair representations. There is a similar conclusion on computer vision (Chen et al., 2020a,b). For MoCo framework, we can get two encoders, an encoder updated by backpropagation and a momentum encoder updated by momentum update. In our experiments, we find the former performs better than the latter.

4.2 Results on SciERC

The baseline methods are (Luan et al., 2019), which learns multiple tasks with ELMo embeddings, and (Wadden et al., 2019) which also adopts multi-task learning with BERT. From the upper part of Table 7, both "BERT" and "SPE" significantly outperform (Luan et al., 2019) in entity performance and relation performance. We attribute the phenomenon to the strong ability of BERT. "SPE" performs better than "BERT", which shows the proposed objectives are useful for entity relation extraction, and can integrate span information into the pre-trained model. Our pre-trained models can match previous state-of-the-art method (Wadden et al., 2019), without additional multi-task learning data. In addition, distantly supervised pre-training also have poor performances.

5 Related Work

Research on entity relation extraction has been extensively investigated. Early pipeline methods suffer the error propagation problem (Chan and Roth, 2011; Lin et al., 2016). Joint model can make better use of the complementarity between the entity model and the relation model to alleviate error propagation. A simple method is joint learning through sharing parameters, which means the entity model and the relation model can share some input vectors or sentence encoder. The typical works include tree LSTM-based model over dependency tree (Miwa and Bansal, 2016) and attention-based model without dependency tree (Katiyar and Cardie, 2017). However, this kind of method does not perform joint decoding, and it can not fully exploit the interaction between output entities and relations. To mitigate the above question, many joint decoding algorithms (Fu et al., 2019; Ren et al., 2017; Li et al., 2019) are applied into this task, such as ILP-based joint decoding algorithms (Yang and Cardie, 2013), joint sequence labelling tag set (Zheng et al., 2017), structured perceptron (Li and Ji, 2014), joint MRT (Sun et al., 2018), joint relational triplets extracting (Chen et al., 2019; Zeng et al., 2018), and transition system (Wang et al., 2018). Besides, (Sun et al., 2019a) perform the joint type inference with GCN on an entity-relation bipartite graph. Especially, our joint model for entity relation extraction is derived from (Sun et al., 2019a) without GCN. In this work, we mainly investigate whether pre-training can help entity relation extraction task. For simplicity, our joint model does not perform joint decoding (only sharing parameters). In addition, transfer learning (Sun and Wu, 2019), multi-task learning (Sanh et al., 2019; Wadden et al., 2019; Luan et al., 2019), and reinforcement learning (Takanobu et al., 2019) were also studied.

Pre-trained models have achieved impressive performance on a wide range of downstream tasks in NLP. Different training objectives have been used for different pre-trained models. For example, ELMo (Peters et al., 2018), BERT (Devlin et al., 2018) and UniLM (Dong et al., 2019) learn different token level objectives and sentence level objectives. Despite their great success, they ignore the incorporation of span-related information, which is vital for the entity relation extraction task. (Zhang et al., 2019) demonstrate that informative entities in KGs can enhance language representation with external knowledge. (Sun et al., 2019b) propose entity-level masking and phrase-level masking to enhance language representation. Comparing with (Zhang et al., 2019; Sun et al., 2019b; Joshi et al., 2020), the proposed objectives can not only integrate span information, but also span pair information. Recently, unsupervised contrastive pretraining methods, MoCo (He et al., 2019), SimCLR (Chen et al., 2020a), InfoWord (Kong et al., 2019) and CURL (Srinivas et al., 2020), have led to great empirical success in computer vision, reinforcement learning and NLP. Constrastive learning learns representations by contrasting positive and negative samples. Inspired by (Kong et al., 2019), we learn better span pair representations with contrastive methods, utilizing a large set of negatives without requiring large training batches and extending the MoCo framework with the proposed span pair objective.

6 Conclusion

We propose a pre-training network architecture with three objectives, which can incorporate intra-span and inter-span information into pre-trained models. In comparison to universal pre-trained model, we introduce a span encoder and a span pair encoder. By designning three pre-training objectives, we can learn better pre-trained encoders customized for entity relation extraction task. Experiments on two benchmark datasets demonstrate the effectiveness of the proposed pre-training method.

Appendices

A Neural Architecture for Fine-tuning

Figure 4 displays our neural architecture adopted in the fine-tuning step. The fine-tuning step can be divided into three subtasks as follow:

1. **Entity Span Detection** Training an entity span detector with the sequence labeling framework.

2. **Entity Recognition** Predicting the entity type for each detected entity span.

3. **Relation Classification** Predicting the relation type for each detected entity span pair.

The three subtasks correspond to three objectives, which are optimized simultaneously in fine-tuning.

B More Evaluations

We list performances on each entity type and realtion type in Table 8 and Table 9 respectively. Table 8 shows that "BERT" and "SPE" have similar entity performance on different entity types. While Table 9 demonstrates that "SPE" significantly improves both precision and recall on different relation types except for "GEN-AFF".

Figure 5(a) illustrates the relation performaces (exactly match) of "BERT" and "SPE" with respect to the number of entities for each sentence. In general, our "SPE" almost outperforms "BERT" when the number of entities is less than 9. Moreover, the performance of "BERT" and "SPE" both rise with as the number of entities increases, which suggests that more entities will help to identify relations. This result proves that the proposed "SPE" model is able to encode more powerful representations of span and span pair when lacking entity information. In other words, our "SPE" is robust to more sparse situations that are common in reality.

Figure 5(b) illustrates the relation performaces (exactly match) of "BERT" and "SPE" with respect to the sentence length of each sentence. We find that "SPE" achieves superior performances compared to "BERT" on different sentence length except that sentence length is between 31 and 50. This result demonstrates that our "SPE" model can handle too long or too short sentences, while the performance sharply decreases when sentence length is between 31 and 50. We think the superior performances of "SPE" verify the effectiveness of the proposed method. Meanwhile, it is valuable to solve the problem of performance decline on medium sentence length in future work.

Finally, we report the performance of "SciBERT" on the SciERC dataset in Table 10. In the experiment, we directly replace BERT with SciBERT and train the model on the SciERC dataset to get the result. We find that the performance of "SciERC" is superior to "BERT" and "SPE", which suggests that the data resources from specific domains are quite important for some tasks. But we believe that we can achieve a higher score on the SciERC dataset when we use the same pre-training dataset as "SciBERT".

Entity Type	Model	P	R	F
WEA (109)	BERT	77.7	**79.8**	78.7

Table 10: Results on the SciERC test data.

C Error Analyses

In this section, we compare the performances of “BERT” and “SPE” on concrete examples. These examples are excerpted from the results of “BERT” and “SPE” on ACE05 test data. In the following examples, we will use notations like “[entity span]$^{\texttt{ENT-TYPE}}_{\texttt{[REL-TYPE\_REL-ID]}}$”. It means that an entity mention (“entity span”) has an entity type `ENT-TYPE`, and (optionally) participates in one or more relations, which can be identified with `REL-TYPE` and `REL-ID`.

First, “SPE” can detect more entities participating in relations. For S1, “SPE” identifies [aol time warner] as the entity `ORG`, while “BERT” identifies [time warner] as the entity `ORG`. Then “SPE” further identifies a `ORG-AFF` relation between [his] and [aol time warner] but “BERT” does not. This may be one of the reasons why “BERT” and “SPE” have similar entity performance while the relation performance of “SPE” is significantly superior to “BERT”.

Next, we give two examples in more complex sentences. For S2, [army] participates two relations (`PART-WHOLE-1` and `PART-WHOLE-2`), “BERT” identifies an wrong relation `ORG-AFF-1` while the results of “SPE” are correct. For S3, the distance between [ship] and [terrorists] is quite long, “SPE” correctly find the relation `ART-2` while “BERT” does not. Hence, we think that our “SPE” can handle more complex situations such as relation overlapping and distant entities.

D Pseudocode (PyTorch-like)

Figure 6 shows the PyTorch-like pseudocode of our span pair contrastive learning.

Two are Better than One:
Joint Entity and Relation Extraction with Table-Sequence Encoders

Abstract

Named entity recognition and relation extraction are two important fundamental problems. Joint learning algorithms have been proposed to solve both tasks simultaneously, and many of them cast the joint task as a table-filling problem. However, they typically focused on learning a single encoder (usually learning representation in the form of a table) to capture information required for both tasks within the same space. We argue that it can be beneficial to design two distinct encoders to capture such two different types of information in the learning process. In this work, we propose the novel *table-sequence encoders* where two different encoders – a table encoder and a sequence encoder are designed to help each other in the representation learning process. Our experiments confirm the advantages of having *two* encoders over *one* encoder. On several standard datasets, our model shows significant improvements over existing approaches.[1]

1 Introduction

Named Entity Recognition (NER, Florian et al. 2006, 2010) and Relation Extraction (RE, Zhao and Grishman 2005; Jiang and Zhai 2007; Sun et al. 2011; Plank and Moschitti 2013) are two fundamental tasks in Information Extraction (IE). Both tasks aim to extract structured information from unstructured texts. One typical approach is to first identify entity mentions, and next perform classification between every two mentions to extract relations, forming a pipeline (Zelenko et al., 2002; Chan and Roth, 2011). An alternative and more recent approach is to perform these two tasks jointly (Li and Ji, 2014; Miwa and Sasaki, 2014; Miwa and Bansal, 2016), which mitigates the error propagation issue associated with the pipeline approach and leverages the interaction between tasks, resulting in improved performance.

Figure 1: An example of table filling for NER and RE.

Among several joint approaches, one popular idea is to cast NER and RE as a table filling problem (Miwa and Sasaki, 2014; Gupta et al., 2016; Zhang et al., 2017). Typically, a two-dimensional (2D) table is formed where each entry captures the interaction between two individual words within a sentence. NER is then regarded as a sequence labeling problem where tags are assigned along the diagonal entries of the table. RE is regarded as the problem of labeling other entries within the table. Such an approach allows NER and RE to be performed using a single model, enabling the potentially useful interaction between these two tasks. One example[2] is illustrated in Figure 1.

Unfortunately, there are limitations with the existing joint methods. First, these methods typically suffer from *feature confusion* as they use a single representation for the two tasks – NER and RE. As a result, features extracted for one task may

---

[1] Our code is available at `https://github.com/LorrinWWW/two-are-better-than-one`.

[2] The exact settings for table filling may be different for different papers. Here we fill the entire table (rather than the lower half of the table), and assign relation tags to cells involving two complete entity spans (rather than part of such spans). We also preserve the direction of the relations.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1706–1721,
November 16–20, 2020.

coincide or conflict with those for the other, thus confusing the learning model. Second, these methods *underutilize* the table structure as they usually convert it to a sequence and then use a sequence labeling approach to fill the table. However, crucial structural information (e.g., the 4 entries at the bottom-left corner of Figure 1 share the same label) in the 2D table might be lost during such conversions.

In this paper, we present a novel approach to address the above limitations. Instead of predicting entities and relations with a single representation, we focus on learning two types of representations, namely *sequence representations* and *table representations*, for NER and RE respectively. On one hand, the two separate representations can be used to capture task-specific information. On the other hand, we design a mechanism to allow them to interact with each other, in order to take advantage of the inherent association underlying the NER and RE tasks. In addition, we employ neural network architectures that can better capture the structural information within the 2D table representation. As we will see, such structural information (in particular the context of neighboring entries in the table) is essential in achieving better performance.

The recent prevalence of BERT (Devlin et al., 2019) has led to great performance gains on various NLP tasks. However, we believe that the previous use of BERT, i.e., employing the contextualized word embeddings, does not fully exploit its potential. One important observation here is that the pairwise self-attention weights maintained by BERT carry knowledge of *word-word interactions*. Our model can effectively use such knowledge, which helps to better learn table representations. To the best of our knowledge, this is the first work to use the attention weights of BERT for learning table representations.

We summarize our contributions as follows:

- We propose to learn two separate encoders – a table encoder and a sequence encoder. They interact with each other, and can capture task-specific information for the NER and RE tasks;
- We propose to use multidimensional recurrent neural networks to better exploit the structural information of the table representation;
- We effectively leverage the word-word interaction information carried in the attention weights from BERT, which further improves the performance.

Our proposed method achieves the state-of-the-art performance on four datasets, namely ACE04, ACE05, CoNLL04, and ADE. We also conduct further experiments to confirm the effectiveness of our proposed approach.

2 Related Work

NER and RE can be tackled by using separate models. By assuming gold entity mentions are given as inputs, RE can be regarded as a classification task. Such models include kernel methods (Zelenko et al., 2002), RNNs (Zhang and Wang, 2015), recursive neural networks (Socher et al., 2012), CNNs (Zeng et al., 2014), and Transformer models (Verga et al., 2018; Wang et al., 2019). Another branch is to detect cross-sentence level relations (Peng et al., 2017; Gupta et al., 2019), and even document-level relations (Yao et al., 2019; Nan et al., 2020). However, entities are usually not directly available in practice, so these approaches may require an additional entity recognizer to form a pipeline.

Joint learning has been shown effective since it can alleviate the error propagation issue and benefit from exploiting the interrelation between NER and RE. Many studies address the joint problem through a cascade approach, i.e., performing NER first followed by RE. Miwa and Bansal (2016) use bi-LSTM (Graves et al., 2013) and tree-LSTM (Tai et al., 2015) for the joint task. Bekoulis et al. (2018a,b) formulate it as a head selection problem. Nguyen and Verspoor (2019) apply biaffine attention (Dozat and Manning, 2017) for RE. Luan et al. (2019), Dixit and Al (2019), and Wadden et al. (2019) use span representations to predict relations.

Miwa and Sasaki (2014) tackle joint NER and RE as from a table filling perspective, where the entry at row i and column j of the table corresponds to the pair of i-th and j-th word of the input sentence. The diagonal of the table is filled with the entity tags and the rest with the relation tags indicating possible relations between word pairs. Similarly, Gupta et al. (2016) employ a bi-RNN structure to label each word pair. Zhang et al. (2017) propose a global optimization method to fill the table. Tran and Kavuluru (2019) investigate CNNs on this task.

Recent work (Luan et al., 2019; Dixit and Al, 2019; Wadden et al., 2019; Li et al., 2019; Eberts and Ulges, 2019) usually leverages pre-trained language models such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), RoBERTa (Liu et al.,

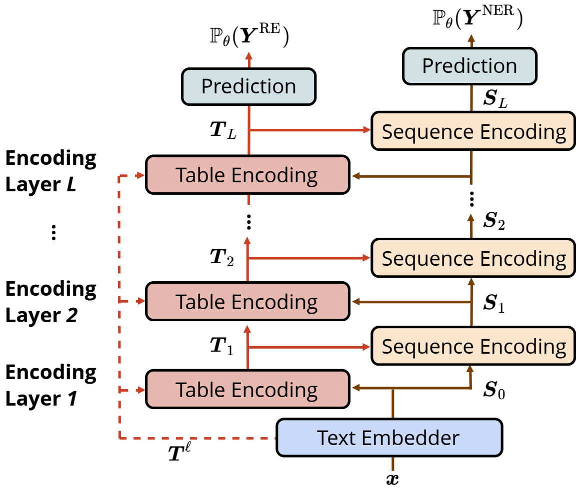

Figure 2: Overview of the table-sequence encoders. Dashed lines are for optional components ($\boldsymbol{T}^\ell$).

2019), and ALBERT (Lan et al., 2019). However, none of them use pre-trained attention weights, which convey rich relational information between words. We believe it can be useful for learning better table representations for RE.

3 Problem Formulation

In this section, we formally formulate the NER and RE tasks. We regard NER as a sequence labeling problem, where the gold entity tags $\boldsymbol{y}^{\text{NER}}$ are in the standard BIO (Begin, Inside, Outside) scheme (Sang and Veenstra, 1999; Ratinov and Roth, 2009). For the RE task, we mainly follow the work of Miwa and Sasaki (2014) to formulate it as a table filling problem. Formally, given an input sentence $\boldsymbol{x} = [x_i]_{1 \le i \le N}$, we maintain a tag table $\boldsymbol{y}^{\text{RE}} = [y^{\text{RE}}_{i,j}]_{1 \le i,j \le N}$. Suppose there is a relation with type r pointing from mention $x_{i^b}, .., x_{i^e}$ to mention $x_{j^b}, .., x_{j^e}$, we have $y^{\text{RE}}_{i,j} = \overrightarrow{r}$ and $y^{\text{RE}}_{j,i} = \overleftarrow{r}$ for all $i \in [i^b, i^e] \wedge j \in [j^b, j^e]$. We use $\perp$ for word pairs with no relation. An example was given earlier in Figure 1.

4 Model

We describe the model in this section. The model consists of two types of interconnected encoders, a table encoder for table representation and a sequence encoder for sequence representation, as shown in Figure 2. Collectively, we call them *table-sequence encoders*. Figure 3 presents the details of each layer of the two encoders, and how they interact with each other. In each layer, the table encoder uses the sequence representation to construct the table representation; and then the sequence encoder uses the table representation to contextualize the sequence representation. With multiple layers, we incrementally improve the quality of both representations.

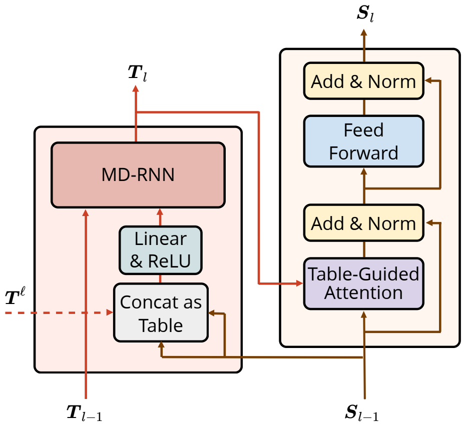

Figure 3: A layer in the table-sequence encoders.

4.1 Text Embedder

For a sentence containing N words $\boldsymbol{x} = [x_i]_{1 \le i \le N}$, we define the word embeddings $\boldsymbol{x}^w \in \mathbb{R}^{N \times d_1}$, as well as character embeddings $\boldsymbol{x}^c \in \mathbb{R}^{N \times d_2}$ computed by an LSTM (Lample et al., 2016). We also consider the contextualized word embeddings $\boldsymbol{x}^\ell \in \mathbb{R}^{N \times d_3}$, which can be produced from language models such as BERT.

We concatenate those embeddings for each word and use a linear projection to form the initial sequence representation $\boldsymbol{S}_0 \in \mathbb{R}^{N \times H}$:

$$\boldsymbol{S}_0 = \text{Linear}([\boldsymbol{x}^c; \boldsymbol{x}^w; \boldsymbol{x}^\ell]) \tag{1}$$

where each word is represented as an H dimensional vector.

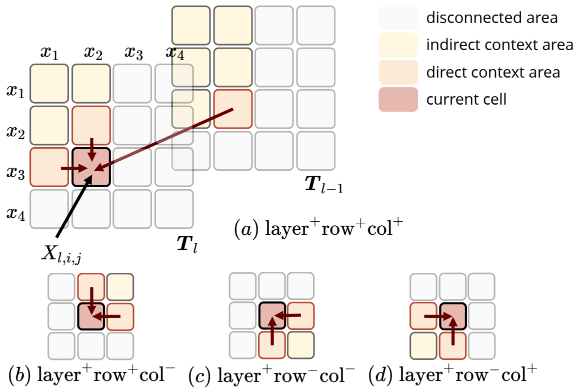
4.2 Table Encoder

The table encoder, shown in the left part of Figure 3, is a neural network used to learn a table representation, an $N \times N$ table of vectors, where the vector at row i and column j corresponds to the i-th and j-th word of the input sentence.

We first construct a non-contextualized table by concatenating every two vectors of the sequence representation followed by a fully-connected layer to halve the hidden size. Formally, for the l-th layer, we have $\boldsymbol{X}_l \in \mathbb{R}^{N \times N \times H}$, where:

$$X_{l,i,j} = \text{ReLU}(\text{Linear}([S_{l-1,i}; S_{l-1,j}])) \tag{2}$$

Next, we use the Multi-Dimensional Recurrent Neural Networks (MD-RNN, Graves et al. 2007)



(a) layer$^+$row$^+$col$^+$

(b) layer$^+$row$^+$col$^-$ (c) layer$^+$row$^-$col$^-$ (d) layer$^+$row$^-$col$^+$

Figure 4: How the hidden states are computed in MD-RNN with 4 directions. We use D^+ or D^- to indicate the direction that the hidden states flow between cells at the D dimension (where D can be *layer*, *row* or *col*). For brevity, we omit the input and the *layer* dimension for cases (b), (c) and (d), as they are the same as (a).

with Gated Recurrent Unit (GRU, Cho et al. 2014) to contextualize $\boldsymbol{X}_l$. We iteratively compute the hidden states of each cell to form the contextualized table representation $\boldsymbol{T}_l$, where:

$$T_{l,i,j} = \mathrm{GRU}(X_{l,i,j}, T_{l-1,i,j}, T_{l,i-1,j}, T_{l,i,j-1}) \quad (3)$$

We provide the multi-dimensional adaptations of GRU in Appendix A to avoid excessive formulas here.

Generally, it exploits the context along *layer*, *row*, and *column* dimensions. That is, it does not consider only the cells at neighbouring rows and columns, but also those of the previous layer.

The time complexity of the naive implementation (i.e., two for-loops) for each layer is $O(N \times N)$ for a sentence with length N. However, antidiagonal entries[3] can be calculated at the same time as they do not depend on each other. Therefore, we can optimize it through parallelization and reduce the effective time complexity to $O(N)$.

The above illustration describes a unidirectional RNN, corresponding to Figure 4(a). Intuitively, we would prefer the network to have access to the surrounding context in all directions. However, this could not be done by one single RNN. For the case of 1D sequence modeling, this problem is resolved by introducing bidirectional RNNs. Graves et al. (2007) discussed quaddirectional RNNs to access the context from four directions for modeling 2D data. Therefore, similar to 2D-RNN, we also need to consider RNNs in four directions[4]. We visualize them in Figure 4.

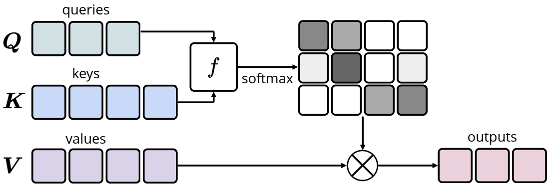


Figure 5: The generalized form of attention. The softmax function is used to normalize the weights of values $\boldsymbol{V}$ for each query Q_i.

Empirically, we found the setting only considering cases (a) and (c) in Figure 4 achieves no worse performance than considering four cases altogether. Therefore, to reduce the amount of computation, we use such a setting as default. The final table representation is then the concatenation of the hidden states of the two RNNs:

$$T^{(a)}_{l,i,j} = \mathrm{GRU}^{(a)}(X_{l,i,j}, T^{(a)}_{l-1,i,j}, T^{(a)}_{l,i-1,j}, T^{(a)}_{l,i,j-1}) \quad (4)$$

$$T^{(c)}_{l,i,j} = \mathrm{GRU}^{(c)}(X_{l,i,j}, T^{(c)}_{l-1,i,j}, T^{(c)}_{l,i+1,j}, T^{(c)}_{l,i,j+1}) \quad (5)$$

$$T_{l,i,j} = [T^{(a)}_{l,i,j}; T^{(c)}_{l,i,j}] \quad (6)$$

4.3 Sequence Encoder

The sequence encoder is used to learn the sequence representation – a sequence of vectors, where the i-th vector corresponds to the i-th word of the input sentence. The architecture is similar to Transformer (Vaswani et al., 2017), shown in the right portion of Figure 3. However, we replace the scaled dot-product attention with our proposed *table-guided attention*. Here, we mainly illustrate why and how the table representation can be used to compute attention weights.

First of all, given $\boldsymbol{Q}$ (queries), $\boldsymbol{K}$ (keys) and $\boldsymbol{V}$ (values), a generalized form of attention is defined in Figure 5. For each query, the output is a weighted sum of the values, where the weight assigned to each value is determined by the relevance (given by score function f) of the query with all the keys.

For each query Q_i and key K_j, Bahdanau et al. (2015) define f in the form of:

$$f(Q_i, K_j) = U \cdot g(Q_i, K_j) \quad (7)$$

where U is a learnable vector and g is the function to map each query-key pair to a vector. Specifically,

---

[3] We define antidiagonal entries to be entries at position (i, j) such that $i+j = N+1+\Delta$, where $\Delta \in [-N+1, N-1]$ is the offset to the main antidiagonal entries.

[4] In our scenario, there is an additional layer dimension. However, as the model always traverses from the first layer to the last layer, only one direction shall be considered for the layer dimension.

they define $g(Q_i, K_j) = \tanh(Q_i W_0 + K_j W_1)$, where W_0, W_1 are learnable parameters.

Our attention mechanism is essentially a self-attention mechanism, where the queries, keys and values are exactly the same. In our case, they are essentially sequence representation S_{l-1} of the previous layer (i.e., $\boldsymbol{Q} = \boldsymbol{K} = \boldsymbol{V} = \boldsymbol{S}_{l-1}$). The attention weights (i.e., the output from the function f in Figure 5) are essentially constructed from both queries and keys (which are the same in our case). On the other hand, we also notice the table representation $\boldsymbol{T}_l$ is also constructed from $\boldsymbol{S}_{l-1}$. So we can consider $\boldsymbol{T}_l$ to be a function of queries and keys, such that $T_{l,i,j} = g(S_{l-1,i}, S_{l-1,j}) = g(Q_i, K_j)$. Then we put back this g function to Equation 7, and get the proposed table-guided attention, whose score function is:

$$f(Q_i, K_j) = U \cdot T_{l,i,j} \tag{8}$$

We show the advantages of using this table-guided attention: (1) we do not have to calculate g function since $\boldsymbol{T}_l$ is already obtained from the table encoder; (2) $\boldsymbol{T}_l$ is contextualized along the *row*, *column*, and *layer* dimensions, which corresponds to queries, keys, and queries and keys in the previous layer, respectively. Such contextual information allows the network to better capture more difficult word-word dependencies; (3) it allows the table encoder to participate in the sequence representation learning process, thereby forming the bidirectional interaction between the two encoders.

The table-guided attention can be extended to have multiple heads (Vaswani et al., 2017), where each head is an attention with independent parameters. We concatenate their outputs and use a fully-connected layer to get the final attention outputs.

The remaining parts are similar to Transformer. For layer l, we use position-wise feedforward neural networks (FFNN) after self-attention, and wrap attention and FFNN with a residual connection (He et al., 2016) and layer normalization (Ba et al. 2016), to get the output sequence representation:

$$\tilde{\boldsymbol{S}}_l = \text{LayerNorm}(\boldsymbol{S}_{l-1} + \text{SelfAttn}(\boldsymbol{S}_{l-1})) \tag{9}$$

$$\boldsymbol{S}_l = \text{LayerNorm}(\tilde{\boldsymbol{S}}_l + \text{FFNN}(\tilde{\boldsymbol{S}}_l)) \tag{10}$$

4.4 Exploit Pre-trained Attention Weights

In this section, we describe the dashed lines in Figures 2 and 3, which we ignored in the previous discussions. Essentially, they exploit information in the form of attention weights from a pre-trained language model such as BERT.

We stack the attention weights of all heads and all layers to form $\boldsymbol{T}^\ell \in \mathbb{R}^{N \times N \times (L^\ell \times A^\ell)}$, where L^ℓ is the number of stacked Transformer layers, and A^ℓ is the number of heads in each layer. We leverage $\boldsymbol{T}^\ell$ to form the inputs of MD-RNNs in the table encoder. Equation 2 is now replaced with:

$$X_{l,i,j} = \text{ReLU}(\text{Linear}([S_{l-1,i}; S_{l-1,j}; T^\ell_{i,j}])) \tag{11}$$

We keep the rest unchanged. We believe this simple yet novel use of the attention weights allows us to effectively incorporate the useful word-word interaction information captured by pre-trained models such as BERT into our table-sequence encoders for improved performance.

5 Training and Evaluation

We use $\boldsymbol{S}_L$ and $\boldsymbol{T}_L$ to predict the probability distribution of the entity and relation tags:

$$P_\theta(\boldsymbol{Y}^{\text{NER}}) = \text{softmax}(\text{Linear}(\boldsymbol{S}_L)) \tag{12}$$

$$P_\theta(\boldsymbol{Y}^{\text{RE}}) = \text{softmax}(\text{Linear}(\boldsymbol{T}_L)) \tag{13}$$

where $\boldsymbol{Y}^{\text{NER}}$ and $\boldsymbol{Y}^{\text{RE}}$ are random variables of the predicted tags, and P_θ is the estimated probability function with θ being our model parameters.

For training, both NER and RE adopt the prevalent cross-entropy loss. Given the input text $\boldsymbol{x}$ and its gold tag sequence $\boldsymbol{y}^{\text{NER}}$ and tag table $\boldsymbol{y}^{\text{RE}}$, we then calculate the following two losses:

$$\mathcal{L}^{\text{NER}} = \sum_{i \in [1,N]} -\log P_\theta(Y_i^{\text{NER}} = y_i^{\text{NER}}) \tag{14}$$

$$\mathcal{L}^{\text{RE}} = \sum_{i,j \in [1,N]; i \neq j} -\log P_\theta(Y_{i,j}^{\text{RE}} = y_{i,j}^{\text{RE}}) \tag{15}$$

The goal is to minimize both losses $\mathcal{L}^{\text{NER}} + \mathcal{L}^{\text{RE}}$.

During evaluation, the prediction of relations relies on the prediction of entities, so we first predict the entities, and then look up the relation probability table $P_\theta(\boldsymbol{Y}^{\text{RE}})$ to see if there exists a valid relation between predicted entities.

Specifically, we predict the entity tag of each word by choosing the class with the highest probability:

$$\underset{e}{\text{argmax}}\, P_\theta(Y_i^{\text{NER}} = e) \tag{16}$$

The whole tag sequence can be transformed into entities with their boundaries and types.

Relations on entities are mapped to relation classes with highest probabilities on words of the entities. We also consider the two directed tags for each relation. Therefore, for two entity spans (i^b, i^e) and (j^b, j^e), their relation is given by:

$$\operatorname*{argmax}_{\overrightarrow{r}} \sum_{i\in[i^b,i^e],j\in[j^b,j^e]} P_\theta(Y^{\mathrm{RE}}_{i,j}=\overrightarrow{r}) + P_\theta(Y^{\mathrm{RE}}_{j,i}=\overleftarrow{r}) \quad (17)$$

where the no-relation type $\perp$ has no direction, so if $\overrightarrow{r} = \perp$, we have $\overleftarrow{r} = \perp$ as well.

6 Experiments

6.1 Data

We evaluate our model on four datasets, namely ACE04 (Doddington et al., 2004), ACE05 (Walker et al., 2006), CoNLL04 (Roth and tau Yih, 2004) and ADE (Gurulingappa et al., 2012). More details could be found in Appendix B.

Following the established line of work, we use the F1 measure to evaluate the performance of NER and RE. For NER, an entity prediction is correct if and only if its type and boundaries both match with those of a gold entity.[5] For RE, a relation prediction is considered correct if its relation type and the boundaries of the two entities match with those in the gold data. We also report the strict relation F1 (denoted RE+), where a relation prediction is considered correct if its relation type as well as the boundaries and types of the two entities all match with those in the gold data. Relations are asymmetric, so the order of the two entities in a relation matters.

6.2 Model Setup

We tune hyperparameters based on results on the development set of ACE05 and use the same setting for other datasets. GloVe vectors (Pennington et al., 2014) are used to initialize word embeddings. We also use the BERT variant – ALBERT as the default pre-trained language model. Both pre-trained word embeddings and language model are fixed without fine-tuning. In addition, we stack three encoding layers ($L = 3$) with independent parameters including the GRU cell in each layer. For the table encoder, we use two separate MD-RNNs with the directions of "layer$^+$row$^+$col$^+$" and "layer$^+$row$^-$col$^-$" respectively. For the sequence encoder, we use eight attention heads to attend to different representation subspaces. We report the averaged F1 scores of 5 runs for our models. For each run, we keep the model that achieves the highest averaged entity F1 and relation F1 on the development set, and evaluate and report its score on the test set. Other hyperparameters could be found in Appendix C.

Table 1: Main results. ▽: micro-averaged F1; ▲: macro-averaged F1.

6.3 Comparison with Other Models

Table 1 presents the comparison of our model with previous methods on four datasets. Our NER performance is increased by 1.2, 0.9, 1.2/0.6 and 0.4 absolute F1 points over the previous best results. Besides, we observe even stronger performance gains in the RE task, which are 3.6, 4.2, 2.1/2.5 (RE+) and 0.9 (RE+) absolute F1 points, respectively. This indicates the effectiveness of our model

---

[5] Follow Li and Ji (2014); Miwa and Bansal (2016), we use head spans for entities in ACE. And we keep the full mention boundary for other corpora.

LM	$+\boldsymbol{x}^\ell$		$+\boldsymbol{x}^\ell$ $+\boldsymbol{T}^\ell$	
	NER	RE	NER	RE
ELMo	86.4	64.3	-	-
BERT	87.8	64.8	88.2	67.4
RoBERTa	88.9	66.2	89.3	67.6
ALBERT	89.4	66.0	89.5	67.6

Table 2: Using different pre-trained language models on ACE05. $+\boldsymbol{x}^\ell$ uses the contextualized word embeddings; $+\boldsymbol{T}^\ell$ uses the attention weights.

Setting	NER	RE	RE (gold)
Default	89.5	67.6	70.4
w/o Relation Loss	89.4	-	-
w/o Table Encoder	88.4	-	-
w/o Entity Loss	-	-	69.8
w/o Sequence Encoder	-	-	69.2
w/o Bi-Interaction	88.2	66.3	69.2
NER on diagonal	89.4	67.1	70.2
w/o Sequence Encoder	88.6	67.0	70.2

Table 3: Ablation of the two encoders on ACE05. Gold entity spans are given in RE (gold).

for jointly extracting entities and their relations. Since our reported numbers are the average of 5 runs, we can consider our model to be achieving new state-of-the-art results.

6.4 Comparison of Pre-trained Models

In this section, we evaluate our method with different pre-trained language models, including ELMo, BERT, RoBERTa and ALBERT, with and without attention weights, to see their individual contribution to the final performance.

Table 2 shows that, even using the relatively earlier contextualized embeddings without attention weights (ELMo $+\boldsymbol{x}^\ell$), our system is still comparable to the state-of-the-art approach (Wadden et al., 2019), which was based on BERT and achieved F1 scores of 88.6 and 63.4 for NER and RE respectively. It is important to note that the model of Wadden et al. (2019) was trained on the additional coreference annotations from OntoNotes (Weischedel et al., 2011) before fine-tuning on ACE05. Nevertheless, our system still achieves comparable results, showing the effectiveness of the table-sequence encoding architecture.

The overall results reported in Table 2 confirm the importance of leveraging the attention weights, which bring improvements for both NER and RE tasks. This allows the system using vanilla BERT to obtain results no worse than RoBERTa and ALBERT in relation extraction.

6.5 Ablation Study

We design several additional experiments to understand the effectiveness of components in our system. The experiments are conducted on ACE05.

We also compare different table filling settings, which are included in Appendix E.

6.5.1 Bidirectional Interaction

We first focus on the understanding of the necessity of modeling the bidirectional interaction between the two encoders. Results are presented in Table 3. "RE (gold)" is presented so as to compare with settings that do not predict entities, where the gold entity spans are used in the evaluation.

We first try optimizing the NER and RE objectives separately, corresponding to "w/o Relation Loss" and "w/o Entity Loss". Compared with learning with a joint objective, the results of these two settings are slightly worse, which indicates that learning better representations for one task not only is helpful for the corresponding task, but also can be beneficial for the other task.

Next, we investigate the individual sequence and table encoder, corresponding to "w/o Table Encoder" and "w/o Sequence Encoder". We also try jointly training the two encoders but cut off the interaction between them, which is "w/o Bi-Interaction". Since no interaction is allowed in the above three settings, the table-guided attention is changed to conventional multi-head scaled dot-product attention, and the table encoding layer always uses the initial sequence representation $\boldsymbol{S}_0$ to enrich the table representation. The results of these settings are all significantly worse than the default one, which indicates the importance of the bidirectional interaction between sequence and table representation in our table-sequence encoders.

We also experiment the use of the main diagonal entries of the table representation to tag entities, with results reported under "NER on diagonal". This setup attempts to address NER and RE in the same encoding space, in line with the original intention of Miwa and Sasaki (2014). By exploiting the interrelation between NER and RE, it achieves better performance compared with models without such information. However, it is worse than our default setting. We ascribe this to the potential incompatibility of the desired encoding space of entities and relations. Finally, although it does not

# Layers	Shared			Non-shared		
	# params	NER	RE	# params	NER	RE
$L = 1$	2.2M	89.2	66.0	1.9M	89.2	66.0
$L = 2$	2.2M	89.5	67.0	3.2M	89.5	67.1
$L = 3$	2.2M	89.3	67.3	4.5M	89.5	67.6
$L = 4$	2.2M	89.7	67.6	5.7M	89.6	67.7
$L = 5$	2.2M	89.6	67.6	7.0M	89.6	67.7

Table 4: The performance on ACE05 with different number of layers. Pre-trained word embeddings and language models are not counted to the number of parameters. The underlined ones are from our default setting.

Setting	NER	RE
Unidirectional	89.6	66.9
Bidirectional	89.5	67.6
Quaddirectional	89.7	67.6
Layer-wise only	89.3	63.9
Bidirectional w/o column	89.5	67.2
Bidirectional w/o row	89.3	67.4
Bidirectional w/o layer	89.3	66.7

Table 5: The effect of the dimensions and directions of MD-RNNs. Experiments are conducted on ACE05. The underlined ones are from our default setting.

directly use the sequence representation, removing the sequence encoder will lead to performance drop for NER, which indicates the sequence encoder can help improve the table encoder by better capturing the structured information within the sequence.

6.5.2 Encoding Layers

Table 4 shows the effect of the number of encoding layers, which is also the number of bidirectional interactions involved. We conduct one set of experiments with shared parameters for the encoding layers and another set with independent parameters. In general, the performance increases when we gradually enlarge the number of layers L. Specifically, since the shared model does not introduce more parameters when tuning L, we consider that our model benefits from the mutual interaction inside table-sequence encoders. Typically, under the same value L, the non-shared model employs more parameters than the shared one to enhance its modeling capability, leading to better performance. However, when $L > 3$, there is no significant improvement by using non-shared model. We believe that increasing the number of layers may bring the risk of over-fitting, which limits the performance of the network. We choose to adopt the non-shared model with $L = 3$ as our default setting.

6.5.3 Settings of MD-RNN

Table 5 presents the comparisons of using different dimensions and directions to learn the table representation, based on MD-RNN. Among those settings, "Unidirectional" refers to an MD-RNN with direction "layer$^+$row$^+$col$^+$"; "Bidirectional" uses two MD-RNNs with directions "layer$^+$row$^+$col$^+$" and "layer$^+$row$^-$col$^-$" respectively; "Quaddirectional" uses MD-RNNs in four directions, illustrated in Figure 4. Their results are improved when adding more directions, showing richer contextual information is beneficial. Since the bidirectional model is almost as good as the quaddirectional one, we leave the former as the default setting.

In addition, we are also curious about the contribution of *layer*, *row*, and *column* dimensions for MD-RNNs. We separately removed the *layer*, *row*, and *column* dimension. As we can see, the results are all lower than the original model without removal of any dimension. "Layer-wise only" removed *row* and *col* dimensions, and is worse than others as it does not exploit the sentential context.

More experiments with more settings are presented in Appendix D. Specifically, all unidirectional RNNs are consistently worse than others, while bidirectional RNNs are usually on-par with quaddirectional RNNs. Besides, we also tried to use CNNs to implement the table encoder. However, since it is usually difficult for CNNs to learn long-range dependencies, we found the performance was worse than the RNN-based models.

6.6 Attention Visualization

We visualize the table-guided attention with bertviz (Vig, 2019)[6] for a better understanding of how the network works. We compare it with pre-trained Transformers (ALBERT) and human-defined ground truth, as presented in Figure 6.

Our discovery is similar to Clark et al. (2019). Most attention heads in the table-guided attention and ALBERT show simple patterns. As shown in the left part of Figure 6, these patterns include attending to the word itself, the next word, the last word, and the punctuation.

The right part of Figure 6 also shows task-related patterns, i.e., entities and relations. For a relation, we connect words from the head entity to the tail entity; For an entity, we connect every two words inside this entity mention. We can find that our pro-

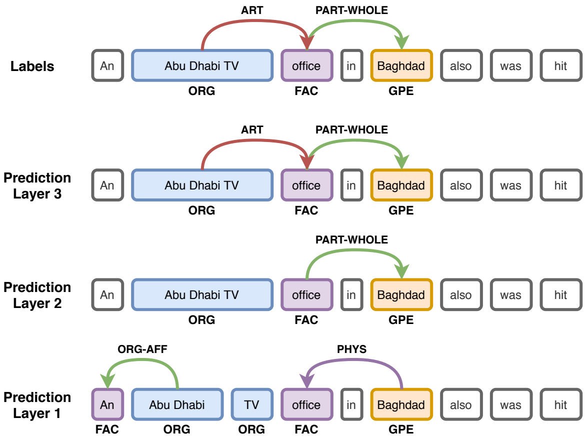

Figure 7: Probing intermediate states

posed table-guided attention has learned more task-related knowledge compared to ALBERT. In fact, not only does it capture the entities and their relations that ALBERT failed to capture, but it also has higher confidence. This indicates that our model has a stronger ability to capture complex patterns other than simple ones.

6.7 Probing Intermediate States

Figure 7 presents an example picked from the development set of ACE05. The prediction layer after training (a linear layer) is used as a probe to display the intermediate state of the model, so we can interpret how the model improves both representations from stacking multiple layers and thus from the bidirectional interaction. Such probing is valid since we use skip connection between two adjacent encoding layers, so the encoding spaces of the outputs of different encoding layers are consistent and therefore compatible with the prediction layer.

In Figure 7, the model made many wrong predictions in the first layer, which were gradually corrected in the next layers. Therefore, we can see that more layers allow more interaction and thus make the model better at capturing entities or relations, especially difficult ones. More cases are presented in Appendix F.

7 Conclusion

In this paper, we introduce the novel *table-sequence encoders* architecture for joint extraction of entities and their relations. It learns two separate encoders rather than one – a sequence encoder and a table encoder where explicit interactions exist between the two encoders. We also introduce a new method to effectively employ useful information captured by the pre-trained language models for such a joint learning task where a table representation is involved. We achieved state-of-the-art F1 scores for both NER and RE tasks across four standard datasets, which confirm the effectiveness of our approach. In the future, we would like to investigate how the table representation may be applied to other tasks. Another direction is to generalize the way in which the table and sequence interact to other types of representations.

A MD-RNN

In this section we present the detailed implementation of MD-RNN with GRU.

Formally, at the time-step layer l, row i, and column j, with the input $X_{l,i,j}$, the cell at layer l, row i and column j calculates the gates as follows:

$$T^{prev}_{l,i,j} = [T_{l-1,i,j}; T_{l,i-1,j}; T_{l,i,j-1}], \in \mathbb{R}^{3H} \tag{18}$$

$$r_{l,i,j} = \sigma([X_{l,i,j}; T^{prev}_{l,i,j}]W^r + b^r)), \in \mathbb{R}^{H} \tag{19}$$

$$z_{l,i,j} = \sigma([X_{l,i,j}; T^{prev}_{l,i,j}]W^z + b^z)), \in \mathbb{R}^{H} \tag{20}$$

$$\tilde{\lambda}_{l,i,j,m} = [X_{l,i,j}; T^{prev}_{l,i,j}]W^{\lambda}_m + b^{\lambda}_m, \in \mathbb{R}^{H} \tag{21}$$

$$\begin{aligned} &\lambda_{l,i,j,0}, \lambda_{l,i,j,1}, \lambda_{l,i,j,2} = \\ &\qquad \mathrm{softmax}(\tilde{\lambda}_{l,i,j,0}, \tilde{\lambda}_{l,i,j,1}, \tilde{\lambda}_{l,i,j,2}) \end{aligned} \tag{22}$$

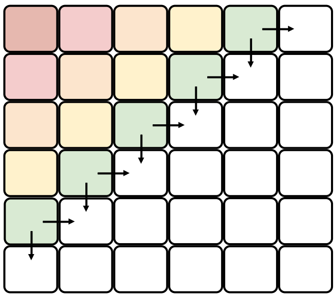

Figure 8: For 2D-RNNs, cells in the same color can be computed in parallel.

And then calculate the hidden states:

$$\begin{aligned} \tilde{T}_{l,i,j} &= \tanh(X_{l,i,j}W^x \\ &\quad + r_{l,i,j} \odot (T^{prev}_{l,i,j}W^p) + b^h), \in \mathbb{R}^H \end{aligned} \tag{23}$$

$$\begin{aligned} \tilde{T}^{prev}_{l,i,j} &= \lambda_{l,i,j,0} \odot T_{l-1,i,j} \\ &\quad + \lambda_{l,i,j,1} \odot T_{l,i-1,j} \\ &\quad + \lambda_{l,i,j,2} \odot T_{l,i,j-1}, \in \mathbb{R}^H \end{aligned} \tag{24}$$

$$\begin{aligned} T_{l,i,j} &= z_{l,i,j} \odot \tilde{T}_{l,i,j} \\ &\quad + (1 - z_{l,i,j}) \odot \tilde{T}^{prev}_{l,i,j}, \in \mathbb{R}^H \end{aligned} \tag{25}$$

where W and b are trainable parameters and please note that they share parameters in different rows and columns but not necessarily in different layers. Besides, $\odot$ is the element-wise product, and σ is the sigmoid function.

As in GRU, r is the *reset* gate controlling whether to forget previous hidden states, and z is the *update* gate, selecting whether the hidden states are to be updated with new hidden states. In addition, we employ a *lambda* gate λ, which is used to weight the predecessor cells before passing them through the *update* gate.

There are two slightly different ways to compute the candidate activation $\tilde{T}_{l,i,j}$, namely

$$\begin{aligned} \tilde{T}_{l,i,j} &= \tanh(X_{l,i,j}W^x \\ &\quad + r_{l,i,j} \odot (T^{prev}_{l,i,j}W^p) + b^h_l) \end{aligned} \tag{26}$$

and

$$\begin{aligned} \tilde{T}_{l,i,j} &= \tanh(W^x_l X_{l,i,j} \\ &\quad + (r_{l,i,j} \odot T^{prev}_{l,i,j})W^p + b^h_l) \end{aligned} \tag{27}$$

And we found in our preliminary experiments that both of them performed as well as each other, and we choose the former, which saves some computation.

The time complexity of the naive implementation (i.e., two for-loops in each layer) is $O(L \times N \times$

	# sentences	# entities (types)	# relations (types)

Table 6: Dataset statistics

N) for a sentence with length N and the number of encoding layer L. However, antidiagonal entries can be calculated at the same time because their values do not depend on each other, shown in the same color in Figure 8. Therefore, we can optimize it through parallelization and reduce the effective time complexity to $O(L \times N)$.

B Data

Table 6 shows the dataset statistics after pre-processing. We keep the same pre-processing and evaluation standards used by most previous works.

The ACE04 and ACE05 corpora are collected from a variety of domains, such as newswire and online forums. We use the same entity and relation types, data splits, and pre-processing as Li and Ji (2014) and Miwa and Bansal (2016)[7]. Specifically, they use head spans for entities but not use the full mention boundary.

The CoNLL04 dataset provides entity and relation labels. We use the same train-test split as Gupta et al. (2016)[8], and we use the same 20% train set as development set as Eberts and Ulges (2019)[9]. Both micro and macro average F1 are used in previous work, so we will specify this while comparing with other systems.

The ADE dataset is constructed from medical reports that describe the adverse effects arising from drug use. It contains a single relation type "Adverse-Effect" and the two entity types "Adverse-Effect" and "Drug". Similar to previous work, we filter out instances containing overlapping entities, only accounting for 2.8% of total.

Following prior work, we perform 5-fold cross-validation for ACE04 and 10-fold for ADE. Besides, we use 15% of the training set as the development set. We report the average score of 5 runs for every dataset. For each run, we use the model that achieves the best performance (averaged entity metric score and relation metric score) on the development set, and evaluate and report its score on the test set.

Setting	Value

char emb dim	30
gradient clipping	5.0

Table 7: Hyperparameters used in our experiments.

C Hyperparameters and Pre-trained Language Models

The detailed hyperparameters are present in Table 7. For the word embeddings, we use 100-dimensional GloVe word embeddings trained on 6B tokens[10] as initialization. We disable updating the word embeddings during training. We set the hidden size to 200, and since we use bidirectional MD-RNNs, the hidden size for each MD-RNN is 100. We use inverse time learning rate decay: $\hat{lr} = lr/(1 + \text{decay\_rate} \times \text{steps}/\text{decay\_steps})$, with decay rate 0.05 and decay steps 1000.

Besides, the tested pre-trained language models are shown as follows:

- **[ELMo]** (Peters et al., 2018): Character-based pre-trained language model. We use the `large` checkpoint, with embeddings of dimension 3072.
- **[BERT]** (Devlin et al., 2019): Pre-trained Transformer. We use the `bert-large-uncased` checkpoint, with embeddings of dimension 1024 and attention weight feature of dimension 384 (24 layers × 16 heads).
- **[RoBERTa]** (Liu et al., 2019): Pre-trained Transformer. We use the `roberta-large` checkpoint, with embeddings of dimension

Table 8: Comparisons with different methods to learn the table representation. For MD-RNN, D^{+}, D^{-} and ~~D~~ are indicators representing the direction, in which the hidden state flows forward, backward, or unable to flow at dimension D (D could be layer, row, or col). When using multiple MD-RNNs, we separate the indicators by ";".

1024 and attention weight feature of dimension 384 (24 layers × 16 heads).

- **[ALBERT]** (Lan et al., 2019): A lite version of BERT with shared layer parameters. We use the `albert-xxlarge-v1` checkpoint, with embeddings of dimension 4096 and attention weight feature of dimension 768 (12 layers × 64 heads). **We by default use this pre-trained model.**

We use the implementation provided by Wolf et al. (2019)[11] and Akbik et al. (2019)[12] to generate contextualized embeddings and attention weights. Specifically, we generate the contextualized word embedding by averaging all sub-word embeddings in the last four layers; we generate the attention weight feature (if available) by summing all sub-word attention weights for each word, which are then concatenated for all layers and all heads. Both of them are fixed without fine-tuning.

D Ways to Leverage the Table Context

Table 8 presents the comparisons of different ways to learn the table representation.

Importance of context Setting "layer^{+}~~row~~ ~~col~~" does not exploit the table context when learning the table representation, instead, only layer-wise operations are used. As a result, it performs much worse than the ones exploiting the context, confirming the importance to leverage the context information.

Context along row and column Neighbors along both the *row* and *column* dimensions are important. setting "layer^{+}row^{+}~~col~~ ; layer^{+}row^{-}~~col~~" and "layer^{+}~~row~~ col^{+}; layer^{+}~~row~~ col^{-}" remove the *row* and *column* dimensions respectively, and their performance is though better than "layer^{+}~~row~~ ~~col~~", but worse than setting "layer^{+}row^{+}col^{+}; layer^{+}row^{-}col^{-}".

Multiple dimensions Since in setting "layer^{+}row^{+}col^{+}", the cell at row i and column j only knows the information before the i-th and j-th word, causing worse performance than bidirectional ("layer^{+}row^{+}col^{+}; layer^{+}row^{-}col^{-}" and "layer^{+}row^{+}col^{-}; layer^{+}row^{-}col^{+}") and quaddirectional ("layer^{+}row^{+}col^{+}; layer^{+}row^{-}col^{-}; layer^{+}row^{+}col^{-}; layer^{+}row^{-}col^{+}") settings. Besides, the quaddirectional model does not show superior performance than bidirectional ones, so we use the latter by default.

Layer dimension Different from the *row* and *column* dimensions, the *layer* dimension does not carry more sentential context information. Instead, it carries the information from previous layers, so the model can reason high-level relations based on low-level dependencies captured by predecessor layers, which may help recognize syntactically and semantically complex relations. Moreover, recurring along the *layer* dimension can also be viewed as a layer-wise short-cut, serving similarly to high way (Srivastava et al., 2015) and residual connection (He et al., 2016) and making it possible for the networks to be very deep. By removing it (results under "~~layer~~ row^{+}col^{+}; ~~layer~~ row^{-}col^{-}"), the performance is harmed.

Other network Our model architecture can be adapted to other table encoders. We try CNN to encode the table representation. For each layer l, given inputs $\boldsymbol{X}_l$, we have:

$$\boldsymbol{T}_l^0 = \mathrm{ReLU}(\mathrm{Linear}([\boldsymbol{X}_l; \boldsymbol{T}_{l-1}])) \quad (28)$$

$$\boldsymbol{T}_l^1 = \mathrm{ReLU}(\mathrm{LayerNorm}(\mathrm{CNN}(\boldsymbol{T}_l^0))) \quad (29)$$

$$\boldsymbol{T}_l = \mathrm{ReLU}(\boldsymbol{T}_{l-1} + \mathrm{LayerNorm}(\mathrm{CNN}(\boldsymbol{T}_l^1))) \quad (30)$$

We also try different kernel sizes for CNN. How-

ever, despite its advantages in training time, its performance is worse than the MD-RNN based ones.

E Table Filling Formulations

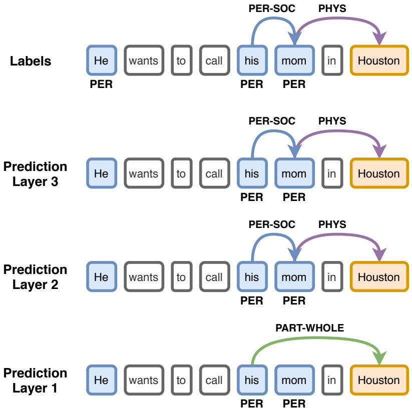
Our table filling formulation does not exactly follow Miwa and Sasaki (2014). Specifically, we fill the entire table instead of only the lower (or higger) triangular part, and we assign relation tags to cells where entity spans intersect instead of where last words intersect. To maintain the ratio of positive instances to negative instances, although the entire table can express directed relations by undirected tags, we still keep the directed relation tags. I.e, if $y^{\text{RE}}_{i,j} = \overrightarrow{r}$ then $y^{\text{RE}}_{j,i} = \overleftarrow{r}$, and vice versa. Table 9 ablates our formulation (last row), and compares it with the original one (Miwa and Sasaki, 2014) (first row).

F Probing Intermediate States

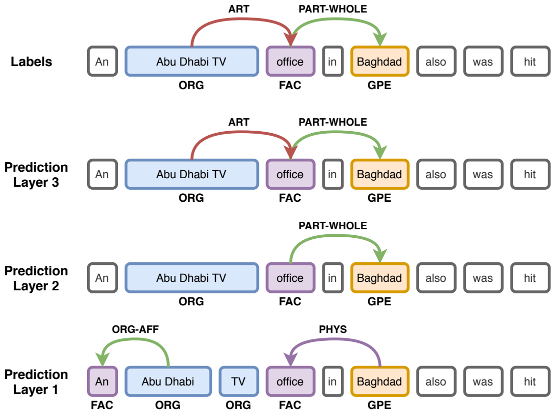
Figure 9 presents examples picked from the development set of ACE05. The prediction layer (a linear layer) after training is used as a probe to display the intermediate state of the model, so we can interpret how the model improves both representations from stacking multiple layers and thus from the bidirectional interaction.

Such probing is valid since for the table encoder, the encoding spaces of different cells are consistent as they are connected through gate mechanism, including cells in different encoding layers; for the sequence encoder, we used residual connection so the encoding spaces of the inputs and outputs are consistent. Therefore, they are all compatible with the prediction layer. Empirically, the intermediate layers did give valid predictions, although they are not directly trained for prediction.

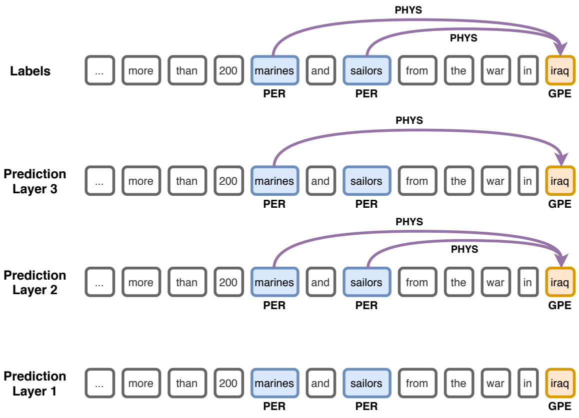
In Figure 9a, the model made a wrong prediction with the representation learned by the first encoding layer. But after the second encoding layer, this mistake has been corrected by the model. This is also the case that happens most frequently, indicating that two encoding layers are already good enough for most situations. For some more compli-



(a) Correct the prediction at the 2nd layer



(b) Correct the prediction at the 3rd layer



(c) A mistake at the last layer

Figure 9: Comparisons of predictions by different encoding layers. We predict relations and entities with the intermediate sequence and table representation, so that we can figure out how the model improves both representations by stacking multiple encoding layers.

cated cases, the model needs three encoding layers to determine the final decision, shown in Figure 9b. Nevertheless, more layers do not always push the prediction towards the correct direction, and Figure 9c shows a negative example, where the model made a correct prediction in the second encoding layer, but in the end it decided not to output one relation, resulting in a false-negative error. But we must note that such errors rarely occur, and the more common errors are that entities or relationships are not properly captured at all encoding layers.

Abstract

Generative models for Information Retrieval, where ranking of documents is viewed as the task of generating a query from a document's language model, were very successful in various IR tasks in the past. However, with the advent of modern deep neural networks, attention has shifted to discriminative ranking functions that model the semantic similarity of documents and queries instead. Recently, deep generative models such as GPT2 and BART have been shown to be excellent text generators, but their effectiveness as rankers have not been demonstrated yet. In this work, we revisit the generative framework for information retrieval and show that our generative approaches are as effective as state-of-the-art semantic similarity-based discriminative models for the answer selection task. Additionally, we demonstrate the effectiveness of unlikelihood losses for IR.

1 Introduction

Most recent approaches for ranking tasks in Information Retrieval (IR) such as passage ranking and retrieval of semantically related questions have focused primarily on discriminative methods using neural networks that learn a similarity function to compare questions and candidate answers (Severyn and Moschitti, 2015; dos Santos et al., 2015; Tan et al., 2016; Tay et al., 2017, 2018). On the other hand, classical literature on probabilistic models for IR showed that language modeling, a type of simple generative model, can be effective for document ranking (Zhai, 2008; Lafferty and Zhai, 2001; Ponte and Croft, 1998). The key idea consists of first training a unique language model lm_i for each candidate document d_i, then using the likelihood of generating the input query using lm_i, denoted by $P(q|lm_i)$, as the ranking score for document d_i.

Recent advances in neural language models (NLMs) have led to impressive improvements in the quality of automatically generated text (Radford et al., 2019). However, to the best of our knowledge, there is no existing work on exploring the effectiveness of modern generative models such as GPT2, for complex ranking tasks such as answer selection. In this work, we intend to fill this gap by demonstrating that large pretrained generative models can be very effective rankers. Unlike classic LM based approaches for IR that employ separate LMs for each document, our proposed method uses a single global LM that applies to all documents. The global pretrained generator is fine-tuned on the task of query generation conditioned on document content as the context. Additionally, in order to leverage both positive and negative examples, we propose the use of (1) unlikelihood loss on negative examples and (2) ranking loss on the likelihood of positive and negative examples. At inference time, given an input query, our method scores each candidate document using the likelihood of generating the query given the document, as estimated by our fine-tuned global LM.

We focus our experiments on the task of answer selection (a.k.a passage ranking). In this task, given an input question and a set of candidate passages, the goal is to rank the candidate passages so that passages containing the correct answer appear at the top of the ranked list. Considerable body of work exists on the use of NNs for this task (Feng et al., 2015; Severyn and Moschitti, 2015; Tan et al., 2016; dos Santos et al., 2016; Rao et al., 2016; Wang et al., 2017), where the most recent ones use BERT-based models that perform discrimination based on the special $[CLS]$ token (Nogueira and Cho, 2019; Li et al., 2019; Xu et al., 2019). A contemporaneous work by Nogueira et al. (2020) also proposes a generative approach for the passage ranking task. However, while their approach decides the relevance of a passage by generating a single keyword (e.g. *true* or *false*), our method

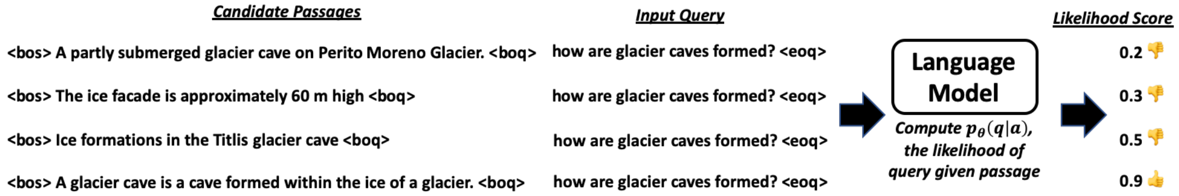

Figure 1: Illustration of the inference step of our *ranking by generation* approach. Each candidate passage a_k is ranked based on the likelihood of generating the question q conditioned on the passage, $p_\theta(q|a_k)$.

uses the conditional likelihood of generating the question given the passage as a relevance score.

We perform extensive experiments using GPT2 (Radford et al., 2019) and BART (Lewis et al., 2019), which are Transformer-based LMs (Vaswani et al., 2017) that were pretrained using large volumes of textual data. The LMs are fine-tuned on four different passage ranking datasets separately: WikipassageQA, WikiQA, InsuranceQA_V2, and YahooQA. Our experimental results indicate that our generative approaches are as effective as state-of-the-art discriminative-based approaches for answer selection.

2 Ranking by Generation

2.1 Background

The goal in language modeling is to learn the probability distribution $p(x)$ over variable-length token sequences $x = (x_1, x_2, ..., x_{|x|})$, where the tokens come from a fixed size vocabulary, $x_i \in V$. When training an LM with *causal objective*, which consists of predicting the next token by looking at the past only, we can represent this distribution by the conditional probability of the next token given the previous ones (Bengio et al., 2003):

$$p(x) = \prod_{i=1}^{|x|} p(x_i|x_{<i}) \qquad (1)$$

GPT2 (Radford et al., 2019) is an example of a state-of-the-art neural LM trained with causal objective. The usual approach to train an LM using a neural network with parameters θ consists on performing maximum likelihood estimation (MLE) by minimizing the negative log-likelihood over a large text corpus $D = \{x^1, x^2, ..., x^{|D|}\}$, where each x_k is a document of length $|x_k|$:

$$\mathcal{L}(D) = -\sum_{k=1}^{|D|}\sum_{i=1}^{|x^k|} \log p_\theta(x_i^k|x_{<i}^k) \qquad (2)$$

Conditional LMs are a simple extension of regular LMs where the generation is conditioned on some additional context c (Keskar et al., 2019):

$$p(x|c) = \prod_{i=1}^{|x|} p(x_i|x_{<i}, c) \qquad (3)$$

2.2 Proposed Ranking Approach

Our proposed approach for passage ranking by generation consists of first fine-tuning a pretrained large LM on the task of question generation conditioned on the passage, using the conditional LM approach shown in Eq. 3. In practice, each input for the fine-tuning step is as follows:

`<bos> passage <boq> question <eoq>`

where the *passage* is considered as a prompt, and the log-likelihood used in the training comes only from the tokens starting after the keyword *<boq>*, since we use the passage as a conditioning context. In other words, at training time, we minimize the negative conditional log-likelihood $-\log P(q|a)$, where a is a passage relevant to the query q. At inference time, given a query q, our conditional LM scores each candidate passage a_k using the likelihood of generating the question conditioned on the passage, $s(a_k) = p_\theta(q|a_k)$. Fig. 1 illustrates the inference step of our proposed approach.

2.3 Unlikelihood Loss for Ranking

Datasets for training passage rankers normally contain both positive and negative examples. Therefore, it is natural to use both types of examples in order to leverage all the available data. Let D be the set of examples (q, a, y), where y is 1 if the passage a is a positive answer for q, or 0 otherwise. We fine-tune the LM using the following loss function:

$$\begin{aligned}\mathcal{L}(D) = -\sum_{(q,a,y)\in D}\sum_{i=1}^{|q|} & y\log(p_\theta(q_i|q_{<i}, a)) \\ & + (1-y)\log(1-p_\theta(q_i|q_{<i}, a))\end{aligned} \qquad (4)$$

The second term in Eq. 4 resembles the unlikelihood training objective of Welleck et al. (2019). However, while we use an unlikelihood objective with the aim of teaching the LM which questions are unlikely given the passage, Welleck et al. (2019) use an unlikelihood objective with the aim of improving text generation. We use the acronym LUL to refer to the loss function in Eq. 4, which performs likelihood and unlikelihood estimation.

We experimented an additional loss function to fine-tuning the LMs which consists on imposing a pairwise ranking loss on the likelihood (RLL) of positive and negative examples as follows:

$$\begin{aligned}\mathcal{L}(D) \quad = & \sum_{(q,a+,a-)\in D} \max\{0, \lambda - \log p_\theta(q|a^+) \\ & + \quad \log p_\theta(q|a^-)\} \qquad (5)\end{aligned}$$

The use of unlikelihood losses to penalize negative examples is a natural choice for fine-tuning generative models. Note that Eq. 4 is an extension of the regular cross-entropy loss where we just added the unlikelihood term, while Eq. 5 is its ranking-based (hinge loss) version. The unlikelihood term in Eq. 4 can also be seen as a regularizer, which makes the ranking model less overconfident when computing query likelihoods.

3 Experiments and Discussion

3.1 Datasets

We use four different publicly available answer selection datasets in our experiments: WikipassageQA (Cohen et al.), WikiQA (Yang et al., 2015), InsuranceQA_V2 (Feng et al., 2015), and YahooQA (Tay et al., 2017). Statistics about the datasets are shown in Table 1. The four datasets also provide validation sets, which have size similar to the respective test sets.

Dataset	Train: #Q (#P/Q)	Test: #Q (#P/Q)
WikiQA	873 (9)	243 (9)
WikipassageQA	3,332 (58.3)	416 (57.6)
InsuranceQA	12,889 (500)	2,000 (500)
YahooQA	50,112 (5)	6,283 (5)

Table 1: Dataset statistics. #Q stands for *number of questions* and #P/Q is the *average number of passages per question*

3.2 Language Model Setup

We use pretrained GPT2-base (12 layers, 117M parameters), GPT2-large (24 layers, 345M params), BART-base (6 layers encoder and 6 layers decoder, 139M params) and BART-large (12 layers encoder and 12 layers decoder, 406M params) models in our experiments. We adopted the implementation and pretrained models from Wolf et al. (2019). We fine-tune GPT2 and BART on each training dataset separately. We perform a maximum of 10 fine-tuning epochs and adopt early stopping using the validation sets. Most of the hyperparmeters used for fine-tuning are the default ones from Wolf et al. (2019)[1], except for learning rate for BART, which we set to $1e-5$.

In the experiments presented below, the subscript MLE corresponds to models fine-tuned using just maximum likelihood estimation (Eq. 2), which means that only positive examples are used. The subscript LUL corresponds to models fine-tuned using maximum likelihood and unlikelihood estimation (Eq. 4), while RLL are models fine-tuned using the ranking loss in Eq. 5. For MLE and LUL, we use a mini-batch size of 64 for InsuranceQA and 32 for the other 3 datasets. The number of negative examples per positive examples is set to 5 in the case of LUL.

When fine-tuning with RLL loss (Eq. 5), we use a batch size of 8. During training, when processing a question we randomly sample 15 negative passages from the set of negative passages of the question. However, only the negative passage with the highest score is used to update the model. Early experiments demonstrated that this strategy performs similarly to the usual pairwise approach.

3.3 Ranking Results

In Table 2 we present the experimental results for our proposed generative approach and four state-of-the-art discriminative baselines, which are based on BERT (Devlin et al., 2019) and BART. Both BERT-Sel (Li et al., 2019) and BERT-PR (Xu et al., 2019) fine-tuned BERT-base using a ranking loss on the score computed with $[CLS]$ token. We trained a BERT-large model using $[CLS]$-based scoring + ranking loss (rows 3). We additionally trained a discriminative version of BART-large (row 4) where the input for the encoder and the decoder are the passage and the question, respectively. As it is normally adopted in BART for classification (Lewis et al., 2019), we take the representation generated by the decoder for the last token and use it to create a score by applying a linear layer. Such as the discriminative BERT models, we also optimize

Table 2: Experimental results for different passage ranking models and datasets.

BART-large using a ranking loss. The performance of the passage ranking models is assessed using the metrics Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and Precision at 1 (P@1). Scores are computed with the official *trec_eval* tool.

In the middle part of Table 2, we compare GPT2-base without any fine-tuning (row 5), and finetuned with either MLE (6), LUL (7) or RLL (8). When the pretrained model only is used (no fine-tuning) the results are very poor. Which is understandable, given that the pattern of having a passage followed by a question might not be very recurrent in the data used to pretrain GPT2. Comparing MLE (row 6) with LUL (row 7), we see that the inclusion of the unlikelihood term (Eq. 4) has a significant positive impact for all datasets but InsuranceQA. We believe the unlikelihood loss does not help on InsuranceQA because this dataset was not human curated and therefore contains a significant number of false-negative examples, which can hurt performance when used to compute the unlikelihood loss. Compared to BERT-base models, GPT2-base$_{LUL}$ is very competitive for most of the datasets except WikiQA, while GPT2-base$_{RLL}$ demonstrates more robust results across the different datasets. In rows 9 and 10 we show results for BART-base, where we see similar trends to GPT2-base with regard to LUL and RLL losses. BART-base$_{RLL}$ is overall better than BART-base$_{LUL}$ and GPT2-base models.

In the bottom part of Table 2, we also show results for GPT2-large and BART-large using LUL and RLL (rows 11 to 14). Overall, the larger generative models do a better job than the smaller ones, as expected. Among the generative approaches, BART-large$_{RLL}$ (row 14) is the model that performs the best for most of the datasets. We believe that BART-based generative models outperform GPT2-based models due to 1) the larger number of pretraining tasks used in BART and 2) the use of bidirectional attention in the encoder side (which processes the passage). Comparing BART-large$_{RLL}$ with discriminative BART-large (row 4), we can see that BART-large$_{RLL}$ produces better results for InsuranceQA, while achieving similar performance for YahooQA, WikiQA and WikipassageQA. Overall, our proposed generative approach produces state-of-the-art results on the four tested datasets in all metrics.

Model	Likelihood	MAP	MRR	P@1
GPT2-base$_{LUL}$	$p_\theta(q\|a)$	.723	.807	**.716**
GPT2-base$_{LUL}$	$p_\theta(a\|q)$	.414	.464	.259
GPT2-base$_{RLL}$	$p_\theta(q\|a)$	**.735**	**.810**	.704
GPT2-base$_{RLL}$	$p_\theta(a\|q)$	.531	.617	.478

Table 3: Experimental results on using passage vs. question as the conditional context. Results are computed on the WikipassageQA dataset

3.4 Ranking with Passage Likelihood

A different setup that can be used for our approach is to compute the likelihood of the passage given the question, where the score for a candidate passage a^k is given by $s(a_k) = p_\theta(a_k|q)$, and the score needs to be normalized by the passage length $|a_k|$. This setup is inherently more difficult because the passage is normally much longer than the question and might contain many tokens that are not relevant for the question.

In Table 3, we present experimental results where we compare the use of either passage or question as the conditional context. As expected, using the likelihood of the passage given the question ($p_\theta(a_k|q)$) as the score results in worse perfor-

Passage	This phenomenon happens usually in the winter. In 2013, Sao Paulo was the most populous city in Brazil and in South America. According to the 2010 IBGE Census, there were 11,244,369 people residing in the city of Sao Paulo. The census found 6,824,668 White people , 3,433,218 Pardo people , 736,083 Black people , 246,244 Asian people and 21,318 Amerindian people . In 2010, the city had 2,146,077 opposite-sex couples and 7,532 same-sex couples. The population of Sao Paulo was 52.6% female and 47.4% male.
Generated Questions	How diverse are the demographics of the city of Sao Paulo? How diverse is the population of the city of Sao Paulo? *Why are people living in the city of Sao Paulo?*
Passage	The presidential electors cast their ballots for President and Vice President, and Congress tallied these votes on January 8, 2009. The voter turnout for this election was broadly predicted to be high by American standards, and a record number of votes were cast. The final tally of total votes counted was 131.3 million, compared to 122.3 million in 2004 . ... . Another estimate puts the eligible voter population at 213,313,508, resulting in a turnout rate of 61.6%, which would be the highest turnout rate since 1968.
Generated Questions	What are the demographics and voting trends of the US presidential elections? What is a voter turnout like in the U.S. presidential elections? *What factors contributed to high voter turnout in 2008?* *Why might voters have difficulty voting?*

Table 4: Examples of automatically generated questions using the GPT2-large$_{LUL}$ model fine-tuned on the WikipassageQA dataset with likelihood $p_\theta(q|a)$. The passages were extracted from the test set.

Question	What was the election turnout for 2008?
Generated Passage	The turnout in the 2008 general election was the highest in the United Kingdom since the 1920s, and the highest turnout in the history of the UK. The turnout was higher than that for the general election of the previous year. The 2008 general election was a close contest, with the Conservatives winning a majority of seats and the Labour Party winning a majority of seats in Parliament. The Conservative Party won the largest majority in Parliament, with 332 of 538 seats, and the Liberal Democrats gained the largest number of seats in the House of Commons, winning 232...
Generated Passage	The turnout was higher in the two states that had been held for the presidency by Barack Obama. The Democratic Party won the state of New Hampshire, the state that Obama won by more than 2 million votes, and the Republican Party won the state of Ohio by nearly 2.5 million votes. In the 2008 presidential election, Obama defeated Mitt Romney by more than 3 million votes, winning 332 of the 435 electoral votes. The election was the second of four presidential elections. The results of the election were announced on November 4. The election was the first in ...

mance for both fine-tuning approaches: LUL and RLL.

3.5 Question and Passage Generation

A good side effect of using generative models to perform ranking is that we can use the trained model to generate new questions given a passage and vice-versa (depending on the conditioning context used for fine-tuning). This type of synthetically generated data could be used as additional training data to improve discriminative models such as BERT-PR (Xu et al., 2019). In Tables 4 and 5, we present some examples of questions and passages, respectively, that were generated using our fine-tuned GPT2-large$_{LUL}$ LM. In both cases we use a mixture of top k-sampling (Fan et al., 2018) and nucleus sampling (Holtzman et al., 2019) to generate the samples. Please note that the passages in Table 4 were extracted from the test set and are not present in the training set. The same applies for the question used in Table 5.

In Table 4, we can see that the generated questions are very fluent and, for most questions (except for the ones in *italic*), the input passage contains the answer for the question. In Table 5, we can observe that the generated passages are quite related to the input question. However, the content is normally not factual and contains inconsistencies and some repetitions.

4 Conclusion

We have proposed a new generative approach for IR based on large pretrained neural language models, and demonstrated their effectiveness as rankers by providing robust experimental results on four different datasets. Additionally, we demonstrated that unlikelihood-based losses are effective for allowing the use of negative examples in generative-based information retrieval. We believe that our approach can also be effectively used for text classification problems, where the score of a class label c is computed as the likelihood of generating the class label c given the document d, $p(c|d)$.

Tired of Topic Models? Clusters of Pretrained Word Embeddings Make for Fast and Good Topics too!

Abstract

Topic models are a useful analysis tool to uncover the underlying themes within document collections. The dominant approach is to use probabilistic topic models that posit a generative story, but in this paper we propose an alternative way to obtain topics: clustering pretrained word embeddings while incorporating document information for weighted clustering and reranking top words. We provide benchmarks for the combination of different word embeddings and clustering algorithms, and analyse their performance under dimensionality reduction with PCA. The best performing combination for our approach performs as well as classical topic models, but with lower runtime and computational complexity.

1 Introduction

Topic models are the standard approach for exploratory document analysis (Boyd-Graber et al., 2017), which aims to uncover main themes and underlying narratives within a corpus. But in times of distributed and even contextualized embeddings, are they the only option?

This work explores an alternative to topic modeling by casting 'key themes' or 'topics' as *clusters of word types* under the modern distributed representation learning paradigm: unsupervised pre-trained word embeddings provide a representation for each word type as a vector, allowing us to cluster them based on their distance in high-dimensional space. The goal of this work is not to strictly outperform, but rather to benchmark standard clustering of modern embedding methods against the classical approach of Latent Dirichlet Allocation (LDA; Blei et al., 2003).

We restrict our study to influential embedding methods and focus on centroid-based clustering algorithms as they provide a natural way to obtain the top words in each cluster based on distance from the cluster center.[1]

Aside from reporting the best performing combination of word embeddings and clustering algorithm, we are also interested in whether there are consistent patterns: embeddings which perform consistently well across clustering algorithms might be good representations for unsupervised document analysis, clustering algorithms that perform consistently well are more likely to generalize to future word embedding methods.

To make our approach reliably work as well as LDA, we incorporate corpus frequency statistics directly into the clustering algorithm, and quantify the effects of two key methods, 1) weighting terms during clustering and 2) reranking terms for obtaining the top J representative words. Our contributions are as follows:

- We systematically apply centroid-based clustering algorithms on top of a variety of pretrained word embeddings and embedding methods for document analysis.
- Through weighted clustering and reranking of top words we obtain sensible topics; the best performing combination is comparable with LDA, but with smaller time complexity and empirical runtime.
- We show that further speedups are possible by reducing the embedding dimensions by up to 80% using PCA.

2 Related Work and Background

Analyzing documents by clustering word embeddings is a natural idea—clustering has been used

---

[1] We found that using non-centroid-based hierarchical, or density based clustering algorithms like DBScan resulted in worse performance and more hyperparameters to tune.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1728–1736,

for readability assessment (Cha et al., 2017), argument mining (Reimers et al., 2019), document classification and document clustering (Sano et al., 2017), *inter alia*. So far, however, clustering word embeddings has not seen much success for the purposes of topic modeling. While many modern efforts have attempted to *incorporate* word embeddings *into* the probabilistic LDA framework (Liu et al., 2015; Nguyen et al., 2015; Das et al., 2015; Zhao et al., 2017; Batmanghelich et al., 2016; Xun et al., 2017; Dieng et al., 2019), relatively little work has examined the feasibility of *clustering embeddings directly*.

Xie and Xing (2013) and Viegas et al. (2019) first cluster documents and subsequently find words within each cluster for document analysis. Sridhar (2015) targets short texts where LDA performs poorly in particular, fitting GMMs to learned word2vec representations. De Miranda et al. (2019) cluster using self-organising maps, but provide only qualitative results.

In contrast, our proposed approach is straightforward to implement, feasible for regular length documents, requires no retraining of embeddings, and yields qualitatively and quantitatively convincing results. We focus on centroid based k-means (KM), Spherical k-means (SK), and k-medoids (KD) for hard clustering, and von Mises-Fisher Models (VMFM) and Gaussian Mixture Models (GMM) for soft clustering; as pre-trained embeddings we consider word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), FastText (Bojanowski et al., 2017), Spherical (Meng et al., 2019), ELMo (Peters et al., 2018), and BERT (Devlin et al., 2018).

3 Methodology

After preprocessing and extracting the vocabulary from our training documents, each word type is converted to its embedding representation (averaging all of its tokens for contextualized embeddings; details in §5.3). Following this we apply the various clustering algorithms on the entire training corpus vocabulary to obtain k clusters, using weighted (§3.2) or unweighted word types. After the clustering algorithm has converged, we obtain the top J words (§3.1) from each cluster for evaluation. Note that one potential shortcoming of our approach is the possibility of outliers forming their own cluster, which we leave to future work.

Figure 1: The figure on the left shows the cluster center ($\star$) without weighting, while the figure on the right shows that after weighting (larger points have higher weight) a hopefully more representative cluster center is found. Note that top words based on distance from the cluster center could still very well be low frequency word types, motivating reranking (§3.3).

3.1 Obtaining top-J words

In traditional topic modeling (LDA), the top J words are those with highest probability under each topic-word distribution. For centroid based clustering algorithms, the top words of some cluster i are naturally those closest to the cluster center $c^{(i)}$, or with highest probability under the cluster parameters. Formally, this means choosing the set of types J as

$$\underset{J:\,|J|=10}{\text{argmin}} \sum_{j \in J} \begin{cases} \|c^{(i)} - x_j\|_2^2 & \text{for KM/KD,} \\ \cos(c^{(i)}, x_j) & \text{for SK,} \\ f(x_j \mid c^{(i)}, \Sigma_i) & \text{for GMM/VMFM.} \end{cases}$$

Our results in §6 focus on KM and GMM, as we observe that k-medoids, spherical KM and von Mises-Fisher tend to perform worse than KM and GMM (see App. A, App. B).

Note that it is possible to extend this approach to obtain the top *topics given a document*: compute similarity scores between learned topic cluster centers and all word embeddings from that particular document, and normalize them using softmax to obtain a (non-calibrated) probability distribution.

Crucial to our method is the incorporation of corpus statistics on top of vanilla clustering algorithms, which we will describe in the remainder of this section.

3.2 Weighting while clustering

The intuition of *weighted clustering* is based on the formulation of classical LDA which models the probability of the word type t belonging to a topic i as $\frac{N_{t,i}+\beta_t}{\sum_{t'} N_{t'i}+\beta_{t'}}$, where $N_{t,i}$ refers to the number of times word type t has been assigned to topic i, and

β is a parameter of the Dirichlet prior on the per-topic word distribution. In our case, illustrated by the schematic in Fig. 1, weighting is a natural way to account for the frequency effects of vocabulary terms during clustering.

3.3 Reranking when obtaining topics

When obtaining the top-J words that make up a cluster's topic, we also consider *reranking* terms, as there is no guarantee that words closest to cluster centers are important word types. We will show in Table 2 that without reranking, clustering yields "sensible" topics but low NPMI scores.

3.4 Which corpus statistics?

To incorporate corpus statistics into the clustering algorithm, we examine three different schemes[2] to assign weights to word types, where n_t is the count of word type t in corpus D, and d is a document:

$$\textbf{tf} = \frac{n_t}{\sum_{t'} n_{t'}} \tag{1}$$

$$\textbf{tf-df} = \text{tf} \cdot \frac{|\{d \in D \mid t \in d\}|}{|D|} \tag{2}$$

$$\textbf{tf-idf} = \text{tf} \cdot \log\left(\frac{|D|}{|\{d \in D \mid t \in d\}| + 1}\right) \tag{3}$$

These scores can now be used for *weighting* word types when clustering ($\diamond^w$), *reranking* top 100 words ($\diamond_r$) after, both ($\diamond_r^w$), or neither (simply $\diamond$). We find that simply using **tf** outperforms the other weighting schemes (App. C). Our results and subsequent analysis in §6 uses **tf** for weighting and reranking.

4 Computational Complexity

The complexity of KM is $O(tknm)$, and of GMM is $O(tknm^3)$, for t iterations,[3] k clusters (topics), n word types (unique vocabulary), and m embedding dimensions. Weighted variants have a one-off cost of weight initialization, and contribute a constant factor when recalulculating the centroid during clustering. Reranking has an additional $O(n \cdot \log(n_k))$ factor, where n_k is the average number of elements in a cluster. In contrast, LDA via collapsed Gibbs sampling has a complexity of $O(tkN)$, where N is the number of all tokens, so when $N \gg n$, clustering methods can potentially achieve better performance-complexity tradeoffs.

Note that running ELMo and BERT over documents also requires iterating over all tokens, but only once, and not for every topic and iteration.

4.1 Cost of obtaining Embeddings

For readily available pretrained word embeddings such as word2vec, FastText, GloVe and Spherical, the embeddings can be considered as 'given' as the practioner does not need to generate these embeddings from scratch. However for contextual embeddings such as ELMo and BERT, there is additional computational cost in obtaining these embeddings before clustering, which requires passing through RNN and transformer layers respectively. This can be trivially parallelised by batching the context window (usually a sentence). We use standard pretrained ELMo and BERT models in our experiments and therefore do not consider the runtime of training these models from scratch.

5 Experimental Setup

Our implementation is freely available online.[4]

5.1 Datasets

We use the 20 newsgroup dataset (20NG) which contains around 18000 documents and 20 categories,[5] and a subset of Reuters21578[6] which contains around 10000 documents.

5.2 Evaluation (Topic Coherence)

We adopt a standard 60-40 train-test split for 20NG and 70-30 for Reuters.

The top 10 words (§3.1) were evaluated using *normalized pointwise mutual information* (NPMI; Bouma, 2009) which has been shown to correlate with human judgements (Lau et al., 2014). NPMI ranges from $[-1, 1]$ with 1 indicating perfect association. The train split is used to obtain the top topic words in an unsupervised fashion (we do not use any document labels), and the test split is used to evaluate the "topic coherence" of these top words. NPMI scores are averaged across all topics.

For both datasets we use 20 topics; which gives best NPMI out of 20, 50, 100 topics for Reuters, and is the ground truth number for 20NG. The

---

[2] We also experimented with various scaling methods such as robust scaling, logistic-sigmoid, and log transform but found that these do not improve performance.

[3] In general, t required for convergence differs for clustering algorithm and embedding representation. However we can specify the maximum number of iterations as a constant factor for worst case analysis.

Table 1: NPMI Results (higher is better) for pre-trained word embeddings and k-means (KM), and Gaussian Mixture Models (GMM). $\diamond^w$ indicates weighted and $\diamond_r$ indicates reranking of top words. For Reuters (left table), LDA has an NPMI score of 0.12, while GMM_r^w BERT achieves 0.15. For 20NG (right), both LDA and KM_r^w Spherical achieve a score of 0.26. All results are averaged across 5 random seeds.

NPMI scores presented in Table 1 are averaged across cluster centers initialized using 5 random seeds.

5.3 Preprocessing

We lowercase tokens, remove stopwords, punctuation and digits, and exclude words that appear in less than 5 documents and appear in long sentences of more than 50 words, removing email artifacts and noisy token sequences which are not valid sentences. An analysis on the effect of rare word removal can be found in §6.2.

For contextualized word embeddings (BERT and ELMo), sentences served as the context window to obtain the token representations. Subword representations were averaged for BERT, which performs better than just using the first subword.

6 Results and Discussion

Our main results are shown in Table 1.

6.1 Runtime

Running LDA with `MALLET` (McCallum, 2002) takes a minute, but performs no better than KM_r^w, which takes little more than 10 seconds on CPU using `sklearn` (Pedregosa et al., 2011), and 3-4 seconds using a simple implementation using JAX (Bradbury et al., 2018) on GPU.

6.2 Weighting

From Table 1, we see that reranking and weighting greatly improves clustering performance across different embeddings. As a first step to uncover why, we investigate how sensitive our methods are to restricting the clustering to only *frequently appearing word types*. Visualized in Fig. 3, we find that as we vary the cutoff term frequency, thus changing the vocabulary size and allowing more rare words on the x-axis, NPMI is more affected for the models without reweighting. This suggests that reweighting using term frequency is effective for clustering without the need for ad-hoc restriction of infrequent terms—without it, all combinations perform poorly compared to LDA. In general, GMM outperforms KM for both weighted and unweighted variants averaged across all embedding methods ($p < 0.05$).[7]

Table 2: Top 10 words in a topic on 20NG and overall NPMI, for k-means (KM) before and after reranking (KM_r): reranking clearly improves NPMI for BERT and Spherical.

6.3 Reranking

For KM, extracted topics before reranking results in reasonable looking themes, but scores poorly on NPMI. Reranking strongly improves KM on average ($p < 0.02$) for both Reuters and 20NG. Examples before and after reranking are provided in Table 2. This indicates that while cluster centers are centered around valid themes, they are surrounded by low frequency word types.

---

[7] Two-tailed t-test for GMM^w vs KM^w.

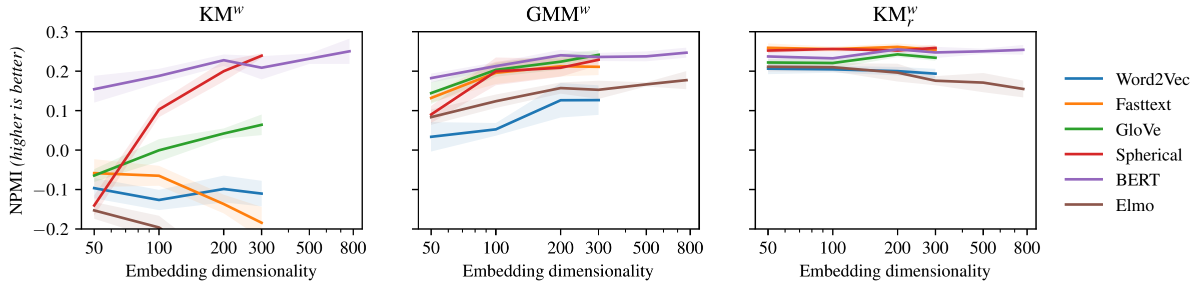

Figure 2: Plots showing the effect of PCA dimension reduction on different embedding and clustering algorithms. KM^w_r which we advocate over GMMs for efficiency, allows for dimension reduction of up to 80%.

We observe that when applying reranking to GMM^w the gains are much less pronounced than KM^w. The top topic words before and after reranking for BERT-GMM^w have an average Jaccard similarity score of 0.910, indicating that the cluster centers learned by weighted GMMs are already centered at word types of high frequency in the training corpus.

6.4 Embeddings

Spherical embeddings and BERT perform consistently well across both datasets. For 20NG, KM^w_r Spherical and LDA both achieve 0.26 NPMI. For Reuters, GMM^w_r BERT achieves the top NPMI score of 0.15 compared to 0.12 of LDA. Word2vec and ELMo (using only the last layer[8]) perform poorly compared to the other embeddings. FastText and GloVe can achieve similar performance to BERT on 20NG but are slightly inferior on Reuters.

Training or fine-tuning embeddings on the given data prior to clustering could potentially achieve better performance, but we leave this to future work.

6.5 Qualitative results

We find that our approach yields a greater diversity within topics as compared to LDA while achieving comparable coherence scores (App. D). Such topics are arguably more valuable for exploratory analysis.

6.6 Dimensionality Reduction

We apply PCA to the word embeddings before clustering to investigate the amount of redundancy in the dimensions of large embeddings, which impact clustering complexity (§4). With reranking, the dimensions of all embeddings can be reduced by more than 80% (Fig. 2).

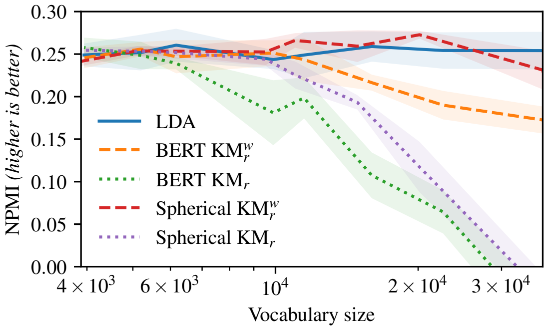

Figure 3: NPMI as a function of vocabulary size reduced by term frequency on 20NG. Embeddings are more sensitive to noisy vocabulary (infrequent terms) than LDA, but reweighting $(\diamond^w)$ helps to alleviate this.

We observe that KM^w_r can consistently reduce the number of dimensions across different embedding types without loss of performance. Although GMM^w does not require reranking for good performance, it's cubic complexity indicates that KM^w_r might be preferred in practical settings.

7 Conclusion

We outlined a methodology for clustering word embeddings for unsupervised document analysis, and presented a systematic comparison of various influential embedding methods and clustering algorithms. Our experiments suggest that pretrained word embeddings (both contextualized and non-contextualized), combined with tf-weighted k-means and tf-based reranking, provide a viable alternative to traditional topic modeling at lower complexity and runtime.

A k-means (KM) vs k-medoids (KD)

To further understand the effect of other centroid based algorithms on topic coherence, we also applied the k-medoids (KD) clustering algorithm. KD is a hard clustering algorithm similar to KM but less sensitive to outliers.

As we can see in Table 3, in all cases KD usually did as well or worse than KM. KD also did relatively poorly after frequency reranking. Where KD did do better than KM, the difference is not very striking and the NPMI scores were still quite below the other top performing models.

B Results for Spherical k-means and Von Mises-Fisher Mixture

Table 4 shows the overall bad performance of spherical clustering methods, specifically Spherical k-Means (SKM) and von-Mises-Fisher mixtures (VMFM).

C Comparing Different Reranking Schemes

We present the results for using different reranking schemes for KM (Table 5) and Weighted KM for Frequency (Table 6).

We can see that compared to the TF results in the main paper, other schemes for reranking such as aggregated TF-IDF and TF-DF improve over the original hard clustering, but fare worse in comparison with reranking with TF.

D Qualitative Comparison of Topics Generated

unlike LDA, which uses the highest posterior probability allowing duplicate words to appear in duplicate topics, using a hard clustering algorithm for assignment mean that each word is assigned to one topic only. We can see compared to the LDA topics which tend to contain topics mostly regarding wealth and profits, clustering with BERT KM^w_r introduces new topics in involving locations and corporate positions. We see overall that using clustering allows for a discovery for a greater diversity of topics due to the greater diversity of words over all the topics.

Abstract

While neural sequence learning methods have made significant progress in single-document summarization (SDS), they produce unsatisfactory results on multi-document summarization (MDS). We observe two major challenges when adapting SDS advances to MDS: (1) MDS involves larger search space and yet more limited training data, setting obstacles for neural methods to learn adequate representations; (2) MDS needs to resolve higher information redundancy among the source documents, which SDS methods are less effective to handle. To close the gap, we present RL-MMR, Maximal Margin Relevance-guided Reinforcement Learning for MDS, which unifies advanced neural SDS methods and statistical measures used in classical MDS. RL-MMR casts MMR guidance on fewer promising candidates, which restrains the search space and thus leads to better representation learning. Additionally, the explicit redundancy measure in MMR helps the neural representation of the summary to better capture redundancy. Extensive experiments demonstrate that RL-MMR achieves state-of-the-art performance on benchmark MDS datasets. In particular, we show the benefits of incorporating MMR into end-to-end learning when adapting SDS to MDS in terms of both learning effectiveness and efficiency.[1]

1 Introduction

Text summarization aims to produce condensed summaries covering salient and non-redundant information in the source documents. Recent studies on single-document summarization (SDS) benefit from the advances in neural sequence learning (Nallapati et al., 2016; See et al., 2017; Chen and Bansal, 2018; Narayan et al., 2018) as well as pre-trained language models (Liu and Lapata, 2019; Lewis et al., 2019; Zhang et al., 2020) and make great progress. However, in multi-document summarization (MDS) tasks, neural models are still facing challenges and often underperform classical statistical methods built upon handcrafted features (Kulesza and Taskar, 2012).

We observe two major challenges when adapting advanced neural SDS methods to MDS: (1) **Large search space**. MDS aims at producing summaries from multiple source documents, which exceeds the capacity of neural SDS models (See et al., 2017) and sets learning obstacles for adequate representations, especially considering that MDS labeled data is more limited. For example, there are 287K training samples (687 words on average) on the CNN/Daily Mail SDS dataset (Nallapati et al., 2016) and only 30 on the DUC 2003 MDS dataset (6,831 words). (2) **High redundancy**. In MDS, the same statement or even sentence can spread across different documents. Although SDS models adopt attention mechanisms as implicit measures to reduce redundancy (Chen and Bansal, 2018), they fail to handle the much higher redundancy of MDS effectively (Sec. 4.2.3).

There have been attempts to solve the aforementioned challenges in MDS. Regarding the **large search space**, prior studies (Lebanoff et al., 2018; Zhang et al., 2018) perform sentence filtering using a sentence ranker and only take top-ranked K sentences. However, such a hard cutoff of the search space makes these approaches insufficient in the exploration of the (already scarce) labeled data and limited by the ranker since most sentences are discarded,[2] albeit the discarded sentences are important and could have been favored. As a result, although these studies perform better than directly applying their base SDS models (See et al.,

[1] Code can be found at `https://github.com/morningmoni/RL-MMR`.

[2] K is set to 7 in Lebanoff et al. (2018) and 15 in Zhang et al. (2018). One document set in DUC 2004 (Paul and James, 2004), for example, averages 265.4 sentences.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1737–1751,
November 16–20, 2020.

2017; Tan et al., 2017) to MDS, they do not outperform state-of-the-art MDS methods (Gillick and Favre, 2009; Kulesza and Taskar, 2012). Regarding the **high redundancy**, various redundancy measures have been proposed, including heuristic post-processing such as counting new bi-grams (Cao et al., 2016) and cosine similarity (Hong et al., 2014), or dynamic scoring that compares each source sentence with the current summary like Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998). Nevertheless, these methods still use lexical features without semantic representation learning. One extension (Cho et al., 2019) of these studies uses capsule networks (Hinton et al., 2018) to improve redundancy measures. However, its capsule networks are pre-trained on SDS and fixed as feature inputs of classical methods without end-to-end representation learning.

In this paper, we present a deep RL framework, MMR-guided Reinforcement Learning (RL-MMR) for MDS, which unifies advances in SDS and one classical MDS approach, MMR (Carbonell and Goldstein, 1998) through end-to-end learning. RL-MMR addresses the MDS challenges as follows: (1) RL-MMR overcomes the **large search space** through *soft attention*. Compared to hard cutoff, our soft attention favors top-ranked candidates of the sentence ranker (MMR). However, it does not discard low-ranked ones, as the ranker is imperfect, and those sentences ranked low may also contribute to a high-quality summary. Soft attention restrains the search space while allowing more exploration of the limited labeled data, leading to better representation learning. Specifically, RL-MMR infuses the entire prediction of MMR into its neural module by attending (restraining) to important sentences and downplaying the rest instead of completely discarding them. (2) RL-MMR resolves the **high redundancy** of MDS in a unified way: the explicit redundancy measure in MMR is incorporated into the neural representation of the current state, and the two modules are coordinated by RL reward optimization, which encourages non-redundant summaries.

We conduct extensive experiments and ablation studies to examine the effectiveness of RL-MMR. Experimental results show that RL-MMR achieves state-of-the-art performance on the DUC 2004 (Paul and James, 2004) and TAC 2011 (Owczarzak and Dang, 2011) datasets (Sec. 4.2.1). A comparison between various combination mechanisms demonstrates the benefits of soft attention in the large search space of MDS (Sec. 4.2.2). In addition, ablation and manual studies confirm that RL-MMR is superior to applying either RL or MMR to MDS alone, and MMR guidance is effective for redundancy avoidance (Sec. 4.2.3).

Contributions. (1) We present an RL-based MDS framework that combines the advances of classical MDS and neural SDS methods via end-to-end learning. (2) We show that our proposed soft attention is better than the hard cutoff of previous methods for learning adequate neural representations. Also, infusing the neural representation of the current summary with explicit MMR measures significantly reduces summary redundancy. (3) We demonstrate that RL-MMR achieves new state-of-the-art results on benchmark MDS datasets.

2 Problem Formulation

We define $\mathcal{D} = \{D_1, D_2, ..., D_N\}$ as a set of documents on the same topic. Each document set $\mathcal{D}$ is paired with a set of (human-written) reference summaries $\mathcal{R}$. For the convenience of notation, we denote the j-th sentence in $\mathcal{D}$ as s_j when concatenating the documents in $\mathcal{D}$. We focus on extractive summarization where a subset of sentences in $\mathcal{D}$ are extracted as the system summary $\boldsymbol{E}$. A desired system summary $\boldsymbol{E}$ covers salient and non-redundant information in $\mathcal{D}$. $\boldsymbol{E}$ is compared with the reference summaries $\mathcal{R}$ for evaluation.

3 The RL-MMR Framework

Overview. At a high level, RL-MMR infuses MMR guidance into end-to-end training of the neural summarization model. RL-MMR uses hierarchical encoding to efficiently encode the sentences in multiple documents and obtains the neural sentence representation $\boldsymbol{A}_j$. RL-MMR models salience by combining MMR and sentence representation $\boldsymbol{A}_j$, and measures redundancy by infusing MMR with neural summary representation $\boldsymbol{z}_t$, which together form the state representation $\boldsymbol{g}_t$. At each time step, one sentence is extracted based on the MMR-guided sentence representation and state representation, and compared with the reference, the result (reward) of which is then back-propagated for the learning of both neural representation and MMR guidance. An illustrative figure of RL-MMR is shown in Fig. 1.

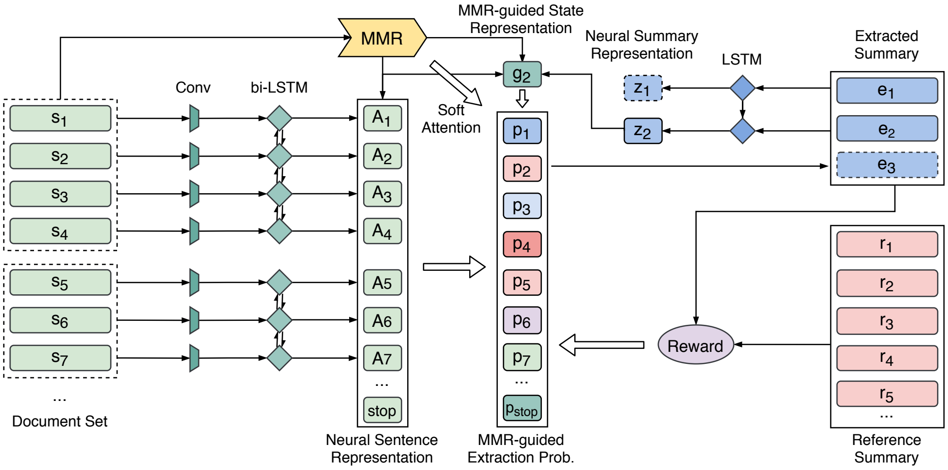

Figure 1: **An overview of the proposed MDS framework RL-MMR**. Neural sentence representation $\boldsymbol{A}_j$ is obtained through sentence-level convolutional encoder and document-level bi-LSTM encoder. MMR guidance is incorporated into neural sentence representation $\boldsymbol{A}_j$ and state representation $\boldsymbol{g}_t$ through soft attention and end-to-end learned through reward optimization.

In the following, we first describe MMR and the neural sentence representation. We then introduce the neural sentence extraction module and how we incorporate MMR guidance into it for better MDS performance. Finally, we illustrate how neural representation and MMR guidance are jointly learned via end-to-end reinforcement learning.

3.1 Maximal Marginal Relevance

Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998) is a general summarization framework that balances summary salience and redundancy. Formally, MMR defines the score of a sentence s_j at time t as $m_j^t = \lambda \mathbf{S}(s_j, \mathcal{D}) - (1-\lambda)\max_{e \in \boldsymbol{E}_t} \mathbf{R}(s_j, e)$, where $\lambda \in [0,1]$ is the weight balancing salience and redundancy. $\mathbf{S}(s_j, \mathcal{D})$ measures how salient a sentence s_j is, estimated by the similarity between s_j and $\mathcal{D}$. $\mathbf{S}(s_j, \mathcal{D})$ does not change during the extraction process. $\boldsymbol{E}_t$ consists of sentences that are already extracted before time t. $\max_{e \in \boldsymbol{E}_t} \mathbf{R}(s_j, e)$ measures the redundancy between s_j and each extracted sentence e and finds the most redundant pair. $\max_{e \in \boldsymbol{E}_t} \mathbf{R}(s_j, e)$ is updated as the size of $\boldsymbol{E}_t$ increases. Intuitively, if s_j is similar to any sentence $e \in \boldsymbol{E}_t$, it would be deemed redundant and less favored by MMR. There are various options regarding the choices of $\mathbf{S}(s_j, \mathcal{D})$ and $\mathbf{R}(s_j, e)$, which we compare in Sec. 4.2.4.

We denote the (index of the) sentence extracted at time t as e_t. MMR greedily extracts one sentence at a time according to the MMR score: $e_t = \arg\max_{s_j \in \mathcal{D} \setminus \boldsymbol{E}_t} m_j^t$. Heuristic and deterministic algorithms like MMR are rather efficient and work reasonably well in some cases. However, they lack holistic modeling of summary quality and the capability of end-to-end representation learning.

3.2 Neural Sentence Representation

To embody end-to-end representation learning, we leverage the advances in SDS neural sequence learning methods. Unlike prior studies on adapting SDS to MDS (Lebanoff et al., 2018), which concatenates all the documents chronologically and encodes them sequentially, we adapt hierarchical encoding for better efficiency and scalability. Specifically, we first encode each sentence s_j via a CNN (Kim, 2014) to obtain its sentence representation. We then separately feed the sentence representations in *each document* D_i to a bi-LSTM (Huang et al., 2015). The bi-LSTM generates a contextualized representation for each sentence s_j, denoted by $\boldsymbol{h}_j$. We form an action matrix $\boldsymbol{A}$ using $\boldsymbol{h}_j$, where the j-th row $\boldsymbol{A}_j$ corresponds to the j-th sentence (s_j) in $\mathcal{D}$. A pseudo sentence indicating the STOP action, whose representation is randomly initialized, is also included in $\boldsymbol{A}$, and sentence extraction is finalized when the STOP action is taken (Mao et al., 2018, 2019).

3.3 Neural Sentence Extraction

We briefly describe the SDS sentence extraction module (Chen and Bansal, 2018) that we base our work on, and elaborate in Sec 3.4 how we adapt it for better MDS performance with MMR guidance.

The probability of neural sentence extraction is measured through a two-hop attention mechanism. Specifically, we first obtain the neural summary representation $\boldsymbol{z}_t$ by feeding previously extracted sentences ($\boldsymbol{A}_{e_i}$) to an LSTM encoder. A time-dependent state representation $\boldsymbol{g}_t$ that considers both sentence representation $\boldsymbol{A}_j$ and summary representation $\boldsymbol{z}_t$ is obtained by the *glimpse* operation (Vinyals et al., 2016):

$$a_j^t = \boldsymbol{v}_1^\intercal \tanh(\boldsymbol{W}_1 \boldsymbol{A}_j + \boldsymbol{W}_2 \boldsymbol{z}_t), \quad (1)$$

$$\boldsymbol{\alpha}^t = \mathrm{softmax}(\boldsymbol{a}^t), \quad (2)$$

$$\boldsymbol{g}_t = \sum_j \boldsymbol{\alpha}_j^t \boldsymbol{W}_1 \boldsymbol{A}_j, \quad (3)$$

where $\boldsymbol{W}_1$, $\boldsymbol{W}_2$, $\boldsymbol{v}_1$ are model parameters. $\boldsymbol{a}^t$ represents the vector composed of a_j^t. With $\boldsymbol{z}_t$, the attention weights $\boldsymbol{\alpha}_j^t$ are aware of previous extraction. Finally, the sentence representation $\boldsymbol{A}_j$ is attended again to estimate the extraction probability.

$$p_j^t = \begin{cases} \boldsymbol{v}_2^\intercal \tanh(\boldsymbol{W}_3 \boldsymbol{A}_j + \boldsymbol{W}_4 \boldsymbol{g}_t) & \text{if } s_j \neq e_i, \forall i < t \\ -\infty & \text{otherwise,} \end{cases} \quad (4)$$

where $\boldsymbol{W}_3$, $\boldsymbol{W}_4$, $\boldsymbol{v}_2$ are model parameters and previously extracted sentences $\{e_i\}$ are excluded.

The summary redundancy here is handled implicitly by $\boldsymbol{g}_t$. Supposedly, a redundant sentence s_j would receive a low attention weight a_j^t after comparing $\boldsymbol{A}_j$ and $\boldsymbol{z}_t$ in Eq. 1. However, we find such latent modeling insufficient for MDS due to its much higher degree of redundancy. For example, when news reports start with semantically similar sentences, using latent redundancy avoidance alone leads to repeated summaries (App B Table 8). Such observations motivate us to incorporate MMR, which models redundancy explicitly, to guide the learning of sentence extraction for MDS.

3.4 MMR-guided Sentence Extraction

In this section, we describe several strategies of incorporating MMR into sentence extraction, which keeps the neural representation for expressiveness while restraining the search space to fewer promising candidates for more adequate representation learning under limited training data.

Hard Cutoff. One straightforward way of incorporating MMR guidance is to only allow extraction from the top-ranked sentences of MMR. We denote the sentence list ranked by MMR scores m_j^t as $\boldsymbol{M}^t$. Given p_j^t – the neural probability of sentence extraction before softmax, we set the probability of the sentences after the first K sentences in $\boldsymbol{M}^t$ to $-\infty$. In this way, the low-ranked sentences in MMR are never selected and thus never included in the extracted summary. We denote this variant as RL-MMR$_{\text{HARD-CUT}}$.

There are two limitations of conducting hard cutoff in the hope of adequate representation learning: **(L1)** Hard cutoff ignores the values of MMR scores and simply uses them to make binary decisions. **(L2)** While hard cutoff reduces the search space, the decision of the RL agent is limited as it cannot extract low-ranked sentences and thus lacks exploration of the (already limited) training data. To tackle L1, a simple fix is to *combine* the MMR score m_j^t with the extraction probability measured by the neural sentence representation.

$$p_j^t = \begin{cases} \beta \boldsymbol{v}_2^\intercal \tanh(\boldsymbol{W}_3 \boldsymbol{A}_j + \boldsymbol{W}_4 \boldsymbol{g}_t) + (1-\beta)\mathrm{FF}(m_j^t) \\ \qquad \text{if } s_j \neq e_i, \forall i < t \text{ and } s_j \in \boldsymbol{M}_{1:K}^t \\ -\infty \qquad \text{otherwise,} \end{cases} \quad (5)$$

where $\beta \in [0, 1]$ is a constant. FF$(\cdot)$ is a two-layer feed-forward network that enables more flexibility than using raw MMR scores, compensating for the magnitude difference between the two terms. We denote this variant as RL-MMR$_{\text{HARD-COMB}}$.

Soft Attention. To deal with L2, we explore soft variants that do not completely discard the low-ranked sentences but encourage the extraction of top-ranked sentences. The first variant, RL-MMR$_{\text{SOFT-COMB}}$, removes the constraint of $s_j \in \boldsymbol{M}_{1:K}^t$ in Eq. 5. This variant solves L2 but may re-expose the RL agent to L1 since its MMR module and neural module are loosely coupled and there is a learnable layer in their combination.

Therefore, we design a second variant, RL-MMR$_{\text{SOFT-ATTN}}$, which addresses both L1 and L2 by tightly incorporating MMR into neural representation learning via soft attention. Specifically, the MMR scores are first transformed and normalized: $\boldsymbol{\mu}^t = \mathrm{softmax}(\mathrm{FF}(\boldsymbol{m}^t))$, and then used to attend neural sentence representation $\boldsymbol{A}_j$ before the two-hop attention: $\boldsymbol{A}'_j = \boldsymbol{\mu}_j^t \boldsymbol{A}_j$. The state representation $\boldsymbol{g}_t$, which captures summary redundancy, is also impacted by MMR through the attention between summary representation $\boldsymbol{z}_t$ and MMR-guided sentence representation $\boldsymbol{A}'_j$ in Eq. 1. L1 is addressed as $\boldsymbol{\mu}^t$ represents the extraction probability estimated by MMR. L2 is resolved since the top-ranked sentences in MMR receive high attention, which empirically is enough to restrain the decision of the RL agent, while the low-ranked sentences are downplayed but not discarded, allowing more exploration of the search space.

3.5 MDS with Reinforcement Learning

The guidance of MMR is incorporated into neural representation learning through end-to-end RL training. Specifically, we formulate extractive MDS as a Markov Decision Process, where the state is defined by $(\mathcal{D} \setminus \boldsymbol{E}_t, \boldsymbol{g}_t)$. At each time step, one action is sampled from $\boldsymbol{A}$ given p_j^t, and its reward is measured by comparing the extracted sentence e_t with the reference $\mathcal{R}$ via ROUGE (Lin, 2004), *i.e.*, $r_t = \text{ROUGE-L}_{\text{F1}}(e_t, \mathcal{R})$. At the final step T when the STOP action is taken, an overall estimation of the summary quality is measured by $r_T = \text{ROUGE-1}_{\text{F1}}(\boldsymbol{E}, \mathcal{R})$. Reward optimization encourages salient and non-redundant summaries – intermediate rewards focus on the sentence salience of the current extracted sentence and the final reward captures the salience and redundancy of the entire summary.

Similar to prior RL-based models on SDS (Paulus et al., 2018; Chen and Bansal, 2018; Narayan et al., 2018), we use policy gradient (Williams, 1992) as the learning algorithm for model parameter updates. In addition, we adopt Advantage Actor-Critic (A2C) optimization – a critic network is added to enhance the stability of vanilla policy gradient. The critic network has a similar architecture to the one described in Sec. 3.2 and uses the sentence representation $\boldsymbol{A}$ to generate an estimation of the discounted reward, which is then used as the baseline subtracted from the actual discounted reward before policy gradient updates.

4 Experiments

We conduct extensive experiments to examine RL-MMR with several key questions: **(Q1)** How does RL-MMR perform compared to state-of-the-art methods? **(Q2)** What are the advantages of soft attention over hard cutoff in learning adequate neural representations under the large search space? **(Q3)** How crucial is the guidance of MMR for adapting SDS to MDS in the face of high redundancy?

4.1 Experimental Setup

Datasets. We take the MDS datasets from DUC and TAC competitions which are widely used in prior studies (Kulesza and Taskar, 2012; Lebanoff et al., 2018). Following convention (Wang et al., 2017; Cao et al., 2017; Cho et al., 2019), DUC 2004 (trained on DUC 2003) and TAC 2011 (trained on TAC 2008-2010) are used as the test sets. We use DUC 2004 as the validation set when evaluated on TAC 2011 and vice versa. More details of the dataset statistics are in App. A.1.

Evaluation Metrics. In line with recent work (Li et al., 2017; Lebanoff et al., 2018; Zhang et al., 2018; Cho et al., 2019), we measure ROUGE-1/2/SU4 F1 scores (Lin, 2004). The evaluation parameters are set according to Hong et al. (2014) with stemming and stopwords not removed. The output length is limited to 100 words. These setups are the same for all compared methods.[3]

Compared Methods. We compare RL-MMR with both classical and neural MDS methods. Note that *some previous methods are incomparable* due to differences such as length limit (100 words or 665 bytes) and evaluation metric (ROUGE F1 or recall). Details of each method and differences in evaluation can be found in App. A.

For extractive methods, we compare with SumBasic (Vanderwende et al., 2007), KL-Summ (Haghighi and Vanderwende, 2009), LexRank (Erkan and Radev, 2004), Centroid (Hong et al., 2014), ICSISumm (Gillick and Favre, 2009), rnn-ext + RL (Chen and Bansal, 2018), DPP (Kulesza and Taskar, 2012), and DPP-Caps-Comb (Cho et al., 2019). For abstractive methods, we compare with Opinosis (Ganesan et al., 2010), Extract+Rewrite (Song et al., 2018), PG (See et al., 2017), and PG-MMR (Lebanoff et al., 2018).

We use RL-MMR$_{\text{SOFT-ATTN}}$ as our default model unless otherwise mentioned. Implementation details can be found in App. A.4. We also report Oracle, an approximate upper bound that greedily extracts sentences to maximize ROUGE-1 F1 given the reference summaries (Nallapati et al., 2017).

4.2 Experimental Results

4.2.1 Comparison with the State-of-the-art

To answer Q1, we compare RL-MMR with state-of-the-art summarization methods and list the comparison results in Tables 1 and 2.

On DUC 2004, we observe that rnn-ext + RL, which we base our framework on, fails to achieve satisfactory performance even after fine-tuning. The large performance gains of RL-MMR over rnn-ext + RL demonstrates the benefits of guiding SDS models with MMR when adapting them to MDS. A similar conclusion is reached when comparing PG and PG-MMR. However, the hard cutoff

in PG-MMR and the lack of in-domain fine-tuning lead to its inferior performance. DPP and DPP-Caps-Comb obtain decent performance but could not outperform RL-MMR due to the lack of end-to-end representation learning. Lastly, RL-MMR achieves new state-of-the-art results, approaching the performance of Oracle, which has access to the reference summaries, especially on ROUGE-2. We observe similar trends on TAC 2011 in which RL-MMR again achieves state-of-the-art performance. The improvement over compared methods is especially significant on ROUGE-1 and ROUGE-SU4.

4.2.2 Analysis of RL-MMR Combination

We answer Q2 by comparing the performance of various combination mechanisms for RL-MMR.

Performance Comparison. As shown in Table 3, RL-MMR$_{\text{Hard-Comb}}$ performs better than RL-MMR$_{\text{Hard-Cut}}$, showing the effectiveness of using MMR scores instead of degenerating them into binary values. We test RL-MMR$_{\text{Soft-Comb}}$ with different β but it generally performs much worse than other variants, which implies that naively incorporating MMR into representation learning through weighted average may loosen the guidance of MMR, losing the benefits of both modules. Infusing MMR via soft attention of the action space performs the best, demonstrating the effectiveness of MMR guidance in RL-MMR$_{\text{Soft-Attn}}$ for sentence representation learning.

Combination	DUC 2004		
	R-1	**R-2**	**R-SU4**
Hard-Cut	38.19	9.26	13.43
Hard-Comb	38.45	9.35	13.64
Soft-Comb	37.70	8.90	12.98
Soft-Attn	**38.56**	**10.02**	**13.80**

Table 3: **Comparison of RL-MMR variants** with different combination mechanisms.

Hard Cutoff vs. Soft Attention. We further compare the extracted summaries of MMR, RL-MMR$_{\text{Hard-Cut}}$, and RL-MMR$_{\text{Soft-Attn}}$ to verify the assumption that there are high-quality sentences not ranked highly by MMR and thus neglected by the hard cutoff. In our analysis, we find that when performing soft attention, 32% (12%) of extracted summaries contain low-ranked sentences that are not from $M^1_{1:K}$ when $K = 1$ ($K = 7$). We then evaluate those samples with low-ranked sentences extracted and conduct a pairwise comparison. On average, we observe a gain of 18.9% ROUGE-2 F1 of RL-MMR$_{\text{Soft-Attn}}$ over MMR, and 2.71% over RL-MMR$_{\text{Hard-Cut}}$, which demonstrates the benefits of soft attention.

Degree of RL-MMR Combination. To study the effect of RL-MMR combination in different degrees, we vary the cutoff K in RL-MMR$_{\text{Hard-Cut}}$ and analyze performance changes. As listed in Table 4, a small $K (= 1)$ imposes tight constraints and practically degrades RL-MMR to vanilla MMR. A large $K (= 50)$ might be too loose to limit the search space effectively, resulting in worse performance than a $K (= 7, 10)$ within the proper range. When K is increased to 100, the impact of MMR further decreases but still positively influences model performance compared to the vanilla RL ($K = \infty$), especially on ROUGE-1.

K	DUC 2004			TAC 2011		
	R-1	R-2	R-SU4	R-1	R-2	R-SU4
1	37.91	8.83	13.10	38.54	10.83	14.43
7	38.19	**9.26**	13.43	**39.22**	**11.10**	**14.78**

50	38.12	9.23	13.42	38.60	11.05	14.55
100	36.92	8.98	12.98	37.94	10.92	14.20
∞	35.93	8.60	12.53	37.13	10.72	14.16

Table 4: **Performance changes of RL-MMR$_{\text{HARD-CUT}}$** when different cutoffs (K) are used.

4.2.3 Effectiveness of MMR Guidance

To answer Q3, we compare RL-MMR with vanilla RL without MMR guidance in terms of both training and test performance. We also inspect details such as runtime and quality of their extracted summaries (provided in App.B).

Training Performance. To examine whether MMR guidance helps with the learning efficiency of MDS, we plot the learning curves of vanilla RL and RL-MMR$_{\text{HARD-CUT}}$ in Fig. 2. RL-MMR receives a significantly better initial reward on the training set because MMR provides prior knowledge to extract high-quality sentences. In addition, RL-MMR has lower variance and achieves faster convergence than RL due to MMR guidance. Note that the final reward of vanilla RL on the plateau is higher than RL-MMR, which is somewhat expected since RL can achieve better fitting on the training set when it has less guidance (constraint).

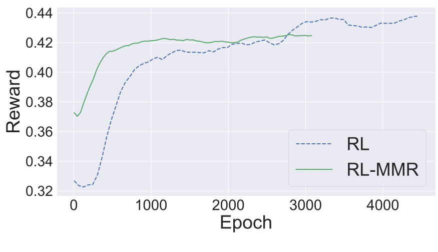

Figure 2: **The learning curves of RL and RL-MMR on DUC 2004**. RL training is more stable and converges faster when equipped with MMR.

Test Performance. We compare the test performance of vanilla RL and RL-MMR in Table 5. Despite the fact that vanilla RL obtains better training performance, its test performance is significantly worse than RL-MMR. Such a contradiction indicates that vanilla RL overfits on the training set and does not generalize well, again demonstrating the benefits of MMR guidance. We also find that, perhaps surprisingly, MMR outperforms vanilla RL even when RL is fine-tuned using in-domain training data. We thus believe that MMR and its methodology are underestimated by prior studies and should be explored further. Finally, RL-MMR achieves significantly better results than either RL or MMR alone, demonstrating the superiority of combining RL with MMR for MDS.

Method	DUC 2004			TAC 2011		
	R-1	R-2	R-SU4	R-1	R-2	R-SU4
RL (pre-train)	32.76	6.09	10.36	33.45	7.37	11.28
RL (fine-tune)	35.93	8.60	12.53	37.13	10.72	14.16
MMR	37.90	8.83	13.10	38.53	10.83	14.44
RL-MMR	**38.56**	**10.02**	**13.80**	**39.65**	**11.44**	**15.02**

Table 5: **Comparison of MMR, RL, and RL-MMR** further shows the effectiveness of MMR guidance.

4.2.4 Ablation of MMR

In this section, we conduct more ablation of MMR given its decent performance. We study the balance between salience and redundancy, and the performance of different similarity measures. Specifically, we use TF-IDF and BERT (Devlin et al., 2019) as the sentence (document) representation and measure cosine similarity in $\mathbf{S}(s_j, \mathcal{D})$ and $\mathbf{R}(s_j, e)$. We also explore whether a semantic textual similarity model, SNN (Latkowski, 2018), is more effective in measuring redundancy $\mathbf{R}(s_j, e)$ than TF-IDF. The TF-IDF features are estimated on the MDS datasets while the neural models are pre-trained on their corresponding tasks.

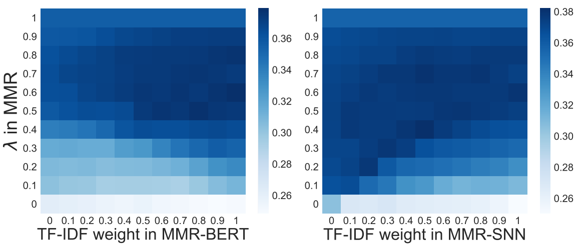

Figure 3: **Performance comparison under different salience-redundancy balances (y-axis), and various weighted combinations** of TF-IDF and BERT *(Left)* or SNN *(Right)* for similarity measure (x-axis). DUC 2004, ROUGE-1 F1, and $\mathbf{R}(s_j, e)$ are used for illustration. The results of other setups are similar.

Balance between Salience and Redundancy. By examining the y-axis in Fig. 3, we observe that con-

Reference Summary: PKK leader Ocalan was arrested on arrival at the Rome airport. He asked for asylum. **Turkey pressured Italy to extradite Ocalan**, whom they consider a terrorist. **Kurds in Europe flocked to Rome to show their support**. **About 1,500 staged a hunger strike outside the hospital where he was held**. Italy began a border crackdown to stop Kurds flocking to Rome. **Greek media and officials oppose extradition**. **Romanian Kurds staged a 1-day business shutdown to protest his arrest**. In a Turkish prison, an Italian prisoner was taken hostage. The Turkish president needed extra security for a trip to Austria. This is Italy's Prime Minister D'Alema's first foreign policy test.	**MMR**: 1. **Turkey wants Italy to extradite the rebel, Abdullah Ocalan**, leader of the Kurdistan Workers' Party, which is seeking Kurdish autonomy in southeastern Turkey. 2. Earlier Monday, while members of D'Alema's government met with Turkish officials who were in Rome for a European ministerial meeting, **thousands of Kurds flooded into Rome** to hold a demonstration and **hunger strike in support of Ocalan**. 3. The **extra effort was prompted** by the arrest last week in Rome of Abdullah Ocalan, the chief of the Turkish Workers Party PKK, Zehetmayr said. 4. **If Italy sends the Kurd leader back to Turkey, he'll be tortured for certain**, said Dino Frisullo, an Italian supporter among the singing, chanting Kurds outside the military hospital.
DPP-Caps-Comb: 1. **Turkey has asked for his extradition and Ocalan has asked for political asylum.** 2. Turkey **stepped up the pressure on Italy for the extradition** of captured Kurdish rebel leader Abdullah Ocalan, warning Sunday that granting him asylum would amount to opening doors to terrorism. 3. **If Italy sends Ocalan back to Turkey, he'll be tortured for certain**, said Dino Frisullo, an Italian supporter among the singing, chanting Kurds outside the military hospital. 4. **Thousands of Kurds living in Romania closed down restaurants, shops and companies to protest the arrest** of leader Abdullah Ocalan by Italian authorities, a newspaper reported Tuesday. 5. **Turkey wants Italy to extradite the rebel, Abdullah Ocalan**, leader of the Kurdistan Workers' Party, which is seeking Kurdish autonomy in southeastern Turkey.	**RL-MMR**: 1. **Turkey wants Italy to extradite the rebel, Abdullah Ocalan**, leader of the Kurdistan Workers' Party, which is seeking Kurdish autonomy in southeastern Turkey. 2. **In Rome, 1,500 Kurds massed** for a second day of demonstrations **outside the military hospital where Ocalan is believed to be held.** 3. **Thousands of Kurds living in Romania closed down restaurants, shops and companies to protest the arrest** of leader Abdullah Ocalan by Italian authorities, a newspaper reported Tuesday. 4. **Greek media and officials leveled strong opposition Sunday to the possible extradition** of Abdullah Ocalan, the arrested Kurdish guerrilla leader, to Greece's traditional rival Turkey.

Table 6: **System summaries of different methods**. Text spans matched (unmatched) with the reference summary are in **blue** (**green**). Redundant spans are in **red**. Spans of the reference covered by RL-MMR are also in **blue**.

sidering both salience and redundancy (best $\lambda = 0.5$ ˜ 0.8) performs much better than only considering salience ($\lambda = 1$) regardless of the specific measures, further indicating the necessity of explicit redundancy avoidance in MDS.

Comparison of Similarity Measures. By varying the x values in Fig. 3, TF-IDF and neural estimations are combined using different weights. Although BERT and SNN (combined with TF-IDF) perform *slightly* better at times, they often require careful hyper-parameter tuning (both x and y). Hence, We use TF-IDF as the representation in MMR throughout our experiments.

4.2.5 Output Analysis

We analyze the outputs of the best-performing methods in Table 6. DPP-Caps-Comb still seems to struggle with redundancy as it extracts three sentences with similar semantics ("Turkey wants Italy to extradite Ocalan"). MMR and DPP-Caps-Comb both extract one sentence regarding a hypothesis that "Ocalan will be tortured", which is not found in the reference. RL-MMR has a more salient and non-redundant summary, as it is end-to-end trained with advances in SDS for sentence representation learning while maintaining the benefits of classical MDS approaches. In contrast, MMR alone only considers lexical similarity; The redundancy measure in DPP-Caps-Comb is pre-trained on one SDS dataset with weak supervision and fixed during the training of DPP.

5 Related Work

Multi-document Summarization. Classical MDS explore both extractive (Erkan and Radev, 2004; Haghighi and Vanderwende, 2009) and abstractive methods (Barzilay et al., 1999; Ganesan et al., 2010). Many neural MDS methods (Yasunaga et al., 2017; Zhang et al., 2018) are merely comparable or even worse than classical methods due to the challenges of large search space and limited training data. Unlike DPP-Caps-Comb (Cho et al., 2019) that incorporates neural measures into classical MDS as features, RL-MMR opts for the opposite by endowing SDS methods with the capability to conduct MDS, enabling the potential of further improvement with advances in SDS.

Bridging SDS and MDS. Initial trials adapting SDS models to MDS (Lebanoff et al., 2018; Zhang et al., 2018) directly reuse SDS models (See et al., 2017; Tan et al., 2017). To deal with the large search space, a sentence ranker is used in the adapted models for candidate pruning. Specifically, Lebanoff et al. (2018) leverages MMR (Carbonell and Goldstein, 1998) to rank sentences, allowing only the words in the top-ranked sentences to appear in the generated summary. Similarly, Zhang et al. (2018) uses topic-sensitive PageRank (Haveliwala, 2002) and computes attention only for the top-ranked sentences. Unlike RL-MMR, these adapted models use hard cutoff and (or) lack end-to-end training, failing to outperform state-of-the-art methods designed specifically for MDS (Gillick and Favre, 2009; Kulesza and Taskar, 2012).

6 Conclusion

We present a reinforcement learning framework for MDS that unifies neural SDS advances and Maximal Marginal Relevance (MMR) through end-to-end learning. The proposed framework leverages the benefits of both neural sequence learning and statistical measures, bridging the gap between SDS and MDS. We conduct extensive experiments on benchmark MDS datasets and demonstrate the superior performance of the proposed framework, especially in handling the large search space and high redundancy of MDS. In the future, we will investigate the feasibility of incorporating classical MDS guidance to abstractive models with large-scale pre-training (Gu et al., 2020) and more challenging settings where each document set may contain hundreds or even thousands of documents.

A Experimental Details

A.1 Dataset Statistics

We list in Table 7 the details of datasets used in our experiments. SDS methods usually take the first 256 or 512 words in the document as model input, which is infeasible for the input size of MDS (5,000 to 7,000 words on average).

Dataset	$\#\mathcal{D}$	$\sum\lvert\mathcal{D}\rvert$	$\overline{\sum\lvert D_i\rvert}$	$\min\sum\lvert D_i\rvert$	$\max\sum\lvert D_i\rvert$	$\overline{\sum\lvert s_j\rvert}$
DUC 2003	30	298	259.0	98	502	6830.5
DUC 2004	50	500	265.4	152	605	6987.1
TAC 2008-2010	138	1380	236.9	41	649	5978.4
TAC 2011	44	440	204.9	48	486	5146.0

Table 7: **Dataset statistics**. $\#\mathcal{D}$ and $\sum|\mathcal{D}|$ denote the number of document sets and the number of documents in total. $\overline{\sum|D_i|}$, $\min\sum|D_i|$, and $\max\sum|D_i|$ denote the average / min / max number of sentences in a document set. $\overline{\sum|s_j|}$ denotes the average number of words in a document set.

A.2 Remarks on Experimental Setup

We note that there are plenty of inconsistencies in the previous work on MDS and some results cannot be directly compared with ours. Specifically, there are three major differences that may lead to incomparable results as follows. First, while in the original DUC competitions an output length of 665 bytes is adopted, more recent studies mostly take a length limit of 100 words following Hong et al. (2014), and some do not have any length limit (usually resulting in higher numbers). Second, some papers report ROUGE recall (Yasunaga et al., 2017; Wang et al., 2017; Cao et al., 2017; Nayeem et al., 2018; Gao et al., 2019) while others (including ours) report ROUGE F1 following the trend on SDS (Lebanoff et al., 2018; Zhang et al., 2018; Cho et al., 2019). Third, while DUC 2004 and TAC 2011 are usually used as test sets, the training sets used in different studies often vary. We follow the same setup as the compared methods to ensure a fair comparison.

A.3 Description of Extractive Baselines

SumBasic (Vanderwende et al., 2007) is based on word frequency and hypothesizes that the words occurring frequently are likely to be included in the summary. KLSumm (Haghighi and Vanderwende, 2009) greedily extracts sentences as long as they can lead to a decrease in KL divergence. LexRank (Erkan and Radev, 2004) computes sentence salience based on eigenvector centrality in a graph-based representation. Centroid (Hong et al., 2014) measures sentence salience based on its cosine similarity with the document centroid, which is similar to the salience measure in MMR. ICSISumm (Gillick and Favre, 2009) uses integer linear programming (ILP) to extract a globally optimal set of sentences that can cover the most important concepts in the document set. DPP (Kulesza and Taskar, 2012) handles sentence salience and redundancy through the determinantal point processes, in which many handcrafted features such as sentence length, sentence position, and personal pronouns are used. DPP-Caps-Comb (Cho et al., 2019) improves upon DPP (Kulesza and Taskar, 2012) by replacing or combining the existing sentence salience and redundancy measures with capsule networks (Hinton et al., 2018). rnn-ext + RL (Chen and Bansal, 2018) is the SDS method that we base our work on. It is pre-trained on the CNN/Daily Mail SDS dataset (Nallapati et al., 2016), and we test its performance with or without fine-tuning on the MDS training set. The pre-trained abstractor in rnn-ext + RL is not used as we found it consistently leads to worse performance.

A.4 Description of Abstractive Baselines

Opinosis (Ganesan et al., 2010) generates summaries by finding salient paths on a word co-occurrence graph of the documents. Extract+Rewrite (Song et al., 2018) scores sentences by LexRank (Erkan and Radev, 2004) and employs an encoder-decoder model pre-trained on Gigaword (Graff et al., 2003) to generate a title-like summary for each sentence. PG (See et al., 2017) is one typical abstractive summarization method for SDS that conducts sequence-to-sequence learning with copy mechanism. PG-MMR (Lebanoff et al., 2018) adapts PG (See et al., 2017) to MDS by concatenating all of the documents in one document set and running pre-trained PG under the constraints of MMR on its vocabulary.

A.5 Implementation Details

Following common practice, we only consider extracting sentences with reasonable length (*i.e.*, 8 to 55 words) (Erkan and Radev, 2004; Yasunaga et al., 2017). We filter sentences that start with a quotation mark or do not end with a period (Wong et al., 2008; Lebanoff et al., 2018). For MMR, we set $\lambda = 0.6$ following Lebanoff et al. (2018). By default, we use TF-IDF features and cosine similarity for both sentence salience and redundancy measurement in MMR. We prefer such measurements

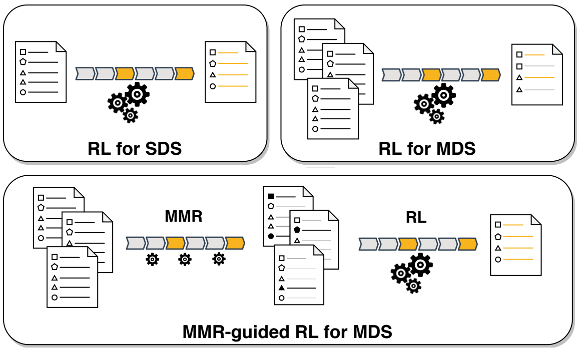

Figure 4: We use the same shape to denote semantically similar sentences. Directly applying RL to MDS encounters large search space and high redundancy, resulting in repeated summaries. MMR guides RL by attending to salient and non-redundant candidates.

instead of ROUGE-based measures (Lebanoff et al., 2018) and advanced neural-based measures (Cho et al., 2019; Devlin et al., 2019; Latkowski, 2018) as they are faster to compute and comparable in performance. We pre-train rnn-ext + RL (Chen and Bansal, 2018) on the CNN/Daily Mail SDS dataset (Nallapati et al., 2016) as in Lebanoff et al. (2018) but continue fine-tuning on the in-domain training set. We train RL-MMR using an Adam optimizer with learning rate 5e-4 for RL-MMR$_{\text{SOFT-ATTN}}$ and 1e-3 for the other variants without weight decay. we tested various reward functions, such as different ROUGE metrics, the MMR scores, and intrinsic measures based on sentence representation, and found them comparable or worse than the current one. One may also use other semantic metrics such as MoverScore (Zhao et al., 2019) and FAR (Mao et al., 2020).

B Detailed Analysis of RL-MMR

Additional Illustration. We provide an illustration in Fig. 4 to better elucidate the motivation of RL-MMR. Note that RL-MMR is mostly based on SDS architectures while achieving state-of-the-art performance on MDS, while existing combination approaches that achieve decent performance (*e.g.*, DPP-Caps) are based on MDS architectures.

Runtime and Memory Usage. RL-MMR is time and space efficient for two reasons. First, its hierarchical sentence encoding is much faster than a word-level sequence encoding mechanism while still capturing global context. Second, the guidance of MMR provides RL-MMR with a “warmup” effect, leading to faster convergence. In our experiments, one epoch of RL-MMR takes 0.87 to 0.91s on a GTX 1080 GPU with less than 1.2 GB memory usage. The number of epochs is set to 10,000 and we adopt early stopping – the training process terminates if RL-MMR cannot achieve better results on the validation set after 30 continuous evaluations. As a result, the runs often terminate before 5,000 epochs, and the overall training time ranges from 40 to 90 minutes.

Detailed Examples. In Table 8, we show the extracted summaries of vanilla RL and RL-MMR for the same document set. Without the guidance of MMR, the RL agent is much more likely to extract redundant sentences. In the first example, RL extracts two semantically equivalent sentences from two different documents. These two sentences would have similar sentence representation $\boldsymbol{h}_j^i$, and the latent state representation $\boldsymbol{g}_t$ itself might not be enough to avoid redundant extraction. In contrast, RL-MMR selects diverse sentences after extracting the same original sentence as RL thanks to the explicit redundancy measure in MMR. In the second example, the issue of redundancy in RL is even more severe – all four extracted sentences of RL are covering the same aspect of the news. RL-MMR again balances sentence salience and redundancy better than vanilla RL, favoring diverse sentences. Such results imply that pure neural representation is insufficient for redundancy avoidance in MDS and that classical approaches can serve as a complement.

RL: 1. President Clinton made an unusual, direct appeal to North Korea on Saturday to set aside any nuclear ambitions in favor of strengthening ties to South Korea and the United States.
2. SEOUL, South Korea (AP) U.S. President Bill Clinton won South Korea's support Saturday for confronting North Korea over a suspected nuclear site, and he warned the North's communist leaders not to squander **an historic chance to make a lasting peace** on the peninsula.
3. SEOUL, South Korea (AP) U.S. President Bill Clinton won South Korea's support Saturday for confronting North Korea over a suspected nuclear site, and he warned the North's communist leaders not to squander **a chance to achieve lasting peace** on the peninsula.

RL-MMR: 1. SEOUL, South Korea (AP) U.S. President Bill Clinton won South Korea's support ... an historic chance to make a lasting peace on the peninsula.
2. The North Koreans have denied that the complex, which is being built on a mountainside about 25 miles northeast of Yongbyon, the former North Korean nuclear research center, is intended to be used for a nuclear weapons program.
3. The United States and North Korea are set to resume talks Friday about inspections of an underground North Korean site suspected of being used to produce nuclear weapons.

RL: 1. Galina Starovoitova, 52, a leader of the liberal Russia's Democratic Choice party, **was shot dead** by unidentified assailants on the stairs of her apartment building in St. Petersburg on Friday night.
2. A liberal lawmaker who planned to run for president in Russia's next elections **was shot to death** Friday in St. Petersburg, **police said**.
3. A liberal lawmaker who planned to run for president in Russia's next elections **was shot to death** Friday in St. Petersburg, **police said**.
4. A liberal lawmaker who planned to run for president in Russia's next elections **was killed** Friday in St. Petersburg, **a news report said**.

RL-MMR: 1. Galina Starovoitova, 52, a leader of the liberal Russia's Democratic Choice party, was shot dead by unidentified assailants on the stairs of her apartment...
2. Starovoitova tried to run for president in the 1996 elections but her registration was turned down for technical reasons.
3. Like that fictional crime, which shone a light on social ferment in the St. Petersburg of its day, the death of Starovoitova was immediately seized upon as a seminal event in the Russia of the late 1990s.
4. She was a member of the Russian parliament and a recently declared candidate for governor of the region around St. Petersburg.

Table 8: **Case studies reveal the insufficient redundancy measure in vanilla RL**. Note that the 2nd and 3rd extracted sentences of RL in the second example are the same but from different documents, which is quite typical in news reports.

Improving Neural Topic Models using Knowledge Distillation

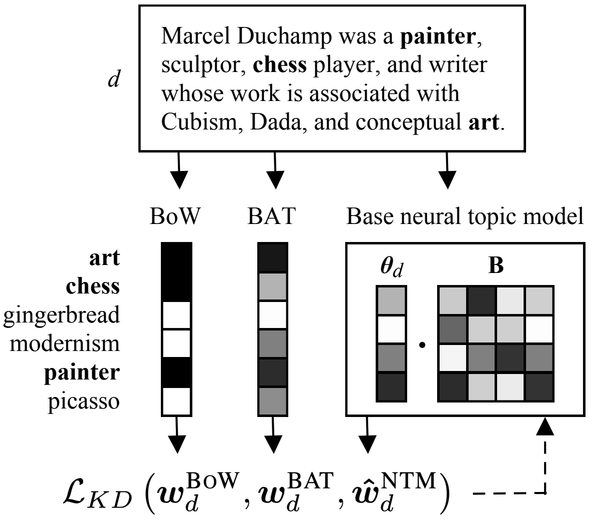
Abstract

Topic models are often used to identify human-interpretable topics to help make sense of large document collections. We use knowledge distillation to combine the best attributes of probabilistic topic models and pretrained transformers. Our modular method can be straightforwardly applied with any neural topic model to improve topic quality, which we demonstrate using two models having disparate architectures, obtaining state-of-the-art topic coherence. We show that our adaptable framework not only improves performance in the aggregate over all estimated topics, as is commonly reported, but also in head-to-head comparisons of aligned topics.

1 Introduction

The core idea behind the predominant *pretrain and fine-tune* paradigm for transfer learning in NLP is that general language knowledge, gleaned from large quantities of data using unsupervised objectives, can serve as a foundation for more specialized endeavors. Current practice involves taking the full model that has amassed such general knowledge and fine-tuning it with a second objective appropriate to the new task (see Raffel et al., 2019, for an overview). Using these methods, pre-trained transformer-based language models (e.g., BERT, Devlin et al., 2019) have been employed to great effect on a wide variety of NLP problems, thanks, in part, to a fine-grained ability to capture aspects of linguistic context (Clark et al., 2019; Liu et al., 2019; Rogers et al., 2020).

However, this paradigm introduces a subtle but insidious limitation that becomes evident when the downstream application is a topic model. A topic model may be cast as a (stochastic) autoencoder (Miao et al., 2016), and we could fine-tune a pretrained transformer with an identical document reconstruction objective. But in replacing the original topic model, we lose the property that makes it desirable: its interpretability. The transformer gains its contextual power from its ability to exploit a huge number of parameters, while the interpretability of a topic model comes from a dramatic dimensionality reduction.



Marcel Duchamp was a **painter**, sculptor, **chess** player, and writer whose work is associated with Cubism, Dada, and conceptual **art**.

Figure 1: Improving a base neural topic model with knowledge distillation. A document is mapped through both a standard BoW representation and a **B**ERT-based **A**uto-encoder "**T**eacher" (BAT), yielding two distributions over words. These are used as the ground truth in the "student" topic model's document reconstruction loss $\mathcal{L}_{KD}$ (backpropagated along the dotted line). Crucially, the BAT distribution assigns mass to unobserved but related terms (unbolded).

We combine the advantages of these two approaches—the rich contextual language knowledge in pretrained transformers and the intelligibility of topic models—using *knowledge distillation* (Hinton et al., 2015). In the original formulation, knowledge distillation involves training a parameter-rich *teacher* classifier on large swaths

---

[*] Equal contribution.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1752–1771,
November 16–20, 2020.

of data, then using its high-quality probability estimates over outputs to guide a smaller *student* model. Since the information contained in these estimates is useful—a picture of an ox will yield higher label probabilities for BUFFALO than APRICOT—the student needs less data to train and can generalize better.

We show how this principle can apply equally well to improve unsupervised topic modeling, which to our knowledge has not previously been attempted. While distillation usually involves two models of the same type, it *can* also apply to models of differing architectures. Our method is conceptually quite straightforward: we fine-tune a pretrained transformer (Sanh et al., 2019) on a document reconstruction objective, where it acts in the capacity of an autoencoder. When a document is passed through this BERT autoencoder, it generates a distribution over words that includes unobserved but related terms. We then incorporate this distilled document representation into the loss function for topic model estimation. (See Figure 1.)

To connect this method to the more standard supervised knowledge distillation, observe that the unsupervised "task" for both an autoencoder and a topic model is the reconstruction of the original document, i.e. prediction of a distribution over the vocabulary. The BERT autoencoder, as "teacher", provides a dense prediction that is richly informed by training on a large corpus. The topic model, as "student", is generating its own prediction of that distribution. We use the former to guide the latter, essentially as if predicting word distributions were a multi-class labeling problem.[1] Our approach, which we call **B**ERT-based **A**utoencoder as **T**eacher **(BAT)**, obtains best-in-class results on the most commonly used measure of topic coherence, normalized pointwise mutual information (NPMI, Aletras and Stevenson, 2013) compared against recent

state-of-the-art-models that serve as our baselines.

In order to accomplish this, we adopt neural topic models (NTM, Miao et al., 2016; Srivastava and Sutton, 2017; Card et al., 2018; Burkhardt and Kramer, 2019; Nan et al., 2019, *inter alia*), which use various forms of black-box distribution-matching (Kingma and Welling, 2014; Tolstikhin et al., 2018).[2] These now surpass traditional methods (e.g. LDA, Blei, 2003, and variants) in topic coherence. In addition, it is easier to modify the generative model of a neural topic model than for a classic probabilistic latent-variable model, where changes generally require investing effort in new variational inference procedures or samplers. In fact, because we leave the base NTM unmodified, our approach is flexible enough to easily accommodate *any* neural topic model, so long as it includes a word-level document reconstruction objective. We support this claim by demonstrating improvements on models based on both Variational (Card et al., 2018) and Wasserstein (Nan et al., 2019) auto-encoders.

To summarize our contributions:

- We introduce a novel coupling of the knowledge distillation technique with generative graphical models.
- We construct knowledge-distilled neural topic models that achieve better topic coherence than their counterparts without distillation on three standard English-language topic-modeling datasets.
- We demonstrate that our method is not only effective but modular, by improving topic coherence in a base state-of-the-art model by modifying only a few lines of code.[3]
- In addition to showing overall improvement across topics, our method preserves the topic analysis of the base model and improves coherence on a topic-by-topic basis.

2 Methodology

2.1 Background on topic models

Topic modeling is a well-established probabilistic method that aims to summarize large document corpora using a much smaller number of latent *topics*. The most prominent instantiation, LDA (Blei, 2003), treats each document as a mixture over K latent topics, $\boldsymbol{\theta}_d$, where each topic is a distribution

---

[1] An interesting conceptual link here can be found in Latent Semantic Analysis (LSA, Landauer and Dumais, 1997), an early predecessor of today's topic models. The original discussion introducing LSA has a very autoencoder-like flavor, explicitly illustrating the deconstruction of a collection of sparsely represented documents and the reconstruction of a dense document-word matrix.

[2] As a standard example, Srivastava and Sutton (2017) encode a document's bag-of-words with a neural network to parameterize the latent topic distribution, then sample from the distribution to reconstruct the BoW.

[3] See Appendix F. Our full implementation, including dataset preprocessing, is available at `github.com/ahoho/kd-topic-models`.

over words β_k. By presenting topics as ranked word lists and documents in terms of their probable topics, topic models can provide legible and concise representations of both the entire corpus and individual documents.

In classical topic models like LDA, distributions over the latent variables are estimated with approximate inference algorithms tailored to the generative process. Changes to the model specification—for instance, the inclusion of a supervised label—requires attendant changes in the inference method, which can prove onerous to derive. For some probabilistic models, this problem may be circumvented by the variational auto-encoder (VAE, Kingma and Welling, 2014), which introduces a *recognition model* that approximates the posterior with a neural network. As a result, *neural topic models* have capitalized on the VAE framework (Srivastava and Sutton, 2017; Card et al., 2018; Burkhardt and Kramer, 2019, *inter alia*) and other deep generative models (Wang et al., 2019; Nan et al., 2019). In addition to their flexibility, the best models now yield more coherent topics than LDA.

Although our method (Section 2.3) is agnostic as to the choice of neural topic model, we borrow from Card et al. (2018) for both formal exposition and our base implementation (Section 3). Card et al. (2018) develop SCHOLAR, a generalization of the first successful VAE-based neural topic model (PRODLDA, Srivastava and Sutton, 2017). The generative story is broadly similar to that of LDA, although the uniform Dirichlet prior is replaced with a logistic normal ($\mathcal{LN}$):[4]

For each document d:
- Draw topic distribution $\boldsymbol{\theta}_d \sim \mathcal{LN}(\boldsymbol{\alpha}_0)$
- For each word w_{id} in the document:
  $w_{id} \sim \text{Multinomial}\left(1, f(\boldsymbol{\theta}_d, \mathbf{B})\right)$

Following PRODLDA, $\mathbf{B}$ is a $K \times V$ matrix where each row corresponds to the kth topic-word probabilities in log-frequency space. The multinomial distribution over a document's words is parameterized by

$$f(\boldsymbol{\theta}_d, \mathbf{B}) = \sigma\left(\boldsymbol{m} + \boldsymbol{\theta}_d^\top \mathbf{B}\right) \tag{1}$$

where $\boldsymbol{m}$ is a vector of fixed empirical background word frequencies and $\sigma(\cdot)$ is the softmax function. We highlight that each document is treated as a bag of words, $\boldsymbol{w}_d^{\text{BoW}}$.

To perform inference on the model, VAE-based models like SCHOLAR approximate the true intractable posterior $p(\boldsymbol{\theta}_d \mid \cdot)$ with a neural *encoder* network $g(\boldsymbol{w}_d)$ that parameterizes the variational distribution $q\left(\boldsymbol{\theta}_d \mid g(\cdot)\right)$ (here, a logistic normal with diagonal covariance). The Evidence Lower BOund (ELBO) is therefore

$$\begin{aligned}\text{ELBO} &= \mathbb{E}_{q(\boldsymbol{\theta}_d \mid \cdot)}\left[\mathcal{L}_R\right] \\ &\quad - \text{KL}\left[q\left(\boldsymbol{\theta}_d \mid \boldsymbol{w}_d^{\text{BoW}}, \boldsymbol{x}_d\right) \,||\, p\left(\boldsymbol{\theta}_d\right)\right], \quad (2)\\ \mathcal{L}_R &= \left(\boldsymbol{w}_d^{\text{BoW}}\right)^\top \log f(\boldsymbol{\theta}_d, \mathbf{B}), \quad (3)\end{aligned}$$

which is optimized with stochastic gradient descent. The form of the reconstruction error $\mathcal{L}_R$ is a consequence of the independent multinomial draws.

2.2 Background on knowledge distillation

It is instructive to think of Eq. (1) as a latent logistic regression, intended to approximate the distribution over words in a document. Under this lens, the neural topic model outlined above can be cast as a multi-label classification problem. Indeed, it accords with the standard structure: there is a softmax over logits estimated by a neural network, coupled with a cross-entropy loss.

However, because $\boldsymbol{w}_d^{\text{BoW}}$ is a sparse bag of words, the model is limited in its ability to generalize. During backpropagation (Eq. (3)), the topic parameters will only update to account for observed terms, which can lead to overfitting and topics with suboptimal coherence.

In contrast, dense document representations can capture rich information that bag-of-words representations cannot.

These observations motivate our use of *knowledge distillation* (KD, Hinton et al., 2015). The authors argue that the knowledge learned by a large "cumbersome" classifier on extensive data—e.g., a deep neural network or an ensemble—is expressed in its probability estimates over classes, and not just contained in its parameters. Hence, these teacher estimates for an input may be repurposed as soft labels to train a smaller student model. In practice, the loss against the true labels is linearly interpolated with a loss against the teacher probabilities, Eq. (4). We discuss alternative ways to integrate outside information in Section 6.

---

[4] This choice is because the reparameterization trick behind VAEs used to be limited to location-scale distributions, but recent developments (e.g., Figurnov et al., 2018) have lifted that restriction, as Burkhardt and Kramer (2019) demonstrate with several Dirichlet-based NTMs using VAEs.

2.3 Combining neural topic modeling with knowledge distillation

The knowledge distillation objective. To apply KD to a "base" neural topic model, we replace the reconstruction term $\mathcal{L}_R$ in Eq. (3) with $\mathcal{L}_{KD}$, as follows:

$$\begin{aligned}\boldsymbol{w}_d^{\text{BAT}} &= \sigma\left(\boldsymbol{z}_d^{\text{BAT}}/T\right) N_d \\ \hat{\boldsymbol{w}} &= f(\boldsymbol{\theta}_d, \mathbf{B}; T) \\ \mathcal{L}_{KD} &= \lambda T^2 \left(\boldsymbol{w}_d^{\text{BAT}}\right)^\top \log \hat{\boldsymbol{w}} + (1-\lambda)\mathcal{L}_R \quad (4)\end{aligned}$$

Here, $\boldsymbol{z}_d^{\text{BAT}}$ are the logits produced by the teacher network for a given input document d, meaning that $\boldsymbol{w}_d^{\text{BAT}}$ acts as a smoothed pseudo-document. T is the softmax temperature, which controls how diffuse the estimated probability mass is over the words (hence $f(\cdot; T)$ is Eq. (1) with the corresponding scaling). This differs from the original KD in two ways: (a) it scales the estimated probabilities by the document length N_d, and (b) it uses a multi-label loss.

The teacher model. We generate the teacher logits $\boldsymbol{z}^{\text{BAT}}$ using the pretrained transformer DISTILBERT (Sanh et al., 2019), itself a distilled version of BERT (Devlin et al., 2019).[5] BERT-like models are generally pretrained on large domain-general corpora with a language-modeling like objective, yielding an ability to capture nuances of linguistic context more effectively than bag-of-words models (Clark et al., 2019; Liu et al., 2019; Rogers et al., 2020). Mirroring the NTM's formulation as a variational auto-encoder, we treat DISTILBERT as a *deterministic* auto-encoder, fine-tuning it with the document-reconstruction objective $\mathcal{L}_R$ on the same dataset. Thus, we use a **B**ERT-based **A**utoencoder as our **T**eacher model, hence **BAT**.[6]

Clipping the logit distribution. Depending on preprocessing, V may number in the tens of thousands of words. This leads to a long tail of probability mass assigned to unlikely terms, and breaks standard assumptions of sparsity. Tang et al. (2020), working in a classification setting, find that truncating the logits to the top-n classes and assigning uniform mass to the rest improves accuracy. We instead choose the top $c\,N_d, c \in \mathbb{R}^+$ logits and assign *zero* probability to the remaining elements to enforce sparsity.

3 Experimental Setup

3.1 Data and Metrics

We validate our approach using three readily available datasets that vary widely in domain, corpus and vocabulary size, and document length: 20 Newsgroups (`20NG`, Lang, 1995),[7] Wikitext-103 (`Wiki`, Merity et al., 2017),[8] and IMDb movie reviews (`IMDb`, Maas et al., 2011).[9] These are commonly used in neural topic modeling, with preprocessed versions provided by various authors; see references in Table 1 for details. For consistency with prior work, we use a train/dev/test split of 48/12/40 for `20NG`, 70/15/15 for `Wiki`, and 50/25/25 for `IMDb`.[10]

We seek to discover a latent space of topics that is meaningful and useful to people (Chang et al., 2009). Accordingly, we evaluate topic coherence using normalized mutual pointwise information (NPMI), which is significantly correlated with human judgments of topic quality (Aletras and Stevenson, 2013; Lau et al., 2014) and widely used to evaluate topic models.[11] We follow precedent and calculate (internal) NPMI using the top ten words in each topic, taking the mean across the NPMI scores for individual topics. Internal NPMI is estimated with reference co-occurrence counts from a held-out dataset from the same corpus,

---

[5] DISTILBERT's light weight accommodates longer documents, necessary for topic modeling. Even with this change, we divide very long documents into chunks, estimating logits for each chunk and taking the pointwise mean. More complex schemes (i.e., LSTMs, Hochreiter and Schmidhuber, 1997) yielded no benefit.

[6] A reader familiar with variational NTMs may notice that we haven't mentioned an obvious means of incorporating representations from a pretrained transformer: encoding the document representation from a BERT-like model. This yields unimpressive results; see Appendix D.1.

[7] `qwone.com/~jason/20Newsgroups`

[8] `s3.amazonaws.com/research.metamind.io/wikitext/wikitext-103-v1.zip`

[9] `ai.stanford.edu/~amaas/data/sentiment`

[10] The splits are used to estimate NPMI. Dev splits are used to select hyperparameters, and test splits are run after hyperparameters are selected and frozen.

[11] We also obtain competitive results for document perplexity, which has also been used widely but correlates negatively with human coherence evaluations (Chang et al., 2009).

i.e., the dev or test split. While internal NPMI is the metric of choice for most prior work, we also provide external NPMI results using Gigaword 5 (Parker et al., 2011), following Card et al. (2018).

3.2 Experimental Baselines

We select three experimental baseline models that represent diverse styles of neural topic modeling.[12] Each achieves the highest NPMI on the majority of its respective datasets, as well as a considerable improvement over previous neural and non-neural topic models (such as Srivastava and Sutton, 2017; Miao et al., 2016; Ding et al., 2018). All our baselines are roughly contemporaneous with one another, and had yet to be compared in a head-to-head fashion prior to our work.

SCHOLAR. Card et al. (2018) use a VAE-based (Kingma and Welling, 2014) neural topic modeling setup (as introduced in Srivastava and Sutton, 2017) with a logistic normal prior to approximate the Dirichlet, and provide an elegant way to incorporate document metadata.

DVAE. Burkhardt and Kramer (2019) use a Dirichlet prior, where its reparameterization is enabled by rejection sampling variational inference. This allows it to tap into the same generative story as the original LDA formulations of Blei (2003), and to enjoy the advantageous properties of the Dirichlet like multi-modality (Wallach et al., 2009; Wang et al., 2020).

W-LDA. Nan et al. (2019) forego the VAE in favor of a Wasserstein auto-encoder (Tolstikhin et al., 2018), using a Dirichlet prior that is matched by minimizing Maximum Mean Discrepancy. They find the method leads to state-of-the-art coherence on several datasets and encourages topics to exhibit greater word diversity.

We demonstrate the modularity of our core innovation by combining our method with both SCHOLAR and W-LDA (Section 4).

3.3 Our Models and Settings

As discussed in Section 2.3, our approach relies on a "base" neural topic model and unnormalized probabilities over words estimated by a transformer as "teacher". We discuss each in turn.

Neural topic models augmented with knowledge distillation. We experiment with both SCHOLAR and W-LDA as base models. The former constitutes our primary model and point of comparison with baselines, while the latter is a proof-of-concept that attests to our method's modularity; we added knowledge distillation to W-LDA with only a few lines of code (Appendix F). We evaluate both at $K = 50$ and $K = 200$ topics.

We tune using NPMI, with reference co-occurrence counts taken from a held-out development set from the relevant corpus. For our baselines, we use the publicly-released author implementations.[13] While we generally attempt to retain the original hyperparameter settings when available, we do perform an exhaustive grid search on the SCHOLAR baselines and SCHOLAR+BAT to ensure fairness in comparison (ranges, optimal values, and other details in Appendix E.1).

Our method also introduces additional hyperparameters: the weight for KD loss, λ (Eq. (4)); the softmax temperature T; and the proportion of the word-level teacher logits that we retain (relative to document length, see clipping in Section 2.3). For most dataset-K pairs, we find that we can improve topic quality under most settings, with a relatively small set of values for each hyperparameter leading to better results. In fact, following the extensive search on SCHOLAR+BAT, we found we could tune W-LDA within a few iterations.

Topic models rely on random sampling procedures, and to ensure that our results are robust, we report the average values across five runs (previously unreported by the authors of our baselines).

The DISTILBERT teacher. We fine-tune a modified version of DISTILBERT with the same document reconstruction objective as the NTM ($\mathcal{L}_R$, Eq. (3)) on the training data. Specifically, DISTILBERT maps a WordPiece-tokenized (Wu et al., 2016) document d to an l-dimensional hidden vector with a transformer (Vaswani et al., 2017), then back to logits over V words (tokenized with the same scheme as the topic model). For long documents, we split into blocks of 512 tokens and mean-pool the transformer outputs. We use the pretrained model made available by the authors (Wolf

---

[12] This use of "baseline" should not be confused with the "base" neural topic model augmented by knowledge distillation (Section 2.3).

[13] SCHOLAR: `github.com/dallascard/scholar`
W-LDA: `github.com/awslabs/w-lda`
DVAE: `github.com/sophieburkhardt/dirichlet-vae-topic-models`
For augmented models we start with our own reimplementations of the baseline approaches in a common codebase, validated by obtaining comparable results to the original authors on their datasets.

	$K = 50$			$K = 200$		
	20NG	**Wiki**	**IMDb**	**20NG**	**Wiki**	**IMDb**
DVAE	0.340	0.490	0.145	0.316	0.450	0.160

SCHOLAR	0.322 (0.007)	0.494 (0.005)	0.168 (0.002)	0.263 (0.002)	0.473 (0.005)	0.140 (0.001)
SCH. + BAT	**0.354** (0.004)	**0.521** (0.009)	**0.182** (0.002)	**0.332** (0.002)	**0.513** (0.001)	**0.175** (0.003)

Table 2: The NPMI for our baselines (Section 3.2) compared with BAT (explained in Section 2.3) using SCHOLAR as our base neural architecture. We achieve better NPMI than all baselines across three datasets and $K = 50$, $K = 200$ topics. We use 5 random restarts and report the standard deviation.

et al., 2019). We train until perplexity converges on the same held-out dev set used in the topic modeling setting. Unsurprisingly, DISTILBERT achieves dramatically lower perplexity than all topic model baselines. Note that we need only train the model once per corpus, and can experiment with different NTM variations using the same z^{BAT}.

4 Results and Discussion

Using the VAE-based SCHOLAR as the base model, topics discovered using BAT are more coherent, as measured via NPMI, than previous state-of-the-art baseline NTMs (Table 2), improving on the DVAE and W-LDA baselines, and the baseline of SCHOLAR without the KD augmentation. We establish the robustness of our approach's improvement by taking the mean across multiple runs with different random seeds, yielding consistent improvement over all baselines for all the datasets. We validate the approach using a smaller and larger number of topics, $K = 50$ and 200, respectively.

In addition to its improved performance, BAT can apply straightforwardly to other models, because it makes very few assumptions about the base model—requiring only that it rely on a word-level reconstruction objective, which is true of the majority of neural topic models proposed to date. We illustrate this by using the Wasserstein auto-encoder (W-LDA) as a base NTM, showing in Table 3 that BAT improves on the unaugmented model.[14]

We report the dev set results (corresponding to the test set results in Tables 2 and 3) in Appendix A—the same pattern of results is obtained, for all the models.

Finally, we also compute NPMI using reference counts from an external corpus (Gigaword 5, Parker et al., 2011) for SCHOLAR and SCHOLAR+BAT (Table 4). We find the same patterns generally hold: in all but one setting (`Wiki`, $K = 50$), BAT improves topic coherence relative to SCHOLAR. These external NPMI results suggest that our model avails itself of the distilled general language knowledge from pretrained BERT, and moreover that our fine-tuning procedure does not overfit to the training data.

	20NG	**Wiki**	**IMDb**
W-LDA	0.279 (0.010)	**0.494** (0.012)	0.136 (0.008)
+BAT	**0.299** (0.010)	**0.505** (0.014)	**0.162** (0.003)

Table 3: Mean NPMI (s.d.) across 5 runs for W-LDA (Nan et al., 2019) and W-LDA+BAT for $K = 50$, showing improvement on two of three datasets. This demonstrates that our method is *modular* and can be used with base neural topic models that vary significantly in architecture.

K		**SCHOLAR**	**+BAT**
50	`20ng`	0.147 (0.002)	**0.170** (0.006)
	`Wiki`	**0.193** (0.006)	**0.187** (0.004)
	`IMDb`	0.149 (0.003)	**0.161** (0.003)
200	`20ng`	0.111 (0.001)	**0.171** (0.002)
	`Wiki`	0.177 (0.003)	**0.190** (0.008)
	`IMDb`	0.122 (0.002)	**0.159** (0.003)

Table 4: External NPMI (s.d.) for the base SCHOLAR and SCHOLAR+BAT. Models selected according to performance on the development set using internal NPMI.

5 Impact of BAT on Individual Topics

Following standard practice, we have established that our models discover more coherent topics *on average* when compared to others (Tables 2 and 3).

---

[14] We note that the W-LDA baseline did not tune well on 200 topics, further complicated by the model's extensive run time. As such, we focus on augmenting that model for 50 topics, consistent with the number of topics on which Nan et al. (2019) report their results. We add preliminary results using BAT with DVAE in Appendix C.

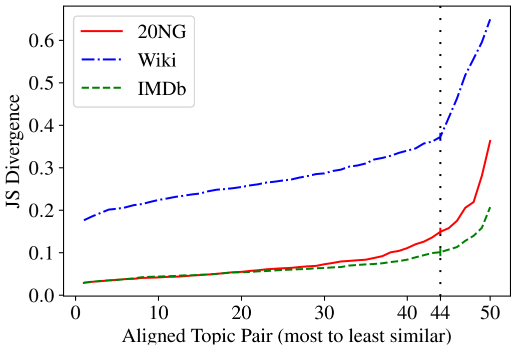

Figure 2: Jensen-Shannon divergence for aligned topic pairs in the SCHOLAR and SCHOLAR+BAT models.

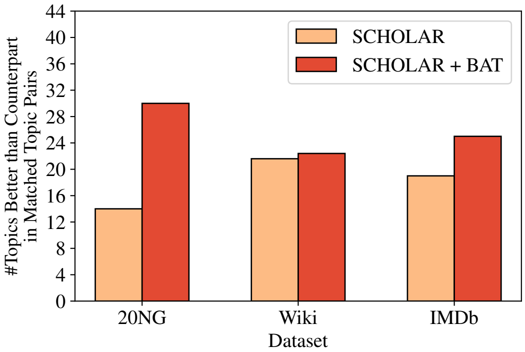

Figure 3: Number of matched topic pairs where SCHOLAR+BAT improves coherence, compared with the number of matched pairs where the baseline improves coherence.

Now, we look more closely at the extent to which those improvements are *meaningful* at the level of individual topics. To do so we directly compare topics discovered by the baseline neural topic model (SCHOLAR) with corresponding topics obtained when that model is augmented with BAT, looking at the NPMIs of the corresponding topics as well as considering them qualitatively.

We align the topics in the base and augmented SCHOLAR models using a variation of competitive linking, which produces a greedy approximation to optimal weighted bipartite graph matching (Melamed, 2000). A fully connected weighted bipartite graph is constructed by linking all topic pairs across (but not within) the two models, with the weight for a topic pair being the similarity between their word distributions as measured by Jenson-Shannon (JS) divergence (Wong and You, 1985; Lin, 1991). We pick the pair (t_i, t_j) with the lowest JS divergence and add it to the resulting alignment, then remove t_i and t_j from consideration and iterate until no pairs are left. The resulting aligned topic pairs can then be sorted by their JS divergences to directly compare corresponding topics.[15]

Fig. 2 shows the JS-divergences for aligned topic pairs, for our three corpora. Based on visual inspection, we choose the 44 most aligned topic pairs as being meaningful for comparison; beyond this point, the topics do not bear a conceptual relationship (using the same threshold for the three datasets for simplicity).

When we consider these conceptually related topic pairs, we see that the model augmented with BAT has the topic with the higher NPMI value more often across all three datasets (Fig. 3). This means that BAT is not just producing improvements in the aggregate (Section 4): its effect can be interpreted more specifically as identifying the same space of topics generated by an existing model and, in most cases, improving the coherence of individual topics. This highlights the modular value of our approach.

Table 5 provides qualitative discussion for one example from each corpus, which we have selected for illustration from a single randomly selected run of the baseline SCHOLAR and SCHOLAR+BAT models for $K = 50$. We find that, consistent with prior work on automatic evaluation of topic models, differences in NPMI do appear to correspond to recognizable subjective differences in topic quality. So that readers may form their own judgments, Appendix G presents 15 aligned pairs for each corpus, selected randomly by stratifying across levels of alignment quality to create a fair sample to review.

6 Related Work

Integrating embeddings into topic models. A key goal in our use of knowledge distillation is to incorporate relationships between words that may not be well supported by the topic model's input documents alone. Some previous topic models have sought to address this issue by incorporating external word information, including word senses (Ferrugento et al., 2016) and pretrained word embeddings (Hu and Tsujii, 2016; Yang et al., 2017; Xun et al., 2017; Ding et al., 2018). More recently, Bianchi et al. (2020) have incorporated BERT embeddings into the encoder to improve

---

[15] Note that more similar topics have lower JS-divergence, so we are seeking to minimize rather than maximize total weight. We use JS-divergence because it is conveniently symmetric and finite.

		NPMI	Topic
`20ng`	SCHOLAR	0.454	nhl hockey player coach ice playoff team league stanley european
	SCHOLAR+BAT	0.523	nhl hockey player team coach playoff cup wings stanley leafs
`Wiki`	SCHOLAR	0.547	jtwc jma typhoon monsoon luzon geophysical pagasa guam cyclone southwestward
	SCHOLAR+BAT	0.621	jtwc jma typhoon meteorological intensification monsoon dissipating shear outflow trough
`IMDb`	SCHOLAR	0.197	adaptation version novel bbc versions jane kenneth handsome adaptations faithful
	SCHOLAR+BAT	0.218	adaptation novel book read books faithful bbc version versions novels

Table 5: Selected examples of SCHOLAR+BAT improving on topics from SCHOLAR. We observe that the improved `20ng` topic is more cleanly focused on the NHL (removing *european*, adding the Toronto Maple *Leafs*, evoking the Stanley *Cup* rather than the more generic *ice*); the improved `wiki` topic about typhoons is more clearly concentrated on meterological terms, rather than interspersing specific locations of typhoons (*luzon*, *guam*); and the improved `IMDb` topic more cleanly reflects what we would characterize as "video adaptations" by bringing in terms about that subject (*book*, *books*, *novels*, *read*) in place of predominant words relating to particular adaptations. Randomly selected examples can be found in Appendix G.

topic coherence. (See Appendix D.1 for our own related experiments, which yielded mixed results.) We refer the reader to Dieng et al. (2020) for an extensive and up-to-date overview.

A limitation of these approaches is that they simply import general, non-corpus-specific word-level information. In contrast, representations from a pretrained transformer can benefit from both general language knowledge and corpus-dependent information, by way of the pretraining and fine-tuning regime. By regularizing toward representations conditioned on the document, we remain coherent relative to the topic model data. An additional key advantage for our method is that it involves only a slight change to the underlying topic model, rather than the specialized designs by the above methods.

Knowledge distillation. While the focus was originally on single-label image classification, KD has also been extended to the multi-label setting (Liu et al., 2018b). In NLP, KD has usually been applied in supervised settings (Kim and Rush, 2016; Huang et al., 2018; Yang et al., 2020), but also in some unsupervised tasks (usually using an unsupervised teacher for a supervised student) (Hu et al., 2020; Sun et al., 2020). Xu et al. (2018) use word embeddings jointly learned with a topic model in a procedure they term distillation, but do not follow the method from Hinton et al. (2015) that we employ (instead opting for joint-learning). Recently, pretrained models like BERT have offered an attractive choice of teacher model, used successfully for a variety of tasks such as sentiment classification and paraphrasing (Tang et al., 2019a,b). Work in distillation often cites a reduction in computational cost as a goal (e.g., Sanh et al., 2019), although we are aware of at least one effort that is focused specifically on interpretability (Liu et al., 2018a).

Topic diversity. Coherence, commonly quantified automatically using NPMI, is the current standard for evaluating topic model quality. Recently several authors (Dieng et al., 2020; Burkhardt and Kramer, 2019; Nan et al., 2019) have proposed additional metrics focused on the diversity or uniqueness of topics (based on top words in topics). However, no one metric has yet achieved acceptance or consensus in the literature. Moreover, such measures fail to distinguish between the case where two topics share the same set of top n words, therefore coming across as essentially identical, versus when one topic's top n words are repeated individually across multiple other topics, indicating a weaker and more diffuse similarity to those topics. We discuss issues related to topic diversity in Appendix D.2.

7 Conclusions and Future Work

To our knowledge, we are the first to distill a "black-box" neural network teacher to guide a probabilistic graphical model. We do this in order to combine the expressivity of probabilistic topic models with the precision of pretrained transformers. Our modular method sits atop any neural topic model (NTM) to improve topic quality, which we demonstrate using two NTMs of highly disparate architectures (VAEs and WAEs), obtaining state-of-the-art topic coherence across three datasets from different domains. Our adaptable framework does not just produce improvements in the aggregate (as is commonly reported): its effect can be interpreted more specifically as identifying the same space of topics generated by an existing model and, in most cases, improving the coherence of individual topics, thus highlighting the modular value of our approach.

In future work, we also hope to explore the effects of the pretraining corpus (Gururangan et al., 2020) and teachers (besides BERT) on the generated topics. Another intriguing direction is exploring the connection between our methods and neural network interpretability. The use of knowledge distillation to facilitate interpretability has also been previously explored, for example, in Liu et al. (2018a) to learn interpretable decision trees from neural networks. In our work, as the weight on the BERT autoencoder logits λ goes to one, the topic model begins to describe less the *corpus* and more the *teacher*. We believe mining this connection can open up further research avenues; for instance, by investigating the differences in such teacher-topics conditioned on the pre-training corpus. Finally, although we are motivated primarily by the widespread use of topic models for identifying interpretable topics (Boyd-Graber et al., 2017, Ch. 3), we plan to explore the ideas presented here further in the context of downstream applications like document classification.

	$K = 50$			$K = 200$		
	20NG	**Wiki**	**IMDb**	**20NG**	**Wiki**	**IMDb**
DVAE	0.341	0.512	0.137	0.312	0.470	0.155
W-LDA	0.294	0.500	0.136	0.203	0.310	0.095
Scholar	0.343 (0.003)	0.504 (0.007)	0.167 (0.002)	0.279 (0.002)	0.478 (0.005)	0.139 (0.002)
Sch. + BAT	0.377 (0.006)	0.526 (0.009)	0.180 (0.002)	0.343 (0.002)	0.518 (0.001)	0.174 (0.003)

Table 6: The development-set NPMI for our baselines (Section 3.2) compared with BAT (explained in Section 2.3) using Scholar as our base neural architecture. We achieve better NPMI than all baselines across three datasets and $K = 50, K = 200$ topics. We use 5 random restarts report the standard deviation.

Appendix

A Dev Set Results

We optimized our models on the dev set, froze the optimal models, and showed the results on the test set in Tables 2 and 3. We show the corresponding dev set results for those models in Tables 6 and 7.

	20NG	**Wiki**	**IMDb**
W-LDA	0.294 (0.014)	0.500 (0.013)	0.136 (0.009)
+BAT	**0.316** (0.010)	**0.511** (0.016)	**0.162** (0.003)

Table 7: The mean development-set NPMI (std. dev.) across 5 runs for W-LDA and W-LDA+BAT for $K = 50$, showing improvement on all datasets. This demonstrates that our innovation is *modular* and can be used with base neural topic models that vary in architecture.

B Extrinsic Classification Results

The primary goal of our method is to improve the coherence of generated topics. It is natural, however, to ask about the impact of our method on downstream applications. We include here a preliminary exploration suggesting that the addition of BAT does not hurt performance in document classification.

In our setup, we seek to predict document labels y_d from the MAP estimate of a document's topic distribution, $\boldsymbol{\theta}_d$. Specifically, we classify the newsgroup to which a document was posted for the 20 newsgroups data (e.g., `talk.politics.misc`) and a binary sentiment label for the IMDb review data. We train a random forest classifier using default parameters from `scikit-learn` (Pedregosa et al., 2011) and report the accuracies in Table 8 (averaged across 5 runs).

Much like other work that is aimed at topic coherence rather than their downstream use in supervised models (Nan et al., 2019), we find that our method has little impact on predictive performance. While it is possible that improvements may be obtained by specifically tuning models for classification, or by integrating BAT into model variations that combine lexical and topic representations (e.g. Nguyen et al., 2013), we leave this to future work.

	K	**Scholar**	**+BAT**
`20ng`	50	0.676 (0.003)	0.669 (0.005)
	200	0.683 (0.002)	0.679 (0.004)
`IMDb`	50	0.829 (0.003)	0.823 (0.011)
	200	0.805 (0.003)	0.814 (0.004)

Table 8: Random forest classification accuracy on `20ng` and `IMDb` datasets, using topic estimates from Scholar and Scholar + BAT .

C Using BAT with DVAE

We further illustrate our method's modularity by applying BAT to our own reimplementation of DVAE (Burkhardt and Kramer, 2019).[16] In contrast to the author's primary implementation, which estimates the model with rejection sampling variational inference (used in Section 4), we reimplemented DVAE, approximating the Dirichlet gradient via pathwise derivatives (Jankowiak and Obermeyer, 2018), similar to Burkhardt and Kramer (2019)'s alternative model variant using implicit gradients.

Our reimplementation shows baseline behavior substantially similar to the author's implementation. In the course of our experimentation, we noted a degeneracy in this model, in which high NPMI is achieved but at the cost of redundant topics. This failure mode is well-established, but as discussed in Appendix D.2, we find the measures proposed to diagnose topic diversity (including those proposed by Burkhardt and Kramer, 2019; Nan et al., 2019) to be problematic. Rather than use these metrics,

---

[16] We appreciate a reviewer's suggestion that we add a +BAT comparison for DVAE.

therefore, we took a coarse but simple approach and filtered out any models that yielded more than one pair of identical topics, averaged across five runs (defined as having two topics with the same set of top-10 words). This filtering eliminated many hyperparameter settings, leading us to believe that DVAE is not robust to this problem.

Ultimately, we find that applying BAT to DVAE does not hurt, and also does not help appreciably (Table 9). In addition, when applying the above filtering criterion to our main SCHOLAR and SCHOLAR + BAT models, we still obtain the positive results reported in Table 6. [17]

	20NG	Wiki	IMDb
DVAE	0.376 (0.004)	**0.517** (0.006)	**0.169** (0.007)
+BAT	**0.401** (0.005)	**0.515** (0.007)	**0.169** (0.006)

Table 9: Mean development set NPMI (s.d.) across 5 runs for DVAE (Burkhardt and Kramer, 2019) and DVAE+BAT for $K = 50$.

D Methodological Notes

D.1 Using BERT in the encoder

In SCHOLAR, the encoder takes the following form:

$$\boldsymbol{\pi}_d = g\left(\left[\boldsymbol{W}\boldsymbol{w}_d^{\mathrm{BoW}}\right]\right) \tag{5}$$

$$\boldsymbol{\theta}_d \sim \mathcal{LN}\left(\mu_\nu(\boldsymbol{\pi}_d),\, \sigma_\nu(\boldsymbol{\pi}_d)\right) \tag{6}$$

Where the weight matrix $\boldsymbol{W}$, along with the parameters of nueral networks $\mu(\cdot)$ and $\sigma(\cdot)$, are our variational parameters.

Card et al. (2018) propose that pre-trained word2vec (Mikolov et al., 2013) embeddings can replace $\boldsymbol{W}$, meaning that the document representation made available to the encoder is an l-dimensional sum of word embeddings. Card et al. (2018) argue that fixed embeddings act as an inductive prior which improves topic coherence. Likewise, we might want to encode the document representation from a BERT-like model and, in fact, this has been attempted with some success (Bianchi et al., 2020). The hypothesis is that a structure-dependent representation of the document can better parameterize its corresponding topic distribution.

Setting	NPMI
Randomly updated embeds.	0.170 (0.007)
Fixed word2vec embeds.	0.172 (0.004)
Random 784-dim doc. rep. + w2v	0.175 (0.007)
Mean-pooled 784-dim BERT output + w2v	0.172 (0.002)
Random 5000-dim doc. rep. + w2v	0.178 (0.007)
5000-dim predicted probs. from BAT + w2v	0.180 (0.008)

Table 10: Effect on topic coherence of passing various document representations to the SCHOLAR encoder (using the IMDb data). Each setting describes the document representation provided to the encoder, which is transformed by one feed-forward layer of 300-dimensions followed by a second down to K dimensions. "+ w2v" indicates that we first concatenated with the sum of the 300-dimensional word2vec embeddings for the document. Note that these early findings are based on a different IMDb development set, a 20% split from the training data. They are thus not directly comparable to the results reported elsewhere in the text, which used a separate held-out development set.

We experimented with this method as well, using both the hidden BERT representation and the predicted probabilities, although we also include a fixed randomized baseline to maintain parameter parity. Results for IMDb are reported in Table 10, and we find at best a mild improvement over the baselines.[18] We suspect the reason for this tepid result is both that (a) in training, the effect of estimated local document-topic proportions on the global topic-word distributions is diffuse and indirect; and (b) the compression of the representation into k dimensions causes too much of the high-level linguistic information to be lost. Nonetheless, owing to the slight benefit, we do pass the logits to the encoder in our SCHOLAR-based model. We avoid this change for the model based on W-LDA to underscore the modularity of our method.

D.2 Topic Diversity

Burkhardt and Kramer (2019) have found a degeneracy in some topic models, wherein a single topic will be repeated more than once with slightly varying terms (e.g., several Dadaism topics). Burkhardt and Kramer (2019) and others (Nan et al., 2019; Dieng et al., 2020) have independently proposed related metrics to quantify the problem, but the literature has not converged on a solution. In contrast to NPMI, we are not aware of any work that as-

---

[17] For $K = 50$. The single-pair threshold proves too restrictive for the $K = 200$ case, where no hyperparameter settings pass the threshold. Increasing the tolerance to a maximum of 5 redundant pairs with $K = 200$ leads to a somewhat lower average NPMI overall, but the same directional improvement, i.e. SCHOLAR+BAT yields a significantly higher NPMI than SCHOLAR.

[18] We also fail to reproduce the findings of Card et al. (2018), showing no meaningful improvement in topic coherence with fixed word2vec embeddings. It appears that this is a consequence of their tuning for perplexity rather than NPMI.

sesses the validity of such metrics with respect to human judgements.

Moreover, all these proposals suffer from a common problem: because they are global measures of word overlap, they fail to account for *how* words are repeated across topics. For instance, Topic Uniqueness (Nan et al., 2019) is identical regardless of whether all of a topic's top words are all repeated in a single second topic, or individual top words from that topic are repeated in several other topics. In addition, the measures inappropriately penalize partially-related topics.

They also penalize polysemy—and, more generally, the contextual flexibility of word meanings. One of the key *advantages* of latent topics, compared to surface lexical summaries, is that the same word can contribute differently to an understanding of what different topics are about. As a real example from our experience, in modeling a set of documents related to paid family and medical leave, words like *parent*, *mother*, and *father* are prominent in one topic related to parental leave when a child is born (accompanying other terms like *newborn* and *maternity_leave*) and also in another topic related to taking leave to care for family members, including elderly parents (accompanying other terms like *elderly* and *aging*). The fact that topic models permit a word like *parent* to be prominent in both of these clearly distinct topics, emphasizing two different aspects of the word relative to the collection as a whole (being a parent taking care of children, being a child taking care of parents), is a feature, not a bug. We consider the question of topic diversity an important direction for future work.

E Experimental Procedures

In this section, we first provide details of our hyperparameters and tuning procedures, then turn to our computing infrastructure and the rough runtime of the SCHOLAR model.

E.1 Hyperparameter Tuning and Optimal Values

We used well-tuned baselines to establish thresholds for performance on NPMI (following the reported hyperparameters in Card et al., 2018; Burkhardt and Kramer, 2019; Nan et al., 2019). While developing our model, we performed a coarse-grained initial hyperparameter sweep to identify ranges that were not beating the threshold, and decided to exclude those ranges when performing a full grid search. We report the hyperparameter ranges used in this search, along with their optimal values (as determined by development set NPMI), in Tables 11 to 15. These produced the final set of results (Tables 2, 3, 6 and 7).

For the DISTILBERT training, we use the default hyperparameter settings for the `bert-base-uncased` model (Wolf et al., 2019). Our code is a modified version of the MM-IMDB multimodal sequence classification code from the same codebase as DISTILBERT (`https://github.com/huggingface/transformers/tree/master/examples/contrib/mm-imdb`), and we use all default hyperparameter settings specified there. We train for 7500 steps for `20ng`, and 17000 steps for `Wiki` and `IMDb` (this corresponds to convergence on development-set perplexity).

E.2 Computing Infrastructure and Runtime

For the full hyperparameter sweep, we used an Amazon Web Services ParallelCluster `https://github.com/aws/aws-parallelcluster` with 40 nodes of `g4dn.xlarge` instances (consisting of Nvidia T4 GPUs with 16 GB RAM), which ran for about 5 days. For initial experimentation, we used a SLURM cluster with a mix of consumer-grade Nvidia GPUs (e.g., 1080, 2080).

In terms of runtime, SCHOLAR) and our own SCHOLAR+BAT are equal and this is true for any of our baseline model augmented with BAT. It is important to note that the overhead in terms of the overall runtime comes only from training the DISTILBERT encoder on the full dataset first and inference time for obtaining the logits after training. Thus, users should keep in mind the initial step of training and inferring teacher model logits and saving them; once that is done for the dataset, our model does not add to the runtime. We show the comparison between the full runtimes, including the initial step, in Fig. 4.

F Changes to W-LDA

In Fig. 5, we show the changes to the W-LDA model necessary to accommodate our method. Ignoring the code to load & clip the logits, also constituting a minor change, we introduce about a dozen lines.

Dataset: 20NG		k = 50		k = 200	
	Values Tried	**SCHOLAR (optimal values)**	**SCHOLAR+BAT (optimal values)**	**SCHOLAR (optimal values)**	**SCHOLAR+BAT (optimal values)**
lr	0.002*	0.002	0.002	0.002	0.002
$\boldsymbol{\alpha}$	1.0*	1.0	1.0	1.0	1.0
$\boldsymbol{\lambda}$	$\{0.25, 0.5, 0.75, 0.95, 0.99, 0.999\}$	-	0.75	-	0.99
$\boldsymbol{T}$	$\{1.0, 2.0, 3.0, 5.0\}$	-	2.0	-	5.0

Table 11: Hyperparameter ranges and optimal values (as determined by development set NPMI) for SCHOLAR and SCHOLAR+BAT , on the **20NG** dataset. **lr** is the learning rate, $\boldsymbol{\alpha}$ is the hyperparameter for the logistic normal prior, $\boldsymbol{\lambda}$ is the weight on the teacher model logits from Eq. (4), and $\boldsymbol{T}$ is the softmax temperature from Eq. (4). Other hyperparamter values (which can be accessed in our code base) which were kept at their default values are not reported here. Values marked with the * are also kept at their default values per the base SCHOLAR model (`https://github.com/dallascard/scholar`). All different sweeps in the grid search were run for **500 epochs** with a **batch size = 200**.

Dataset: Wiki		k = 50		k = 200

Optimal Dirichlet Prior	0.6		0.2	0.6		0.2

Table 15: For DVAE, we tried four values for the Dirichlet Prior (as per the values tried by the authors in Burkhardt and Kramer (2019)) - $\{0.01, 0.1, 0.2, 0.6\}$ and report the optimal values corresponding to the dev set results (Table 2) and test set results (Table 6) in this table. Within the model variations available in the codebase for DVAE (`https://github.com/sophieburkhardt/dirichlet-vae-topic-models`) we use the Dirichlet VAE based on RSVI which is shown to give the highest NPMI scores in Burkhardt and Kramer (2019).

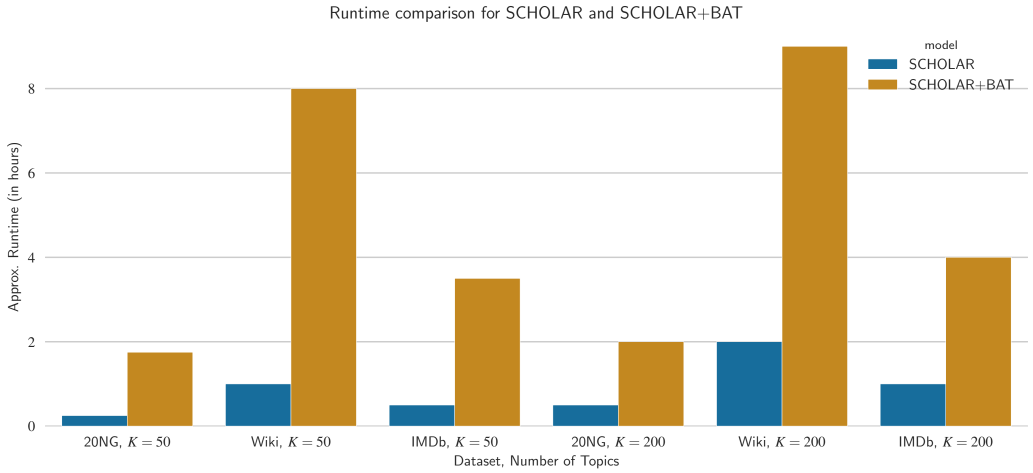

Figure 4: Runtime comparison for SCHOLAR) and our own SCHOLAR+BAT - Note that the overhead due to BAT is only a due to the training and inference time required to obtain the DISTILBERT encoder logits on the full dataset first, and once the teacher logits are available, the run time of both models is the same. We depict the full approximate time (in hours) including this initial overhead in case of BAT .

G Impact of BAT on Individual Topics: Aligned Topic Pair Examples

For each corpus (20NG, Wiki, and IMDb), a single comparison of base and BAT-augmented (SCHOLAR vs. SCHOLAR+BAT) 50-topic models was selected randomly, from the five runs used in computing average performance in Fig. 3.

For each of those pairs of models, we then randomly selected 15 aligned topic pairs from that set of 50 to include in the tables below. Specifically, a full set of 50 topic pairs was partitioned according to JS divergence into the 10 most similar pairs, the next 10 most similar, and so forth, for a total of five "brackets" of topic alignment quality. Three topic pairs were then selected at random from each bracket, hence 15 pairs in all, in order to yield a fair picture of what pairs look like at various qualities of topic alignment.

In the tables below (Tables 16 to 18), we present pairs sorted from best to worst alignment quality. Recall that for NPMI, higher is better, and for JS divergence, lower score indicates a higher quality match (or alignment) for the topic pair.

```
### In `compute_op.py`

## Retrieve BERT logits
docs = self.data.get_documents(key='train')
if self.args['use_kd']:
    split_on = docs.shape[1] // 2
    docs, bert_logits = docs[:,:split_on], docs[:,split_on:]
    t = self.args['kd_softmax_temp']
    kd_docs = nd.softmax(bert_logits / t) * nd.sum(docs, axis=1, keepdims=True)

# [... unchanged lines ...]

## Compute loss

Abstract

Topic models have been prevailing for many years on discovering latent semantics while modeling long documents. However, for short texts they generally suffer from data sparsity because of extremely limited word co-occurrences; thus tend to yield repetitive or trivial topics with low quality. In this paper, to address this issue, we propose a novel neural topic model in the framework of autoencoding with a new topic distribution quantization approach generating peakier distributions that are more appropriate for modeling short texts. Besides the encoding, to tackle this issue in terms of decoding, we further propose a novel negative sampling decoder learning from negative samples to avoid yielding repetitive topics. We observe that our model can highly improve short text topic modeling performance. Through extensive experiments on real-world datasets, we demonstrate our model can outperform both strong traditional and neural baselines under extreme data sparsity scenes, producing high-quality topics.

1 Introduction

In addition to formal documents, short texts play an increasingly more important role in the era of information explosion where people could instantly share ideas, feelings, and comments via short text fragments, including tweets, headlines, and product reviews, etc. The latent semantics or topics discovered among these short texts can be utilized in many applications, such as content summarization (Ma et al., 2012), classification(Zeng et al., 2018a), and recommendations (Zeng et al., 2018b; Mehrotra et al., 2013). However, conventional topic models (Blei et al., 2003) work reasonably well on various kinds of long documents, but perform poorly on short texts. The main underlying reason is that the co-occurrence information from short texts is extremely limited as known as the data sparsity problem which hinders the topic models from learning effective semantics and high-quality topics in a pure unsupervised learning fashion. Therefore, several approaches have been proposed to alleviate this issue. One simple approach is to yield pseudo texts (Quan et al., 2015), so that the conventional topic models can apply, e.g., user data (Weng et al., 2010), hashtags (Mehrotra et al., 2013) and external corpora (Zuo et al., 2016), but auxiliary information is not always available. In another vein, extra structural information or semantics are incorporated with the models. For instance, Biterm Topic Model (BTM) (Yan et al., 2013) directly constructs the topic distributions over unordered word-pairs (biterms); Generalized Pólya Urn-DMM (GPUDMM) (Li et al., 2016) applies auxiliary pre-trained word embeddings to introduce external information from other sources. However, the data sparsity problem of short texts remains to be solved, especially resulting in repetitive and trivial topics. For example, as illustrated in Table 1, we can see several repetitive topics about sports including repeated words like "football", "games", and "tennis", and trivial topics composed of incoherent words are discovered from short texts. These topics are of low quality and could impair the performance of downstream tasks.

In this paper, we aim to design a model that can generate high-quality topics from short texts and is more robust to rigorous data sparsity scenarios

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1772–1782,
November 16–20, 2020.

without any auxiliary corpus. Different from previous methods, we propose a new **Negative sampling and Quantization Topic Model (NQTM)** in an auto-encoding framework to address the unsupervised short text modeling problem including two essential and novel methods. First, for short texts, we need peakier topic distributions for decoding since short texts cover few primary topics, like Dirichlet Multinomial Mixture (DMM) (Nigam et al., 2000; Yin and Wang, 2014) that assumes each short text only covers one topic. In the autoencoding framework, a possible and straightforward way is using gumbel-softmax (Jang et al., 2016), but its performance is highly determined by the temperature parameter that necessarily needs to be tuned across topic numbers and corpora; therefore, it may not guarantee high-quality topics. Another way is quantizing the latent representations like VQ-VAE (van den Oord and Vinyals, 2017). Unfortunately, the original quantization of VQ-VAE is for image generation and cannot produce peakier distributions for short text topic modeling. Therefore, we propose the novel topic distribution quantization for short texts by separably mapping topic distributions into an appropriate defined embedding space. With this new method, our model can naturally encourage discretization to flexibly yield peakier distributions for decoding, resulting in much better topic quality performance.

Second, we propose a new negative sampling decoder to improve the topic diversity performance. As mentioned previously, short texts are extremely sparse inputs, so the learning signals are too weak to converge to a good local minimum, notably in an unsupervised learning fashion, leading to repetitive topics. Therefore, instead of using a straightforward log-likelihood objective, we propose a negative sampling decoder with the reconstruction by selecting target words from assigned topics and negative words from the topics that are unlikely to be assigned. It acts as an inductive bias that encourages the topic-word distributions to be pushed away from each other, resulting in a better learning objective for generating diverse topics. The main contributions[1] of this paper can be concluded as

- We propose a neural model with a novel topic distribution quantization method to produce peakier distributions for improving short text topic modeling;
- We also propose a negative sampling decoder to enhance the diversity of short text topics instead of conventional log-likelihood maximization;
- We conduct comprehensive experiments on real-world datasets and demonstrate that our model can effectively alleviate the data sparsity problem and generate higher quality topics for short texts (more coherent and diverse);
- We further discuss the trade-off of short text topic models between topic coherence and diversity in detail and show our model outperforms baselines on both these aspects.

2 Related Work

Conventional topic models Conventional probabilistic topic models, e.g., Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003), work very well on formal documents with long texts. To improve the performance of short text topic modeling, Biterm Topic Model (BTM) (Yan et al., 2013) and Dirichlet Multinomial Mixture (DMM) model (Nigam et al., 2000; Sadamitsu et al., 2007; Yin and Wang, 2014) are two basic short text probabilistic topic models which employ traditional Bayesian inference methods including Gibbs Sampling (Steyvers and Griffiths, 2007) and Variational Inference (Blei et al., 2017). Several extensions based on BTM and DMM are also proposed, such as Generalized Pólya Urn-DMM (GPUDMM) (Li et al., 2016) with word embeddings and Multiterm Topic Model (Wu and Li, 2019). Besides, Semantics-assisted Non-negative Matrix Factorization (SeaNMF) (Shi et al., 2018) was lately proposed as an NMF topic model incorporating word-context semantic correlations solved by a block coordinate descent algorithm.

Neural topic models More recently, deep neural networks have shown great potential for learning complicated distributions for unsupervised models. Due to the success of Variational AutoEncoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014), various neural topic models are proposed (Nan et al., 2019; Wu et al., 2020). Neural Variational Document Model (NVDM) (Miao et al., 2016) is the first VAE-based neural topic model that adopts the reparameterization trick of Gaussian distributions and achieves remarkable results

---

[1] The code is available at `https://github.com/bobxwu/NQTM`

on normal text topic modeling. Some extensions like Gaussian Softmax Construction (GSM) have been explored in (Miao et al., 2017). Product of expert LDA (ProdLDA) is proposed by Srivastava and Sutton (2017) using Logistic Normal distribution due to the difficulty of taking the reparameterization trick for Dirichlet distribution, which is important for topic modeling. Topic Memory Network (TMN) (Zeng et al., 2018a) is proposed for supervised short text topic modeling and classification with pre-trained word embeddings, incorporating the neural topic model (Miao et al., 2016) with memory networks (Weston et al., 2014). Different from these neural topic models, the proposed model aims to improve short text topic modeling without any extra information. Our model relies on the novel topic distribution quantization to discrete the latent representations in the auto-encoding framework instead of the VAE assumption. Meanwhile, a new objective under the negative sampling decoder replaces the traditional log-likelihood maximization objective to especially alleviate the data sparsity of short texts.

3 Negative sampling and Quantization Topic Model

3.1 A Brief Review of Topic Models

LDA (Blei et al., 2003) is one of the most classic probabilistic topic models. In its formulation, a topic is defined as a distribution of words and each word in a text is drawn from a mixture of Multinomial distributions with Dirichlet distribution as the priori. In LDA, the latent variable z denotes the topic assignment of word x_i and $\boldsymbol{\theta}$ is the topic distribution of a text. According to the generation procedure of LDA, the marginal likelihood of a text $\boldsymbol{x}$ is

$$\begin{aligned}&p(\boldsymbol{x}|\boldsymbol{\alpha},\boldsymbol{\beta})\\&=\int_{\boldsymbol{\theta}}\left(\prod_{i=1}^{N}\sum_{z=1}^{K}p\left(x_i|z,\boldsymbol{\beta}\right)p\left(z|\boldsymbol{\theta}\right)\right)p(\boldsymbol{\theta}|\boldsymbol{\alpha})d\boldsymbol{\theta}\end{aligned}$$

where N refers to the number of words in text $\boldsymbol{x}$, $\boldsymbol{\alpha}$ is the hyperparameter of Dirichlet distribution, $\boldsymbol{\beta}_z$ refers to the topic distribution over words given the topic assignment z and $\boldsymbol{\beta}=(\boldsymbol{\beta}_1,\dots,\boldsymbol{\beta}_K)\in\mathbb{R}^{V\times K}$ is the matrix of all topic words probability vectors (V is the vocabulary size and K is the topic numbder). Then, approximation methods, like Variational Inference or Gibbs Sampling, are employed to approximate the intractable posterior.

In a different way, with the help of neural variational inference, neural topic models (Miao et al., 2017; Srivastava and Sutton, 2017) have been proposed to simplify the inference and the model can be directly updated by gradient backpropagation. These models adopt a simplification that the discrete latent variable z is integrated out in the marginal likelihood as

$$p(\boldsymbol{x}|\boldsymbol{\alpha},\boldsymbol{\beta})=\int_{\boldsymbol{\theta}}\left(\prod_{i=1}^{N}p\left(x_i|\boldsymbol{\theta},\boldsymbol{\beta}\right)\right)p(\boldsymbol{\theta}|\boldsymbol{\alpha})d\boldsymbol{\theta} \tag{1}$$

Based on these preceding neural topic models, we present our proposed model for short text topic modeling.

3.2 Network Architecture

In this section, we detail the proposed Negative sampling and Quantization Topic Model (NQTM). Figure 1 shows the overall architecture including three main parts.

3.2.1 Short Text Encoder

Topic models discover semantic information (topics) among large unlabeled datasets using word co-occurrence, so topic models typically apply the bag-of-words assumption ignoring the sequence for simplification. Thus, we adopt MLPs that are eligible enough for both encoder and decoder. We assume the short text $\boldsymbol{x}$ is in the form of bag-of-words which produces continuous representations through the short text encoder. We adopt the following simple network structure as our short text encoder:

$$\boldsymbol{\pi}_1=\zeta(\boldsymbol{W}_1\boldsymbol{x}+\boldsymbol{b}_1) \tag{2}$$

$$\boldsymbol{\pi}_2=\zeta(\boldsymbol{W}_2\boldsymbol{\pi}_1+\boldsymbol{b}_2) \tag{3}$$

$$\boldsymbol{\theta}_e=\sigma(\boldsymbol{\pi}_2) \tag{4}$$

where $\boldsymbol{W}_1$ and $\boldsymbol{W}_2$ are linear transformations, and $\boldsymbol{\pi}_1$ and $\boldsymbol{\pi}_2$ are intermediate outputs; $\sigma(\cdot)$ means softmax function for normalization and $\zeta(\cdot)$ denotes softplus function. After the encoder, we have the lower dimensional representation $\boldsymbol{\theta}_e$ of the short text $\boldsymbol{x}$.

3.2.2 Topic Distribution Quantization

Instead of directly feeding the continuous representation $\boldsymbol{\theta}_e$ to the decoder as previous neural topic models (Miao et al., 2016, 2017; Srivastava and Sutton, 2017), we employ the quantization step ahead. Unfortunately, we find that directly using

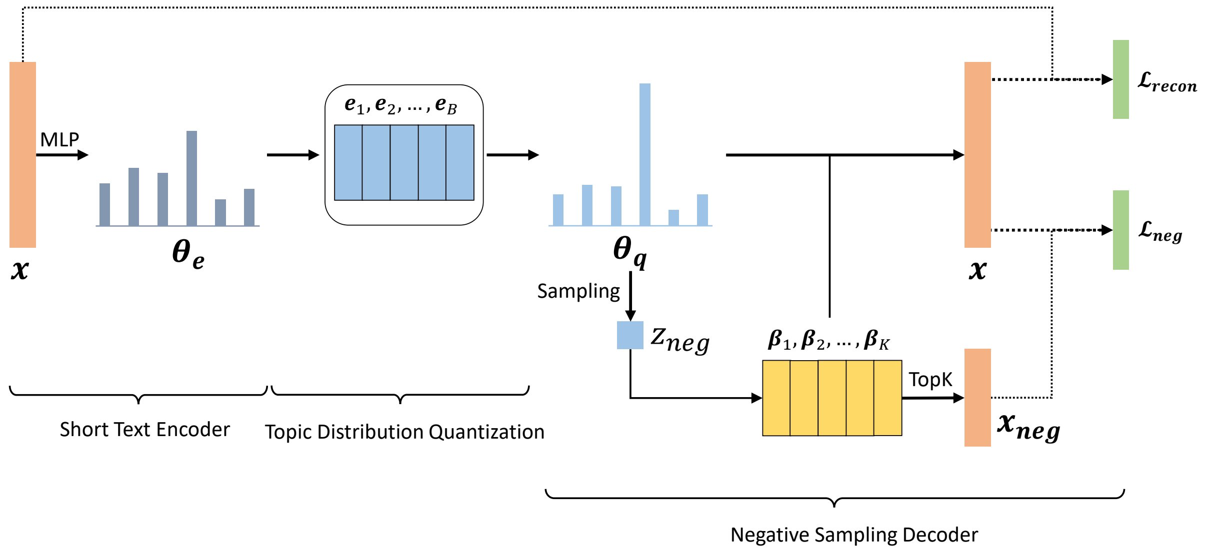

Figure 1: The overall architecture of NQTM with three main components including the short text encoder, the novel topic distribution quantization for short texts, and the new negative sampling decoder.

ordinary quantization is not a guarantee for better topic quality, because the latent representations can not be distinguished during optimization. More precisely, since the original embedding space of VQ-VAE is randomly initialized with uniform distributions, these embedding vectors of VQ-VAE are too close to each other to distinguish. Thus, it is arduous for the model to learn to separably map the latent representations of different topics to the embedding vectors, resulting in extremely repetitive topics.

To this end, we propose a novel topic distribution quantization method to alleviate the data sparsity problem of short texts especially. We first set a discrete embedding space $\boldsymbol{e} = (\boldsymbol{e}_1, \boldsymbol{e}_2, \dots, \boldsymbol{e}_B) \in \mathbb{R}^{K \times B}$ where B is the size of the embedding space. To encourage the maximum of distances between embedding vectors and have peakier topic distributions, the first K vectors $(\boldsymbol{e}_1 \cdots \boldsymbol{e}_K)$ are initialized with identity matrix and the remaining vectors $(\boldsymbol{e}_{K+1} \cdots \boldsymbol{e}_B)$ are initialized with uniform unit scaling $Uniform(-\sqrt{3/K}, \sqrt{3/K})$. Therefore, the embedding space $\boldsymbol{e}$ can be written as

$$\boldsymbol{e} = \begin{bmatrix} 1 & 0 & \dots & 0 & & & \\ 0 & 1 & \dots & 0 & & & \\ \vdots & \vdots & \ddots & \vdots & \boldsymbol{e}_{K+1} & \dots & \boldsymbol{e}_B \\ 0 & 0 & \dots & 1 & & & \end{bmatrix} \quad (5)$$

which can be seen as an extended identity matrix. The continuous representation $\boldsymbol{\theta}_e$ is mapped to the nearest vector $\boldsymbol{\theta}_q$ of the embedding space $\boldsymbol{e}$ as

$$\boldsymbol{\theta}_q = \boldsymbol{e}_k, \quad \text{where } k = \operatorname{argmin}_j \|\boldsymbol{\theta}_e - \boldsymbol{e}_j\|_2 . \quad (6)$$

In this way, the proposed new quantizing topic distributions method for short texts can make the latent representations separably map to distinguished embedding vectors and flexibly generate peakier topic distributions, which can stimulate our model to tackle the data sparsity and improve the diversity and coherence of topics.

3.2.3 Negative Sampling Decoder

After the topic distribution quantization, $\boldsymbol{\theta}_q$ is fed to the decoder for reconstruction. It has been found that normalizing topic words probability matrix $\boldsymbol{\beta}$, such as $\sigma(\boldsymbol{\beta})$, results in trivial and less discriminative topics (Srivastava and Sutton, 2017). Hence, according to Equation (1), the reconstruction of a word x_i in the text $\boldsymbol{x}$ is modeled as $x_i \sim \text{Mult}(\sigma(\boldsymbol{\beta}\boldsymbol{\theta}_q))$.

Negative sampling algorithm In contrast to the standard decoder with log-likelihood maximization objective function, we propose to take advantage of the negative sampling scheme and formulate a new decoder to generate more diverse topics. Similar ideas are mentioned in some data sparsity fields like collaborative filtering (Liang et al., 2018) where if for a short text , the negative samples simply are all the words that do not exist in it. But this method is unable to distinguish the words from different topics explicitly.

Thus, instead of applying this simple solution, we further propose the negative sampling decoder. We take the words with high probabilities in the other topics but not assigned to the current text fragment as negative samples. The intuition is to strengthen the discrimination between the words drawn from the assigned topic distribution and a negative draw from other topics that are not assigned to the text. Therefore, we introduce an inductive bias that prompts the topic-word distributions to be pushed away from each other. In the meantime, the neural model benefits from a better learning signal other than the ordinary softmax loss. As shown in Figure 1, given a short document and its topic distribution, we first remove the top t probable topics and sample one negative topic z_{neg} from the left $(K-t)$ topics with equal probability, which is

$$z_{neg} \sim \text{Mult}(\boldsymbol{p}, 1) \tag{7}$$

where $\boldsymbol{p} = (p_1, p_2, \ldots, p_K)$ and p_k is the probability of choosing topic k, defined as

$$p_k = \begin{cases} 0 & \text{topic } k \text{ is included in top } t \text{ topics} \\ \frac{1}{K-t} & \text{otherwise} \end{cases}$$

Therefore, z_{neg} represents a topic that the document is unlikely to cover because of its low probability to be assigned. Then, we generate M words from $\boldsymbol{\beta}_{z_{neg}}$ by TopK function as

$$\boldsymbol{x}_{neg} = \text{TopK}(\boldsymbol{\beta}_{z_{neg}}, M) \tag{8}$$

where $\boldsymbol{x}_{neg}$ denotes the M words that topic z_{neg} is more likely to contain. But since the document is supposed to not cover z_{neg}, the decoder should avoid generating them during reconstruction. This heuristic acts as a positive bias to help the model discover high-quality topics and the negative samples $\boldsymbol{x}_{neg}$ can amplify the learning signals for better optimizing the neural model and improving topic diversity.

Objective function With the negative sampling decoder, we can then construct our objective function. The reconstruction error and the negative sampling error are

$$\mathcal{L}_{recon}(\boldsymbol{x}^{(i)}) = -\boldsymbol{x}^{(i)} \cdot \log\big(\sigma(\boldsymbol{\beta}\boldsymbol{\theta}_q^{(i)})\big) \tag{9}$$

$$\mathcal{L}_{neg}(\boldsymbol{x}^{(i)}) = -\boldsymbol{x}_{neg}^{(i)} \cdot \log\big(1 - \sigma(\boldsymbol{\beta}\boldsymbol{\theta}_q^{(i)})\big) \tag{10}$$

where $\boldsymbol{x}^{(i)}$ refers to the i-th short text in the corpus. As indicated previously, $\boldsymbol{\theta}_e^{(i)}$ means the latent representation outputted by the encoder for $\boldsymbol{x}^{(i)}$ and $\boldsymbol{\theta}_q^{(i)}$ is the discrete representation after the new topic distribution quantization part. We apply the cross-entropy between inputs $\boldsymbol{x}^{(i)}$ and $\sigma(\boldsymbol{\beta}\boldsymbol{\theta}_q^{(i)})$ to calculate the reconstruction error. For the negative sampling error, we also use the cross-entropy between $\boldsymbol{x}_{neg}^{(i)}$ and $(1-\sigma(\boldsymbol{\beta}\boldsymbol{\theta}_q^{(i)}))$ to enrich learning signals. Therefore, the overall training objective with the negative sampling decoder can be written as

$$\mathcal{L}(\boldsymbol{\Theta}) = \sum_{i=1}^{D} \Big[\mathcal{L}_{recon}(\boldsymbol{x}^{(i)}) + \mathcal{L}_{neg}(\boldsymbol{x}^{(i)}) + \big\|sg(\boldsymbol{\theta}_e^{(i)}) - \boldsymbol{\theta}_q^{(i)}\big\|_2^2 + \lambda\big\|sg(\boldsymbol{\theta}_q^{(i)}) - \boldsymbol{\theta}_e^{(i)}\big\|_2^2\Big]$$

where $\boldsymbol{\Theta}$ means all parameters and D is the number of texts in a corpus. In order to minimize the distance between the embedding vector $\boldsymbol{\theta}_q^{(i)}$ and the encoder output $\boldsymbol{\theta}_e^{(i)}$, training objective includes the l_2 regularization between them. In detail, λ is a hyper parameter and $sg(\cdot)$ operator means the stop-gradient operation defined as

$$sg(x) = \begin{cases} x & \text{forward pass} \\ 0 & \text{backward pass} \end{cases}$$

that blocks gradients from flowing into its argument.

The above is the architecture of our proposed model NQTM and moreover, we name a simple variant of NQTM without the negative sampling error $\mathcal{L}_{neg}$ as **Quantization Topic Model (QTM)**. From the above description, our model NQTM differs from the VQ-VAE in two aspects. First, instead of a standard decoder, our model includes the new negative sampling decoder. Second, a novel topic distribution quantization method is proposed particularly for short texts to yield sharper distributions. These approaches are both to alleviate the data sparsity issue and we demonstrate the effectiveness of these two technical contributions in the next sections.

4 Experiments Setup

4.1 Datasets

Several real-world short text datasets are adopted in our experiment. The details are listed as

- **StackOverflow**[2] This dataset originates from

---

[2] https://github.com/jacoxu/StackOverflow

Datasets	# of docs	Average length	# of labels	Vocabulary size
StackOverflow	19,901	4.6	20	2,607
TagMyNews Title	31,223	5.2	7	6,391
Snippet	10,053	10.3	8	4,004
Yahoo Answer	19,027	4.1	10	3,243

Table 2: Statistics of datasets after preprocessing. Labels refer to the class labels of the corpus.

the challenge data published in Kaggle[3] . We use the dataset containing randomly selected 20,000 question titles provided by Xu et al. (2015). Each question title is annotated with an information technology name like “matlab”, “osx” and “visual studio” as labels.

- **TagMyNews Title**[4] This dataset contains titles and contents of English news released by Vitale et al. (2012). We utilize the news titles as short texts in our experiment. Each news is assigned with a ground-truth label, e.g., “sci-tech”, and “business”, etc.

- **Snippet**[5] This dataset is provided by Phan et al. (2008) composed of the web content from Google search snippets. Eight labels are included in this dataset, such as “Culture-Arts-Entertainment” and “Computers”, etc.

- **Yahoo Answer**[6] We obtained this dataset from Zhang et al. (2015) through the Yahoo Webscope program, including question titles, contents, and best answers. We adopt the question titles for topic modeling, totally containing ten labels.

To preprocess the raw content, we conduct the following steps: (1) tokenize each text and remove non-Latin characters and stop words by using NLTK[7] ; (2) filter out short texts with length less than 2; (3) remove words with document frequency less than 5; (4) convert all letters into lower cases. The statistics of each dataset after preprocessing are summarized in Table 2.

4.2 Baseline Models

We take both conventional and neural topic models as baselines for comparison. For traditional topic models, we consider LDA (Blei et al., 2003), BTM[8] (Yan et al., 2013), DMM[9] (Yin and Wang, 2014), GPUDMM[10] (Li et al., 2016), and SeaNMF[11] (Shi et al., 2018). Note that SeaNMF is the state-of-the-art conventional model. In terms of neural topic models, we compare our model with NVDM[12] (Miao et al., 2016), GSM (Miao et al., 2017) and ProdLDA[13] (Srivastava and Sutton, 2017). Recently proposed supervised model TMN[14] (Zeng et al., 2018a) is also taken into consideration. We also compare our model with VQ-VAE to demonstrate the effectiveness of our proposed topic distribution quantization method.

5 Experimental Results

5.1 Topic Quality Evaluation

Topic Quality Metrics As mentioned before, the challenge of data sparsity in short texts results in two problems: generated topic words tend to be incoherent (trivial topics), and highly similar topics with repeated words are also yielded (repetitive topics). Therefore, we focus on the evaluation of topic quality referring to these two aspects, topic coherence and diversity. Topic coherence metrics depend on co-occurrences of topic words learned by models in the external corpus assuming that coherent words should co-occur within a certain distance. A new topic coherence metric C_V was introduced by Röder et al. (2015), which has been proven to perform better than other coherence metrics like widely-used NPMI (Bouma, 2009; Newman et al., 2010; Chang et al., 2009) and UMASS(Mimno et al., 2011). According to Krasnashchok and Jouili (2018), given a topic z and its top T words $(x_1, x_2, ..., x_T)$ sorted by the probability, the definition of C_V is

$$C_V(z) = \frac{1}{T}\sum_{i=1}^{T} s_{\cos}(\boldsymbol{v}_{\text{NPMI}}(x_i), \boldsymbol{v}_{\text{NPMI}}(\boldsymbol{x}_{1:T}))$$

where $s_{cos}(\cdot)$ means cosine similarity function and the vectors are defined as

Table 3: Topic coherence (C_V) and unique score (TU) of the top 15 words. K is the topic number. **QTM** means the variant of NQTM without negative sampling. The best in each unsupervised topic model is in bold.

$$\boldsymbol{v}_{\text{NPMI}}(x_i) = \{\text{NPMI}(x_i, x_j)\}_{j=1,\dots,T}$$

$$\boldsymbol{v}_{\text{NPMI}}(\boldsymbol{x}_{1:T}) = \left\{ \sum_{i=1}^{T} \text{NPMI}\left(x_i, x_j\right) \right\}_{j=1,\dots,T}.$$

Then, the NPMI is calculated as

$$\text{NPMI}(x_i, x_j) = \frac{\log \frac{p(x_i, x_j)+\epsilon}{p(x_i)p(x_j)}}{-\log(p(x_i, x_j) + \epsilon)}$$

where $p(x_i)$ is the probability of x_i, $p(x_i, x_j)$ the coocurrance probability of x_i, x_j within a window in the reference corpus and ϵ is used to avoid zero. We use the public tool[15] to compute C_V provided by Röder et al. (2015).

Besides C_V score, we employ the topic unique metric (TU) (Nan et al., 2019) for topic diversity evaluation. For the top T words of topic z, it is defined as

$$TU(z) = \frac{1}{T} \sum_{i=1}^{T} \frac{1}{\text{cnt}(x_i)}$$

where $\text{cnt}(x_i)$ is the total number of times that word x_i appears in the top T words of all topics. Therefore TU score ranges from $1/K$ to 1 and a higher value means the generated topics are more diverse due to fewer duplicated words across other topics. It is crucial to note that in general, higher TU scores tend to cause lower C_V scores because coherent words seldom repeat, and higher C_V scores often lead to lower TU scores because coherent words frequently repeat across topics. We show our model can achieve significantly better performance on both aspects in the following.

Result Analysis Table 3 reports the topic coherence (C_V) and unique scores (TU) of the top 15 words under topic number $K = 20$ and 50. To be more specific, when topic number $K = 20$, NQTM can achieve significantly higher C_V scores, and we notice that TU scores of NQTM reach the highest on all datasets. When $K = 50$, NQTM still surpasses all unsupervised baselines on StackOverflow and TMN title in terms of both TU and C_V scores. Although C_V scores of ProdLDA and BTM are higher on Snippet and Yahoo Answer, TU scores of NQTM are much better than them. As mentioned earlier, the reason is that the C_V scores can be easily tricked by the repetitive topics composed of prominent words while with low topic diversity performance (further illustrated in Section 5.4). This issue is evenly severer for TMN. Notably, we can see TU scores of TMN are among the worst of all baselines, which is because the diversity of topics learned from TMN is not encouraged with the strong learning signal from the classification loss. Although some discovered topics seem coherent from the above baselines, unfortunately, many repetitive and less informative topics are ineffective in downstream applications; thus, their higher C_V scores are meaningless. On the contrary, we can observe the topic diversity performance of NQTM is

---

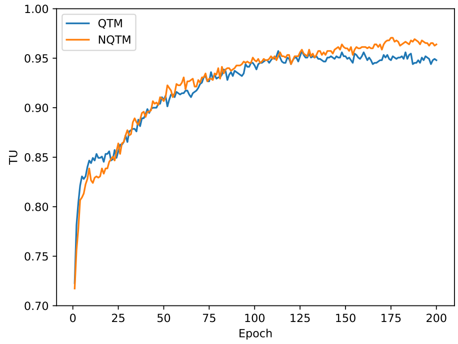

Figure 3: Change of TU scores along training epochs.

clearly superior with high coherence performance at the same time, which demonstrates the effectiveness of our model to alleviate the data sparsity problem.

5.2 Ablation Study

To conduct an ablation study, we also compare NQTM with VQ-VAE and QTM in Table 3. We can notice VQ-VAE sometimes has higher C_V scores, but as indicated in Section 5.1, it is useless because of its much lower TU scores. However, we can see QTM clearly has higher TU scores than VQ-VAE. This is because our new topic distribution quantization can separably distinguish topic distributions from different topics, while VQ-VAE cannot and leads massive texts under different topics to map to the same embedding vector. This contrast shows the effectiveness of our new topic distribution quantization method. Moreover, compared to QTM, we can see NQTM performs comparatively better on C_V scores and achieves obvious improvements on TU scores. This is because our negative sampling decoder provides extra learning signals to encourage topic-word distributions to differ from each other, bringing about better topic diversity performance. The change of TU scores of QTM and NQTM along training epochs is shown in Figure 3 that illustrates the TU score of NQTM gradually becomes higher than QTM during the training process. It is necessary to note that one advantage of QTM over NQTM is that QTM is faster on training since the negative sampling error is not required.

According to the above comparisons between VQ-VAE, QTM and NQTM, we can observe that our proposed new topic distribution quantization and negative sampling decoder are effective in improving the topic quality of short texts.

5.3 Data Sparsity Analysis

Since data sparsity is the essential challenge of short text topic modeling, to further demonstrate the advantages of our model, we explore the topic coherence and diversity performance under varying data sparsity degrees regarding two aspects, topic numbers (K) and minimum document frequencies (min-df) in preprocessing (see Section 4.1). Experimental results of NVDM, ProdLDA, SeaNMF are reported as these baselines perform relatively better in traditional and neural topic models respectively. Figures 2a and 2b show the C_V and TU scores of StackOverflow with topic number K ranging from 10 to 100. We can see although the TU scores of all models tend to decline due to the lack of word co-occurrences, NQTM decreases much slower than others by a large margin and also surpasses other baseline models in terms of C_V. Figures 2c and 2d present the C_V and TU scores of StackOverflow preprocessed by different min-df, from 0 to 10 under $K = 50$. Note that data sparsity becomes severer when preprocessing corpora with a bigger min-df. We can see that NQTM remains higher C_V scores than others and especially, TU scores of baselines fall sharply while NQTM still obviously keeps up.

Based on the above results under various data sparsity conditions, we can conclude that NQTM is grossly more robust in tackling the data sparsity challenge of short texts, which means NQTM can be better utilized in downstream applications.

Table 4: Topic words examples under $K = 50$. Repetitive words are underlined.

5.4 Topic Examples Evaluation

To qualitatively illustrate the high-quality topics generated by our model, Table 4 presents the examples of topic words yielded by DMM, GPUDMM, SeaNMF, NVDM, ProdLDA, and NQTM in one experiment. We can observe that baseline models generate some repetitive topics with repeated words, such as "movie", "qt" and "processor", and although the topics of NVDM seem diverse, they're less informative. However, we can see that NQTM only generates a single coherent topic for each corresponding topic and the topic quality of NQTM is apparently higher.

5.5 Visualization of Latent Space

Figure 4 shows the t-SNE (van der Maaten and Hinton, 2008) visualization for topic distributions of texts under $K = 50$. It obviously illustrates that the points of NQTM are relatively more aggregated as groups and well separately scattered in the canvas, which is because NQTM can generate peakier topic distributions for short text topic modeling. The discretization and separation of the latent space can explain why NQTM is able to achieve higher topic coherence and diversity performance.

6 Conclusion

In this paper, for short text topic modeling, we propose the Negative sampling and Quantization Topic Model (NQTM) with a novel topic distribution quantization mechanism to yield peakier distributions and a new negative sampling decoder to enrich the learning signals. Experiments on benchmark datasets quantitatively and qualitatively show our model significantly outperforms baselines to overcome the data sparsity problem of short texts. Future works could focus on employing the proposed model in more downstream tasks.

Querying Across Genres for Medical Claims in News

Chaoyuan Zuo, Narayan Acharya, and **Ritwik Banerjee**
Computer Science, Stony Brook University
`{chzuo, nacharya, rbanerjee}@cs.stonybrook.edu`

Abstract

We present a query-based biomedical information retrieval task across two vastly different genres – newswire and research literature – where the goal is to find the research publication that supports the primary claim made in a health-related news article. For this task, we present a new dataset of 5,034 claims from news paired with research abstracts. Our approach consists of two steps: (i) selecting the most relevant candidates from a collection of 222k research abstracts, and (ii) re-ranking this list. We compare the classical IR approach using BM25 with more recent transformer-based models. Our results show that cross-genre medical IR is a viable task, but incorporating domain-specific knowledge is crucial.

1 Introduction

In recent years, the general population has increasingly sought out online sources for medical information (Fox, 2011; Fox and Duggan, 2013). Among the various types of sources, they mostly rely on online news articles, which often serve to disseminate medical findings from research studies (Medlock et al., 2015). It is, however, important to identify the source of a medical claim, especially during times of pervasive misinformation and during a pandemic, when people may not be able to visit a healthcare professional. When reporting a medical study, many news articles cite the original study either by embedding hyperlinks or explicitly showing a citation, thus providing the reader with critical markers of credibility (Fogg et al., 2009). Not all articles do this, however. Here, we present our work on finding scientific research publications that support the primary claims being made in a health-related news article. We design it as cross-genre query-based (or *ad hoc*) information retrieval (IR): given a medical claim made in a news article, retrieve the research publication supporting it.

(1a) *Tea drinkers live longer.*†

(1b) *Tea drinkers live longer, with the biggest boost linked to green variants.*‡

(2) *Tea consumption was associated with reduced risks of atherosclerotic cardiovascular disease and all-cause mortality, especially among habitual tea drinkers.*

† www.sciencedaily.com/releases/2020/01/200109105508.htm (accessed: May 31, 2020) cites the source and provides a hyperlink to it.

‡ www.telegraph.co.uk/news/2020/01/09/tea-drinkers-live-year-half-longer (accessed: May 31, 2020) incomplete source information and no hyperlink to the original research.

Table 1: Cross-genre medical IR where the claims (1a and 1b) are presented in lay terms in the news and serve as queries. The support (2) is provided in a research publication, expressed in specialist language.

When scientific research makes its way out of conferences and journals into news meant for general consumption, the information is presented in a drastically different language. The general audience is often poorly equipped for specialist language comprehension, to the extent that changing domain-specific language to one meant for a general audience has been treated as a discipline by itself (Swales, 2000). So this change is necessary on one hand, but on the other hand, it also increases the difficulty of IR, especially so in token-based methods such as BM25 (Robertson et al., 2009).

In this work, we present a dataset (Sec. 2) of claims made in medical news articles, where each claim is associated with at least one peer-reviewed research publication supporting it. For each claim, we present an IR task in Sec. 3 – search for the corresponding publication from a large corpus of medical research literature. The task itself is divided into two stages: (i) retrieve a candidate list of 500 abstracts from a large corpus, and (ii) re-rank them to obtain the correct publication. After discussing our findings, we present an overview of related research in Sec. 4 before concluding.

November 16–20, 2020.

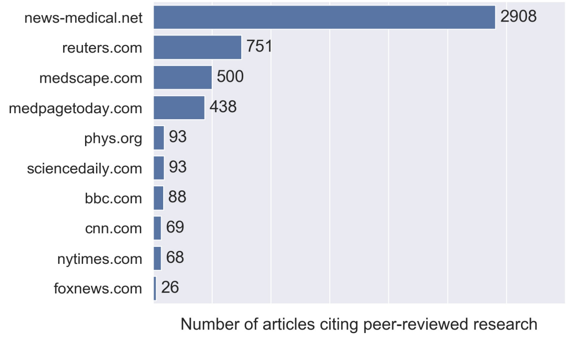

Figure 1: Distribution over sources of medical news articles that provide hyperlinks to cited research.

2 Dataset

Over a period of 18 months (Oct 2018 – March 2020), we collect 72,028 news articles from the RSS feeds of several medical news websites and also from the health category of popular general news websites. To ensure that only articles citing peer-reviewed scientific publications are retained, we check every document for hyperlinks to domains listed by Wikipedia as medical journals[1] and the list of top scientific publications on Alexa,[2] leaving 17,712 articles (24.6%) in our collection. Further, many articles were aggregations of disparate medical studies. We discard these using a combination of heuristics and manual verification, and retain only those articles that report on a single study or on a series of research studies that closely relate to each other. For articles retained after this step, the headline reflects the focal claim or finding of the cited research. This was observed by three independent readers who were given a random sample of 371 articles (7.4% of the dataset). All three agreed that for each one of these 371 articles, the headline did, indeed, present the main research finding. Since some articles cite using embedded hyperlinks, while others offer a reference section at the end of the article, we are able to collect the abstracts of the cited research.

Our final dataset[3] consists of tuples of the form $(h, \{a_i\})$, where h is the headline from a news article, and a_i are the abstracts of the research publications cited by that article. The publication titles are retained as well. There are 5,034 headlines and 4,566 abstracts (since some research publications are cited by multiple news articles). Fig. 1 shows the distribution of the news headlines over the top ten news domains in our collection.

Since not all research is open-access, we restrict ourselves to collecting the abstracts instead of the entire publication. We believe this does not prove to be a hindrance to the task, since it is reasonable to assume that the primary findings of a research study are mentioned in the abstract. We collect these abstracts through PubMed.[4] Further, to mimic the realistic scenario where a human reader or fact-checker needs to retrieve the correct publication (i.e., the research actually upholding the claim being made in a news article) from a vast collection, we also add 217,665 spurious abstracts from the biomedical research literature. We collect these abstracts from the non-commercial use open-access subset of PubMed Central,[5] to serve as the negative samples in our IR task.

3 Experiments

Our task is formulated in two stages, similar to other recent ad hoc IR (MacAvaney et al., 2019a; Yilmaz et al., 2019; Dai and Callan, 2019) – a token-based first step to obtain a candidate list, and then the final ranking by a transformer (Wolf et al., 2019). In spite of recent advances, the transformer-based models are large, and using them to compare each query with each document is computationally expensive even for a small corpus. Thus, the two-stage approach remains a prudent choice.

3.1 Candidate Selection

Given the size of the corpus of biomedical abstracts ($>$ 222k), our goal in this first stage is to reduce the search space for the final ranking task. For this, we consider the classical IR approach of token-based bag-of-words models (e.g., BM25) as well as embedding-based models that encode the claim (i.e., the news headline) and the research abstract in the same space. For the latter, we use the inner product of the embedded representations to measure the similarity between a headline and an abstract (Chang et al., 2020). Since most news articles cite only one research publication, and no article in our dataset cites more than three, precision is not an important measure for this task. Instead, we measure recall@k ($k = 1, 5, 20, 100, 500$). As argued in other recent two-stage approaches (Nie et al., 2019; Soleimani et al., 2020), a high recall is

BC-BERT$_A^{\text{MED}}$	0.144	0.256	0.364	0.511	0.665
BC-BERT$_B^{\text{MED}}$	0.148	0.265	0.369	0.509	0.666

Table 2: **Candidate selection results.** The token-based model with preprocessing steps (†) achieves significantly better results compared to all other models. BC-BERT is the Bio+Clinical model, where $^{\text{MED}}$ denotes fine-tuning on the medical STS data, with A and B denoting the two modifications handling labeled abstracts: the entire abstract being encoded, and only the first and last three sentences being encoded.

crucial here, as the correct abstract will otherwise be left out from the final ranking.

As part of the token-based approaches, we use Okapi BM25 (Robertson et al., 2009) and a variant, BM25+ (Lv and Zhai, 2011a). We employ the Rank-BM25 tool,[6] based on Trotman et al. (2014). We evaluate these with and without preprocessing, where the preprocessing comprises converting the words into lowercase, removing function words, and stemming.[7] We also notice that several abbreviations are used in medical news that are not commonly found in the research literature (BP for "blood pressure", Tx for "treatment", etc.). If such an abbreviation appears more than twice in our dataset, we map it to its expansion, based on a dictionary of medical abbreviations.[8]

For the embedding-based approaches, we use two pre-trained models to encode the claim h and the abstracts a_i – BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), from Sentence-BERT (Reimers and Gurevych, 2019). We obtain the ranked list of abstracts pertinent to the claim based on the inner products $\langle h, a_i \rangle$. The pre-trained models are fine-tuned on the Natural Language Inference (NLI) and the Semantic Textual Similarity (STS) benchmark datasets (Cer et al., 2017). Considering our dataset comprises medical news and biomedical literature while BERT and RoBERTa are trained on general texts, we also use the Bio+Clinical BERT (Alsentzer et al., 2019) model and tune it on the NLI and STS benchmark datasets. Additionally, we also tune the Bio+Clinical model on the medical STS dataset (Wang et al., 2018). It is worth noting that many medical research abstracts are further divided into labeled sections (e.g., 'Background', 'Results', 'Conclusion'). In our dataset, 36% of the abstracts featured such labels. We conduct three experiments where

(a) the whole abstract is encoded regardless of labeled sections being present (BC-BERT$^{\text{MED}}$),
(b) only the 'Background' and 'Conclusion' are encoded for abstracts with labeled sections (BC-BERT$_A^{\text{MED}}$), and
(c) identical to (b) when there are labeled sections, but only the first and last three sentences are encoded otherwise (BC-BERT$_B^{\text{MED}}$).

Table 2 shows that token-based models significantly outperform all embedding models in the candidate selection stage, with BM25+ achieving the best recall for all k when the preprocessing steps are included. Among the embeddings, fine-tuning on the medical STS data provides a significant improvement, which indicates the importance of domain-specific training. The BC-BERT$_B^{\text{MED}}$ experiment was conducted based on our observation that even in abstracts without labeled sections, the primary claims are seldom made in the middle region. The results appear to support this as well. Its improvement over the other variants of BC-BERT, however, is not significant.

3.2 Transformer-based Ranking

We keep $3,000$ headlines for training, $1,000$ for development, and $1,034$ for testing. We first use the best candidate selection model (BM25+†) to generate a list of 500 abstracts for each headline, and then concatenate a headline with an abstract. These concatenated strings serve as training data for our task. The ground-truth label is 1 for an input $h + a$ where a is, indeed, the abstract cited by the article with headline h. For other inputs, the label is 0. We use this labeled data to tune pre-trained transformer models. During prediction, we use the softmax probabilities of the classification scores to re-rank the abstracts for each headline, and calculate recall@k for $k = 1, 3, 5, 20$, as well as the mean reciprocal rank (MRR).

It is possible that the correct abstract was not retrieved during candidate selection. In that case, we add it back during training (but not testing). Since this data is highly imbalanced (roughly a $1 : 500$ ra-

BC-BERT$_{(0,1)}$	0.311	0.527	0.601	0.775	0.447
BC-BERT$_{(4,10)}$	0.538	0.702	0.759	0.825	0.636
BC-BERT$_{(20,50)}$	**0.626**	**0.743**	**0.783**	**0.828**	**0.695**

Table 3: **Ranking results.** The Bio+Clinical model is denoted by BC-BERT. A model tuned on m positive (by augmentation) and n negative samples is shown by the subscript (m, n). The best performance is achieved by Bio+Clinical BERT with 1 epoch, batch size of 24 and maximum sequence length of 512 tokens.

tio for the classes labeled 1 and 0, respectively), we use natural language data augmentation (Ma, 2019) to oversample the positive class. These augmentations work by either inserting or substituting words that are highly likely based on distributional similarity. For training, we choose the augmentation parameters such that at most 10 but not exceeding 30% of the tokens in a sentence are augmented. We generate 4 augmented samples (2 insertions, 2 substitutions) and 20 augmented samples (10 insertions, 10 substitutions) when we use the top 10 and 50 negative samples, respectively, in the list of 500 abstracts for each headline.

As part of our experiments, we train different models – BERT, Bio+Clinical BERT, XLNet (Yang et al., 2019), and DistilBERT (Sanh et al., 2019) – with transformer. We train them on different versions of the datasets controlling for the number of negative samples per claim and the number of augmented positive samples. All models are trained for 1 and 2 epoch, batch size of 16 and 24, maximum sequence length of 256 and 512 tokens, and a learning rate of 5×10^{-5}. The final hyperparameters are manually chosen based on MRR achieved on the development set. All experiments are conducted on NVIDIA Tesla V110 GPUs.

3.3 Discussion

First, there is the existential question about candidate selection: why not simply train the final ranking algorithm with random negative samples instead of the token-based first step? With random negative sampling, we found that it was rather *obvious* for both human readers and learning algorithms that the negative samples did not support the claim, simply because random sampling often draws publications not related to the claim at all. This would defeat the objective of our work, which is to aid readers in attempting to fact-check a health-related claim based on the citation provided in a news article. It is unlikely that readers will compare a publication on a topic vastly different from the one being reported (*e.g.*, the news article makes a claim about COVID-19 while the research is about 'haemophilia'). Thus, even though random negative sampling is commonly used to train fact-checking systems (e.g., Hanselowski et al. (2018); Nie et al. (2019)), it is ill suited for the task presented here.

It is also worth pointing out that our evaluation relies on relevance labels obtained from citations from news articles. It is possible that some documents ranked higher are relevant and provide support to the medical claim, but were judged as irrelevant because they were not cited by the news article. Despite this, recall@k and MRR are meaningful. For instance, if the cited publication is ranked third, while two other relevant publications are ranked above it, recall@k will effectively find success at $k = 3$. With exhaustively verified non-relevance labels, this hypothetical scenario would yield $k = 1$. Obtaining these labels is a daunting task, however. Indeed, many IR benchmark datasets – *e.g.*, MS-MARCO (Nguyen et al., 2016) – do not provide strong non-relevance labels. In this general evaluation setup, the results may instead be viewed as a lower bound (*i.e.*, with exhaustive ground-truth labels of non-relevance, they are better, not worse).

BM25 is hard to beat as a baseline for candidate selection, but token-based methods err when the words in the news headline do not appear in the abstract, which is common when synonymous or similar meanings are expressed using different terms across two different genres. The best embedding-based model, BC-BERT$_B^{\text{MED}}$, was able to include 33% of the abstracts that BM25+† failed to retrieve in the top 500 candidates. This also indicates why contextual embeddings improve the ranking results (Table 3). [9] From candidate selection on the test set, the best recall@500 is 0.834, which serves as the upper bound for the ranking task. After training, the transformer-based models can nearly attain this bound for $k = 20$. This is true even for the general BERT embeddings tuned on just 20 positive and 50 negative samples. The Bio+Clinical variant outperforms the other models. The relative improvement over BERT, however, is not significant.

---

[9] Run times and results on the development set are provided in the Appendix.

Overall, our results show that these embeddings do not need much task-specific tuning on the final ranking. However, both token- and embedding-based approaches fail when the claim is fairly generic (e.g., “Research could help design better flu vaccines”), and these errors happen during candidate selection as well as the final ranking.

4 Related Work

Modern *ad hoc* IR systems are largely built upon bag-of-words representations, using term-weighting techniques like BM25 (Robertson et al., 2009) or its variants (Lv and Zhai, 2011a,b). Catena et al. (2019) used such a variation for query-based news retrieval, which focuses on specific regions in an article. They use the headlines as queries and formulate the task as retrieving the corresponding article. Such headline-content pairs from newswire have similarly been used in neural IR models as well (MacAvaney et al., 2019b).

Neural models have also recently been used in biomedical IR tasks, due to the availability of large datasets. Mohan et al. (2018) introduce a deep learning model to retrieve biomedical research literature. Further, deep neural architectures have been coupled with external knowledge bases (Zhao et al., 2019), where research documents are retrieved as part of a precision medicine task. In this body of work, the query is either an in-domain keyword, or structured information. As such, they cannot be readily used where the query may be expressed using complex linguistic structures found in the newswire. Example 1b in Table 1, for instance, stresses on a specific aspect of the claim using an adjectival clause as a modifier.

Given the success of BERT and its successors in natural language inference tasks, *ad hoc* IR systems have used them for claim verification (Hanselowski et al., 2018; Nie et al., 2019; Liu et al., 2019; Yang et al., 2019). Applications of such models to binary classification for query-based passage re-ranking suggest that contextual information can be valuable when re-ranking an initial list of possibly relevant documents retrieved by BM25 model (Nogueira and Cho, 2019). These approaches are not readily suitable for cross-genre IR, but they motivated some of our technical choices. For instance, our use of pointwise (instead of pairwise) loss was based on the discussion in Soleimani et al. (2020) regarding IR tasks with BERT-style models.

Fact-checking is a critical component in fighting misinformation, but medical misinformation is known to be nuanced. For example, instead of outright false claims, statements are known to undergo exaggeration. In this general context of thwarting medical misinformation, there is some notable work that, while being distinct from the IR task discussed here, complements our research. For instance, Sumner et al. (2014) studied the exaggeration of medical claims in the news vis-à-vis the original findings in research publications.

5 Conclusion

In contrast to recent research in ad hoc neural IR, which require large amounts of training data (Mitra and Craswell, 2018), we present a system that combines term-weighting techniques and neural models across two distinct linguistic genres. We also provide a novel dataset of medical newswire queries linked to research literature. Our results show that while neural models excel at re-ranking a small number of documents when pre-trained contextual embeddings are tuned on domain-specific data, classical token-based approaches remain difficult to beat in a cross-genre retrieval scenario when the search space is larger. Our data collection process also reveals that even in a domain as critically important as medical news, only a small fraction of news articles (24.6%) include a complete citation and a link to the original research. Thus, the presented task has utility in medical fact-checking, identifying health-related misinformation, and assessing some empirically verifiable aspects of health news reporting.

Abstract

Open-domain Keyphrase extraction (KPE) on the Web is a fundamental yet complex NLP task with a wide range of practical applications within the field of Information Retrieval. In contrast to other document types, web page designs are intended for easy navigation and information finding. Effective designs encode within the layout and formatting signals that point to where the important information can be found. In this work, we propose a modeling approach that leverages these multi-modal signals to aid in the KPE task. In particular, we leverage both lexical and visual features (e.g., size, font, position) at the micro-level to enable effective strategy induction, and meta-level features that describe pages at a macro-level to aid in strategy selection. Our evaluation demonstrates that a combination of effective strategy induction and strategy selection within this approach for the KPE task outperforms state-of-the-art models. A qualitative post-hoc analysis illustrates how these features function within the model.

1 Introduction

We present a novel multi-modal approach to **K**ey**P**hrase **E**xtraction (KPE), which is the task of automatically extracting salient phrases from a given document. The KPE task is a foundational task, which plays a facilitating role in many Information Retrieval (IR) tasks, including classification, summarization, and document indexing (Hasan and Ng, 2014). Specifically, the KPE task requires accurate selection of the phrases that best capture the web document's topic. Well-performing approaches take advantage of document structure and entity co-occurrences.

Over the history of work in this area, there have been a variety of benchmarks (Medelyan and Witten, 2002; Nguyen and Kan, 2007; Wan and Xiao, 2008; Meng et al., 2017) and an equally wide variety of both non-neural (Grineva et al., 2009; Liu et al., 2009, 2010) and neural modeling approaches (Meng et al., 2017; Zhang et al., 2017; Chen et al., 2018). The earliest KPE approaches were mainly limited to domain-specific keyphrase extraction. The recent release of **OpenKP** (Xiong et al., 2019), a large-scale feature-rich dataset specifically developed for open-domain web-page keyphrase extraction, has encouraged further research related to the KPE task. A novel characteristic of this data set is the inclusion of features related to visual properties.

Visual properties of words and web page layout offer a KPE model utility in at least two respects. First, **micro-level features** operating at the word level, including lexical features as well as features related to size, font, color, and position of words, signal relative importance of words within extended texts. Intuitively, texts that are highlighted with colored, bold or bigger font or placed in more obvious places within a web page are more likely to be important, and should correspondingly be given higher probability as a keyphrase. Next, **macro-level features** describing the layout and type of page (e.g., News, Storefront, etc.) are related to the distribution of keyphrases. For example, for a news or blog website, the title or the first paragraph of its main content are likely locations for finding keyphrases, while for an Indexing page, the important phrases will more likely be found in lists. Important information may also be listed underneath or beside pictures.

Based on these insights, we propose a multi-modal framework, **S**trategy-based **M**ultimodal **AR**chi**T**ecture for **K**ey**P**hrase **E**xtraction (SMART-KPE), addressing the web KPE task in two steps: **Multimodal Strategy Induction** to apply specific extraction tactics with a refined use of micro-level features and **Strategy Selection**

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1790–1800,
November 16–20, 2020.

to choose results from different tactics using macro-level features. In our evaluation, we compare SMART-KPE with several state-of-the-art baselines, where SMART-KPE shows its better ability to locate and extract keyphrases. We offer post-hoc case studies and ablation studies to illustrate model strengths and weaknesses. In addition to the improvement over SOTA baselines for the KPE task, to the best of our knowledge, Strategy-based Multimodal Architecture for Keyphrase Extraction is the most comprehensive treatment of multimodality in open-domain KPE.

2 Related Work

2.1 Development of Open-domain Web Keyphrase Extraction

Originally, the concept *keyphrase* was first used by authors of scientific papers when they indicated by hand a few phrases they decided best summarized their paper (Çano and Bojar, 2019). The first corpora for automated keyphrase extraction were likewise assembled out of publications from scientific fields including technical reports (Witten et al., 1999), paper abstracts (Hulth, 2003), and scientific papers (Nguyen and Kan, 2007; Medelyan et al., 2009; Kim et al., 2010). To this day, scientific publications still serve as a fundamental fixed-domain benchmark for neural KPE methods (Meng et al., 2017; Alzaidy et al., 2019; Sahrawat et al., 2019) due to the availability of ample data of this kind. However, experiments have revealed that KPE methods trained directly on such corpora do not generalize well to other web-related genres or other types of documents (Chen et al., 2018; Xiong et al., 2019), where there may be far more heterogeneity in topics, content and structure, and there may be more variation in terms of where a key phrase may appear.

Past researchers have collected corpora for KPE in Internet and social media environments, including web pages (Yih et al., 2006; Hammouda et al., 2005), blogs (Grineva et al., 2009), email (Dredze et al., 2008), news articles (Wan and Xiao, 2008; Hulth and Megyesi, 2006) and live chats (Kim and Baldwin, 2012), but most of these existing corpora fall prey to similar problems with respect to robust model training for neural models due to data sparsity and lack of representativeness in topic distribution. The recently released OpenKP (Xiong et al., 2019) is the first large-scale KPE dataset with a broad distribution of topic domains. This recent dataset facilitates work on model generalization and the opportunity to develop nuanced models that can adapt their performance based on the type of document they are applied to. This property of the dataset has inspired our proposed method where strategies are selected based on the detected type of document using macro-level features.

2.2 Neural Keyphrase Extraction Approaches

The earliest neural KPE models treat the KPE task as a standard encoder-decoder task, which first creates an encoding of the input using an RNN (Meng et al., 2017) or CNN (Zhang et al., 2017), and then decodes the predicted keyphrases. These early approaches were strictly limited to textual data representations.

The release of OpenKP (Xiong et al., 2019) has introduced opportunities for research in multimodal KPE. OpenKP is now a recently added branch of MS-MARCO(Nguyen et al., 2016), with a public leaderboard for the KPE task held by Microsoft[1]. Built from Web data, it serves as the first large-scale benchmark for open-domain neural keyphrase extraction. In addition to providing the raw *text* of each document, OpenKP also includes various *visual features* associated with each text term, such as position, size, font, etc. Along with OpenKP, Xiong et al. (2019) also proposed BLING-KPE, the first neural model baseline for open-domain keyphrase extraction using visual features along with text. BLING-KPE first generates a hybrid embedding for each term by concatenating: (1) the ELMo (Peters et al., 2018) representation of the term, (2) standard sinusoidal position embedding (Vaswani et al., 2017), and (3) 18 of the 20 **visual features** of the term available in the OpenKP dataset. It models n-grams using multiple CNNs, and utilizes a Transformer (Vaswani et al., 2017) layer and feed-forward layer for scoring. This approach represents the first attempt at multimodal KPE.

Recently, Sun et al. (2020) achieved greater success on the OpenKP task by modeling keyphrase extraction as multiple traditional text tasks, including sequence labeling, chunking, salience ranking, etc. From this work we adopt the idea of modeling KPE as a sequence labeling task, where one of five tags is assigned to each document term: **NO**n

---

[1] `https://microsoft.github.io/msmarco/`

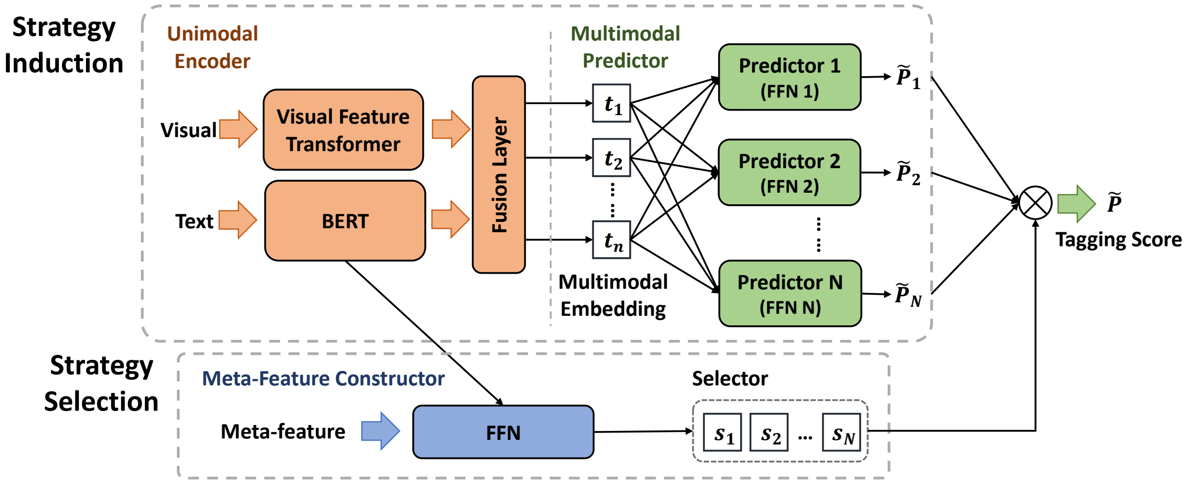

Figure 1: The SMART-KPE model architecture. Arrow between *BERT* and *FFN* represents the overall textual representation $\vec{w}_{CLS}$.

keyphrase, **B**egin word of the keyphrase, M**I**ddle word of the keyphrase, **E**nd word of the keyphrase, and **U**ni-word keyphrase.

However, despite multiple recent efforts on this newly proposed dataset, published work so far in multimodal KPE has either omitted available features (Sun et al., 2020), or has adopted a brute force approach to feature encoding (direct concatenation of raw features) (Xiong et al., 2019). Therefore, in this work we strive for a more nuanced approach to leveraging available features for multimodal KPE and offer a uniquely comprehensive approach.

3 Model

3.1 Task Definition

Here we formalize the keyphrase extraction task (KPE) under the web page setting: Given a document $D = \{W, V, M\}$, where $W = \{w_1, w_2, \ldots, w_n\}$ are the text terms of the web page with length n, $V = \{v_1, v_2, \ldots, v_n\}$ are the respective visual features of each term and M is the set of macro-level meta-features describing the document, we aim to find the set of word sub-sequences $S = \{S_1, S_2, ..., S_K\}$ where $S_i = \{w_{j_i}, \ldots, w_{j_i+k_i-1}\}$ are the extracted keyphrases from the document text that are the most salient and best represent the keypoints of the document.

We adopt the method used by Sun et al. (2020)(**BERT2Tag**), where KPE is modeled as a **sequence labeling** problem on text terms W. For a given document, each term is assigned one of five labels: namely, $\{O, B, I, E, U\}$, which represent n**O**n keyphrase, **B**egin word of the keyphrase, Middle word of the keyphrase, **E**nd word of the keyphrase and **U**ni-word keyphrase respectively. In the following sections, we elaborate on the details of training and testing for this sequence labeling task.

3.2 Model Structure

We divide the web KPE task into two steps: **multimodal strategy induction**, where specific tactics are applied to micro-level multimodal features, and **strategy selection**, where macro-level features are used to choose the best available strategy matching the form of the current page. We devise **S**trategy-based **M**ultimodal **AR**chi**T**ecture for **K**ey**P**hrase **E**xtraction (SMART-KPE), a multimodal framework that extends the sequence labeling foundation.

Figure 1 illustrates the architecture of SMART-KPE. Specifically, it incorporates three components: Unimodal Encoder, Multimodal Predictor and Meta-Feature Constructor.

3.2.1 Multimodal Strategy Induction

In this step, strategies are learned from selected subsets of available micro-level features for the KPE task. Specifically, our model first generates contextualized embeddings for both textual and visual features separately in the Unimodal Encoder. These embeddings are fused and subsequently fed into several distinct strategy-specific sequence labeling networks in the Multimodal Predictor, each generating a separate probability distribution of each token's possible tag.

The micro-level features used during this step are provided by the dataset, specified in Section 4.1.

Unimodal Encoder The Unimodal Encoder is designed to build each term's multimodal representation based on both textual and visual modalities. We use a pretrained uncased BERT model (Devlin et al., 2018) to generate the contextualize term embeddings. Similarly, we apply a separate transformer (Vaswani et al., 2017) to the visual features. This can be formulated as:

$$\vec{w}_{[CLS]}, \vec{w}_1, ..., \vec{w}_n = \mathrm{BERT}(W), \quad (1)$$

$$\vec{v}_1, ..., \vec{v}_n = \mathrm{Vis\_Transformer}(V). \quad (2)$$

where $\vec{w}_i$ and $\vec{v}_i$ are the contextualized text and visual embeddings of word w_i respectively. $\vec{w}_{CLS}$ is the BERT representation of the [CLS] token, which we use later as a representation of the whole document in the Meta-Feature Constructor.

We motivate our handling of visual features using two intuitions. First, similar to text, visual features can be expected to achieve completely different visual effects depending on the page context: e.g., a word with font size 20 might be commonly used in one web page while it could mark the largest word in another. Second, the behavior and characteristics of visual and text modality features are different from one another. Therefore the first-step self-attention should be modeled in separate networks for text and visual features.

At the end of the Unimodal Encoder, textual and visual embeddings are concatenated as the final representation of a term and fused globally with another transformer:

$$\vec{e}_i = \vec{w}_i || \vec{v}_i, \quad (3)$$

$$\vec{t}_1, ..., \vec{t}_n = \mathrm{Transformer}(\vec{e}_1, ..., \vec{e}_n). \quad (4)$$

Multimodal Predictor The Multimodal Predictor consists of N label predictors representing N different extraction strategies. Each predictor takes the textual and visual embeddings given by Eq. 4 and generates a tag score distribution $\mathcal{P}_{i,k}$ for the term i independently using a 2-layer feed-forward network:

$$\mathcal{P}_{i,k} = softmax(\mathrm{FFN}_k(\vec{t}_i)). \quad (5)$$

Note that all the strategies here are defined implicitly, which means we do not introduce any human assigned prior related to identification of page type. Rather, we allow latent information on page types to emerge and differentiate between strategies as the network's learning process finds through optimization. This avoids a time-consuming labeling process and also mitigates the risk that types that seem intuitive from a cognitive standpoint might nevertheless not offer utility within the optimization.

3.2.2 Strategy Selection

In order to obtain the overall sequence labeling result, the Meta-Feature Constructor encodes the macro-level meta-features to perform a weighted selection upon predictors in the Multimodal Predictor. In this work, we use the following kinds of macro-level meta-features:

Whole-Text Representation Here we use $\vec{w}_{CLS}$, the representation of the [CLS] token of our BERT model in the Unimodal Encoder as an estimated overall textual representation of both the website document and the title.

Snapshot The visual embedding extracted from the snapshot of the original web page using Resnet-152 (He et al., 2016). This is a novel aspect of our work that offers the model the opportunity to identify characteristics of the overall layout and appearance of the web page.

This architecture is designed to flexibly include more meta-features given extra data or resources. All the meta-features are concatenated within a meta-feature embedding $\vec{m}$, after which a feed-forward network is applied to generate a normalized N-dimensional selector vector:

$$\vec{S} = (s_1, ..., s_N) = softmax(\mathrm{FFN}(\vec{m})), \quad (6)$$

$$s_k = \underset{k}{softmax}(s'_1, ..., s'_N). \quad (7)$$

We use the selector vector s_k as the weights for the N sequence label predictors in Multimodal Predictor to generate the overall probability that each tag is assigned to a term.

$$\tilde{\mathcal{P}}_i = \sum_{k=1}^{N} s_k \mathcal{P}_{i,k}, \quad (8)$$

$$p_{i,T} = \tilde{\mathcal{P}}_i(T), \quad (9)$$

where $p_{i,T}$ is the probability of term i being labeled as tag $T \in \{O, B, I, E, U\}$, as described in Section 3.1.

3.3 Training and Keyphrase Prediction

The SMART-KPE model is trained in an end-to-end way using term-wise cross-entropy loss:

$$loss = -\sum_{i=1}^{n} \log \tilde{\mathcal{P}}_i(y_i), \tag{10}$$

where y_i is the correct tagging label for word w_i according to its relation to the golden keyphrases.

For keyphrase prediction, after SMART-KPE predicts the tag probability distribution for each term, the score of each phrase is calculated as follows:

$$Score(S_{i:i+k}) = \min_{j \in [i, i+k)} p_{j,T'_j},$$

where T'_j is the corresponding tag for term w_j given $S_{i:i+k}$ is a keyphrase, and p_{i,T'_i} is the predicted probability of w_j being labeled as T'_j. Min-pooling is used here to enable keyphrases to be treated in a comparable fashion regardless of length.

4 Experimental Methodology

4.1 Dataset

We set OpenKP as the main dataset for our task. OpenKP consists of ∼150K documents sampled from the Bing search engine, within which neither the domain nor type of original web pages are restricted.

For each document, the following information is given:

- **URL:** The link to the respective web page.
- **Text:** Cleaned body text of a document.
- **Visual DOM features:** A set of vectors representing the visual characteristics of text terms, listed in Table 1. For each term, features describing itself and its parent block in the DOM Tree are included.

Feature Name	Dimension
Block Position	2×2
Block Size	2×2
Font Size	1×2
Is Bold	1×2
Is Heading Element	1×2
Is Block Element	1×2
Is Inline Element	1×2
Is Leaf Element	1×2

Table 1: Visual features in OpenKP

Property	Value
# of Training Docs	134,894
# of Validation Docs	6,616
# of Test Docs	6,614
Average Doc Length	900.4
Average KPs per Doc	1.8
Average KP Length	2.0
Doc Vocab size	1.5M
KP vocab size	62K

Table 2: Statistics of OpenKP

The keyphrases for each document in the given dataset were labeled by expert annotators, with each document assigned 1-3 keyphrases. As a requirement, all the keyphrases were ones that appeared in the original document. The detailed statistics of OpenKP are displayed in Table 2.

In the original dataset, no meta-features are provided except the website URL. We downloaded the title of each website and concatenated the titles with the cleaned body text as the text input of our model. We also took a snapshot in the Google Chrome Browser for the web page with display size 600 × 800 and all the element shrunk to 50% in order to get a more comprehensive view of the website. [2]

4.2 Baselines and Evaluation Metrics

We compare SMART-KPE with the following baselines on the OpenKP dataset:

BLING-KPE (Xiong et al., 2019) *Beyond Language UnderstandING KeyPhrase Extraction*, the official baseline proposed with the OpenKP dataset. It concatenates ELMo, visual and positional features and uses a CNN structure to generate k-gram phrase embeddings for binary prediction.

BERT2{Span,Chunk,Tag,Rank,Joint} (Sun et al., 2020) A set of models applying different keyphrase extraction methods (Span prediction, Chunking, Tagging, Ranking and Joint method) upon BERT and its variants. Note that for fair comparison, we report all results obtained by BERT-based baseline models and compare them

* These numbers are not included in the original paper and are estimated with Precision and Recall.
** These results are re-evaluated on the updated official dataset.
*** Since no macro-level meta-features are used in these model variants, the number of Predictors is set to 1.

Table 3: Model performances on the OpenKP development set. F1@3 is the main metric for this task. SMART-KPE-Full is the complete model and Skeleton, Micro and Macro denote for ablations where no additional features, only micro-level visual features, or only macro-level features are introduced respectively. SMART-KPE+R2J is our complete model equipped with the state-of-the-art extracting method (RoBERTa2Joint).

with the basic version of SMART-KPE which also uses BERT. For further comparison, we also report the strongest baseline result (RoBERTa2Joint) presented by Sun et al. (2020), and compare it to a RoBERTa-based variant of SMART-KPE in Section 5.1.

For evaluation of our generated keyphrases, we follow the official MS-MARCO guide and evaluation code [3]. Retrieval metrics include Precision, Recall and F1 at positions 1, 3 and 5, of which F1@3 is considered the main metric.

4.3 Implementation and Training Details

The model was implemented in Pytorch (Paszke et al., 2019) using the huggingface reimplementation of BERT (Wolf et al., 2019). Table 4 lists the parameters of our model. The maximum document length is 512 due to BERT limitations, and documents are zero-padded or truncated to this length. The model contains approximately 120M trainable parameters and was trained on a single GeForce GTX 1080 Ti GPU for around 12 hours to achieve best performance.

Hyperparameter	Dimension or Value
BERT Embedding	768
Visual Feature	18
Snapshot Embedding	512
Visual Transformer	3-head, 2-layer, 18-d hidden
Predictor Transformer	6-head, 2-layer, 786-d hidden
Predictor Number	4
Predictor FFN	128-ReLU-5
Meta-feature FFN	256-ReLU-4
Optimizer	AdamW
Learning Rate	1×10^{-5}
Batch Size	32

Table 4: Parameters used for training SMART-KPE.

5 Experimental Results and Analysis

5.1 Evaluation Results

Experimental results on the OpenKP dataset are listed in Table 3. We perform experiments on the full SMART-KPE model and its 3 variants, where *only micro-level visual features* (SMART-KPE-Micro), *only macro-level meta-features* (SMART-KPE-Macro), and *neither set of features* (SMART-KPE-Skeleton) are applied respectively. We see that all variants of BERT-based SMART-KPE outperform BERT2Tag and BERT2Joint on all metrics, suggesting the effectiveness of feature construction and strategy selection.

Table 5: Case Study of 3 web pages. Part of the original text, all golden keyphrases and top 3 predicted keyphrases are presented for each case. The correctly predicted keyphrases are highlighted in red. The snapshots of these 3 web pages are shown in Figure 2. Note that in the original data, punctuation is absent and keyphrases are case-insensitive. The text snippets we show here are restored from the original websites.

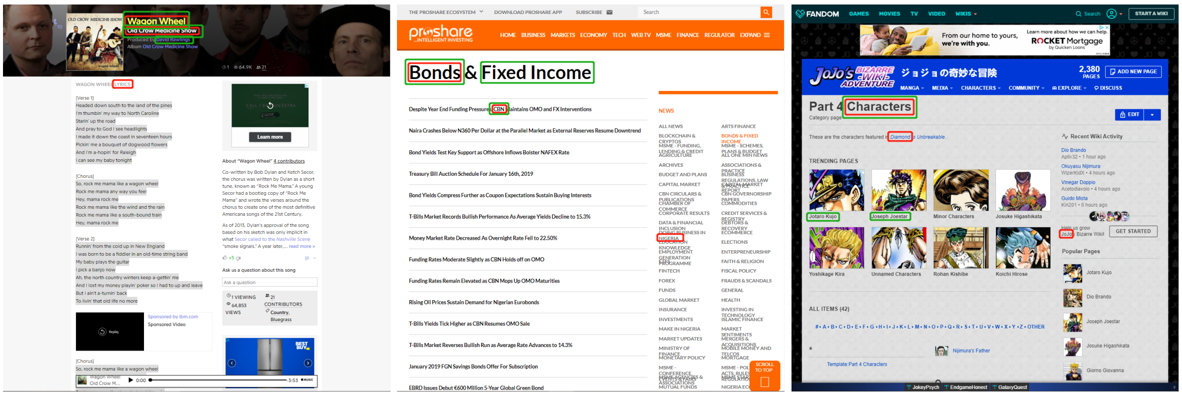
We further explore how different kinds of features function when extracting keyphrases. SMART-KPE-Skeleton outperforms the baselines even without the use of micro-level visual features and macro-level meta-features. This is due to the addition of title information as well as a more effective model structure. We observe further improvements as each multimodal feature component is added upon SMART-KPE-Skeleton, with the full model being the best combination. This analysis reveals the separate and joint effects of using meta-features and performing strategy selection, which formulates a complete approach to extract keyphrases.

We also change the BERT base in Unimodal Encoder to RoBERTa and replace the predictors in Multimodal Predictor from the tagging method to the joint extraction method(Sun et al., 2020) to fairly compare with the baseline with the best performance, RoBERTa2Joint. Experiment results are listed in the last two rows of Table 3. RoBERTa-based SMART-KPE outperforms both the baseline model and SMART-KPE-Full in all metrics, further demonstrating our model's flexibility to benefit from a more advanced text-based extraction backbone.

5.2 Case Study of Visual Feature Usage

We demonstrate the effects of introducing micro-level visual features by showing 3 cases from the validation set of OpenKP in Table 5. We present prediction results from SMART-KPE-Skeleton (SMART-KPE using only text features) and the complete SMART-KPE model. Snapshots of the original web pages are presented in Figure 2.

Cases #1 and #2 show how micro-level visual features help find the correct keyphrases. In Case #1, all the keyphrases are in the middle part of the webpage and more obvious than other words with different colors. The full model, successfully utilizing micro-level visual features, focuses on all of the keyphrases, while the skeleton model chooses a topic word in the first paragraph "Lyrics", resulting in a mistake. Case #2 shows a similar situation where the model with visual features finds the proper keyphrases that are much larger in font size, while the text-only model selects nouns elsewhere. On the other hand, Case #3 demonstrates a typical kind of web page where visual features can be misleading: an indexing page. In this kind of page, words larger in size and in bold are mostly



(a) Case #1 (b) Case #2 (c) Case #3

Figure 2: The snapshot of the websites listed in Table 5. Texts with green bounding boxes are keyphrases predicted by SMART-KPE-Full, and texts with red bounding boxes are keyphrases predicted by SMART-KPE-Skeleton. We can see the preference of the former model to focus on larger, bold and colorful texts.

entries to detailed contents, while the summarizing words before them, which are sometimes hidden in the small contents and easy to be omitted, are more likely to become keyphrases.

(b) Case #2

Figure 3: The predicted keyphrases of different predictors. Each color represents a specific predictor.

5.3 Analysis of Prediction Strategy Selection

In order to confirm that our predictors apply different tactics rather than simply duplicating each other, we calculate the overlap rate among the extracted keyphrases of different predictors.

We define the overlap rate for n sets as:

$$O.R. = \frac{\sum_{k=1}^{n}(k-1)n_k}{(n-1)\sum_{k=1}^{n} n_k}, \qquad (11)$$

where n_k is the number of elements shared by k different sets. An overlap rate of 0 indicates that no elements exist in more than one set while 1 indicates totally identical sets. As shown in Table 6, the overlap rates are low at all positions, which means the predictors are generating diverse keyphrases, leaving space for the selector to pick up final results with macro-level features.

	O.R.@1	**O.R.@3**	**O.R.@5**
SMART-KPE	0.252	0.284	0.320

Table 6: Overlap rate of SMART-KPE predictions.

We also looked back into the data to see the keyphrases in context. Figure 3 presents the locations of extracted keyphrases by different predictors. We can generally conclude the difference as the result of: (1) Focus bias of modalities. Some multimodal predictors behave similarly to a purely textual predictor while others focus more on distinctly visual features. (2) Chunking bias of words. Different predictors will chunk words in different ways. (3) Ranking bias of keyphrases. Even if the same keyphrases are selected in different instances, the influence of their scores depends on other scores being compared. The more keyphrases being compared, the less utility an individual score has. We see an increase in overlap rate when more keyphrases are considered.

5.4 Paragraph Length

We investigate whether paragraph length or segmented length affects performance. In the experiments section, we truncate the document and only use the first 512 words. Apart from statistical results indicating that the majority of keyphrases appear rather near the front for most web pages, we calculated P@3 and F1@3 for different maximum document lengths to see how the extent of truncation affects the extent of the model's ability to generate reasonable keyphrases. The results are presented in Figure 4.

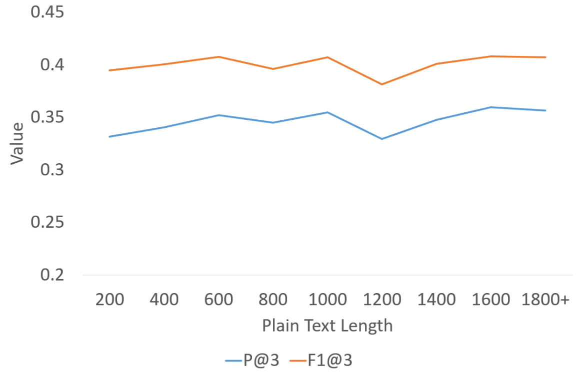

Figure 4: P@3 and F1@3 score from SMART-KPE for websites of different lengths.

From the figure, we can conclude that in our experiment, P@3 and F1@3 values are not heavily influenced by the length of the documents or amount of truncation. This is consistent with the intuition that keyphrases often appear at the top of the document(title, heading, first paragraph). Although there are advantages of increasing maximum text length, it is very resource-intensive and increases the difficulty of training because the amount of noise relative to the amount of signal increases as the maximum length increases.

6 Conclusions and Future Work

In this work we propose a Strategy-based Multimodal Architecture for Keyphrase Extraction (SMART-KPE) as a new state-of-the-art method for multimodal web-page keyphrase extraction. Different from traditional keyphrase extraction models mainly focusing on text, SMART-KPE illustrates the advantage of incorporating other modalities to help keyphrases location and salience prediction. Our proposed model outperforms several state-of-the-art baselines with the introduction of multimodal information. Through several case studies, we further illustrate how micro and macro-level features lead to the model's correct or incorrect selections.

As a first attempt to introduce macro-level meta-features for strategy selection, we believe there is much potential to refine and improve our approach. One high-level idea is to add further supervision to the current selector model based on empirical web page clustering, to better train the model to develop a set of more distinct keyphrase prediction strategies, and more effectively adjust the respective selector weights. We also plan to add more types of meta-features to generate richer multimodal representations. Furthermore, the SMART-KPE framework can be easily adapted to other NLP tasks, and we believe there is much potential in combining SMART-KPE with different models to further boost performance on open-domain KPE and other web-related tasks.

Figure 1: Overview of in-the-wild monologue videos and sentence utterances in the CMU-MOSEAS dataset. Each sentence is annotated for 20 labels including sentiment, subjectivity, emotions and attributes. "L" denotes Likert (intensity) and "B" denotes Binary for the type of the labels. The example above is a Portuguese video.

Abstract

Modeling multimodal language is a core research area in natural language processing. While languages such as English have relatively large multimodal language resources, other widely spoken languages across the globe have few or no large-scale datasets in this area. This disproportionately affects native speakers of languages other than English. As a step towards building more equitable and inclusive multimodal systems, we introduce the first large-scale multimodal language dataset for Spanish, Portuguese, German and French. The proposed dataset, called CMU-MOSEAS (CMU Multimodal Opinion Sentiment, Emotions and Attributes), is the largest of its kind with $40,000$ total labelled sentences. It covers a diverse set topics and speakers, and carries supervision of 20 labels including sentiment (and subjectivity), emotions, and attributes. Our evaluations on a state-of-the-art multimodal model demonstrates that CMU-MOSEAS enables further research for multilingual studies in multimodal language.

1 Introduction

Humans use a coordinated multimodal signal to communicate with each other. This communication signal is called multimodal language (Perniss, 2018); a complex temporal and idiosyncratic signal which includes the modalities of language, visual and acoustic. On a daily basis across the world, intentions and emotions are conveyed through joint utilization of these three modalities. While English, Chinese, and Spanish languages have resources for computational analysis of multimodal language (focusing on analysis of sentiment, subjectivity, or emotions (Yu et al., 2020; Poria et al., 2019; Zadeh et al., 2018b; Park et al., 2014; Wöllmer et al., 2013; Poria et al., 2020)), other commonly spoken languages across the globe lag behind. As Artificial Intelligence

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1801–1812,
November 16–20, 2020.

(AI) increasingly blends into everyday life across the globe, there is a genuine need for intelligent entities capable of understanding multimodal language in different cultures. The lack of large-scale in-the-wild resources presents a substantial impediment to multilingual progress in this fundamental research area in NLP.

In this paper, we introduce a large-scale dataset for 4 languages of Spanish, Portuguese, German and French. The dataset, called CMU-MOSEAS (CMU Multimodal Opinion Sentiment, Emotions and Attributes) contains $10,000$ annotated sentences from across a wide variety of speakers and topics. The dataset also contains a large subset of unlabeled samples across the 4 languages to enable unsupervised pretraining of multimodal representations. Figure 1 shows an example sentence from CMU-MOSEAS dataset along with the provided multimodal features and annotations. Annotations include sentiment, subjectivity, emotions, and attributes. We believe that data of this scale presents a step towards learning human communication at a more fine-grained level, with the long-term goal of building more equitable and inclusive NLP systems.

In the continuation of this paper, we first discuss the related resources and previous works. Subsequently, we outline the dataset creation steps, including the data acquisition, verification, and annotations. We also discuss the steps taken to protect the speakers and uphold the ethical standards of the scientific community. Finally, we experiment with a state-of-the-art multimodal language model, and demonstrate that CMU-MOSEAS presents new challenges to the NLP community.

2 Background

The related work to the content of this paper is split in two parts. We first discuss the related datasets, alongside comparisons with CMU-MOSEAS. Afterwards, we discuss the machine learning literature for modeling multimodal language.

2.1 Related Resources

We highlight the most relevant multimodal and unimodal datasets to CMU-MOSEAS. Further details of the below datasets, as well as comparison to CMU-MOSEAS is presented in Table 1.

CMU-MOSEI (Zadeh et al., 2018b) is a large-scale dataset of multimodal sentiment and emotion analysis in English. It contains over $23,000$ sentences from across 1000 speakers and 250 topics. **CH-SIMS** (Yu et al., 2020) is a dataset of Chinese multimodal sentiment analysis with fine-grained annotations of sentiment per modality. **IEMOCAP** (Busso et al., 2008) is an in-lab recorded dataset which consists of 151 videos of scripted dialogues between acting participants. **POM** dataset contains $1,000$ videos annotated for attributes (Park et al., 2014). The language of the dataset is English. **ICT-MMMO** (Wöllmer et al., 2013) consists of online social review videos annotated at the video level for sentiment. **CMU-MOSI** (Zadeh et al., 2016b) is a collection of 2199 opinion video clips each annotated with sentiment in the range $[-3, 3]$. **YouTube** (Morency et al., 2011) contains videos from the social media web site YouTube that span a wide range of product reviews and opinion videos. **MOUD** (Perez-Rosas et al., 2013) consists of product review videos in Spanish, annotated for sentiment. **AMMER** (Cevher et al., 2019) is a German emotion recognition dataset collected from a driver's interactions with both a virtual agent as well as a co-driver in a simulated driving environment. **UR-FUNNY** (Hasan et al., 2019) consists of more than 16000 video samples from TED talks annotated for humor. **Vera am Mittag (VAM)** (Grimm et al., 2008) corpus consists of recordings from the German TV talk-show "Vera am Mittag". This audio-visual dataset is labeled for continuous emotions of valence, activation and dominance. **RECOLA** (Ringeval et al., 2013) is an acted dataset of French language, consisting of 9.5 hours of audio, visual, and physiological (electrocardiogram, and electrodermal activity) signals. **EmoDB** (Burkhardt et al., 2005; Vondra and Vích, 2009) is a dataset of emotion recognition in German for speech and acoustic modalities.

Aside the aforementioned multimodal datasets, the following are related datasets that use only the text modality. **Stanford Sentiment Treebank (SST)** (Socher et al., 2013) includes fine grained sentiment labels for phrases in the parse trees of sentences collected from movie review data. **Large Movie Review** dataset (Maas et al., 2011) contains text from highly polar movie reviews. Textual annotated Spanish datasets have been collected from Twitter (**TASS**) (Villena Roma¡n et al., 2013-03; Pla and Hurtado, 2018; Miranda

Table 1: Best viewed zoomed in. Comparison between CMU-MOSEAS and relevant datasets. CMU-MOSEAS presents a unique resource for languages of Spanish, Portuguese, German and French. $[l, v, a]$ denote [language, vision and acoustic] modalities. Duration is in the HH:MM format.

and Guzman, 2017) and hotel reviews (Molina-González et al., 2014). Polarity classification tasks based on Twitter data have also been collected in Portuguese (Brum and das Graças Volpe Nunes, 2017) (**TweetSentBR**), German (Cieliebak et al., 2017; Flender and Gips, 2017) (**SB10k**), and French (Rhouati et al., 2018). Another line of related work aims to predict humor from text in multiple languages (Castro et al., 2016, 2017).

Table 1 demonstrates that CMU-MOSEAS is a unique resource for the languages of Spanish, Portuguese, German and French.

2.2 Computational Models of Multimodal Language

Studies of multimodal language have particularly focused on the tasks of sentiment analysis (Morency et al., 2011; Yadav et al., 2015), emotion recognition (Busso et al., 2008), and personality traits recognition (Park et al., 2014). Works in this area often focus on novel multimodal neural architectures based on Transformer (Tsai et al., 2019a; Mai et al., 2019; Zadeh et al., 2019) and recurrent fusion approaches (Rahman et al., 2019; Liang et al., 2018; Zadeh et al., 2018a, 2017), as well as learning via statistical techniques such as correlation analysis (Sun et al., 2019) and tensor methods (Hou et al., 2019; Zadeh et al., 2017).

In addition to these purely discriminative approaches, recent work has also explored generative-discriminative methods for learning from multimodal language (Tsai et al., 2019b), learning from noisy or missing modalities (Mai et al., 2019; Liang et al., 2019b; Pham et al., 2019), strong baselines suitable for learning from limited data (Liang et al., 2019a), and interpretable models for language analysis (Karimi, 2018; Zadeh et al., 2018b). Several other lines of work have focuses on building stronger unimodal representations such as language (Kordjamshidi et al., 2017; Beinborn et al., 2018) and speech (Sanabria et al., 2018; Lakomkin et al., 2019; Gu et al., 2019) for multimodal language understanding.

3 CMU-MOSEAS (CMU Multimodal Opinion Sentiment, Emotions and Attributes) Dataset

The CMU-MOSEAS dataset covers 4 languages of Spanish (>500M total speakers globally), Portuguese (>200M speakers globally), German (>200M speakers globally), and French (>200M speakers globally). These languages either have Romance or Germanic roots (Renfrew, 1989). They originate from Europe, which is also the main region for our video acquisition. The languages are also spoken in the American continent

Language	Spanish	Portuguese	German	French
Total number of videos	$1,000$	$1,000$	$1,000$	$1,000$
Total number of sentences	$29,544$	$34,633$	$30,549$	$34,042$
Total number of annotated sentences	$10,000$	$10,000$	$10,000$	$10,000$
Total number of distinct speakers	341	399	480	425
Total number of distinct topics	250	250	250	250
Average length of videos (in sentences)	29.54	34.63	30.55	34.04
Average length of videos (in words)	582.22	606.23	361.00	646.84
Average length of videos (in seconds)	210.95	217.29	218.79	208.66
Average length of sentences (in words)	17.67	16.72	13.13	16.63
Average length of sentences (in seconds)	6.70	5.77	6.70	5.63
Speech rate (number of words per second)	2.76	2.79	1.65	3.10
Vocabulary size	$36,120$	$34,982$	$37,969$	$41,762$

Table 2: CMU-MOSEAS multimedia and linguistic statistics for languages of Spanish, Portuguese, German and French.

(north and south), as well as portions of Africa and the Caribbean (with different dialects, however, the European dialect is mostly comprehensible across different regions with some exceptions[1]).

Subsequently, in this section, we discuss the data acquisition and verification process, followed by outlining the annotated labels. We prioritize important details in the body of the main paper, and refer the reader to supplementary material for extra details about the dataset.

3.1 Acquisition and Verification

Monologue videos offer a rich source of multimodal language across different identities, genders, and topics. Users share their opinions online on a daily basis on websites such as YouTube[2]. In this paper, the process of finding and manually verifying monologue videos falls into the following 3 main steps:

Monologue Acquisition: In this step, monologue videos are manually found from across YouTube, using a diverse set of more than 250 search terms (see supplementary for search terms). The following regions are chosen for each language: [Spanish: Spain], [Portuguese: Portugal], [German: Germany and Austria], [French: France]. The YouTube search parameters are set based on the correct language and region. No more than 5 videos are gathered from individual channels to ensure diversity across speakers (average video to speaker ratio is 2.43 across the dataset). Only monologues with high video and audio quality are acquired. A particular focus in this step has been to acquire a set of gender-balanced videos for each language and region.

Monologue Verification: The acquired monologues in the previous step are subsequently checked by 2 native speakers of each language to ensure: 1) the language is correct and understandable, 2) the region is correct, 3) gathered transcription is high-quality, 4) the grammar and punctuation in transcriptions are correct (the transcripts are also corrected for errors). Only the videos that passed all the filters are allowed to pass this step.

Forced Alignment Verification: The text-audio synchronization is an essential step for in-depth studies of multimodal language. It allows for modeling intermodal relations at the word or phoneme levels using continuous alignment (Chen et al., 2017). All the languages in CMU-MOSEAS have pre-trained acoustic and G2P (Grapheme-2-Phoneme) models which allow for forced alignment between text and audio. The monologue videos are subsequently aligned using MFA - Montreal Forced Aligner (McAuliffe et al., 2017). Afterwards, the forced alignment output is manually checked by native speakers to ensure the high quality of the alignment.

Utilizing the above pipeline, a total of $1,000$ monologue videos for each language of Spanish, Portuguese, German, and French are acquired (over the course of two years). From across these

---

[1] Such as Swiss German.

[2] With licenses allowing for fair usage of their content `https://www.youtube.com/intl/en-GB/about/copyright/fair-use/`

videos, a total of $10,000$ sentences are annotated according to Section 3.3. The sentence splitting follows a similar procedure as reported in the creation of CMU-MOSEI. Therefore, the size of the dataset is a total of $40,000$ annotated samples ($10,000$ for each language), accompanied by a large unsupervised set of sentences for each language. Table 2 shows the overall statistics of the data (see Section 3.6 for the methodology of face identification).

3.2 Privacy and Ethics

A specific focus of CMU-MOSEAS is on protecting the privacy of the speakers. Even though videos are publicly available on YouTube, a specific EULA (End User License Agreement) is required to download the labels (to see the EULA, please refer to supplementary). Non-invertible high-level computational features are provided publicly online. These features cannot be inverted to recreate the video or audio. For example, FAU (Facial Action Units) intensities. In simple terms, no speaker can deterministically be identified by these features.

3.3 Annotator Selection

Annotation of videos in CMU-MOSEAS is done by crowd workers[3] of the Amazon Mechanical Turk (AMT) platform. The workers are filtered to have higher than 95% acceptance rate over at least $5,000$ completed jobs. The annotators are native speakers of the languages discussed in Section 3.1. For each annotation, the annotators are given a sentence utterance and asked to annotate the labels of CMU-MOSEAS (discussed in Section 3.4). Labels are arranged on a web-page which allows the users to annotate them after watching the sentence utterance. At the beginning of the annotation process, the annotators are given a 5 minute training video describing the annotation scheme in their respective language (see supplementary for annotation user interface and training material). Each sentence utterance is annotated by 3 distinct annotators. Annotations are subsequently checked for criteria such as the speed of annotation, or answering secret key questions. Annotators with poor performance are subsequently removed.

3.4 Labels

The labels and an overview of their annotation scheme is as follows. Labels are annotated based on Likert (i.e. intensity) or Binary steps. Labels are checked via cyclic translation to eliminate divergence in their meaning caused by language barriers. Annotation scheme also help in this regard since all languages follow the same translation method, closely supervised by the authors of this paper.

Sentiment (Likert): We follow a similar annotation scheme as designed in prior literature for multimodal sentiment analysis (Morency et al., 2011; Wöllmer et al., 2013), and closely inspired by utterance sentiment annotations (Zadeh et al., 2016b). Sentence utterances are individually annotated for their perceived sentiment (i.e. the sentiment of the speaker in the video). Each sentence is annotated for sentiment on a $[-3, 3]$ Likert scale of: $[-3$: highly negative, -2 negative, -1 weakly negative, 0 neutral, $+1$ weakly positive, $+2$ positive, $+3$ highly positive$]$.

Subjectivity (Binary): The sentence utterances are annotated for whether or not the speaker expresses an opinion, as opposed to a factual statement (Wiebe et al., 2005). Subjectivity can be conveyed through either an explicit or implicit mention of a private state (Zadeh et al., 2016a), both of which are included in the annotation scheme.

Emotions (Likert): Ekman emotions (Ekman et al., 1980) of $\{$Happiness (HA), Sadness (SA), Anger (AN), Fear (FE), Disgust (DI), Surprise (SU)$\}$ are annotated on a $[0, 3]$ Likert scale for presence of emotion x: $[0$: no evidence of x, 1: weakly x, 2: x, 3: highly $x]$. Parenthesis denotes column name in Table 3. Sentence utterances are annotated for their perceived emotions (speaker's emotions).

Attributes (Binary): The attribute annotations are inspired by Persuasion Opinion Multimodal (POM) Dataset (Park et al., 2014) and follows a similar annotation scheme. The annotators are asked for their opinion about certain attributes being applicable to the speaker or the utterance (sentence). The following attributes are annotated: Dominant (DO), Confident (CO), Passion-

---

[3] AMT screens annotators and tags reliable ones as Master workers.

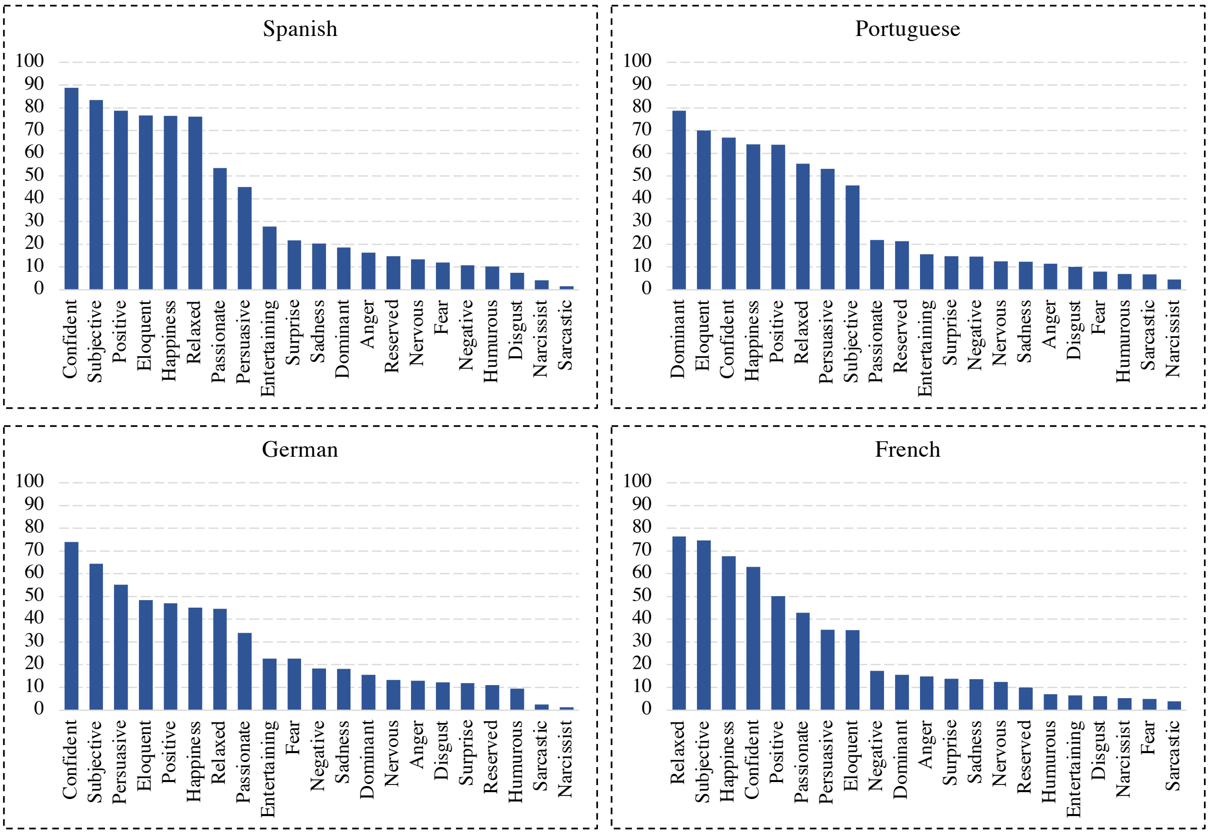

Figure 2: Label statistics of the CMU-MOSEAS. y-axis denotes the percentage of the label being present, and x-axis denotes the sentiment, subjectivity, emotions, and personality attribute labels. "Positive" and "Negative" denote sentiment.

ate (PA), Persuasive (PE), Relaxed (REL), Eloquent (EL), Nervous (NE), Entertaining (EN), Reserved (RES), Narcissist (NA), Sarcastic (SAR), and Humorous (HU). Similar to emotions, parenthesis denotes the column in Table 3.

3.5 Label Statistics

A unique aspect of CMU-MOSEAS is allowing for multimodal statistical comparisons between various languages. We outline some preliminary such comparisons in this section. Figure 2 shows the distribution of labels for CMU-MOSEAS dataset. The individual labels across different languages roughly follow a similar distribution. However, subtle differences exemplify a unique characteristic for each language.

The data suggests that perception of dominance in Portuguese may be fundamentally different than other languages. While dominance is neither a sparse nor a common label for Spanish, German and French, in Portuguese it is the most common label.

Positive sentiment seems to be reported more commonly in Spanish videos. German and French report a near toss-up for positive as opposed to negative or neutral combined (non-positive). Note, English also follows near toss-up between the positive vs non-positive (Zadeh et al., 2018b). Spanish and Portuguese report positive sentiment more commonly.

Spanish videos are more commonly labelled as confident than other languages, while other languages are at a similar level for this label.

Perception of relaxed attribute is also different across languages. French subset reports the relaxed label as the most common among labels. Overall French and Spanish are higher in this attribute than German and Portuguese.

Positive and Happiness labels closely follow each other, except for French language.

A large portion of the sentences are subjective as they convey personal opinions (as opposed to factual statements such as news broadcast).

Labels such as sadness, anger, humorous, and narcissist are similarly distributed between the languages.

Majority of labels have at least $1,000$ data points. Some labels are less frequent than others. This is aligned with findings from previous datasets for emotions (Zadeh et al., 2018b) and attributes (Park et al., 2014). For example, sarcasm is a rare attribute, even in entertainment and comedy TV shows (Castro et al., 2019).

Overall, languages seem to have intriguing similarities and differences which CMU-MOSEAS allows for studying.

3.6 Multimodal Feature Extraction

Data points in CMU-MOSEAS come in video format and include three main modalities. The extracted descriptors for each modality are as follows:

Language and Forced Alignment: All videos in CMU-MOSEAS have manual and punctuated transcriptions. Transcriptions are checked and corrected for both (see Section 3.1). Punctuation markers are used to separate sentences, similar to CMU-MOSEI. Words and audio are aligned at phoneme level using Montreal Forced Aligner (McAuliffe et al., 2017). This alignment is subsequently manually checked and corrected.

Visual: Frames are extracted from the full videos at 30Hz. The bounding box of the face is extracted using the RetinaFace (Deng et al., 2019b). Identities are extracted using ArcFace (Deng et al., 2019a). The parameters of both tools are tuned to reflect the correct number of identities. MultiComp OpenFace 2.0 (Baltrusaitis et al., 2018) is used to extract facial action units (depicting facial muscle movements), facial shape parameters (acquired using a projected latent shape by Structure from Motion), facial landmarks (68 3D landmarks on inside and boundary of face), head pose (position and Euler angles) and eye gaze (Euler angles). Visual feature extraction is done at $30Hz$.

Acoustic: We use the COVAREP software (Degottex et al., 2014) to extract acoustic features including 12 Mel-frequency cepstral coefficients, pitch tracking and voiced/unvoiced segmenting features (Drugman and Alwan, 2011), glottal source parameters (Childers and Lee, 1991; Drugman et al., 2012; Titze and Sundberg, 1992; Alku, 1992; Alku et al., 1997, 2002), peak slope parameters and maxima dispersion quotients (Kane and Gobl, 2013). Similar features are also extracted using OpenSmile (Eyben et al., 2010). Acoustic feature extraction is done at $100Hz$.

Dataset and features are available for download from the CMU Multimodal SDK, via the link `https://bit.ly/2Svbg9f`. This link provides the most accurate and up to date scoreboard, features and announcements for future readers. The original videos require submission of an EULA to the authors of this paper. EULA may change to reflect the latest privacy rules. Users in different countries and jurisdictions may need to submit additional forms.

4 Experimental Baselines

In this section we establish baselines for CMU-MOSEAS dataset. We choose a state of the art transformer-based neural model for this purpose. The model has shown state-of-the-art performance across several multimodal language tasks including multimodal sentiment analysis and emotion recognition. The CMU-MOSEAS dataset is split in the folds of train, validation and test (available on the CMU Multimodal SDK). What follows is a brief description of the baseline model.

Multimodal Transformer (MulT): Multimodal Transformer (Tsai et al., 2019a) is an extension of the well-known Transformer model (Vaswani et al., 2017) to multimodal time-series data. Each modality has a separate Transformer encoding the information hierarchically. The key component of MulT is a set of cross-modal attention blocks that cross-attend between time-series data from two modalities. MulT is among state-of-the-art models on both aligned and unaligned versions of the CMU-MOSEI and CMU-MOSI datasets. We use the author provided code for these experiments[4], with learning rate of $10e-4$ and the Adam optimizer (Kingma and Ba, 2014). The Transformer hidden unit size is 40 with 4 cross-modal blocks and 10 attention heads. Dropout is universally set at 0.1. The best model is chosen using the validation set of each language. We use the aligned variant of MulT.

For each language, we perform word-level alignment to acquire the expectation of visual

FR	MulT	0.60	0.68	0.60	0.73	0.63	0.68	0.59	0.64	0.69	0.65	0.57	0.50	0.52	0.59	0.65	0.67	0.70	0.84	0.77	0.81
PT	MulT	0.62	0.70	0.59	0.62	0.68	0.77	0.66	0.76	0.59	0.60	0.61	0.56	0.58	0.61	0.73	0.71	0.64	0.80	0.72	0.76

Table 3: Results of baseline experiments on CMU-MOSEAS dataset, using MulT neural model. The reported measure is weighted F1 score. Results indicate that the current state of the art is still far from desirable performance. A special focus enabled by CMU-MOSEAS is generalization of such models to multilingual scenarios.

and acoustic contexts per word (Chen et al., 2017), identical to the methodology used by MulT (aligned variant). The maximum sequence length is set at 50. Sequences are padded on the left with zeros. For language, we use the one-hot representation of the words. For acoustic, we concatenate COVAREP and OpenSmile features. The experiments are performed tri-label for sentiment (negative, neutral, positive) and binary for emotions and attributes; similar methodology is employed by MulT. The above models are trained to minimize Mean-Absolute Error (MAE). The metric used to evaluate model performance is the F1 measure, which is a more suitable metric when there are imbalanced classes as is the case for some labels in our dataset (i.e. rare attributes). For extra details of experiments, as well as other results including MAE and correlation, please refer to the github.

Table 3 reports the F1 measure for the performance of MulT over different languages in the CMU-MOSEAS dataset. Information from all modalities are used as input to the model. While the model is capable of predicting the labels from multimodal data to some extent, the performance is still far from perfect. Therefore, we believe the CMU-MOSEAS dataset brings new challenges to the field of NLP and modeling multimodal language.

5 Conclusion

In this paper, we introduced a new large-scale in-the-wild dataset of multimodal language, called CMU-MOSEAS (CMU Multimodal Opinion Sentiment, Emotions and Attributes). The CMU-MOSEAS dataset is the largest of its kind in all four constituent languages (French, German, Portuguese, and Spanish) with 40,000 total samples spanning 1,645 speakers and 250 topics. CMU-MOSEAS contains 20 annotated labels including sentiment (and subjectivity), emotions, and personality traits. The dataset and accompanied descriptors will be made publicly available, and regularly updated with new feature descriptors as multimodal learning advances. To protect the privacy of the speakers, the released descriptors will not carry invertible information, and no video or audio can be reconstructed based on the extracted features. A state-of-the-art model was trained to establish strong baselines for future studies. We believe that data of this scale presents a step towards learning human communication at a more fine-grained level, with the long-term goal of building more equitable and inclusive NLP systems across multiple languages.

`{slwang, zywang, car, tliu}@ir.hit.edu.cn`

Abstract

Most existing approaches to disfluency detection heavily rely on human-annotated corpora, which is expensive to obtain in practice. There have been several proposals to alleviate this issue with, for instance, self-supervised learning techniques, but they still require human-annotated corpora. In this work, we explore the unsupervised learning paradigm which can potentially work with unlabeled text corpora that are cheaper and easier to obtain. Our model builds upon the recent work on Noisy Student Training, a semi-supervised learning approach that extends the idea of self-training. Experimental results on the commonly used English Switchboard test set show that our approach achieves competitive performance compared to the previous state-of-the-art supervised systems using contextualized word embeddings (e.g. BERT and ELECTRA).

1 Introduction

Automatic speech recognition (ASR) outputs often contain various disfluencies, which is a characteristic of spontaneous speech and create barriers to subsequent text processing tasks like parsing, machine translation, and summarization. Disfluency detection (Zayats et al., 2016; Wang et al., 2016; Wu et al., 2015) focuses on recognizing the disfluencies from ASR outputs. As shown in Figure 1, a standard annotation of the disfluency structure indicates the reparandum (words that the speaker intends to discard), the interruption point (denoted as '+', marking the end of the reparandum), an optional interregnum (filled pauses, discourse cue words, etc.) and the associated repair (Shriberg, 1994).

$$\text{a flight [}\underbrace{\textit{to Boston}}_{\text{RM}} + \underbrace{\{\textit{um I mean}\}}_{\text{IM}}\ \underbrace{\text{to Denver}}_{\text{RP}}\text{]}$$

Figure 1: A sentence from the English Switchboard corpus with disfluencies annotated. RM=Reparandum, IM=Interregnum, RP=Repair. The preceding RM is corrected by the following RP.

Type	Annotation
repair	[the + they 're] voice activated
repair	[we want + {well} in our area we want] to
repetition	[we got + {uh} we got] to talking
restart	[we would like +] let's go to the

Table 1: Different types of disfluencies.

Ignoring the interregnum, disfluencies are categorized into three types: restarts, repetitions and corrections. Table 1 gives a few examples. Interregnums are relatively easier to detect as they are often fixed phrases, e.g. "uh", "you know". On the other hand, reparandums are more difficult to detect in that they are in free form. As a result, most previous disfluency detection work focuses on detecting reparandums.

Most work (Zayats and Ostendorf, 2018; Lou and Johnson, 2017; Wang et al., 2017; Jamshid Lou et al., 2018; Zayats and Ostendorf, 2019) on disfluency detection heavily relies on human-annotated corpora, which is scarce and expensive to obtain in practice. There have been several proposals to alleviate this issue with, for instance, self-supervised learning (Wang et al., 2019) and semi-supervised learning techniques (Wang et al., 2018), but they still require human-annotated corpora. In this work, we completely remove the need of human-annotated corpora and propose a novel method to train a disfluency detection system in a completely unsupervised manner, relying on nothing but unlabeled text corpora.

Our model builds upon the recent work on Noisy Student Training (Xie et al., 2019), a semi-supervised learning approach based on the idea of

November 16–20, 2020.

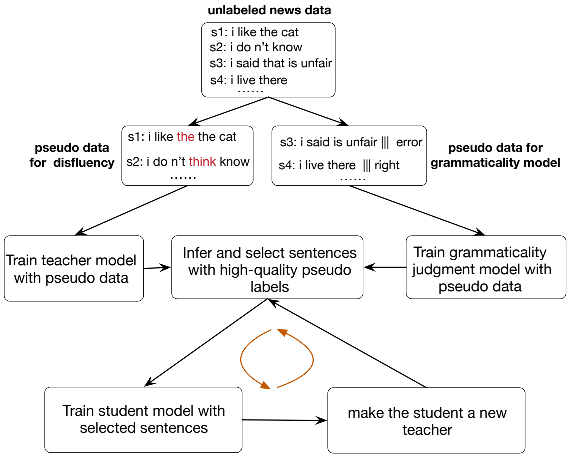

Figure 2: Illustration of our proposed methods.

self-training. Noisy Student Training first trains a supervised model on labeled corpora and uses it as a teacher to generate pseudo labels for unlabeled corpora. It then trains a larger model as a student model on the combination of labeled and pseudo labeled corpora. This process is iterated by putting back the student as the teacher. The result showed that it is possible to use unlabeled corpora to significantly advance both accuracy and robustness of state-of-the-art supervised models. However, the performance of Noisy Student Training still relies on human-annotated corpora.

In this work, we extend Noisy Student Training to unsupervised disfluency detection by combining self-training and self-supervised learning methods. More concretely, as shown in Figure 2, we use the self-supervised learning method to train a weak disfluency detection model on large-scale pseudo training corpora as a teacher, which completely remove the need of human-annotated corpora. We also use the self-supervised learning method to train a sentence grammaticality judgment model to help select sentences with high-quality pseudo labels.

Experimental results on the commonly used English Switchboard set show that our approach achieves competitive performance compared to the previous state-of-the-art supervised systems using contextualized word embeddings (e.g. BERT and ELECTRA). Besides the experiment on the commonly used English Switchboard set, we evaluate our approach on another three different speech genres, and also achieve competitive performance compared to the supervised systems using contextualized word embeddings.

Algorithm 1 : Learning algorithm of our unsupervised model for disfluency detection

```
Require: Pseudo data for disfluency detection $(x_i, y_i)_{i=1}^{N}$,
    pseudo data for grammaticality judgment model
    $(\hat{x}_i, \hat{y}_i)_{i=1}^{M}$, and unlabeled ASR outputs $\{\tilde{x}_1, \tilde{x}_2, ..., \tilde{x}_K\}$.
1: Learn sentence grammaticality judgment model $\theta_*^g$ which
   minimizes the cross entropy loss on $(\hat{x}_i, \hat{y}_i)_{i=1}^{M}$
       $\frac{1}{M}\sum_{i=1}^{M} \ell(\hat{y}_i, f^g(\hat{x}_i, \theta^g))$
2: Learn teacher model $\theta_*^t$ which minimizes the cross entropy loss on $(x_i, y_i)_{i=1}^{N}$
       $\frac{1}{N}\sum_{i=1}^{N} \ell(y_i, f^t(x_i, \theta^t))$
3: Use teacher model to generate pseudo labels for
   $\{\tilde{x}_1, \tilde{x}_2, ..., \tilde{x}_L\}$ collected from $\{\tilde{x}_1, \tilde{x}_2, ..., \tilde{x}_K\}$ by random sampling
       $\tilde{y}_i = f^t(\tilde{x}_i, \theta_*^t), \forall i = 1, ..., L$
4: Use sentence grammaticality judgment model to help select sentences with high-quality pseudo labels $(\tilde{x}_i, \tilde{y}_i)_{i=1}^{J}$
   from $(\tilde{x}_i, \tilde{y}_i)_{i=1}^{L}$.
5: Learn a student model $\theta_*^s$ which minimizes the cross entropy loss on $(\tilde{x}_i, \tilde{y}_i)_{i=1}^{J}$
       $\frac{1}{J}\sum_{i=1}^{J} \ell(\tilde{y}_i, f^s(\tilde{x}_i, \theta^s))$
6: Iterative training until the performance stops growing:
   Use the student as a teacher and go back to step 3.
```

The code is released[1].

2 Proposed Approach

2.1 Unsupervised Training Process

Algorithm 1 and Figure 2 give an overview of our unsupervised training. The inputs to the algorithm are all unlabeled sentences, including news data and ASR outputs. We first construct large-scale pseudo data by randomly adding or deleting words to a fluent sentence, and use the self-supervised learning method to train a sentence grammaticality judgment model. The sentence grammaticality judgment model has the ability to judge whether an input sentence is grammatically-correct or not. We then construct large-scale pseudo data by randomly adding words to a fluent sentence, and use the self-supervised learning method to train a weak disfluency detection model as a teacher. Next, we use

---

[1] https://github.com/scir-zywang/self-training-self-supervised-disfluency/

the teacher model to generate pseudo labels on unlabeled ASR outputs. Once a sentence is given correct pseudo labels, the rest after deleting the words with disfluency labels is fluent and grammatically-correct. Based on this fact, we use the sentence grammaticality judgment model to help select sentences with high-quality pseudo labels. We then train a student model on the selected pseudo labeled sentences. Finally, we iterate the process until performance stops growing by putting back the student as a teacher to generate new pseudo labels and train a new student. We choose the student model achieving the best performance on human-annotated dev set as our final model.

2.2 System Architecture

Train Teacher Model

Traditional self-training method trains the teacher model on labeled corpus. In our work, we completely remove the need of human-annotated corpora and use the self-supervised learning method to train a weak disfluency detection model as a teacher.

We first construct large-scale pseudo data for the teacher model inspired by the work of Wang et al. (2019). Let S be an ordered sequence, which is taken from raw unlabeled news data, assumed to be fluent. We start from S and introduce random perturbations to generate a disfluent sentence S_{disf}. More specifically, we propose two types of perturbations:

- *Repetition*(k) : the m (randomly selected from one to six) words starting from the position k are repeated.
- *Inserting*(k) : we randomly pick a m-gram (m is randomly selected from one to six) from the news corpus and insert it to the position k.

For S, we randomly choose one to $three$ positions, and then randomly take one of the two perturbations for each selected position to generate the disfluent sentence $S_{disf} = \{w_1, w_2, ..., w_n\}$. The training goal is to detect the added noisy words by associating a label for each word, where the labels D and O means that the word is an added word and a fluent word, respectively. We directly fine-tune the ELECTRA model (the discriminator) (Clark et al., 2020) on our pseudo data. Note that the distribution of our pseudo data is different from the distribution of the gold disfluency detection data, which limits the performance of our teacher model on real test data.

Grammaticality Judgment Model

Once a sentence $\{w_1, w_2, ..., w_n\}$ is given correct pseudo labels $\{t_1, t_2, ..., t_n\}$ by a teacher model, the rest parts $\{\bar{w}_1, \bar{w}_2, ..., \bar{w}_m\}$ by deleting the words with label D is fluent and grammatically-correct. Based on this fact, we train a sentence grammaticality judgment model to help select sentences with high-quality pseudo labels.

We first construct large-scale pseudo data for the sentence grammaticality judgment model. The input contains two kinds of sentences: (i) S_{right} which is directly taken from raw unlabeled news data. (ii) S_{error} which is generated by adding some perturbations to S_{right}. We introduce three types of perturbations to generate S_{error}. The first two types of perturbations are *Repetition*(k) and *Inserting*(k) as described previously. The third type of perturbations is:

- *Delete*(k) : for selected position k, m (randomly selected from one to six) words starting from this position are deleted.

For an input sentence S, we randomly choose one to $three$ positions, and then randomly take one of the three perturbations for each selected position to generate the disfluent sentence $S_{disf} = \{w_1, w_2, ..., w_n\}$. The training goal is to detect the type of an input sentence, where the labels $right$ and $error$ means that the sentence is grammatically-correct and grammatically-incorrect, respectively. We directly fine-tune the ELECTRA model (the discriminator) (Clark et al., 2020) on our pseudo data.

Infer and Select Sentences

We use the teacher model to generate pseudo labels on unlabeled ASR outputs. The performance of teacher model starts at a very low level, and it will bring too much noise if we directly use the full unlabeled ASR outputs. So we gradually increase the amount of unlabeled ASR outputs by random sampling from the full unlabeled ASR outputs in each iteration.

For an input sentence $S = \{w_1, w_2, ..., w_n\}$, the teacher model give pseudo labels $T = \{t_1, t_2, ..., t_n\}, \forall t_i \in \{O, D\}$. Limited by the performance of teacher model, it will bring much noise if we directly train a student model on all the selected pseudo labeled sentences. We use the sentence grammaticality judgment model to help select sentences with high-quality pseudo labels. Given a sentence $S = \{w_1, w_2, ..., w_n\}$ and its pseudo labeles $T = \{t_1, t_2, ..., t_n\}$, we get a sub-sentence $S_{sub} = \{\bar{w}_1, \bar{w}_2, ..., \bar{w}_m\}$ by deleting the words with the label D. If the sentence grammaticality judgment model generates $right$ label on S_{sub}, we assume that the pseudo labels T is the same as gold labels and keep (S, D) for student model training.

Train Student Model

In this step, we directly fine-tune the first teacher model as shown in Step 2 of Algorithm 1 on the selected pseudo labeled ASR outputs, instead of fine-tuning the ELECTRA model. Although the difference of distribution between our pseudo data and the golden disfluency detection data limits the performance of teacher model, this stage converges faster than fine-tuning the ELECTRA model as it only needs to adapt to the idiosyncrasies of the target disfluency detection data.

3 Experiment

3.1 Settings

Dataset. English Switchboard (SWBD) (Godfrey et al., 1992) is the standard and largest (1.73×10^5 sentences for training) corpus used for disfluency detection. We use English Switchboard as main data. Following the experiment settings in Charniak and Johnson (2001), we split the Switchboard corpus into train, dev and test set as follows: train data consists of all sw[23]∗.dff files, dev data consists of all sw4[5-9]∗.dff files and test data consists of all sw4[0-1]∗.dff files. Following Honnibal and Johnson (2014), we lower-case the text and remove all punctuations and partial words.[2] We also discard the ‘um’ and ‘uh’ tokens and merge ‘you know’ and ‘i mean’ into single tokens.

In addition to Switchboard, we test our models on three out-of-domain publicly available datasets annotated with disfluencies (Zayats et al., 2014; Zayats and Ostendorf, 2018):

- **CallHome:** phone conversations between family members and close friends;
- **SCOTUS:** transcribed Supreme Court oral arguments between justices and advocates;
- **FCIC:** two transcribed hearings from Financial Crisis Inquiry Commission.

Corpora	training	test
SWBD	1.3M	65K
SCOTUS	46K	30K
CallHome	-	43K
FCIC	-	54K

Table 2: The number of words in training and testing data for different corpora. Note that we do not use the training data for our unsupervised methods.

The size of training and test sets for all corpora are given in Table 2.

Unlabeled sentences include news data and ASR outputs. News data are randomly extracted from WMT2017 monolingual language model training data (News Discussions. Version 2).[3] Then we use the methods described in Section 2.2 to construct the pre-training dataset for the teacher model and grammaticality judgment model. The training set of the teacher model contains 2 million sentences. We use 5 million sentences for the grammaticality judgment model, in which half of them are grammatically-incorrect sentences and others are grammatically-correct sentences directly extracted from the news corpus. The unlabeled ASR outputs we use include Fisher Speech Transcripts Part 1 (Cieri et al., 2004) and Part 2 (Christopher Cieri and Walker, 2005), which contains about 835k sentences.

Metric. Following previous works (Ferguson et al., 2015), token-based precision (P), recall (R), and F1 are used as the evaluation metrics.

3.2 Training Details

In all experiments including the ELECTRA model, we use English ELECTRA-Base model with 110M hidden units, 12 heads, 12 hidden layers.[4] For the self-supervised teacher models and grammaticality judgment model, we use streams of 128 tokens and a mini-batches of size 256. We use learning rate of 1e-4 and epoch of 30.

When training the student model with selected pseudo labeled ASR outputs, most model hyper-parameters are the same as in the grammaticality judgment model, with the exception of the batch size, learning rate, and number of training epochs. We use batch size of 128, learning rate of 2e-5, and epoch of 10.

Our Method	88.2	87.8	**88.0**

Table 4: Comparison with previous state-of-the-art methods on the Switchboard test set. The first part (from row 1 to row 4) is the methods without using contextualized word embeddings (e.g. ELMo (Peters et al., 2018) and ELECTRA), the second part (row 5 to 7) is the methods using contextualized word embeddings.

3.3 Performance on English Switchboard

As shown in Table 3, we build six baseline systems: (1) **Transition-based** is a neural transition-based model (Wang et al., 2017). We directly use the code released by Wang et al. (2017);[5] (2) **BERT-Base fine-tuning** means fine-tuning BERT-Base model on Switchboard train set; (3) **ELECTRA-Small fine-tuning** means fine-tuning ELECTRA-Small (the discriminator) model on Switchboard train set; (4) **ELECTRA-Base fine-tuning** means fine-tuning ELECTRA-Base (the discriminator) model on Switchboard train set; (5) **Unsupervised teacher** is the teacher model as shown in Step 2 of Algorithm 1; (6) **Teacher fine-tuning** means fine-tuning unsupervised teacher model on Switchboard train set.

Table 3 shows the overall performances of our model on the Switchboard dev set. Our unsupervised model achieves almost 17 point improvements over the baseline unsupervised teacher model. Even compared with supervised systems using full set of Switchboard training data and contextualized word embeddings, our unsupervised approach achieves competitive performance.

Method	**CallHome**	**SCOTUS**	**FCIC**
Unsupervised teacher	45.7	63.9	43.2
ELECTRA-Base	60.9	79.4	62.8
Teacher fine-tuning	63.7	81.9	64.3
Pattern-match	65.2	79.9	66.1
Our unsupervised	60.2	80.3	63.3

Table 5: F1 scores on cross-domain disfluency detection. "Pattern-match" (Zayats and Ostendorf, 2018) is a pattern match neural network architecture trained on Switchboard train set, and achieves state-of-the-art performance in cross-domain scenarios.

Finally, we compare our unsupervised model to state-of-the-art supervised and semi-supervised methods from the literature on the Switchboard test set, which can be divided into the following two categories: the methods without using contextualized word embeddings, and the methods using contextualized word embeddings. Table 4 shows that our unsupervised model is competitive with recent models using full set of Switchboard training data. In particular, our unsupervised model even achieves slightly improvement over the supervised methods without using contextualized word embeddings, demonstrating the effectiveness of our unsupervised model.

3.4 Performance on Cross-domain Data

To prove the robustness of our methods, we also test our unsupervised model on three out-of-domain publicly available datasets. As shown in Table 5, we use four baseline systems: (1) **Unsupervised teacher** is the teacher model as shown in Step 2 of Algorithm 1 trained on pseudo train set; (2) **ELECTRA-Base fine-tuning** means fine-tuning ELECTRA-Base (the discriminator) model on Switchboard train set; (3) **Teacher fine-tuning** means fine-tuning unsupervised teacher model on Switchboard train set; (4) **Pattern-match** (Zayats and Ostendorf, 2018) means a pattern match neural network architecture trained on Switchboard train set, and achieves state-of-the-art performance in cross-domain scenarios.

For both the baseline and our unsupervised sys-

Figure 3: (**a**) Plot showing the effects of iterative training. (**b**) Plot showing the impact of pseudo training data size to the teacher model. (**c**) Plot showing the change of F1 score before and after using grammaticality judgment model.

Method	SWBD	CallHome	SCOTUS	FCIC
Teacher	72.3	45.7	63.9	43.2
No-select	83.4	55.9	70.4	56.1
Select	89.6	60.2	80.3	63.3

Table 6: Ablation study of grammaticality judgment model. “Teacher” means unsupervised teacher models. “No-select” means our unsupervised self-training method without grammaticality judgment model. “Select” means our unsupervised self-training method with grammaticality judgment model. “SWBD” means the Switchboard dev set.

tems, we directly use the model achieving state-of-the-art F1 score on the Switchboard dev set and directly test it on the out-of-domain data without retraining. Table 5 shows that our unsupervised model achieves consistent performance in both Switchboard and the three cross-domain datas. In contrast to the performance on the Switchboard dev set as shown in Table 3, our unsupervised model achieves performance similar to the ELECTRA-Base fine-tuning model. This surprising observation shows that our unsupervised model is robust in cross-domain testing. We conjecture that our method uses a large amount of unlabeled news data and ASR outputs, which make it survive the domain mismatch problem in cross-domain testing. Even compared with the supervised Pattern-match model (Zayats and Ostendorf, 2018) achieving state-of-the-art performance in cross-domain scenarios, our model achieves competitive performance.

4 Ablation Studies

In this section, we study the importance of grammaticality judgment model and iterative training.

4.1 The Importance of Grammaticality Judgment Model

To demonstrate the effect of grammaticality judgment model, we further conduct an experiment without grammaticality judgment model. As shown in Table 6, both of our two models achieve significant improvement compared with the baseline unsupervised teacher model. Higher performance is achieved through the introduction of grammaticality judgment model. We conjecture that grammaticality judgment model can help filter out the sentence with false pseudo labels.

4.2 A Study of Iterative Training

Here, we show the detailed effects of iterative training. As mentioned in Section 2.1, we first train a weak disfluency detection model on large-scale pseudo data and then use it as the teacher to train a student model. Then, we iterate this process by putting back the new student model as the teacher model.

We plot F1-score with respect to the number of iteration for the two models with and without grammaticality judgment model. As shown in Figure 3 (a), both the two models keep increasing until reaching an experiment upper limit, and achieve significant improvement over the model in the first iteration. These results indicate that iterative training is effective in producing increasingly better models.

5 Analysis

5.1 Varying Amounts of Pseudo Data for Teacher Model

We observed the impact of pseudo training data size to the teacher model as shown in Step 2 of

Method	**Repet**	**Non-repet**	**Either**
ELECTRA-Base	95.6	77.7	92.0
Unsupervised Teacher	91.4	54.3	72.3
Our Unsupervised	94.1	74.6	89.6

Table 7: F1-score of different types of reparandums on English Switchboard dev data.

Algorithm 1. Figure 3 (b) reports the results of adding varying amounts of pseudo training data to the self-supervised teacher model. We observe that F1-score on the Switchboard dev set keeps growing until reaching an upper limit when the amount of pseudo data increases. The upper limit is only about 72.3 F1-score, which is much lower than the supervised methods. We conjecture that the distribution of our pseudo data is different from the distribution of the gold disfluency detection data, which limits the performance of our teacher model on real data. The result also shows that disfluencies in ASR outputs are complex, and disfluency detection cannot be fully solved by pretraining on pseudo disfluency data.

5.2 Quantitative Analysis of Grammaticality Judgment Model

The ablation test demonstrates the effect of grammaticality judgment model. To prove the conjecture that grammaticality judgment model help filter out the sentence with false pseudo labels, we make two quantitative analyses for grammaticality judgment model.

The first quantitative analysis gives the classification accuracy of grammaticality judgment model on the Switchboard dev set. Grammaticality judgment model achieves a 85% accuracy. The result shows that grammaticality judgment model has the ability to judge whether an input sentence is grammatically-correct, and will always help select sentences with high-quality pseudo labels.

For the second quantitative analysis, we observed the change of F1 score by simulating the infer and select process of iterative training on the Switchboard dev set. For each iteration, we first use the teacher model to generate pseudo labels on the Switchboard dev set, and compute one F1 score. Then we use grammaticality judgment model to select sentences. We compute another F1 score on the selected sentences. Figure 3 (c) reports the change of F1 score in each iteration. The F1 score on selected sentences is always significantly higher than that without selecting. The result shows that grammaticality judgment model can always help select sentences with high-quality pseudo labels.

5.3 Repetitions vs Non-repetitions

Repetition disfluencies are much easier to detect than other disfluencies, although not trivial since some repetitions can be fluent. In order to better understand model performances, we evaluate our model's ability to detect repetition vs. non-repetition (other) reparandum on the Switchboard dev set. The results are shown in Table 7. All three models achieve high scores on repetition reparandum. Our unsupervised model is much better in predicting non-repetitions compared to the unsupervised teacher model. Even compared with the supervised ELECTRA-Base model, our model achieves competitive performance on non-repetitions. The result shows that our unsupervised model has the ability to solve complex disfluencies. We conjecture that our self-supervised tasks can capture more sentence-level structural information.

6 Related Work

Disfluency Detection

Most work on disfluency detection focus on supervised learning methods, which mainly fall into three main categories: sequence tagging, noisy-channel, and parsing-based approaches. Sequence tagging approaches label words as fluent or disfluent using a variety of different techniques, including conditional random fields (CRF) (Georgila, 2009; Ostendorf and Hahn, 2013; Zayats et al., 2014), Max-Margin Markov Networks (M^3N) (Qian and Liu, 2013), Semi-Markov CRF (Ferguson et al., 2015), and recurrent neural networks (Hough and Schlangen, 2015; Zayats et al., 2016; Wang et al., 2016). The main benefit of sequential models is the ability to capture long-term relationships between reparandum and repairs. Noisy channel models (Charniak and Johnson, 2001; Johnson and Charniak, 2004; Zwarts et al., 2010; Lou and Johnson, 2017) use the similarity between reparandum and repair as an indicator of disfluency. Parsing-based approaches (Rasooli and Tetreault, 2013; Honnibal and Johnson, 2014; Wu et al., 2015; Yoshikawa et al., 2016; Jamshid Lou et al., 2019) jointly perform parsing and disfluency detection. The joint models can capture long-range dependency of disfluencies as well as chunk-level information. However, training a parsing-based model requires large annotated tree-banks that contain both disfluencies and syntactic structures.

All of the above works heavily rely on human-annotated data. There exist a limited effort to tackle the training data bottleneck. Wang et al. (2018) and Dong et al. (2019) use an autoencoder method to help for disfluency detection by jointly training the autoencoder model and disfluency detection model. Wang et al. (2019) use self-supervised learning to tackle the training data bottleneck. Their self-supervised method can substantially reduce the need for human-annotated training data. Lou and Johnson (2020) shows that self-training and ensembling are effective methods for improving disfluency detection. These semi-supervised methods achieve higher performance by introducing pseudo training sentences. However, the performance still relies on human-annotated data. We explore unsupervised disfluency detection, taking inspiration from the success of self-supervised learning and self-training on disfluency detection.

Self-Supervised Representation Learning

Self-supervised learning aims to train a network on an auxiliary task where ground-truth is obtained automatically. Over the last few years, many self-supervised tasks have been introduced in image processing domain, which make use of non-visual signals, intrinsically correlated to the image, as a form to supervise visual feature learning (Agrawal et al., 2015; Wang and Gupta, 2015; Doersch et al., 2015).

In natural language processing domain, self-supervised research mainly focus on word embedding (Mikolov et al., 2013a,b) and language model learning (Bengio et al., 2003; Peters et al., 2018; Radford et al., 2018). For word embedding learning, the idea is to train a model that maps each word to a feature vector, such that it is easy to predict the words in the context given the vector. This converts an apparently unsupervised problem into a "self-supervised" one: learning a function from a given word to the words surrounding it.

Language model pre-training (Bengio et al., 2003; Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019) is another line of self-supervised learning task. A trained language model learns a function to predict the likelihood of occurrence of a word based on the surrounding sequence of words used in the text. There are mainly two existing strategies for applying pre-trained language representations to down-stream tasks: feature-based and fine-tuning. The feature-based approach, such as ELMo (Peters et al., 2018), uses task-specific architectures that include the pre-trained representations as additional features. The fine-tuning approach, such as the Generative Pre-trained Transformer (OpenAI GPT) (Radford et al., 2018) and BERT (Devlin et al., 2019), introduces minimal task-specific parameters and is trained on the down-stream tasks by simply fine-tuning the pre-trained parameters.

Motivated by the success of self-supervised learning, we use self-supervised learning method to train a weak disfluency detection model as teacher model. We also train a sentence grammaticality judgment model to help select sentences with high-quality pseudo labels.

Self-Training

Self-training (McClosky et al., 2006) first uses labeled data to train a good teacher model, then use the teacher model to label unlabeled data and finally use the labeled data and unlabeled data to jointly train a student model. Self-training has also been shown to work well for a variety of tasks including leveraging noisy data (Veit et al., 2017), semantic segmentation (Babakhin et al., 2019), text classification (Li et al., 2019). Xie et al. (2019) present Noisy Student Training, which extends the idea of self-training with the use of equal-or-larger student models and noise added to the student during learning.

Our model builds upon the recent work on Noisy Student Training (Xie et al., 2019) and further extend it to unsupervised disfluency detection by combining self-training and self-supervised learning methods.

7 Conclusion

In this work, we explore unsupervised disfluency detection by combining self-training and self-supervised learning. We showed that it is possible to completely remove the need of human-annotated data and train a high-performance disfluency detection system in a completely unsupervised manner.

Multimodal Routing: Improving Local and Global Interpretability of Multimodal Language Analysis

Abstract

The human language can be expressed through multiple sources of information known as modalities, including tones of voice, facial gestures, and spoken language. Recent multimodal learning with strong performances on human-centric tasks such as sentiment analysis and emotion recognition are often black-box, with very limited interpretability. In this paper we propose *Multimodal Routing*, which dynamically adjusts weights between input modalities and output representations differently for each input sample. Multimodal routing can identify relative importance of both individual modalities and cross-modality features. Moreover, the weight assignment by routing allows us to interpret modality-prediction relationships not only globally (i.e. general trends over the whole dataset), but also locally for each single input sample, meanwhile keeping competitive performance compared to state-of-the-art methods.

1 Introduction

The human language contains multimodal cues, including textual (e.g., spoken or written words), visual (e.g., body gestures), and acoustic (e.g., voice tones) modalities. It acts as a medium for human communication and has been advanced in areas spanning affect recognition (Busso et al., 2008), media description (Lin et al., 2014), and multimedia information retrieval (Abu-El-Haija et al., 2016). Modeling multimodal sources requires to understand the relative importance of not only each single modality (defined as *unimodal explanatory features*) but also the interactions (defined as *bimodal* or *trimodal explanatory features*) (Büchel et al., 1998). Recent work (Liu et al., 2018; Williams et al., 2018; Ortega et al., 2019) proposed methods to fuse information across modalities and yielded superior performance, but these models are often black-box with very limited interpretability.

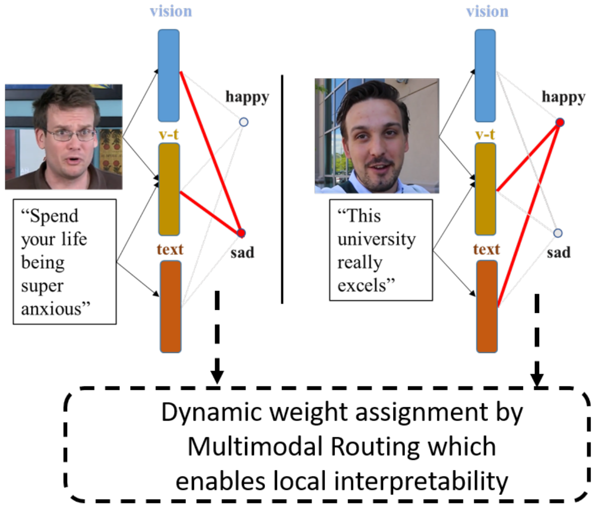

Figure 1: An example of Multimodal Routing, where the weights between visual, textual, and visual-textual explanatory features and concepts of emotions (happy and sad) are dynamically adjusted given every input sample. The model associates vision and v-t features to sad concept in the left sample, and v-t and text features to happy concept in the right example, showing local weights interpretation upon different input features.

Interpretability matters. It allows us to identify crucial explanatory features for predictions. Such interpretability knowledge could be used to provide insights into multimodal learning, improve the model design, or debug a dataset. This interpretability is useful at two levels: the global and the local level. The global interpretation reflects the general (averaged) trends of explanatory feature importance over the whole dataset. The local interpretation is arguably harder but can give a high-resolution insight of feature importance specifically depending on each *individual* samples during training and inference. These two levels of interpretability should provide us an understanding of unimodal, bimodal and trimodal explanatory features.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1823–1833,
November 16–20, 2020.

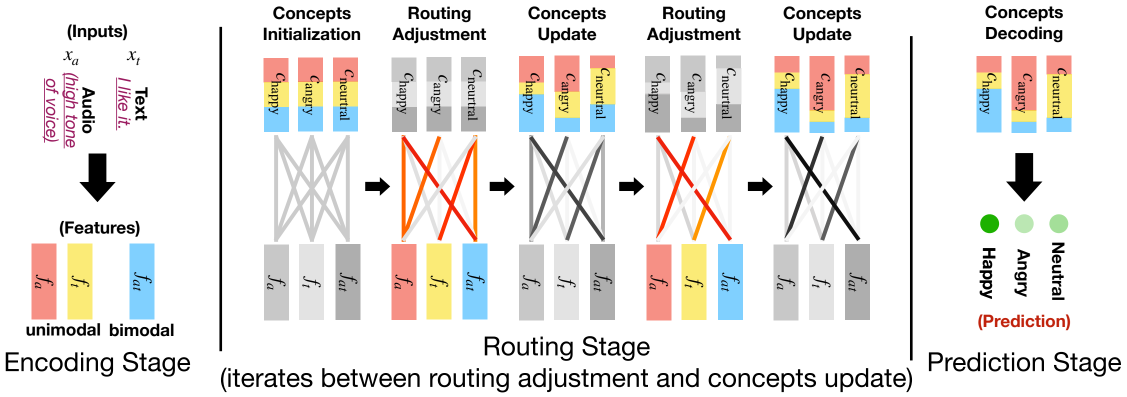

Figure 2: Overview of Multimodal Routing, which contains encoding, routing, and prediction stages. We consider only two input modalities in this example. The encoding stage computes unimodal and bimodal explanatory features with the inputs from different modalities. The routing stage iteratively performs *concepts update* and *routing adjustment*. The prediction stage decodes the concepts to the model's prediction. The routing associates the text and the visual-text features with negative sentiment in the left example, and the vision and the visual-text features with positive sentiment in the right example *before making predictions*.

In this paper we address both local and global interpretability of unimodal, bimodal and trimodal explanatory featuress by presenting *Multimodal Routing*. In human multimodal language, such routing dynamically changes weights between modalities and output labels for each sample as shown in Fig. 1. The most significant contribution of Multimodal Routing is its ability to establish local weights dynamically for each input sample between modality features and the labels during training and inference, thus providing local interpretation for each sample.

Our experiments focus on two tasks of sentiment analysis and emotion recognition tasks using two benchmark multimodal language datasets, IEMOCAP (Busso et al., 2008) and CMU-MOSEI (Zadeh et al., 2018). We first study how our model compares with the state-of-the-art methods on these tasks. More importantly we provide local interpretation by qualitatively analyzing adjusted local weights for each sample. Then we also analyze the global interpretation using statistical techniques to reveal crucial features for prediction on average. Such interpretation of different resolutions strengthens our understanding of multimodal language learning.

2 Related Work

Multimodal language learning is based on the fact that human integrates multiple sources such as acoustic, textual, and visual information to learn language (McGurk and MacDonald, 1976; Ngiam et al., 2011; Baltrušaitis et al., 2018). Recent advances in modeling multimodal language using deep neural networks are not interpretable (Wang et al., 2019; Tsai et al., 2019a). Linear method like the Generalized Additive Models (GAMs) (Hastie, 2017) do not offer local interpretability. Even though we could use post hoc (interpret predictions given an arbitrary model) methods such as LIME (Ribeiro et al., 2016), SHAP (Lundberg and Lee, 2017), and L2X (Chen et al., 2018) to interpret these black-box models, these interpretation methods are designed to detect the contributions only from unimodal features but not bimodal or trimodal explanatory features. It is shown that in human communication, modality interactions are more important than individual modalities (Engle, 1998).

Two recent methods, Graph-MFN (Zadeh et al., 2018) and Multimodal Factorized Model (MFM) (Tsai et al., 2019b), attempted to interpret relationships between modality interactions and learning for human language. Nonetheless, Graph-MFN did not separate the contributions among unimodal and multimodal explanatory features, and MFM only provided the analysis on trimodal interaction feature. Both of them cannot interpret how both single modality and modality interactions contribute to final prediction at the same time.

Our method is inspired and related to Capsule Networks (Sabour et al., 2017; Hinton et al., 2018), which performs routing between layers of capsules. Each capsule is a group of neurons that encapsulates spatial information as well as the probability of an object being present. On the other hand, our method performs routing between multimodal features (i.e., unimodal, bimodal, and trimodal explanatory features) and concepts of the model's decision.

3 Method

The proposed Multimodal Routing contains three stages shown in Fig. 2: encoding, routing, and prediction. The encoding stage encodes raw inputs (speech, text, and visual data) to unimodal, bimodal, and trimodal features. The routing stage contains a routing mechanism (Sabour et al., 2017; Hinton et al., 2018), which 1) updates some hidden representations and 2) adjusts local weights between each feature and each hidden representation by pairwise similarity. Following previous work (Mao et al., 2019), we call the hidden representations "concepts", and each of them is associated to specific a prediction label (in our case sentiment or an emotion). Finally, the prediction stage takes the inferred concepts to perform model prediction.

3.1 Multimodal Routing

We use v(isual), a(coustic), and t(ext) to denote the three commonly considered modalities in human multimodal language. Let $x = \{x_a, x_v, x_t\}$ represent the multimodal input. $x_a \in \mathbb{R}^{T_a \times d_a}$ is an audio stream with time length T_a and feature dimension d_a (at each time step). Similarly, $x_v \in \mathbb{R}^{T_v \times d_v}$ is the visual stream and $x_t \in \mathbb{R}^{T_t \times d_t}$ is the text stream. In our paper, we consider multiclass or multilabel prediction tasks for the multimodal language modeling, in which we use $y \in \mathbb{R}^J$ to denote the ground truth label with J being the number of classes or labels, and $\hat{y}$ to represent the model's prediction. Our goal is to find the relative importance of the contributions from unimodal (e.g., x_a itself), bimodal (e.g., the interaction between x_a and x_v), and trimodal features (e.g., the interaction between x_a, x_v, and x_t) to the model prediction $\hat{y}$.

Encoding Stage. The encoding stage encodes multimodal inputs $\{x_a, x_v, x_t\}$ into explanatory features. We use $f_i \in \mathbb{R}^{d_f}$ to denote the features with $i \in \{a, v, t\}$ being unimodal, $i \in \{av, vt, ta\}$ being bimodal, and $i \in \{avt\}$ being trimodal interactions. d_f is the dimension of the feature. To be specific, $f_a = F_a(x_a; \theta)$, $f_{av} = F_{av}(x_a, x_v; \theta)$, and $f_{avt} = F_{avt}(x_a, x_v, x_t; \theta)$ with θ as the parameters of the encoding functions and F as the encoding functions. Multimodal Transformer (MulT) (Tsai et al., 2019a) is adopted as the design of the encoding functions F_i. Here the trimodal function F_{avt} encodes sequences from three modalities into a unified representation, F_{av} encodes acoustic and visual modalities, and F_a encodes acoustic input. Next, $p_i \in [0, 1]$ is a scalar representing how each feature f_i is activated in the model. Similar to f_i, we also use MulT to encode p_i from the input x_i. That is, $p_a = P_a(x_a; \theta')$, $p_{av} = P_{av}(x_a, x_v, \theta')$, and $p_{avt} = P_{avt}(x_a, x_v, x_t, \theta')$ with θ' as the parameters of MulT and P_i as corresponding encoding functions (details in the Supplementary).

Routing Stage. The goal of routing is to infer interpretable hidden representations (termed here as "concepts") for each output label. The first step of routing is to initialize the concepts with equal weights, where all explanatory features are as important. Then the core part of routing is an iterative process which will enforce for each explanatory feature to be assigned to only one output representations (a.k.a the "concepts"; in reality it is a soft assignment) that shows high similarity with a concept. Formally each concept $c_j \in \mathbb{R}^{d_c}$ is represented as a one-dimensional vector of dimension d_c. Linear weights r_{ij}, which we term *routing coefficient*, are defined between each concept c_j and explanatory factor f_i.

The first half of routing, which we call *routing adjustment*, is about finding new assignment (i.e. the routing coefficients) between the input features and the newly learned concepts by taking a softmax of the dot product over all concepts, thus only the features showing high similarity of a concept (sentiment or an emotion in our case) will be assigned close to 1, instead of having all features assigned to all concepts. This will help local interpretability because we can always distinguish important explanatory features from non-important ones. The second half of routing, which we call *concept update*, is to update concepts by linearly aggregating the new input features weighted by the routing coefficients, so that it is local to each input samples.

- Routing adjustment. We define the *routing coefficient* $r_{ij} \in [0, 1]$ by measuring the similarity [1]

---

[1] We use dot-product as the similarity measurement as in prior work (Sabour et al., 2017). Note that routing only changes r_{ij}, not W_{ij}. Another choice can be the probability of a fit under a Gaussian distribution (Hinton et al., 2018).

Procedure 1 Multimodal Routing

```
procedure ROUTING($\{f_i\}$, $\{p_i\}$, $\{W_{ij}\}$)
    Concepts are initialized with uniform weights
    for $t$ iterations do
        /* Routing Adjustment */
        for all feature $i$ and concept $j$: $s_{ij} \leftarrow (f_i W_{ij})^\top c_j$
        for all feature $i$: $r_{ij} \leftarrow \exp(s_{ij}) / \sum_{j'} \exp(s_{ij'})$
        /* Concepts Update */
        for all concept $j$: $c_j \leftarrow \sum_i p_i r_{ij} (f_i W_{ij})$
    return $\{c_j\}$
```

between $f_i W_{ij}$ and c_j:

$$r_{ij} = \frac{\exp(\langle f_i W_{ij}, c_j \rangle)}{\sum_{j'} \exp(\langle f_i W_{ij'}, c_{j'} \rangle)} \tag{1}$$

We note that r_{ij} is normalized over all concepts c_j. Hence, it is a coefficient which takes high value only when f_i is in agreement with c_j but not with $c_{j'}$, where $j' \neq j$.

- *Concept update.* After obtaining p_i from encoding stage, we update concepts c_j using weighted average as follows: updates the concepts based on the routing weights by summing input features f_i projected by weight matrix W_{ij} to the space of the jth concept

$$c_j = \sum_i p_i r_{ij} (f_i W_{ij}) \tag{2}$$

c_j is now essentially a linear aggregation from $(f_i W_{ij})$ with weights $p_i r_{ij}$.

We summarize the routing procedure in Procedure 1, which returns concepts (c_j) given explanatory features (f_i), local weights (W_{ij}) and p_i. First, we initialize the concepts with uniform weights. Then, we iteratively perform adjustment on routing coefficients (r_{ij}) and concept updates. Finally, we return the updated concepts.

Prediction Stage. The prediction stage takes the inferred concepts to make predictions $\hat{y}$. Here, we apply linear transformations to concept c_j to obtain the logits. Specifically, the jth logit is formulated as

$$\begin{aligned} \text{logit}_j &= o_j^\top c_j \\ &= \sum_i p_i r_{ij} o_j^\top (f_i W_{ij}) \end{aligned} \tag{3}$$

where $o_j \in \mathbb{R}^{d_c}$ and is the weight of the linear transformation for the jth concept. Then, the *Softmax* (for multi-class task) or *Sigmoid* (for multi-label task) function is applied on the logits to obtain the prediction $\hat{y}$.

3.2 Interpretability

In this section, we provide the framework of locally interpreting relative importance of unimodal, bimodal, and trimodal explanatory features to model prediction given different samples, by interpreting the routing coefficients r_{ij}, which represents the weight assignment between feature f_i and concept c_j. We also provide methods to globally interpret the model across the whole dataset.

3.2.1 Local Interpretation

The goal of local interpretation is trying to understand how the importance of modality and modality interaction features change, given different multimodal samples. In eq. (3), a decision logit considers an addition of the contributions from the unimodal $\{f_a, f_v, f_t\}$, bimodal $\{f_{av}, f_{vt}, f_{ta}\}$, and trimodal f_{avt} explanatory features. The particular contribution from the feature f_i to the jth concept is represented by $p_i r_{ij} o_j^\top (f_i W_{ij})$. It takes large value when 1) p_i of the feature f_i is large; 2) the agreement r_{ij} is high (the feature f_i is in agreement with concept c_j and is not in agreement with $c_{j'}$, where $j' \neq j$); and 3) the dot product $o_j^\top (f_i W_{ij})$ is large. Intuitively, any of the three scenarios requires high similarity between a modality feature and a concept vector which represents a specific sentiment or emotion. Note that p_i, r_{ij} and f_i are the covariates and o_j and W_{ij} are the parameters in the model. Since different input samples yield distinct p_i and r_{ij}, we can locally interpret p_i and r_{ij} as the effects of the modality feature f_i contributing to the jth logit of the model, which is roughly a confidence of predicting jth sentiment or emotion. We will show examples of local interpretations in the Interpretation Analysis section.

3.2.2 Global Interpretation

To globally interpret Multimodal Routing, we analyze $\overline{r_{ij}}$, the average values of routing coefficients r_{ij}s over the entire dataset. Since eq. (3) considers a linear effect from f_i, p_i and r_{ij} to logit$_j$, $\overline{r_{ij}}$ represents the *average* assignment from feature f_i to the jth logit. Instead of reporting the values for $\overline{r_{ij}}$, we provide a statistical interpretation on $\overline{r_{ij}}$ using confidence intervals to provide a range of possible plausible coefficients with probability guarantees. Similar tests on p_i and $p_i r_{ij}$ are provided in Supplementary Materials. Here we choose confidence intervals over p-values because they provide much richer information (Ranstam, 2012; Du Prel et al., 2009). Suppose we have n data with the corresponding $\mathbf{r}_{ij} = \{r_{ij,1}, r_{ij,2}, \cdots r_{ij,n}\}$. If n is large enough and $\mathbf{r}_{ij}$ has finite mean and finite variance (it suffices since $r_{ij} \in [0, 1]$ is bounded), according to Central Limit Theorem, $\overline{r_{ij}}$ (i.e., mean of $\mathbf{r}_{ij}$) follows a Normal distribution:

$$\overline{r_{ij}} \sim \mathcal{N}\left(\mu, \frac{s_n^2}{n}\right), \tag{4}$$

where μ is the true mean of r_{ij} and s_n^2 is the sample variance in $\mathbf{r}_{ij}$. Using eq. (4), we can provide a confidence interval for $\overline{r_{ij}}$. We follow 95% confidence in our analysis.

4 Experiments

In this section, we first provide details of experiments we perform and comparison between our proposed model and state-of-the-art (SOTA) method, as well as baseline models. We include interpretability analysis in the next section.

4.1 Datasets

We perform experiments on two publicly available benchmarks for human multimodal affect recognition: CMU-MOSEI (Zadeh et al., 2018) and IEMOCAP (Busso et al., 2008). CMU-MOSEI (Zadeh et al., 2018) contains $23,454$ movie review video clips taken from YouTube. For each clip, there are two tasks: sentiment prediction (multiclass classification) and emotion recognition (multilabel classification). For the sentiment prediction task, each sample is labeled by an integer score in the range $[-3, 3]$, indicating highly negative sentiment (-3) to highly positive sentiment $(+3)$. We use some metrics as in prior work (Zadeh et al., 2018): seven class accuracy (Acc_7: seven class classification in $\mathbb{Z} \in [-3, 3]$), binary accuracy (Acc_2: two-class classification in $\{-1, +1\}$), and F1 score of predictions. For the emotion recognition task, each sample is labeled by one or more emotions from $\{$Happy, Sad, Angry, Fear, Disgust, Surprise$\}$. We report the metrics (Zadeh et al., 2018): six-class accuracy (multilabel accuracy of predicting six emotion labels) and F1 score.

IEMOCAP consists of 10K video clips for human emotion analysis. Each clip is evaluated and then assigned (possibly more than one) labels of emotions, making it a multilabel learning task. Following prior work and insight (Tsai et al., 2019a; Tripathi et al., 2018; Jack et al., 2014), we report on four emotions (happy, sad, angry, and neutral), with metrics four-class accuracy and F1 score.

For both datasets, we use the extracted features from a public SDK `https://github.com/A2Zadeh/CMU-MultimodalSDK`, whose features are extracted from textual (GloVe word embedding (Pennington et al., 2014)), visual (Facet (iMotions, 2019)), and acoustic (COVAREP (Degottex et al., 2014)) modalities. The acoustic and vision features are processed to be aligned with the words (i.e., text features). We present results using this word-aligned setting in this paper, but ours can work on unaligned multimodal language sequences. The train, valid and test set split are following previous work (Wang et al., 2019; Tsai et al., 2019a).

4.2 Ablation Study and Baseline Models

We provide two ablation studies for interpretable methods as baselines: The first is based on Generalized Additive Model (GAM) (Hastie, 2017) which directly sums over unimodal, bimodal, and trimodal features and then applies a linear transformation to obtain a prediction. This is equivalent to only using weight p_i and no routing coefficients. The second is our denoted as Multimodal Routing*, which performs only one routing iteration (by setting $t = 1$ in Procedure 1) and does not iteratively adjust the routing and update the concepts.

We also choose other non-interpretable methods that achieved state-of-the-art to compare the performance of our approach to: Early Fusion LSTM (EF-LSTM), Late Fusion LSTM (LF-LSTM) (Hochreiter and Schmidhuber, 1997), Recurrent Attended Variation Embedding Network (RAVEN) (Wang et al., 2019), and Multimodal Transformer (Tsai et al., 2019a).

4.3 Results and Discussions

We trained our model on 1 RTX 2080 GPU. We use 7 layers in the Multimodal Transformer, and choose the batch size as 32. The model is trained with initial learning rate of 10^{-4} and Adam optimizer.

CMU-MOSEI sentiment. Table 1 summarizes the results on this dataset. We first compare all the interpretable methods. We see that Multimodal Routing enjoys performance improvement over both GAM (Hastie, 2017), a linear model on encoded features, and Multimodal Routing*, a non-iterative feed-forward net with same parameters as Multimodal Routing. The improvement suggests the proposed iterative routing can obtain a more robust prediction by dynamically associating the features and the concepts of the model's predictions. Next, when comparing to the non-

Table 2: CMU-MOSEI emotion recognition. Multimodal Routing* denotes our method without iterative routing. We make our results bold if it is the best or close to the best ($\leq 1\%$).

interpretable methods, Multimodal Routing outperforms EF-LSTM, LF-LSTM and RAVEN models and performs competitively when compared with MulT (Tsai et al., 2019a). It is good to see that our method can competitive performance with the added advantage of local and global interpretability (see analysis in the later section). The configuration of our model is in the supplementary file.

CMU-MOSEI emotion. We report the results in Table 2. We do not report RAVEN (Wang et al., 2019) and MulT (Tsai et al., 2019a) since they did not report CMU-MOSEI results. Compared with all the baselines, Multimodal Routing performs again competitively on most of the results metrics. We note that the distribution of labels is skewed (e.g., there are disproportionately very few samples labeled as "surprise"). Hence, this skewness somehow results in the fact that all models end up predicting not "surprise", thus the same accuracy for "surprise" across all different approaches.

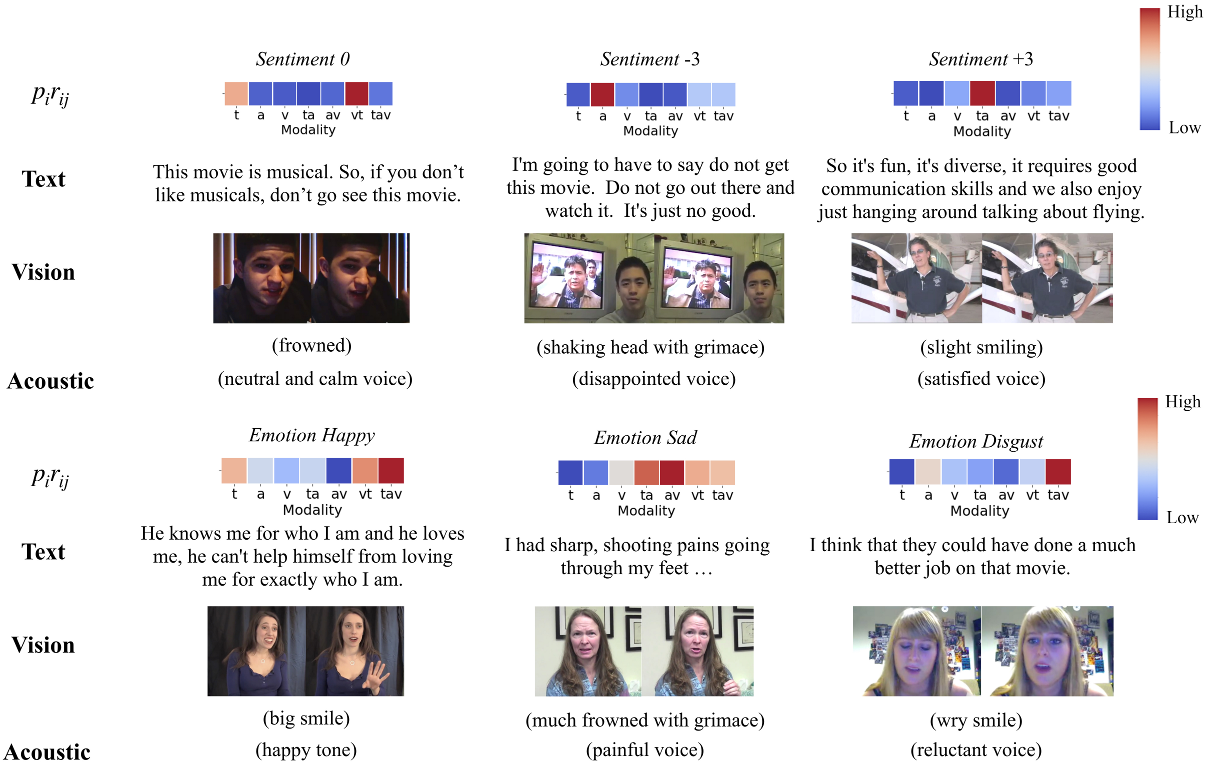
IEMOCAP emotion. When looking at the IEMOCAP results in Table 1, we see similar trends with CMU-MOSEI sentiment and CMU-MOSEI emotion, that multimodal routing achieves performance close to the SOTA method. We see a performance drop in the emotion "happy", but our model outperforms the SOTA method for the emotion "angry".

5 Interpretation Analysis

In this section, we revisit our initial research question: how to locally identify the importance or contribution of unimodal features and the bimodal or trimodal interactions? We provide examples in this section on how multimodal routing can be used to see the variation of contributions. We first present the local interpretation and then the global interpretation.

5.1 Local Interpretation Analysis

We show how our model makes decisions locally for each specific input sample by looking at inferred coefficients $p_i r_{ij}$. Different samples create different p_i and r_{ij}, and their product represents how each feature vector contributes to final prediction locally, thus providing local interpretability. We provide such interpretability analysis on examples from CMU-MOSEI sentiment prediction and



This movie is musical. So, if you don't like musicals, don't go see this movie.

I'm going to have to say do not get this movie. Do not go out there and watch it. It's just no good.

So it's fun, it's diverse, it requires good communication skills and we also enjoy just hanging around talking about flying.

(frowned)
(neutral and calm voice)

(shaking head with grimace)
(disappointed voice)

(slight smiling)
(satisfied voice)

He knows me for who I am and he loves me, he can't help himself from loving me for exactly who I am.

I had sharp, shooting pains going through my feet …

I think that they could have done a much better job on that movie.

(big smile)
(happy tone)

(much frowned with grimace)
(painful voice)

(wry smile)
(reluctant voice)

Figure 3: Local interpretation (qualitative results) for Multimodal Routing. The upper row contains three examples from CMU-MOSEI sentiment prediction task; the bottom row contains three examples from CMU-MOSEI emotion recognition task. $p_i r_{ij}$ represents the contribution from the explanatory features i (unimodal/bimodal/trimodal interaction features) to the prediction logit_j (see eq. 3). In these examples, j is chosen to be the ground truth label.

emotion recognition, and illustrate them in Fig. 3. For sentiment prediction, we show samples with true labels neutral (0), most negative sentiment (-3), and most positive ($+3$) sentiment score. For emotion recognition, we illustrate examples with true label "happy", "sad", and "disgust" emotions. A color leaning towards red in the rightmost spectrum stands for a high association, while a color leaning towards blue suggests a low association.

In the upper-left example in Fig. 3, a speaker is introducing movie *Sweeny Todd*. He says the movie is a musical and suggests those who dislike musicals not to see the movie. Since he has no personal judgment on whether he personally likes or dislikes the movie, his sentiment is classified as neutral (0), although the text modality (i.e., transcript) contains a "don't". In the vision modality (i.e., videos), he frowns when he mentions this movie is musical, but we cannot conclude his sentiment to be neutral by only looking at the visual modality. By looking at both vision and text together (their interaction), the confidence in neutral is high. The model gives the text-vision interaction feature a high value of $p_i r_{ij}$ to suggest it highly contributes to the prediction, which confirms our reasoning above.

Similarly, for the bottom-left example, the speaker is sharing her experience on how to audition for a Broadway show. She talks about a very detailed and successful experience of herself and describes "love" in her audition monologue, which is present in the text. Also, she has a dramatic smile and a happy tone. We believe all modalities play a role in the prediction. As a result, the trimodal interaction feature contributes significantly to the prediction of happiness, according to our model.

Notably, by looking at the six examples overall, we could see each individual sample bears a different pattern of feature importance, even when the sentiment is the same. This is a good debuging and interpretation tool. For global interpretation, all these samples will be averaged giving more of a general trend.

5.2 Global Interpretation Analysis

Here we analyze the global interpretation of Multimodal Routing. Given the averaged routing coefficients $\overline{r_{ij}}$ generated and aggregated locally from samples, we want to know the overall connection between each modality or modality interaction and each concept across the whole dataset. To evaluate

	Sentiment						
	-3	-2	-1	0	1	2	3
$\overline{r_t}$	(0.052, 0.066)	**(0.349, 0.511)**	(0.094, 0.125)	**(0.194, 0.328)**	(0.078, 0.166)	(0.025, 0.042)	(0.017, 0.039)

Table 3: Global interpretation (quantitative results) for Multimodal Routing. Confidence Interval of $\overline{r_{ij}}$, sampled from CMU-MOSEI sentiment task (top) and emotion task (bottom). We bold the values that have the largest mean in each emotion and are significantly larger than a uniform routing ($1/J = 1/7 = 0.143$).

these routing coefficients we will compare them to uniform weighting, i.e., $\frac{1}{J}$ where J is the number of concepts. To perform such analysis, we provide confidence intervals of each $\overline{r_{ij}}$. If this interval is outside of $\frac{1}{J}$, we can interpret it as a distinguishably significant feature. See Supplementary for similar analysis performed on $\overline{p_i r_{ij}}$ and $\overline{p_i}$.

First we provide confidence intervals of $\overline{r_{ij}}$ sampled from CMU-MOSEI sentiment. We compare our confidence intervals with the value $\frac{1}{J}$. From top part of Table 3, we can see that our model relies identified language modality for neutral sentiment predictions; acoustic modality for extremely negative predictions (row $\overline{r_a}$ column -3); and text-acoustic bimodal interaction for extremely positive predictions (row $\overline{r_{ta}}$ column 3). Similarly, we analyze $\overline{r_{ij}}$ sampled from CMU-MOSEI emotion (bottom part of Table 3). We can see that our model identified the text modality for predicting emotion fear (row $\overline{r_t}$ column *Fear*, the same indexing for later cases), the acoustic modality for predicting emotion disgust, the text-acoustic interaction for predicting emotion surprise, and the acoustic-visual interaction for predicting emotion angry. For emotion happy and sad, either trimodal interaction has the most significant connection, or the routing is not significantly different among modalities.

Interestingly, these results echo previous research. In both sentiment and emotion cases, acoustic features are crucial for predicting negative sentiment or emotions. This well aligns with research results in behavior science (Lima et al., 2013). Furthermore, (Livingstone and Russo, 2018) showed that the intensity of emotion angry is stronger in acoustic-visual than in either acoustic or visual modality in human speech.

6 Conclusion

In this paper, we presented Multimodal Routing to identify the contributions from unimodal, bimodal and trimodal explanatory features to predictions in a locally manner. For each specific input, our method dynamically associates an explanatory feature with a prediction if the feature explains the prediction well. Then, we interpret our approach by analyzing the routing coefficients, showing great variation of feature importance in different samples. We also conduct global interpretation over the whole datasets, and show that the acoustic features are crucial for predicting negative sentiment or emotions, and the acoustic-visual interactions are crucial for predicting emotion angry. These observations align with prior work in psychological research. The advantage of both local and global interpretation is achieved without much loss of performance compared to the SOTA methods. We believe that this work sheds light on the advantages of understanding human behaviors from a multimodal perspective, and makes a step towards introducing more interpretable multimodal language models.

A.1 Encoding p_i from input

In practice, we use the same MulT to encode f_i and p_i simultaneously. We design MulT to have an output dimension $d_f + 1$. A sigmoid function is applied to the last dimension of the output. For this output, the first d_f dimensions refers to f_i and the last dimension refers to p_i.

A.2 Training Details and Hyper-parameters

Our model is trained using the Adam (Kingma and Ba, 2014) optimizer with a batch size of 32. The learning rate is 1e-4 for CMU-MOSEI Sentiment and IEMOCAP, and 1e-5 for CMU-MOSEI emotion. We apply a dropout (Srivastava et al., 2014) of 0.5 during training.

For the encoding stage, we use MulT (Tsai et al., 2019a) as feature extractor. After the encoder producing unimodal, bimodal, and trimodal features, we performs linear transformation for each feature, and output feature vectors with dimension $d_f = 64$.

We perform two iterations of routing between features and concepts with dimension $d_c = 64$ where d_c is the dimension of concepts. All experi-

ments use the same hyper-parameter configuration in this paper.

A.3 Remarks on CMU-MOSEI Sentiment

Our model poses the problem as classification and predicts only integer labels, so we don't provide mean average error and correlation metrics.

A.4 Remarks on CMU-MOSEI Emotion

Due to the introduction of concepts in our model, we transform the CMU-MOSEI emotion recognition task from a regression problem (every emotion has a score in $[0, 3]$ indicating how strong the evidence of that emotion is) to a classification problem. For each sample with six emotion scores, we label all emotions with scores greater than zero to be present in the sample. Then a data sample would have a multiclass label.

A.5 Global Interpretation Result

We analyze global interpretation of both CMU-MOSEI sentiment and emotion task.

CMU-MOSEI Sentiment The analysis of the routing coefficients $\overline{r_{ij}}$ is included in the main paper. We then analyze $\overline{p_i}$ (table 6) and the products $\overline{p_i r_{ij}}$ (table 4). Same as analysis in the main paper, our model relies on acoustic modality for extremely negative predictions (row $\overline{r_a}$ column -3) and text-acoustic bimodal interaction for extremely positive predictions (row $\overline{r_{ta}}$ column 3). The sentiment that is neutral or less extreme are predicted by contributions from many different modalities / interactions. The activation table shows high activation value (> 0.8) for most modality / interactions except $\overline{p_{vl}}$.

CMU-MOSEI Emotion Same as above, we analyze $\overline{p_i}$ (Table 7) and the product $\overline{p_i r_{ij}}$ (Table 5).The result is very similar to that of $\overline{r_{ij}}$. The activation table shows high activation value (> 0.8) for most modality / interactions except $\overline{p_{vl}}$, same as CMU-MOSEI sentiment. We see strong connections between audio-visual interactions and angry, text modality and fear, audio modality and disgust, and text-audio interactions and surprise. The activation table shows high activation value (> 0.8) for most modality / interactions except $\overline{p_{vl}}$ as well.

Multistage Fusion with Forget Gate for Multimodal Summarization in Open-Domain Videos

Abstract

Multimodal summarization for open-domain videos is an emerging task, aiming to generate a summary from multisource information (video, audio, transcript). Despite the success of recent multiencoder-decoder frameworks on this task, existing methods lack fine-grained multimodality interactions of multisource inputs. Besides, unlike other multimodal tasks, this task has longer multimodal sequences with more redundancy and noise. To address these two issues, we propose a multistage fusion network with the fusion forget gate module, which builds upon this approach by modeling fine-grained interactions between the multisource modalities through a multistep fusion schema and controlling the flow of redundant information between multimodal long sequences via a forgetting module. Experimental results on the How2 dataset show that our proposed model achieves a new state-of-the-art performance. Comprehensive analysis empirically verifies the effectiveness of our fusion schema and forgetting module on multiple encoder-decoder architectures. Specially, when using high noise ASR transcripts (WER>30%), our model still achieves performance close to the ground-truth transcript model, which reduces manual annotation cost.

1 Introduction

With the popularity of video platforms, personal videos abound on the Internet. Multimodal summarization for open-domain videos, first organized as a track of the How2 Challenge at the ICML 2019 workshop, aims to integrate multisource information of videos (video, audio, transcript) into a fluent textual summary. An example can be seen in Figure 1. This study, which uses compressed text description to reflect the salient parts of videos, is of considerable significance for helping users better retrieve and recommend videos.

Existing approaches have obtained promising results. For example, Libovickỳ et al. (2018) and Palaskar et al. (2019) utilize multiple encoders to encode videos and audio transcripts and a joint decoder to decode the multisource encodings, which acquire better performance than single modality structures. Despite the effectiveness of these approaches, they only perform multimodal fusion during the decoding stage to generate a target sequence, lacking fine-grained interactions between multisource inputs to complete the missing information of each modality. For example, as shown in Figure 1, text context representations containing birds should be associated with visual semantic information containing parrots to build thorough multimodal representations.

Besides, unlike other multimodal tasks such as visual question answering (Antol et al., 2015; Gao et al., 2015) and multimodal machine translation (Elliott et al., 2015; Specia et al., 2016), a major challenge is that this task has longer input sequences with more noise and redundancy. The flow of noise information during multimodal fusion, such as redundant frames in video and noisy words in transcription, interferes with the interaction and complementarity of the effective information between modalities, which leads to a significant negative effect on the model. Moreover, when using an automatic speech recognition (ASR) system to transform audio to transcription instead of ground-truth transcription, high noise ASR-output transcripts further reduce model performance.

To address these two issues, we propose a multistage fusion network with the fusion forget gate module for multimodal summarization in videos. The model involves multiple information fusion processes to capture the correlation between multisource modalities spontaneously, and a fusion for-

in this clip we 're going to file allister 's nails down with a drill . that will help smooth out the nails once again making it comfortable for you to hold your bird as well as comfortable for him . you do n't want any sharp edges on there . it just files it down . you want to use a medium speed on the drill so that you have control over it and it 's not going too fast . and all we 're doing with this is taking off the very tip of the nail after we 've trimmed it just to smooth it out . we 're not going to need to do much with it other than to make it smooth so it 's comfortable to hold him . the bird does not get hurt by the drill but you do want to make sure that the other toes are out of the way of the drill so that the drill piece is not going against their skin . once again , that can be difficult to do , you have to pry their toes apart to get them opened to drill them .

*after trimming your **parrot** 's nails , file them with a dremel to make the nail smooth ; learn more pet **parrot** care in this free pet care video about **parrots** .*

Figure 1: The audio transcript does not mention “**parrot**”, only “**bird**” or “**allister**”. The complete summary has to be derived from multi-source. This example is taken from the How2 dataset.

get gate is proposed to effectively suppress the flow of unnecessary multimodal noise. As illustrated in Figure 2, our proposed multistage fusion model mainly consists of four modules: 1) multisource encoders to build representations for video and audio (ground-truth or ASR-output transcript); 2) cross fusion block in which cross fusion generator (CFG) and a feature-level fusion layer are designed to generate and fuse latent adaptive streams from one modality to another at low levels of granularity; 3) hierarchical fusion decoder (HFD) in which hierchical attention networks are designed to progressively fuse multisource features carrying adaptive streams from other modalities to generate a target sequence; 4) fusion forget gate (FFG) (detailed in Figure 3) in which a memory vector and a forget vector are created for the information streams in the cross fusion block to alleviate interference from long-range redundant multimodal information.

We build our proposed model on both RNN-based (Sutskever et al., 2014) and transformer-based (Vaswani et al., 2017) encoder-decoder architectures and evaluate our approach on the large-scale public multimodal summarization dataset, How2 (Sanabria et al., 2018). Experiments show that our model achieves a new state-of-the-art performance. Comprehensive ablation experiments and visualization analysis demonstrate the effectiveness of our multistage fusion schema and forgetting module.

Specially, we also evaluate the model performances under the ASR-output transcript. We use an automatic speech recognition (ASR) system (Google-Speech-V2) to generate audio transcripts (word error rate>30%) to replace the ground-truth transcripts provided by the How2 dataset. Experiments show that our model still achieves performance close to the model trained with ground-truth transcripts, and significantly outperforms the state-of-the-art system, which indicates the advantage of our model in the absence of ground-truth transcript annotation.

The extracted ASR-output transcripts and code will be released on `https://github.com/forkarinda/MFN`.

2 Related Work

Unlike conventional summarization (Rush et al., 2015; See et al., 2017; Narayan et al., 2018), multimodal summarization compresses multimedia documents. According to different tasks, the input modalities are also different, such as text+image (Wang et al., 2012; Bian et al., 2013, 2014; Wang et al., 2016), and video+audio+text (Evangelopoulos et al., 2013; Li et al., 2017), which mainly focus on extractive approaches. With the popularity of sequence-to-sequence learning (Sutskever et al., 2014), the use of corpora with human-written summaries for multimodal abstractive summarization has attracted interest (Li et al., 2018; Zhu et al., 2018, 2020).

The above abstractive summarization research mainly focuses on text and image. Sanabria et al. (2018) first release the How2 dataset for multimodal abstractive summarization for open-domain videos. The dataset provides multisource information, including video, audio, text transcription and human-generated summary. This task is more challenging due to the diversity of multimodal information in the video and the complexity of the video feature space. The task was also added to the How2 Challenge in the 2019 ICML workshop,

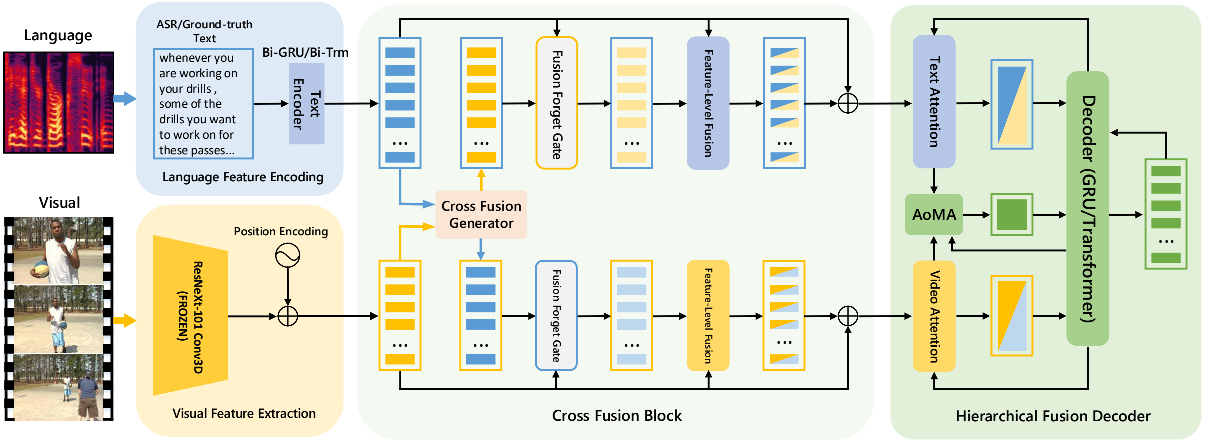

Figure 2: The structure of our full model. It is built on RNN-based and Transformer-based frameworks, respectively.

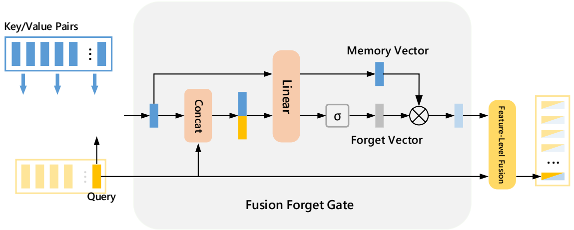

Figure 3: Detail of fusion forget gate. A memory vector and a forgetting vector are created for the information stream flowing through it, and then we get the product of two vectors as the final noise-filtered representation.

which we focus on in this paper. A similar task is video captioning (Venugopalan et al., 2015a,b), which mainly places emphasis on the use of visual information to generate descriptions, but this task focuses on how to make full use of multisource and multimodal long inputs to obtain a summary and additionally needs ground-truth transcripts. Recent methods use multiencoder-decoder RNNs to process multisource inputs but lack the interaction and complementarity between multisource modalities and the ability to resist the flow of multimodal noise. To handle above two challenges, our multistage fusion model is introduced.

3 Multistage Fusion with Forget Gate

In this section, we will explain our model in detail. The overall architecture of our proposed model is shown in Figure 2, and the fusion forget gate inside is illustrated in Figure 3. Specifically, multistage fusion consists of the cross fusion block and hierarchical fusion decoder, which aims to model the correlation and complementarity between modalities spontaneously. In addition, the fusion forget gate is applied in the cross fusion block to filter the flow of redundant information streams. We build our model based on the RNN and transformer encoder-decoder architectures, respectively.

3.1 Problem Definition

Our multimodal summarization system takes a video and a ground-truth or ASR-output audio transcription as input and generates a textual summary that describes the most salient part of the video. Formally, the transcript is a sequence of word tokens $T = (t_1, ..., t_n)$ and the video representation is denoted by $V = (v_1, ..., v_m)$, where v_m is the feature vector extracted by a pretrained model. The output summary is denoted as a sequence of word tokens $S = (s_1, ..., s_l)$ consisting of several sentences. The task aims to predict the best summary sequence S by finding:

$$\arg\max_{\theta} Prob(S|T, V; \theta) \tag{1}$$

where θ is the set of trainable parameters.

3.2 Multisource Encoders

Encoding Video. The video encoding features are obtained by a pretrained action recognition model: a ResNeXt-101 3D convolutional neural network (Hara et al., 2018) trained for recognizing 400 different human actions in the Kinetics dataset (Kay et al., 2017).

$$V = 3DCNN_{ResNeXt-101}(Frames) \tag{2}$$

The video representation features denoted by $V = (v_1, ..., v_m)$ are extracted every 16 nonoverlapping frames, where v_m is the 2048-dimensional vector.

We add learnable position embeddings for video features.

Encoding Transcript. For the RNN encoder, we use a bidirectional GRU (Cho et al., 2014) to encode the text to obtain a contextualized representation for each word:

$$T_{RNN} = BiGRU(t_1, t_2, ..., t_n) \tag{3}$$

For the transformer encoder, we employ an universal bidirectional transformer encoder (Vaswani et al., 2017) in which each layer is composed of a multihead self-attention layer followed by a feed-forward sublayer with residual connections (He et al., 2016) and layer normalizations (Ba et al., 2016), and denoted by the following equation:

$$T_{Trm} = BiTrm(t_1, t_2, ..., t_n) \tag{4}$$

We use learnable position embedding instead of sinusoidal position embedding.

3.3 Cross Fusion Generator

The cross fusion generator (CFG) is used to correlate meaningful elements across modalities. We apply the CFG to generate the adaptive fusion information from one modality encoding to another. The CFG learns two cross-modal attention maps, one is from text to video, and the other is from video to text. It is inspired by parallel co-attention (Lu et al., 2016), which computes an affinity matrix between two sequences, while we apply two unidirectional matrices instead of assigning shared parameters to both directions, and use scaled dot-product attention (Vaswani et al., 2017). At each of the cross-modal attention maps, the low-level signals from the source modality are transformed to key and value pairs to interact with the target modality as a query. Following the two maps, CFG is divided into the video-to-text fusion generator (V2TFG) and text-to-video fusion generator (T2VFG), which are detailed as follows:

Text-to-video Fusion Generator (T2VFG). The T2VFG generates the most relevant video information to low-level text features by a text-to-video cross-modal attention map. The cross-modal attention consists of text queries $Q_T = TW_{Q_T}$, video key and value pairs $K_T = VW_{K_T}, V_T = V$. The contextual video vector derived from the cross-modal attention map is calculated by

$$\begin{aligned} V_{Gen} &= CFG_{T\leftarrow V}(T,V) \\ &= softmax(\frac{Q_T(K_T)^T}{d})V_T \\ &= softmax(\frac{TW_{Q_T}(VW_{K_T})^T}{d})V \\ &= softmax(\frac{TW_{Q_T}(W_{K_T})^T V^T}{d})V \\ &= softmax(\frac{TW_\alpha V^T}{d})V \end{aligned} \tag{5}$$

where the common spatial parameter W_α is used to simplify the calculations.

Video-to-Text Fusion Generator (V2TFG). Similar to the T2VFG, the V2TFG aims to generate the latent adaptive text information stream for video modality. The difference between the V2TFG and T2VFG is that they flow in opposite directions. We transform the low-level video features to queries $Q_V = VW_{Q_V}$ and the text to key and value pairs $K_V = TW_{K_V}, V_V = T$, then calculate:

$$\begin{aligned} T_{Gen} &= CFG_{V\leftarrow T}(T,V) \\ &= softmax(\frac{VW_\beta T^T}{d})T \end{aligned} \tag{6}$$

where W_β is a mapping of text flowing to video.

3.4 Fusion Forget Gate

Although the CFG builds an unsupervised low-level signal alignment between original multi-source features, noise modality information generated by CFG is hard to be suppressed. In particular, when the whole modality cannot guide the task at all, the forced normalization of the softmax function in the attention structure makes the calculated fusion vector generated by the noise modality hard to be suppressed. For this reason, we propose a fusion forget gate (FFG) to filter low-level cross-modal adaptation information of each modality generated by the CFG.

The FFG reads the original modal signals as well as the adaptation information derived from other modalities, and determines whether the adaptation information is noise and matches the original modality. As shown in Figure 3, we assign a video FFG and a text FFG to receive bidirectional adaptation information that originated from the CFG.

Specifically, it creates a memory vector and a forget gate to control the flow of noise and mismatched information. First, we project the connected source and target modality embeddings and activate them with a sigmoid function to obtain a forget vector:

$$Forget_V(V_{Gen}, T) = \sigma([T; V_{Gen}]W_V + b_V) \quad (7)$$

$$Forget_T(T_{Gen}, V) = \sigma([V; T_{Gen}]W_T + b_T) \quad (8)$$

Then the adaptation information passes a linear mapping to obtain a memory vector, which prevents essential information from being weighted down due to the scaling limit of the sigmoid function ranging from 0 to 1. We apply the dot-product to the memory vector and the forget vector to represent the cross-modal adaptive stream after FFG filtering, which is finally calculated as follows:

$$\begin{aligned} T'_{Gen} &= FFG_T(T_{Gen}, V) = \\ &Memory_T(T_{Gen}) \odot Forget_T(T_{Gen}, V) \\ &= (T_{Gen}W_1 + b_1) \odot Forget_T(T_{Gen}, V) \end{aligned} \quad (9)$$

$$\begin{aligned} V'_{Gen} &= FFG_V(V_{Gen}, T) = \\ &Memory_V(V_{Gen}) \odot Forget_V(V_{Gen}, T) \\ &= (V_{Gen}W_2 + b_2) \odot Forget_V(V_{Gen}, T) \end{aligned} \quad (10)$$

where $\odot$ represents elementwise dot production and $W_V, W_T, W_1, W_2, b_V, b_T, b_1$ and b_2 are trainable parameters.

3.5 Feature-Level Fusion

This module combines the low-level signal T/V of the original modality with the matching adaptive stream V'/T' of other modalities. The fusion vector flowing through CFG and FFG has the same sequence length as the original modality so that we apply a concat&forward layer with a ReLU activation function. In addition, we specially add a residual connection inside the fusion layer to deepen the neural network's memory of the original modality. The calculation formulas are below:

$$T_F = Relu(T + [T; V'_{Gen}]W_1 + b_1) \quad (11)$$

$$V_F = Relu(V + [V; T'_{Gen}])W_2 + b_2) \quad (12)$$

where W_1, W_2, b_1, b_2 are trainable parameters.

3.6 Hierarchical Fusion Decoder

The HFD receives multimodal information of different granularity from multisource inputs and generates a target sequence. Inspired by hierarchical attention (Libovický and Helcl, 2017), HFD transforms the decoder hidden states and multisource encodings into a context vector by three attention maps: video attention, text attention, and attention over multimodal attention (AoMA). At each decoding time step t, the decoder hidden state h_t attends to video/text encodings V_F/T_F carrying aligned multimodal information separately via video/text attention to calculate the video/text context vector:

$$C_V = Attn(h_t, V_F) \quad (13)$$

$$C_T = Attn(h_t, T_F) \quad (14)$$

Then, a second attention mechanism is constructed over the two context vectors, and a higher-level context vector is computed. We concatenate the two contexts and apply a new MLP attention:

$$\begin{aligned} C_c =& AoMA(h_t, C_V, C_T) \\ =& softmax(W_1 \tanh(W_2 h_t + \\ & W_3[C_V; V_T])) \cdot [C_V; V_T] \end{aligned} \quad (15)$$

The context vector of hierarchical multimodal fusion is finally obtained and combined with the decoder hidden state vector to compute an output for attending the next decoder layer or caculating the vocabulary distribution.

$$y_{t+1} = Decoder_{RNN/Trm}(x_t, h_t, C_c) \quad (16)$$

Corresponding to the two encoders introduced in section 3.2, we design RNN-based and transformer-based decoding strategies. The formula expression and model diagram of the two structures are detailed in Appendix A.1.

4 Experimental Setup

4.1 How2 Dataset

We evaluate our method on the How2 dataset (Sanabria et al., 2018). The How2 dataset is a large-scale dataset of open-domain videos, spanning different topics, such as cooking, sports, indoor/outdoor activities, and music. It consists of 79,114 how-to instructional videos with an average length of 1.5 minutes and a total of 2,000 hours, accompanied by corresponding ground-truth English transcripts with an average length of 291 words, crowdsourced Portuguese translations of transcripts and user-generated summaries with an average length of 33 words. The statistics are shown in Figure 4 and Table 1.

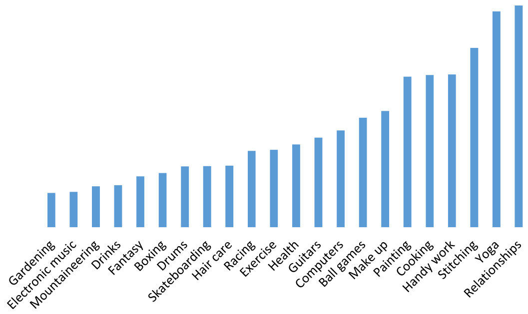

Figure 4: LDA topic distributions of the How2 dataset.

	train	val	test
Videos	73,993	2,965	2,156
Hours	1,766.6	71.3	51.7

Table 1: Statistics of How2 dataset.

4.2 Audio Recognition

We also extract audio transcripts by a speech recognition system (Google-Speech-V2). The word error rate (WER) of the speech-recognition output on the How2 test data is 32.9%.

4.3 Baseline Models

We compare our model with the following baseline models of single or multiple modalities:

S2S (Luong et al., 2015): a standard sequence-to-sequence architecture using an RNN encoder-decoder with a global attention mechanism.

PG (See et al., 2017): a commonly used encoder-decoder summarization model with attention (Bahdanau et al., 2015), which combines copying words from source documents and outputting words from a vocabulary.

FT: a strong baseline that applies a transformer-based encoder-decoder model to a flat sequence.

VideoRNN (Palaskar et al., 2019): a baseline of the video-only model implemented on the How2 dataset.

MT (Zhou et al., 2018): a transformer-based encoder-decoder architecture receiving sequence features of video for end-to-end dense video captions.

HA (RNN/Transformer) (Palaskar et al., 2019): a multisource sequence-to-sequence model with a hierarchical attention approach to combine textual and visual modalities, which is currently the state-of-the-art method for the multimodal summarization task on the How2 dataset.

4.4 Implement Details

For the RNN-based models, we uniformly use a 2-layer GRU with 128-dimensional word embeddings and 256-dimensional hidden states for each direction. We truncate the maximum text sequence length to 600.

For the transformer-based models, we uniformly use a 4-layer transformer of 512 dimensions with 8 heads. We truncate the maximum text sequence length to 800, and the maximum video sequence length to 1024.

For both the two architectures, we use the cross-entropy loss and Adam optimizer (Kingma and Ba, 2015). The initial learning rate is set to $1.5e^{-4}$. All trainable parameters are randomly initialized with the Kaiming initialization (He et al., 2015). The training of the proposed models are conducted on $\{1, 2\}$ GeForce RTX 2080 Ti GPUs for 50 epochs with a batch size of $\{4, 16\}$. During decoding for prediction, we use beam search with a beam size of 6 and a length penalty with $\alpha = 1$ (Wu et al., 2016).

For a fair comparison, following Palaskar et al. (2019), all the methods take the same 2048-dimensional video features extracted from a ResNeXt-101 3D convolutional neural network (Hara et al., 2018) as input; the vocabulary is built based on the How2 data, and do not use pre-trained word embeddings.

5 Results and Analysis

5.1 Model Performance

We adopt multiple automatic metrics to comprehensively evaluate model performance: BLEU (1,2,3,4) (Papineni et al., 2002), ROUGE (1,2,L) (Lin, 2004), METEOR (Banerjee and Lavie, 2005) and CIDEr (Vedantam et al., 2015). Table 2 shows the results for different models on the How2 dataset. Table 3 shows the model performances of using automatic transcripts obtained from a speech recognition system instead of ground-truth transcripts provided by the dataset. The results show that our proposed model achieves the state-of-the-art performance in each evaluation metric on both the RNN-based and transformer-based models. It can also be seen that the performances of the pure video modality models are modest because of the frozen video features extracted from a task-independent pretraining model.

In particular, Table 3 shows that when the performances of all the prior models trained with ASR-

Figure 5: A example taken from How2 test set. For the extracted ASR-output transcripts, we use the period "." as the separator of the automatically segmented audio clips.

output transcripts drop sharply due to the high error rate ($WER = 32.9\%$) of speech recognition, our model still has good performance close to the models trained with ground-truth transcripts. In using ASR-output transcripts, our framework outperforms the HA 8.3 BLEU-4 points, 7.4 ROUGE-L points, 3.9 METEOR points, and 71.8 CIDEr points on the RNN-based architecture, and 6.9 BLEU-4 points, 4.9 ROUGE-L points, 2.7 METEOR points, and 42.8 CIDEr points on the transformer-based architecture, which fully shows the effectiveness of our approach.

5.2 Ablations

The purpose of this study is to examine the role of the proposed multistage fusion and fusion forget gate (FFG). We divide the fusion process into transcript-to-video-fusion (T2VF) and video-to-transcript fusion (V2TF) in the cross fusion block, the following FFG, and the final HFD, and retrain our approach by ablating one or more of them.

- We retrain only T2VF and only V2TF and replace HFD with a standard decoder to handle single-source multimodal encodings.
- We add the FFG to the above T2VF and V2TF models separately.
- We retain T2VF, V2TF, HFD, and remove all the FFG of the full model.

Table 4 lists the results on the How2 dataset. We can observe that: 1) except that the V2TF's performance is weaker than the single-text modality on RNN $\{1a\}$, the performances of all the V2TF and T2VF models $\{3a, 1b, 3b\}$ exceed the performances of the single-modality models. 2) Compared with using only V2TF or T2VF, using V2TF and T2VF together with HFD $\{5a, 5b\}$ further improves the model effect. 3) When FFG is added, the performances of all the fusion structures improve, which is particularly evident in the RNN-based models. 4) Only one-way fusion structures with FFG $\{2a,4a,2b,4b\}$ can achieve comparable and even better performance compared to the HA. These results demonstrate the effectiveness of the multistage fusion and inside FFG.

Table 5 lists the results of using the ASR-output transcript instead of the provided ground-truth transcript. The observation results are similar to those observed in Table 4. In particular, we can see a greater increase in the performance of the FFG when using high noise ASR-output trancript compared to using the ground-truth transcript. This further verifies the ability of FFG to the resist the flow of multimodal noise.

Additionally, we also evaluate 1) the effect of model depth and 2) the effect of FFG on HFD. We deepen the model depth, and apply FFG to the multimodal context representation generated by the AoMA in HFD. The results in Table 6 indicate that the two measures do not improve model performance.

Figure 6: A visualization of FFG and attention in CFG.

5.3 Qualitative Analysis

We provide some example outputs from trained models. The example is taken from the How2 test set, and we show its ground-truth transcript and the extracted ASR-output transcript in Figure 5. Table 7 lists the generated results. We can observe that: 1) compared to single-modality models, the multi-modality models can generate more accurate and fluent contents. 2) In using ground-truth transcript, both HA and our proposed model generate accurate and fluent summaries. 3) In using ASR-output transcripts, our proposed model still generates a relatively accurate summary while the content generated by HA is not accurate enough, which intuitively illustrates the advantage of our model in the absence of ground-truth transcripts.

To better understand what our model has learned, we take the sample shown in Figure 1 to visualize the FFG and cross-attention in CFG. We sum the FFG weights and use the color depth of the word to represent the intensity of the FFG of controlling the flow of video to text, and demonstrate the interaction between video and text by displaying the video frame with the highest transcript-to-video attention when generating adaptive video streams. As shown in Figure 6, in the input segment, we can observe the following: 1) For some words related to the summary such as “file”, “nails”, the FFG retains video streams for it, in contrast, for words such as “once again”, the FFG forgets most of the video information. 2) For the words that FFG remembers deeply, the corresponding video frame has a certain correlation with it, for example, “file allister’s nails” point to a close-up of manicuring the parrot’s nails.

6 Conclusions

We introduce a multistage fusion network with fusion forget gate for generating text summaries for the open-domain videos. We propose a multistep fusion schema to model fine-grained interactions between multisource modalities and a fusion forget gate module to handle the flow of multimodal noise of multisource long sequences. Experiments on the How2 dataset show the effectiveness of the proposed models. Furthermore, when using high noise speech recognition transcription, our model still achieves the effect of being close to the ground-truth transcription model, which reduces the manual annotation cost of transcripts.

A Appendices

A.1 Hierarchical Fusion Decoder

In this section, The formula expression and model diagram of RNN-based and Transformer-based decoder are illustrated. The structures are shown in Figure 7.

RNN-based HFD. At each decoding time step, an unidirectional GRU receives the target token embeddings x_t and previous hidden state h_{t-1} to

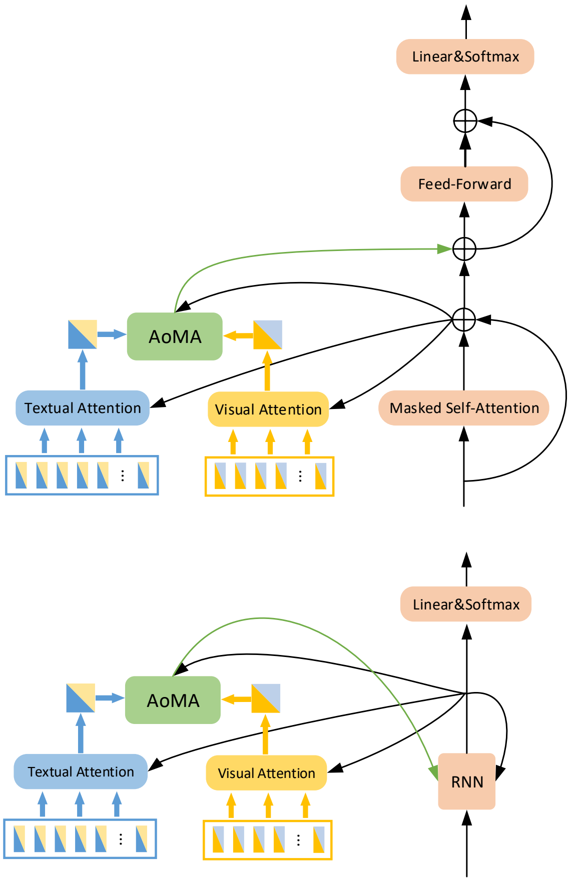

Figure 7: Transformer-based decoder is above, and RNN-based decoder is below.

compute a new hidden state h_t, which is defined as:

$$h_t = GRU(x_t, h_{t-1}) \tag{17}$$

The context vectors of each modality are firstly calculated by:

$$C_V = Attn_{MLP}(h_t, V_F) \tag{18}$$

$$C_T = Attn_{MLP}(h_t, T_F) \tag{19}$$

We adopt an MLP attention for RNN-based methods. Then the second attention AoMA over the video context vectors C_V and text context vectors C_T are implemented as:

$$\begin{aligned} C_c =& AoMA(h_t, C_V, C_T) \\ =& softmax(W_1 \tanh(W_2 h_t + \\ & W_3[C_V; V_T])) \cdot [C_V; V_T] \end{aligned} \tag{20}$$

The context vector C_C of multimodal fusion and the decoder state h_t are merged to get the output state y_{t+1}:

$$y_{t+1} = tanh(W[h_t; C_C] + b) \tag{21}$$

where W_1, W_2, W_3, W and b are trainable parameters.

Transformer-based HFD. Transformer-based HFD has a similar strategy as RNN-based. We mainly introduce how it absorbs multimodal information. It firstly receives target token embeddings x_t through the masked multi-head self-attention and residual connection to obtain the hidden state vector h_t, denoted as:

$$h_t = MHA_{masked}(x_t) \tag{22}$$

Then h_t is transformed into a query, separately attends to a set of key and value pairs mapped by previous encodings of each modality by the multi-head encoder-decoder attention, denoted as:

$$C_V = MHA(h_t, V_F) \tag{23}$$

$$C_T = MHA(h_t, T_F) \tag{24}$$

Similarly, the generated multimodal context vectors are fused by AoMA:

$$C_c = AoMA(h_t, C_V, C_T) \tag{25}$$

The final output state reaches through the feed-forward and add&norm layer like the general transformer, calculated as the following equation:

$$y_{t+1} = W_2 ReLu(W_1(C_c + h_t) + b_1) + b_2 + C_c + h_t \tag{26}$$

where W_1, W_2, b_1 and b_2 are trainable parameters.

A.2 Evalution Metrics

We use the nmtpytorch evaluation library https://github.com/lium-lst/nmtpytorch suggested by the How2 Challenge, which includes BLEU (1, 2, 3, 4), ROUGE-L, METEOR, and CIDEr evaluation metrics. As an alternative, nlg-eval https://github.com/Maluuba/nlg-eval can obtain the same evaluation score as nmtpytorch.

In addition, we also use a ROUGE evaluation library https://github.com/neural-dialogue-metrics/rouge, which supports the evaluation of ROUGE series metrics (ROUGE-N, ROUGE-L and ROUGE-W).

A.3 Data

The extracted ASR-output transcript data is available on https://github.com/forkarinda/MFN.

BiST: Bi-directional Spatio-Temporal Reasoning for Video-Grounded Dialogues

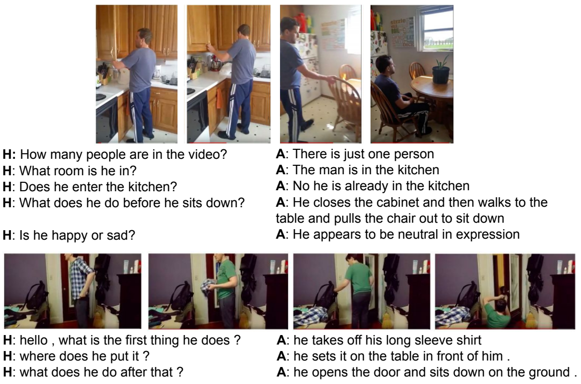
Abstract

Video-grounded dialogues are very challenging due to (i) the complexity of videos which contain both spatial and temporal variations, and (ii) the complexity of user utterances which query different segments and/or different objects in videos over multiple dialogue turns. However, existing approaches to video-grounded dialogues often focus on superficial temporal-level visual cues, but neglect more fine-grained spatial signals from videos. To address this drawback, we propose Bi-directional Spatio-Temporal Learning (BiST), a vision-language neural framework for high-resolution queries in videos based on textual cues. Specifically, our approach not only exploits both spatial and temporal-level information, but also learns dynamic information diffusion between the two feature spaces through spatial-to-temporal and temporal-to-spatial reasoning. The bidirectional strategy aims to tackle the evolving semantics of user queries in the dialogue setting. The retrieved visual cues are used as contextual information to construct relevant responses to the users. Our empirical results and comprehensive qualitative analysis show that BiST achieves competitive performance and generates reasonable responses on a large-scale AVSD benchmark. We also adapt our BiST models to the Video QA setting, and substantially outperform prior approaches on the TGIF-QA benchmark.



H: How many people are in the video?	**A**: There is just one person
H: What room is he in?	**A**: The man is in the kitchen
H: Does he enter the kitchen?	**A**: No he is already in the kitchen
H: What does he do before he sits down?	**A**: He closes the cabinet and then walks to the table and pulls the chair out to sit down
H: Is he happy or sad?	**A**: He appears to be neutral in expression

H: hello , what is the first thing he does ?	**A**: he takes off his long sleeve shirt
H: where does he put it ?	**A**: he sets it on the table in front of him .
H: what does he do after that ?	**A**: he opens the door and sits down on the ground .

Figure 1: Examples of video-grounded dialogues from the benchmark datasets of Audio-Visual Scene Aware Dialogues (AVSD) challenge (Alamri et al., 2018, 2019). **H**: human, **A**: the dialogue agent.

1 Introduction

A video-grounded dialogue agent aims to converse with humans not only based on signals from natural language but also from other modalities such as sound and vision of the input video. Recent efforts (Alamri et al., 2018; Sanabria et al., 2019; Alamri et al., 2019) consider video-grounded dialogues as an extension of video Question-Answering (QA) (Tapaswi et al., 2016; Jang et al., 2017; Lei et al., 2018) whereby the agent answers questions from humans over multiple turns rather than a single turn (See Figure 1). This is a very complex task as the dialogue agent needs to possess not only strong language understanding to generate natural responses but also sophisticated reasoning over video information, including the related objects, their positions and motions, etc. Compared to image-based NLP tasks such as image QA and captioning (Antol et al., 2015; Xu et al., 2015; Goyal et al., 2017), video-grounded dialogues are more challenging as the feature representation of a video involves both spatial and temporal dimensions. Ideally, a dialogue agent has to process information of both dimensions to address the two major questions: "where to look" (spatial reasoning) and "when to look" (temporal reasoning) in the video.

However, current approaches in video-grounded dialogues (Hori et al., 2019; Le et al., 2019b; Sanabria et al., 2019) often overlook spatial features and assume each spatial region is equally important to the current task (each spatial region is

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1846–1859,
November 16–20, 2020. ©2020 Association for Computational Linguistics

assigned with a uniform weight). Such approach is appropriate for cases where the video involves just few objects and spatial positions can be treated similarly. However, in many scenarios (e.g. examples in Figure 1), each video frame often contains multiple distinct objects and not all of them are relevant to the given question.

Related tasks to video-grounded dialogues are video QA and video captioning. Previous efforts in these research areas such as (Jang et al., 2017; Aafaq et al., 2019) explicitly consider both spatial and temporal features of input video. These models learn to summarize spatial features based on their importance to question rather than considering each region equally. We are motivated by these approaches and propose to extend spatio-temporal reasoning to dialogues. However, rather than fixing on processing spatial inputs then learning temporal inputs, we note that in some cases, e.g. extended videos over a long period, it is more practical to first identify the relevant video segments before pinpointing the specific subjects of interest. Considering questions in a dialogue setting, it is appropriate to assume the questions are relevant to varying temporal locations of the video rather than just a small fixed segment. We, thus, propose to explore a bidirectional vision-language reasoning approach to fully exploit both spatial and temporal-level features through two reasoning directions.

Our approach includes two parallel networks to learn relevant visual signals from the input video based on the language signals from user utterances. Each network projects the language-based features to a three-dimensional tensor which is then used to independently learn video signals following a reasoning direction either as *spatial→temporal* or *temporal→spatial*. The output from each network is dynamically combined by importance scores computed based on language and visual features. The weighted output is recurrently used as input to the reasoning modules to allow the models to progressively derive relevant video signals over multiple steps. Intuitively, *spatial→temporal* reasoning is more appropriate for human queries related to specific entities or for input video involving many objects. *temporal→spatial* reasoning is more suitable for human queries about a particular video segment or for videos of extensive lengths.

We name our proposed approach Bidirectional Spatio-Temporal Learning (*BiST*), with the following contributions: (1) Rather than exploiting temporal-level information only, our approach equally emphasizes both spatial and temporal features of videos for higher-resolution queries of visual cues. (2) To tackle the diverse queried information from conversational queries, we propose a bidirectional strategy, denoted *spatial↔temporal*, to enable comprehensive information diffusion between the two visual feature spaces. (3) Our models achieve competitive performance on the "AVSD" (Audio-Visual Scene Aware Dialogues) benchmark from the 7^{th} Dialogue System Technology Challenge (DSTC7) (Alamri et al., 2018, 2019). We adapt our models to a video QA task "TGIF-QA" (Jang et al., 2017) and achieve significant performance gains. (4) We conduct a comprehensive ablation and qualitative analysis and demonstrate the efficacy of our bidirectional reasoning approach.

2 Related Work

Our work is related to two research topics: video-grounded dialogues and spatio-temporal learning.

Video-grounded Dialogues. Following recent efforts that combine NLP and Computer Vision research (Antol et al., 2015; Xu et al., 2015; Goyal et al., 2017), video-grounded dialogues are extended from the two major research fields: video action recognition and detection (Simonyan and Zisserman, 2014; Yang et al., 2016; Carreira and Zisserman, 2017) and dialogues/QA (Rajpurkar et al., 2016; Budzianowski et al., 2018; Gao et al., 2019a). Approaches to video-grounded dialogues (Sanabria et al., 2019; Hori et al., 2019; Le et al., 2019b) typically use pretrained video models, such as 2D CNN models on video frames (Donahue et al., 2015; Feichtenhofer et al., 2016), and 3D CNN models on video clips (Tran et al., 2015; Carreira and Zisserman, 2017), to extract visual features. However, these approaches mostly exploit the superficial information from the temporal dimension and neglect spatial-level signals. These approaches integrate spatial-level features simply through sum pooling with equal weights to obtain a global representation at the temporal level. They are, thus, not ideal for complex questions that investigate entity-level or spatial-level information (Jang et al., 2017; Alamri et al., 2019). The dialogue setting exacerbates this limitation as it allows users to explore various aspects of the video contents, including both low-level (spatial) and high-level (temporal) information, over multiple dialogue turns. Our approach aims to address this challenge in video-grounded dialogues by retrieving fine-grained information from video through a bidirectional reasoning framework.

Spatio-temporal Learning. Most efforts in spatio-temporal learning focus on action recognition or detection tasks. (Yang et al., 2019) proposes to progressively refine coarse-scale information through temporal extension and spatial displacement for action detection. (Li et al., 2019a) uses a shared network of 2D CNNs over three orthogonal views of video to obtain spatial and temporal signals for action recognition. (Qiu et al., 2019) adopts a two-path network architecture that integrates global and local information of both temporal and spatial dimensions for video classification. Other research areas that investigate spatio-temporal learning include video captioning (Aafaq et al., 2019), video super-resolution (Li et al., 2019b), and video object segmentation (Xu et al., 2019). In general, spatio-temporal learning approaches aim to process higher-resolution information from complex videos that involve multiple objects in each video frame or motions over video segments (Yang et al., 2019). We are motivated by a similar reason observed in video-grounded dialogues and explore a vision-language bidirectional reasoning approach to obtain more fine-grained visual features.

3 BiST Model

The input includes a video V, dialogue history of $(t-1)$ turns (where t is the current turn), each including a pair of (human utterance H, dialogue agent response A) $(H_1, A_1, ..., H_{t-1}, A_{t-1})$, and current human utterance H_t. The output is a system response A_t that can address current human utterance. The input video can contain features in different modalities, including vision, audio, and text (such as video caption or subtitle). Without loss of generalization, we can denote each text input as a sequence of tokens, each represented by a unique token index from a vocabulary set V: dialogue history X_{his}, user utterance X_{que}, text input of video X_{cap} , and output response Y. We also denote L_{S} as the length of a sequence S. For instance, L_{que} is the length of X_{que}.

Our model is composed of four parts: (1) The encoders encode text sequences and video inputs, including visual, audio, and text features, into continuous representations. For non-text features such as vision and sound, we follow previous work (Lei et al., 2018; Hori et al., 2019) and assume access to pre-trained models. (2) Several neural reasoning components learn dependencies between user utterances/queries and video features of multiple modalities. For video visual features, we propose to learn dependencies at both spatial and temporal levels in two directions (see Figure 2). Specifically, we allow interaction between each token in user query and each spatial position or temporal step of the video. The outputs from spatial-based or temporal-based reasoning are sequentially incorporated in two directions, *temporal→spatial* and *spatial→temporal*. The bidirectional strategy enables information being fused dynamically and captures complex dependencies between textual signals from dialogues and visual signals from videos. (3) The decoder passes encoded system responses over multiple attention steps, each of which integrates information from textual or video representations. The decoder output is passed to a generator to generate tokens by an auto-regressive way. (4) The generator computes three distributions over the vocabulary set, one distribution as output from a linear transformation and the others based on pointer attention scores over positions of input sequences.

3.1 Encoders

Text Encoder. We use an encoder to embed text-based input X into continuous representations $Z \in \mathbb{R}^{L_X \times d}$. L_X is the length of sequence X and d is the embedding dimension. A text encoder includes a token-level embedding layer and a layer normalization (Ba et al., 2016). The embedding layer includes a trainable matrix $E \in \mathbb{R}^{|V| \times d}$, with each row representing a token in the vocabulary set V as a vector of dimension d. We denote $E(X)$ as the embedding function that looks up the vector of each token in input sequence X: $Z_{\text{emb}} = E(X) \in \mathbb{R}^{L_X \times d}$. To incorporate the positional encoding layer, we adopt the approach from (Vaswani et al., 2017) with each token position represented as a sine or cosine function. The output from positional encoding and token-level embedding is combined through element-wise summation and layer normalization. The encoder outputs include representations for dialogue history Z_{his}, user query Z_{que}, video caption Z_{cap}, and target response Z_{res}. For target response, during training, the sequence is shifted left by one position to allow prediction in the decoding step i is auto-regressive on the previous positions $1, ..., (i-1)$. We share the embedding matrix E to encode all text sequences.

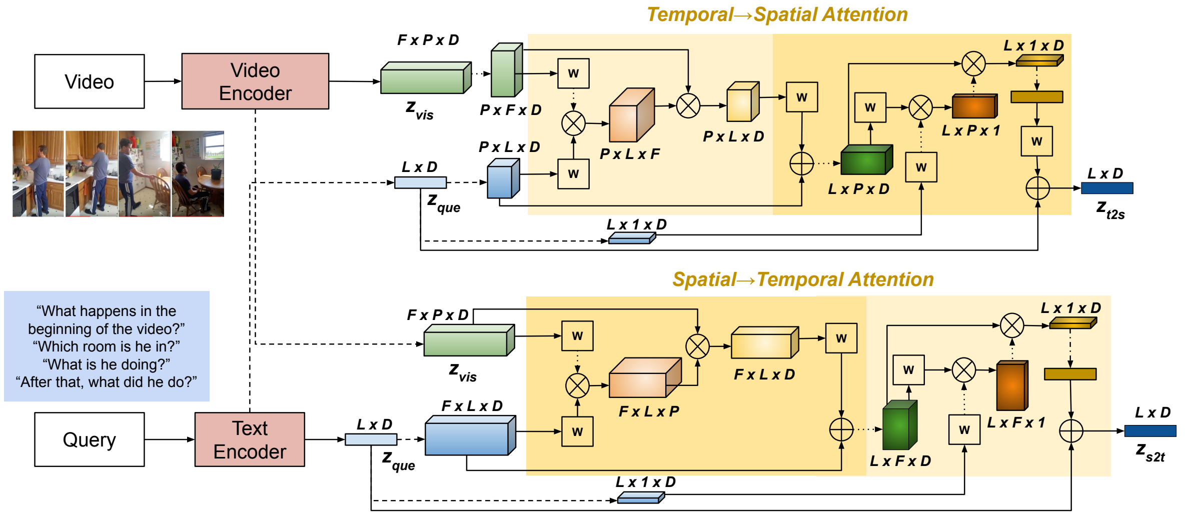

Figure 2: Our bidirectional approach models the dependencies between text and vision in two reasoning directions: spatial→temporal and temporal→spatial. ⊗ and ⊕ denote dot-product operation and element-wise summation.

Video Encoder. We make use of a 3D-CNN video model to extract spatio-temporal visual features. The dimensions of the resulting output depend on the configuration of sampling stride and clip length. We denote the output from a pretrained visual model as $Z_{\text{vis}}^{\text{pre}} \in \mathbb{R}^{F\times P\times d_{\text{vis}}^{\text{pre}}}$ where F is the number of sampled video clips, P is the spatial dimension from a 3D CNN layer, and $d_{\text{vis}}^{\text{pre}}$ is the feature dimension. We apply a linear layer with ReLU and layer normalization to reduce feature dimension to $d \ll d_{\text{vis}}^{\text{pre}}$. For audio features, we follow similar procedure to obtain audio representation $Z_{\text{aud}} \in \mathbb{R}^{F\times d}$. We keep the pretrained visual and audio models fixed and directly use extracted features to our dialogue models.

3.2 Bi-directional Reasoning

We propose a bidirectional architecture whereby the text features are used to select relevant information in both spatial and temporal dimensions in two reasoning directions (See Figure 2).

Temporal→spatial. In one direction, the user query is used to select relevant information along temporal steps of each spatial region independently. We first stack the encoded query features to P spatial positions and denote the stacked features as $Z_{\text{que}}^{\text{stack}} \in \mathbb{R}^{P\times L_{\text{que}}\times d}$. For each spatial position, the model learns the dependencies between question and each of F temporal steps through an attention mechanism as follows:

$$Z_{t2s}^{(1)} = Z_{\text{vis}}^{\mathsf{T}} W_{t2s}^{(1)} \in \mathbb{R}^{P\times F\times d_{\text{att}}} \quad (1)$$

$$Z_{t2s}^{(2)} = Z_{\text{que}}^{\text{stack}} W_{t2s}^{(2)} \in \mathbb{R}^{P\times L_{\text{que}}\times d_{\text{att}}} \quad (2)$$

$$S_{t2s}^{(1)} = \text{Softmax}(Z_{t2s}^{(2)} {Z_{t2s}^{(1)}}^{\mathsf{T}}) \in \mathbb{R}^{P\times L_{\text{que}}\times F} \quad (3)$$

where d_{att} is the dimension of the attention hidden layer, $W_{t2s}^{(1)} \in \mathbb{R}^{d\times d_{att}}$ and $W_{t2s}^{(2)} \in \mathbb{R}^{d\times d_{att}}$. The attention scores $S_{t2s}^{(1)}$ are used to obtain weighted sum along the temporal dimension of each spatial position of Z_{vis}. The resulting tensor is passed through a linear transformation and ReLU layer. The output contains temporally attended visual features and are combined with language features through skip connection. We denote the output by vector Z_{t2s}^{t}.

From the temporally attended features, user query is used again to obtain dependencies along the spatial dimension. We use a similar attention network to model the interaction between each token in query and each temporally attended spatial region.

$$Z_{t2s}^{(3)} = Z_{t2s}^{t} W_{t2s}^{(3)} \in \mathbb{R}^{L_{\text{que}}\times P\times d_{\text{att}}} \quad (4)$$

$$Z_{t2s}^{(4)} = Z_{\text{que}} W_{t2s}^{(4)} \in \mathbb{R}^{L_{\text{que}}\times d_{\text{att}}} \quad (5)$$

$$S_{t2s}^{(2)} = \text{Softmax}(Z_{t2s}^{(3)} {Z_{t2s}^{(4)}}^{\mathsf{T}}) \in \mathbb{R}^{L_{\text{que}}\times P} \quad (6)$$

where $W_{t2s}^{(3)} \in \mathbb{R}^{d\times d_{\text{att}}}$ and $W_{t2s}^{(4)} \in \mathbb{R}^{d\times d_{\text{att}}}$. The attention scores $S_{t2s}^{(2)}$ is used to obtain the weighted sum of all spatial positions from Z_{t2s}^{t}. The output is temporal-to-spatially attended visual features and is incorporated into language features through skip connection. We denote the resulting output as Z_{t2s}.

Spatial→temporal. In this reasoning direction, similar neural operations are used to compute spatially attended features followed by temporally attended features. The main difference from the other

reasoning direction is that we stacked the query features to F temporal steps to obtain $Z_{\text{que}}^{\text{stack}} \in \mathbb{R}^{F \times L_{\text{que}} \times d}$. Other network components, including two attention layers, are as described in Equation 1 to 6. The final output is denoted as Z_{s2t}.
Previous approaches in video-based NLP tasks (Yu et al., 2016; Jang et al., 2017; Hori et al., 2019) focus on the interaction between global representations of questions and temporal-level representations of videos. This strategy potentially loses critical information on spatial variations in video frames. Our approach does not only emphasize both spatial and temporal feature spaces but also allows neural models to diffuse information from these feature spaces in two different ways. As we can consider spatial information as local signals and temporal information as global signals, our approach enables global-to-local and local-to-global diffusion of visual cues in video. This approach is similar to (Qiu et al., 2019) in which local and global visual signals are learned and diffused iteratively. However, different from this approach, our approach focuses on language-vision reasoning for more accurate visual information queries.

Multimodal Reasoning. In addition to language-vision reasoning, our models also consider learning of other information dependencies between queries and audio inputs or textual video inputs.

- Language→Audio Reasoning. We adopt similar neural operations from language-vision reasoning. The difference is that we directly use the query features without stacking the features into Equation 1 to 3. The resulting output of text-audio reasoning is denoted as Z_{q2a} which contains query-guided temporally attended features of Z_{aud}.
- Language→Language Reasoning. This reasoning module focuses on the unimodal dependencies between user query and video caption (if the caption is available). As the caption can contain useful information about the video content, we apply the dot-product attention mechanism similarly as with audio features to obtain Z_{q2c}.

Multimodal Fusioning. Given the attended features, we combine them to obtained query-guided video representation, incorporating information from all modalities. We denote the concatenated representation in the following:

$$Z_{\text{q2vid}} = [Z_{\text{que}}; Z_{t2s}; Z_{s2t}, Z_{\text{q2a}}, Z_{\text{q2c}}] \in \mathbb{R}^{L_{\text{que}} \times 5d}$$

where ; is the concatenation operation. The features are combined through an importance score matrix:

$$S_{\text{vid}} = \text{Softmax}(Z_{\text{q2vid}} W_{\text{q2vid}}) \in \mathbb{R}^{L_{\text{que}} \times 4}$$

where $W_{\text{q2vid}} \in \mathbb{R}^{5d \times 4}$. The scores from S_{vid} are used to obtain the weighted sum of component video modalities, resulting in a fusion vector from multiple modalities. We denote the resulting output Z_{vid}. Compared to previous work such as (Hori et al., 2019; Le et al., 2019b) which generally treat all modalities equally, our multimodal features are fused in a question-dependent manner. Potentially, our approach can avoid noisy or unnecessary signals, e.g. audio features not needed for questions only concerning visual contents.

3.3 Response Decoder

The decoder aims to decode system responses in an auto-regressive manner. During inference, a special token $\langle \text{sos} \rangle$ is fed to the decoder. The output token is then concatenated to this special token as input to the decoder again to decode the second token. This repeats until reaching a limit of decoding rounds or when the special token $\langle \text{eos} \rangle$ is predicted. We apply a similar decoding architecture as (Le et al., 2019b). The decoder includes three attention layers to incorporate contextual cues from textual components to the output token representations. The first layer is a self-attention to learn dependencies among the current tokens. Intuitively, this helps to shape a more semantically structured sequence. The second and third attention steps are used to capture contextual information from dialogue history and current user query to make the responses coherently connected to the whole dialogue context. To incorporate contextual cues from video components, our decoder is slightly different from (Le et al., 2019b). Instead of sequentially going through multiple attention layers, we only need one layer on the fused features Z_{vid}. This is more memory efficient since it only requires a single attention operation. It also does not depend on the design decision of the ordering of attention layers. At decoding step j, we denote the decoder output as $Z_{\text{dec}} \in \mathbb{R}^{j \times d}$.

3.4 Pointer Generator

Given the output from the decoder, the generator network is used to materialize responses in natural language. A linear transformation is used to obtain distribution over the vocabulary set V.

$$P_{\text{vocab}} = \text{Softmax}(Z_{\text{dec}} W_{\text{vocab}}) \in \mathbb{R}^{j \times |V|}$$

where $W_{\text{vocab}} \in \mathbb{R}^{d \times |V|}$. We share the weights between W_{vocab} and E as the semantics between source sequences and target responses are similar. To strengthen the model generation capability, we adopt pointer networks (Vinyals et al., 2015) to emphasize tokens from source sequences, i.e. user queries and video captions. We denote $\text{Ptr}(Z_1, Z_2)$ as the pointer network operation i.e. each token in Z_2 is "pointed" to all tokens in Z_1 through a learnable probability distribution. The resulting probability distribution is aggregated by all tokens in Z_1 to obtain $\text{Ptr}(Z_1, Z_2) \in L_{Z_2} \times |V|$. The final output distribution, denoted $P_{\text{out}} \in \mathbb{R}^{j \times |V|}$, is the weighted sum of three distributions: P_{vocab}, $\text{Ptr}(Z_{\text{que}}, Z_{\text{dec}})$, and $\text{Ptr}(Z_{\text{cap}}, Z_{\text{dec}})$. The weights for this fusion are learned via a linear transformation with softmax: $\alpha = \text{Softmax}(Z_{\text{gen}} W_{\text{gen}}) \in \mathbb{R}^{L_{\text{res}} \times 3}$ where $Z_{\text{gen}} = [Z_{\text{res}}; Z_{\text{dec}}; Z_{\text{que}}^{\text{exp}}; Z_{\text{cap}}^{\text{exp}}] \in \mathbb{R}^{j \times 4d}$, $W_{gen} \in \mathbb{R}^{4d \times 3}$, and $Z_{\text{que}}^{\text{exp}}$ and $Z_{\text{cap}}^{\text{exp}}$ are the stacked tensors of caption and user queries to j dimensions.

Optimization. During training, we learn all model parameters by minimizing the generation loss:

$$\mathcal{L} = \sum_{j=0}^{L_Y} -\log(P_{\text{out}}(y_j)).$$

4 Experiments

4.1 Experimental Setups

Datasets. We use the AVSD benchmark from DSTC7 (Alamri et al., 2018, 2019) which contains dialogues grounded on the Charades videos (Sigurdsson et al., 2016). In addition, we adapt our models to the video QA benchmark TGIF-QA (Jang et al., 2017). (See Table 1 for a summary of the two datasets). To extract visual and audio features, we used 3D-CNN ResNext-101 (Xie et al., 2017) pretrained on Kinetics (Hara et al., 2018) to obtain spatio-temporal visual features and VGGish pretrained on YouTube videos (Hershey et al., 2017) to extract (temporal) audio features. We sample video clips to extract visual features with a window size of 16 frames, and stride of 16 and 4 in AVSD and TGIF-QA respectively. In TGIF-QA experiments, we also extract visual features from pretrained ResNet-152 (He et al., 2016) for a fair comparison with existing work. In AVSD experiments, we make use of the video summary as the video-dependent text input X_{cap}.

Training Procedure. We adopt the Adam optimizer (Kingma and Ba, 2015) and the learning rate strategy from (Vaswani et al., 2017). We set the learning rate *warm-up* steps equivalent to 5 epochs and train models up to 50 epochs. We select the best models based on the average loss per epoch in the validation set. We initialize all model parameters with uniform distribution (Glorot and Bengio, 2010). During training, we adopt the auxiliary auto-encoder loss function from (Le et al., 2019b). We adopt Transformer attention (Vaswani et al., 2017) in our models and select the following hyper-parameters: $d = d_{\text{att}} = 128$, $N_{\text{att}} = N_{\text{dec}} = 3$, and $h_{\text{att}} = 8$ where N_{att} and N_{dec} are the number of Transformer blocks in multimodal reasoning and decoder networks and h_{att} is the number of attention heads. We tuned other hyper-parameters following grid-search over the validation set. In AVSD experiments, we train our models by applying label smoothing (Szegedy et al., 2016) on the target system responses Y. We adopt a beam search technique with a beam size 5.

Benchmark	#	**Train**	**Val.**	**Test**
AVSD	Dialogs	7,659	1,787	1,710
	Turns	153,180	35,740	13,490
	Words	1,450,754	339,006	110,252
TGIF-QA	Count QA	24,159	2,684	3,554
	Action QA	18,428	2,047	2,274
	Trans. QA	47,434	5,270	6,232
	Frame QA	35,453	3,939	13,691

Table 1: Summary of DSTC7 AVSD and TGIF-QA benchmark. The TGIF-QA contains 4 different tasks: (1) Count: open-ended QA which counts the number of repetitions of an action. (2) Action: multi-choice (MC) QA about a certain action occurring a fixed number of times. (3) Transition: MC QA about the temporal variation of video. (4) Frame: open-ended QA which can be answered from one video frame.

4.2 Modifications for Video QA

In many Video QA benchmarks such as TGIF-QA (Jang et al., 2017), the tasks are retrieval-based (e.g. output a single score for each output candidate) rather than generation-based as in many dialogue tasks. Following (Fan et al., 2019), we first concatenate the question with each candidate answer individually and treat this as Z_{que} to our models. As there is no target response to be decoded, we adapt our models to this setting by using a trainable vector $z_j \in \mathbb{R}^d$ to represent a candidate response R_j, replacing $Z_{\text{res}} \in \mathbb{R}^{j \times d}$ in a dialogue, as input to the decoder. The output, denoted $Z_{j,\text{dec}} \in \mathbb{R}^d$, is passed to a linear transformation layer to obtain a score $s_{j,\text{out}} = Z_{j,\text{dec}} W_{\text{out}} \in \mathbb{R}$

Table 2: Evaluation results on the test split of the AVSD benchmark. The results are presented in 4 settings by video feature components: (1) visual-only, (2) visual and text, (3) visual and audio, and (4) visual, audio, and text.

where $W_{\text{out}} \in \mathbb{R}^{d\times 1}$. In this setting, we remove the language→language and language→audio reasoning modules. The loss function is the summed pairwise hinge loss (Jang et al., 2017) between scores of positive answer s^p_{out} and each negative answer $s^n_{j,\text{out}}$. $\mathcal{L} = \sum_{j=1}^{K} max(0, m - (s^p_{\text{out}} - s^n_{j,\text{out}}))$ where K is the total number of candidate answers and m is a hyper-parameter used as a margin between positive and negative answers.

Training. Multiple-choice tasks, including *Action* and *Transition*, are trained following the pairwise loss with $K = 5$ and $m = 1$. *Count* task is trained with similar approach but as a regression problem with a single output score s_{out}. The loss function is measured as mean square error between output s_{out} and label y. The open-ended *Frame* task is trained as a generation task, similarly to the dialogue response generation task, with a single-token output. We use the the vector $z \in \mathbb{R}^d$ as input to the decoder. The generator includes a single linear layer with $W_{\text{out}} \in \mathbb{R}^{d\times|v|}$. We do not apply pointer network in this case as the output is only a single-token response.

4.3 Results

AVSD Results. We report the objective scores, including BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004), and CIDEr (Vedantam et al., 2015). These metrics, which formulate lexical overlaps between generated and ground-truth dialogue responses, are borrowed from language generation tasks such as machine translation and captioning. We compare our generated responses with 6 reference responses. Major baseline models are: (1) *Baseline* (Alamri et al., 2018; Hori et al., 2019) consists of LSTM-based encoder-encoder with attention layers between user queries and temporal-level visual and audio features. (2) *Baseline+GRU+HierAttn.* (Le et al., 2019a) extends (1) through GRU and question-guided self-attention and caption attention. (3) *FA+HRED* (Nguyen et al., 2018) adopts FiLM neural blocks for language-vision dependency learning. (4) *Video Summarization* (Sanabria et al., 2019) reformulates the task as a video summarization task and enhances the models with transfer learning from a large-scale summarization benchmark. (5) *Student-Teacher* (Hori et al., 2019) adopts dual network architecture in which a student network is trained to mimic a teacher network trained with additional video-dependent text input. (6) *MTN* (Le et al., 2019b) fuses temporal features of different modalities sequentially through a Transformer decoder architecture. (7) *FGA* (Schwartz et al., 2019) consists of attention networks between all pairs of modalities and the models aggregate attention scores along edges of an attention graph.

In Table 2, we present the scores by different combinations of features, including vision Z_{vis}, audio Z_{aud}, and text Z_{cap}. In all settings, our models outperform the existing approaches. The performance of our models in the visual-only setting shows the performance gain coming from our bidirectional language-vision reasoning approach. We

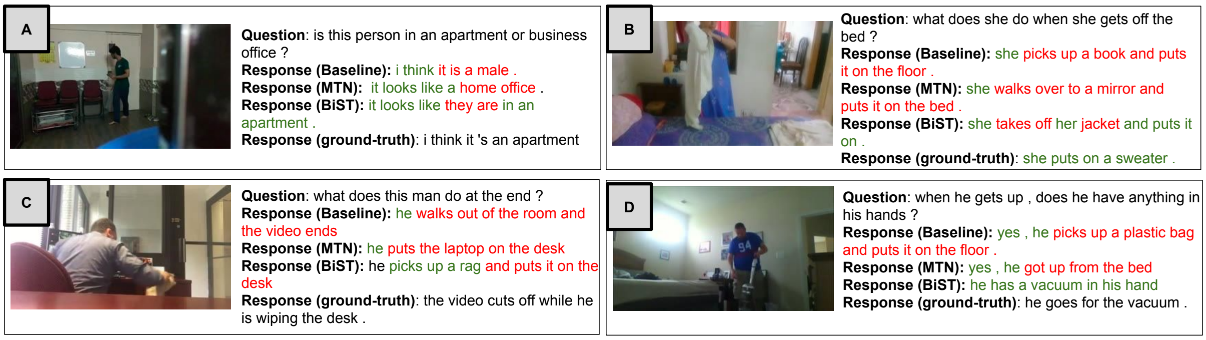
Table 3: Evaluation results on the test split of the TGIF-QA benchmark. Visual features are: R(ResNet), C(C3D), F(FlowCNN), RX(ResNext).

also observe a performance boost whenever the text feature from video is considered. When we add the audio features, however, the performance gain is not significant. This reveals a potential future extension in our work to better combine visual and audio feature representations. FGA (Schwartz et al., 2019) reports the CIDEr score of 0.806 in the visual-only setting. Compared to FGA, our performance gain indicates the efficacy of learning fine-grained dependencies between query and visual features at both spatial and temporal levels to select relevant information from video.

TGIF-QA Results. We give the L2 loss for *Count* task and accuracy for the other three QA tasks (See Appendix A for description of baseline models). From Table 3, our model outperforms existing approaches across all QA tasks, using either frame-level (appearance) feature, ResNet, or sequence-level feature, ResNext. Our models perform better with ResNext as we expect sequence-level feature is more consistent than frame-level feature. Experiments on this benchmark show clearer performance gain of our bidirectional language-vision reasoning approach as the performance is not affected by errors of generation components as in the AVSD experiments. By focusing on learning high-resolution dependencies from spatio-temporal features, our models can fully exploit contextual cues and select better answers for video QA tasks.

Impacts of Spatio-temporal Learning. We consider model variants based on the spatio-temporal dynamics and report the results in Table 4. We noted that when using a single reasoning direction, the model with *temporal→spatial* performs better than one with the reverse reasoning direction. This observation is different from prior approaches of spatio-temporal learning such as (Jang et al., 2017) which are limited to the reasoning order *spatial→temporal*. This can be explained as the videos in the AVSD benchmark are typically longer than other QA benchmarks. It is practical to focus on temporal locations in frame sequences first before selecting spatial regions in individual frames. In addition, dialogue queries are positioned in a multi-turn setting whereby each turn is relevant to different video segments as the dialogue evolves. Potentially, this observation indicates an important difference of video-grounded dialogues compared to video QA. Secondly, we also observe that our model performance improves when we use both reasoning directions rather than only one of them. Our motivation for this approach is similar to (Schuster and Paliwal, 1997) who proposes a bidirectional strategy to process sequences in both forward and backward directions. Similarly, our approach exploits visual information through a bidirectional information diffusion strategy that can interpret information from both spatial or temporal aspects based on language input. Finally, we observe that using spatio-temporal features is better



Question: is this person in an apartment or business office ?
Response (Baseline): i think it is a male .
Response (MTN): it looks like a home office .
Response (BiST): it looks like they are in an apartment .
Response (ground-truth): i think it 's an apartment

Question: what does she do when she gets off the bed ?
Response (Baseline): she picks up a book and puts it on the floor .
Response (MTN): she walks over to a mirror and puts it on the bed .
Response (BiST): she takes off her jacket and puts it on .
Response (ground-truth): she puts on a sweater .

Question: what does this man do at the end ?
Response (Baseline): he walks out of the room and the video ends
Response (MTN): he puts the laptop on the desk
Response (BiST): he picks up a rag and puts it on the desk
Response (ground-truth): the video cuts off while he is wiping the desk .

Question: when he gets up , does he have anything in his hands ?
Response (Baseline): yes , he picks up a plastic bag and puts it on the floor .
Response (MTN): yes , he got up from the bed
Response (BiST): he has a vacuum in his hand
Response (ground-truth): he goes for the vacuum .

Figure 3: Comparison of dialogue response outputs of BiST against the baseline models. Parts of the outputs that match and do not match the ground truth are highlighted in green and red respectively.

than only using one of them, demonstrating the importance of information in both dimensions. To obtain Z_{vis} for spatial-only or temporal-only features, the spatio-temporal features are passed through an average pooling operation along the temporal or spatial dimensions respectively.

Table 4: Ablation analysis on the AVSD benchmark with variants of BiST by spatio-temporal dynamics.

Ablation Analysis. We conduct experiments with model variants of different hyper-parameter settings. Specifically, we vary the the number of attention rounds N_{att} and attention heads h_{att}. From Table 5, we noted the contribution of the multi-round architecture to language-vision reasoning as the performance improves with larger reasoning steps, i.e. up to three attention rounds. However, we observe that as we increase to more than 3 reasoning steps, the model performance only improves slightly. We also note that using a multi-head attention mechanism is suitable for tasks dealing with information-intensive media such as video and dialogues. The multi-head structure enables feature projection to multiple subspaces and capture complex language-vision dependencies.

Qualitative Analysis. In Figure 3, we present some example outputs. We note that the predicted dialogue responses of BiST models are closer to the ground-truth responses. Particularly for complex questions that query specific segments (example B, C, D), and/or specific spatial locations (Example D), our approach can generally produce better responses. Another observation is that for ambiguous examples such as Example C (where the visual appearance is not clear to differentiate "apartment" and "business office"), our model can return the correct answer. Potentially this can be explained by the extracted signals from spatial-level feature representations. Finally, we note that there are still some errors that make the output sentences partially wrong, such as mismatching subjects (example A), wrong entities (Example B), or wrong actions (Example C). For detailed qualitative analysis, please refer to Appendix B.

5 Conclusion

We proposed BiST, a novel deep neural network approach for video-grounded dialogues and video QA, which exploits the complex visual nuances of videos through a bidirectional reasoning framework in both spatial and temporal dimensions. Our experimental results show that BiST can extract relevant, high-resolution visual cues from videos and generate quality dialogue responses/answers.

A TGIF-QA Baselines

In TGIF-QA experiments, we compare our models with the following baselines: (1) *VIS* (Ren et al., 2015) and (2) *MCB* (Fukui et al., 2016) are two image-based VQA baselines which were adapted to TGIF-QA by (Jang et al., 2017). (3) Yu *et al.* (Yu et al., 2017) uses a high-level concept word detector and the detected words are used for semantic reasoning. (4) *ST-VQA* (Jang et al., 2017) integrates temporal and spatial features by first pretraining temporal part and then finetuning the spatial part. (5) *Co-Mem* (Gao et al., 2018) includes a co-memory mechanism on two video streams based on motion and appearance features. (6) *PSAC* (Li et al., 2019c) uses multi-head attention layers to exploit the dependencies between text and temporal variation of video. (7) *HME* (Fan et al., 2019) is a memory network with read and write operations to update global context representations. (8) *STA* (Gao et al., 2019b) divides video into N segments and uses temporal attention modules on each segment independently. (9) *CRN+MAC* (Le et al., 2019c) is a clip-based reasoning framework by aggregating frame-level features into clips through temporal attention. (10) *MQL* (Lei et al., 2020) exploits the semantic relations among questions and proposes a multi-label prediction task. (11) *QueST* (Jiang et al., 2020) has two types of question embeddings: spatial and temporal embeddings based on attention guided by video features. (12) *HGA* (Jiang and Han, 2020) is a graph alignment network consisting of inter- and intra-modality edges to model the interaction between video and question. (13) *GCN* (Huang et al., 2020) is a similar approach with graph network but utilizes the video object-level features as node representations. (14) *HCRN* (Le et al., 2020) extends (Le et al., 2019c) with a hierarchical relation network over temporal-level video features.

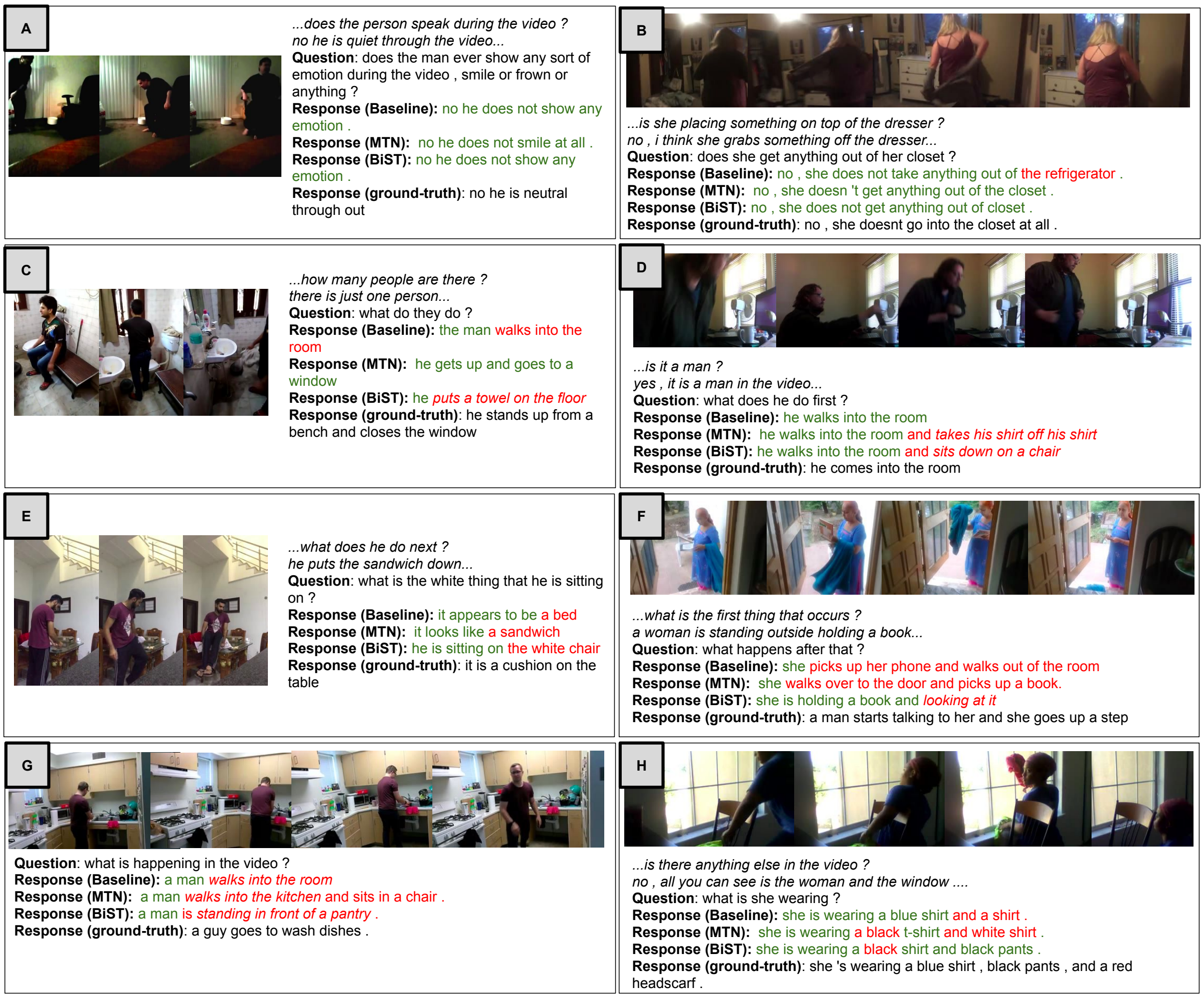
B Qualitative Analysis

We present additional example outputs in Figure 4. For each examples, we include the last dialogue turn from the dialogue history. In general, BiST can generate responses that better match the ground truth than the Baseline (Hori et al., 2019) and MTN (Le et al., 2019b) (example A, B). Furthermore, we analyze both negative and positive outputs and have the following observations:

- In cases where the videos contain more than one actions, our models can predict responses that describe multiple actions in their correct *orders of appearance*. For instance, in example D, even though our model response does not completely match the ground truth, it is still correctly explaining the sequence of actions, including first "walking into the room" and "sits down on a chair", matching the visual input from video. MTN response in the same example can express multiple actions but fail to detect the second action before "takes his shirt off". A similar observation can be found in the example F.

- In cases where the entities are hard to detect due to weak *visual distinction*, BiST can materialize the correct entity in its responses, e.g. in example C, "a towel" was seen in the last sampled video frame. Another example is example H where BiST detects both "shirt" and "pants" entities (even though their color attributes are not totally correct). However, in example E, all models fail to identify the entity "a cushion", possibly because of the ambiguous and subdue visual features of this object in the video. This displays an important challenge for more fine-grained information extraction in video-grounded dialogues.

- We noted our model fails in the following complex cases. First, for case with *ambiguous questions* such as example C, BiST emphasizes an action in the later part of the video (3^{rd} sampled frame) rather than the early part of the video (1^{st} and 2^{nd} sampled frame). This error might be due to the implied temporal specification in the question. Similarly, in example G, the ambiguous question results in generated responses of different action-level granularity from all models and some responses are partially correct. Secondly, in cases where the ground-truth answer involves *unseen entity* (example F with the entity "a man" without any visual appearance but possibly detected by his voice in the audio input), our model fails to include this entity in the response. A possible explanation for this example is that our model is not able to detect the entity based on audio input, i.e. "a man talking". This presents the retaining challenge to fully combine multiple modalities into natural language responses in dialogues.



...does the person speak during the video ?
no he is quiet through the video...
Question: does the man ever show any sort of emotion during the video , smile or frown or anything ?
Response (Baseline): no he does not show any emotion .
Response (MTN): no he does not smile at all .
Response (BiST): no he does not show any emotion .
Response (ground-truth): no he is neutral through out

...is she placing something on top of the dresser ?
no , i think she grabs something off the dresser...
Question: does she get anything out of her closet ?
Response (Baseline): no , she does not take anything out of the refrigerator .
Response (MTN): no , she doesn 't get anything out of the closet .
Response (BiST): no , she does not get anything out of closet .
Response (ground-truth): no , she doesnt go into the closet at all .

...how many people are there ?
there is just one person...
Question: what do they do ?
Response (Baseline): the man walks into the room
Response (MTN): he gets up and goes to a window
Response (BiST): he *puts a towel on the floor*
Response (ground-truth): he stands up from a bench and closes the window

...is it a man ?
yes , it is a man in the video...
Question: what does he do first ?
Response (Baseline): he walks into the room
Response (MTN): he walks into the room and *takes his shirt off his shirt*
Response (BiST): he walks into the room and *sits down on a chair*
Response (ground-truth): he comes into the room

...what does he do next ?
he puts the sandwich down...
Question: what is the white thing that he is sitting on ?
Response (Baseline): it appears to be a bed
Response (MTN): it looks like a sandwich
Response (BiST): he is sitting on the white chair
Response (ground-truth): it is a cushion on the table

...what is the first thing that occurs ?
a woman is standing outside holding a book...
Question: what happens after that ?
Response (Baseline): she picks up her phone and walks out of the room
Response (MTN): she walks over to the door and picks up a book.
Response (BiST): she is holding a book and *looking at it*
Response (ground-truth): a man starts talking to her and she goes up a step

Question: what is happening in the video ?
Response (Baseline): a man *walks into the room*
Response (MTN): a man *walks into the kitchen* and sits in a chair .
Response (BiST): a man is *standing in front of a pantry* .
Response (ground-truth): a guy goes to wash dishes .

...is there anything else in the video ?
no , all you can see is the woman and the window ....
Question: what is she wearing ?
Response (Baseline): she is wearing a blue shirt and a shirt .
Response (MTN): she is wearing a black t-shirt and white shirt .
Response (BiST): she is wearing a black shirt and black pants .
Response (ground-truth): she 's wearing a blue shirt , black pants , and a red headscarf .

Figure 4: Comparison of dialogue response outputs of BiST against the baseline models: *Baseline* (Hori et al., 2019) and *MTN* (Le et al., 2019b). Parts of the outputs that match and do not match the ground truth are highlighted in green and red respectively.

UniConv: A Unified Conversational Neural Architecture for Multi-domain Task-oriented Dialogues

Abstract

Building an end-to-end conversational agent for multi-domain task-oriented dialogues has been an open challenge for two main reasons. First, tracking dialogue states of multiple domains is non-trivial as the dialogue agent must obtain complete states from all relevant domains, some of which might have shared slots among domains as well as unique slots specifically for one domain only. Second, the dialogue agent must also process various types of information across domains, including dialogue context, dialogue states, and database, to generate natural responses to users. Unlike the existing approaches that are often designed to train each module separately, we propose "UniConv" — a novel unified neural architecture for end-to-end conversational systems in multi-domain task-oriented dialogues, which is designed to jointly train (i) a Bi-level State Tracker which tracks dialogue states by learning signals at both slot and domain level independently, and (ii) a Joint Dialogue Act and Response Generator which incorporates information from various input components and models dialogue acts and target responses simultaneously. We conduct comprehensive experiments in dialogue state tracking, context-to-text, and end-to-end settings on the MultiWOZ2.1 benchmark, achieving superior performance over competitive baselines.

1 Introduction

A conventional approach to task-oriented dialogues is to solve four distinct tasks: (1) natural language understanding (NLU) which parses user utterance into a semantic frame, (2) dialogue state tracking (DST) which updates the slots and values from semantic frames to the latest values for knowledge base retrieval, (3) dialogue policy which determines an appropriate dialogue act for the next system response, and (4) response generation which generates a natural language sequence conditioned on the dialogue act. This traditional pipeline modular framework has achieved remarkable successes in task-oriented dialogues (Wen et al., 2017; Liu and Lane, 2017; Williams et al., 2017; Zhao et al., 2017). However, such kind of dialogue system is not fully optimized as the modules are loosely integrated and often not trained jointly in an end-to-end manner, and thus may suffer from increasing error propagation between the modules as the complexity of the dialogues evolves.

A typical case of a complex dialogue setting is when the dialogue extends over multiple domains. A dialogue state in a multi-domain dialogue should include slots of all applicable domains up to the current turn (See Table 1). Each domain can have shared slots that are common among domains or unique slots that are not shared with any. Directly applying single-domain DST to multi-domain dialogues is not straightforward because the dialogue states extend to multiple domains. A possible approach is to process a dialogue of N_D domains multiple times, each time obtaining a dialogue state of one domain. However, this approach does not allow learning co-reference in dialogues in which users can switch from one domain to another.

As the number of dialogue domains increases, traditional pipeline approaches propagate errors from dialogue states to dialogue policy and subsequently, to natural language generator. Recent efforts (Eric et al., 2017; Madotto et al., 2018; Wu et al., 2019b) address this problem with an integrated sequence-to-sequence structure. These approaches often consider knowledge bases as memory tuples rather than relational entity tables. While achieving impressive performance, these approaches are not scalable to large-scale knowledge-bases, e.g. thousands of entities, as the memory cost to query entity attributes increases substantially. Another limitation of these approaches is the absence of dialogue act modelling. Dialogue act

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1860–1877,
November 16–20, 2020.

Human: hello *Dialogue state: {}*	**Dialogue agent**: hi ! how can i help you ? *Dialogue acts: [greeting]*
Human: i would like a place to eat in the expensive price range *Dialogue state: {restaurant: {pricerange: expensive}}*	**Dialogue agent**: sure , what type of food are you interested in ? *Dialogue acts: [request-food]*
Human: could you make a suggestion ? one in the centre ? *Dialogue state: {restaurant: {pricerange: expensive, area: centre}}* ...	**Dialogue agent**: fitzbillies restaurant is an expensive british restaurant in the centre . can i book that for you ? *Dialogue acts: [inform-restaurant, request-booking]* ...
Human: also , i need the number for kings hedges learner pool . *Dialogue state: {restaurant: {pricerange: expensive, area: centre, name=fizbillies restaurant, request=[address]}, attraction: {name: kings hedges learner pool, request=[phone]}}*	**Dialogue agent**: the phone number for the pool is 01234567 , is there something else i can help you ? *Dialogue acts: [inform-phone]*

Table 1: Example of a multi-domain dialogue with two domains: *restaurant* and *attraction*.

is particularly important in task-oriented dialogues as it determines the general decision towards task completion before a dialogue agent can materialize it into natural language response (See Table 1).

To tackle the challenges in multi-domain task-oriented dialogues while reducing error propagation among dialogue system modules and keeping the models scalable, we propose UniConv, a unified neural network architecture for end-to-end dialogue systems. UniConv consists of a Bi-level State Tracking (BDST) module which embeds natural language understanding as it can directly parse dialogue context into a structured dialogue state rather than relying on the semantic frame output from an NLU module in each dialogue turn. BDST implicitly models and integrates slot representations from dialogue contextual cues to directly generate slot values in each turn and thus, remove the need for explicit slot tagging features from an NLU. This approach is more practical than the traditional pipeline models as we do not need slot tagging annotation. Furthermore, BDST tracks dialogue states in dialogue context in both slot and domain levels. The output representations from two levels are combined in a *late fusion* approach to learn multi-domain dialogue states. Our dialogue state tracker disentangles slot and domain representation learning while enabling deep learning of shared representations of slots common among domains.

UniConv integrates BDST with a Joint Dialogue Act and Response Generator (DARG) that simultaneously models dialogue acts and generates system responses by learning a latent variable representing dialogue acts and semantically conditioning output response tokens on this latent variable. The multi-task setting of DARG allows our models to model dialogue acts and utilize the distributed representations of dialogue acts, rather than hard discrete output values from a dialogue policy module, on output response tokens. Our response generator incorporates information from dialogue input components and intermediate representations progressively over multiple attention steps. The output representations are refined after each step to obtain high-resolution signals needed to generate appropriate dialogue acts and responses. We combine both BDST and DARG for end-to-end neural dialogue systems, from input dialogues to output system responses.

We evaluate our models on the large-scale MultiWOZ benchmark (Budzianowski et al., 2018), and compare with the existing methods in DST, context-to-text generation, and end-to-end settings. The promising performance in all tasks validates the efficacy of our method.

2 Related Work

Dialogue State Tracking. Traditionally, DST models are designed to track states of single-domain dialogues such as WOZ (Wen et al., 2017) and DSTC2 (Henderson et al., 2014a) benchmarks. There have been recent efforts that aim to tackle multi-domain DST such as (Ramadan et al., 2018; Lee et al., 2019; Wu et al., 2019a; Goel et al., 2019). These models can be categorized into two main categories: Fixed vocabulary models (Zhong et al., 2018; Ramadan et al., 2018; Lee et al., 2019), which assume known slot ontology with a fixed candidate set for each slot. On the other hand, open-vocabulary models (Lei et al., 2018; Wu et al., 2019a; Gao et al., 2019; Ren et al., 2019; Le et al., 2020) derive the candidate set based on the source sequence i.e. dialogue history, itself. Our approach is more related to the open-vocabulary approach as we aim to generate unique dialogue states depending on the input dialogue. Different from previous

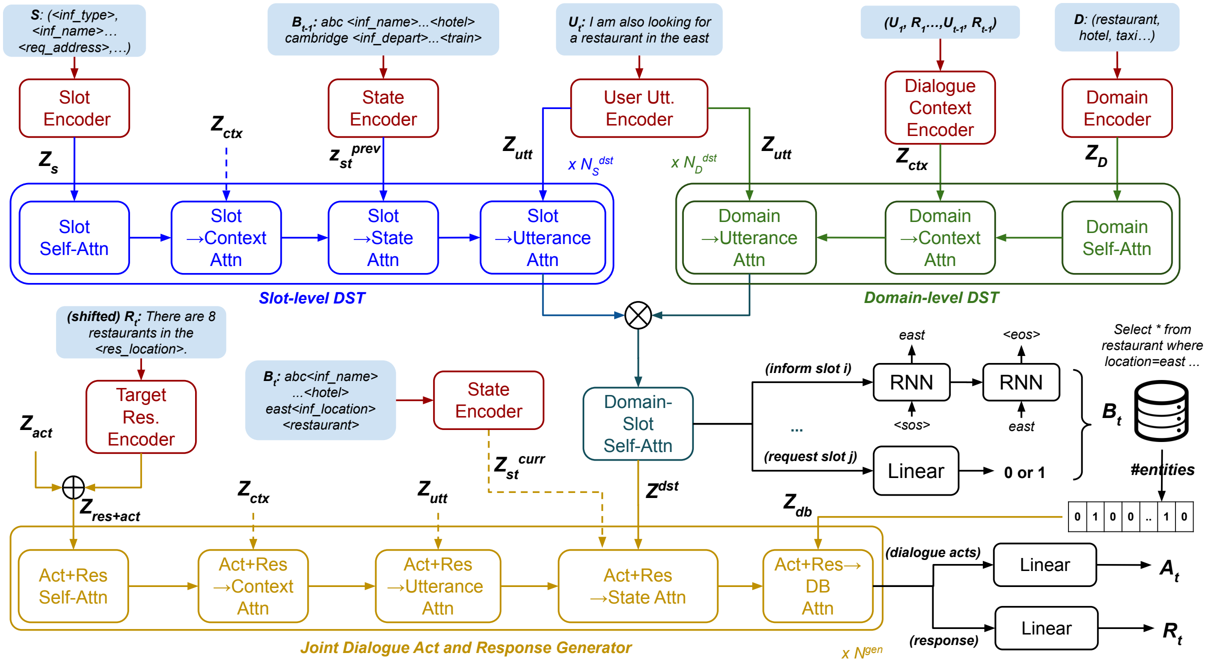

Figure 1: Our unified architecture has three components: (1) *Encoders* encode all text input into continuous representations; (2) *Bi-level State Tracker (BDST)* includes 2 modules for slot-level and domain-level representation learning; and (3) *Joint Dialogue Act and Response Generator (DARG)* obtains dependencies between the target response representations and other dialogue components.

generation-based approaches, our state tracker can incorporate contextual information into domain and slot representations independently.

Context-to-Text Generation. This task was traditionally solved by two separate dialogue modules: Dialogue Policy (Peng et al., 2017, 2018) and NLG (Wen et al., 2016; Su et al., 2018). Recent work attempts to combine these two modules to directly generate system responses with or without modeling dialogue acts. Zhao et al. (2019) models action space of dialogue agent as latent variables. Chen et al. (2019) predicts dialogue acts using a hierarchical graph structure with each path representing a unique act. Pei et al. (2019); Peng et al. (2019) use multiple dialogue agents, each trained for a specific dialogue domain, and combine them through a common dialogue agent. Mehri et al. (2019) models dialogue policy and NLG separately and fuses feature representations at different levels to generate responses. Our models simultaneously learn dialogue acts as a latent variable while allowing semantic conditioning on distributed representations of dialogue acts rather than hard discrete features.

End-to-End Dialogue Systems. In this task, conventional approaches combine Natural Language Understanding (NLU), DST, Dialogue Policy, and NLG, into a pipeline architecture (Wen et al., 2017; Bordes et al., 2016; Liu and Lane, 2017; Li et al., 2017; Liu and Perez, 2017; Williams et al., 2017; Zhao et al., 2017; Jhunjhunwala et al., 2020). Another framework does not explicitly modularize these components but incorporate them through a sequence-to-sequence framework (Serban et al., 2016; Lei et al., 2018; Yavuz et al., 2019) and a memory-based entity dataset of triplets (Eric and Manning, 2017; Eric et al., 2017; Madotto et al., 2018; Qin et al., 2019; Gangi Reddy et al., 2019; Wu et al., 2019b). These approaches bypass dialogue state and/or act modeling and aim to generate output responses directly. They achieve impressive success in generating dialogue responses in open-domain dialogues with unstructured knowledge bases. However, in a task-oriented setting with an entity dataset, they might suffer from an explosion of memory size when the number of entities from multiple dialogue domains increases. Our work is more related to the traditional pipeline strategy but we integrate our dialogue models by unifying two major components rather than using the traditional four-module architecture, to alleviate error propagation from upstream to downstream components. Different from prior work such as (Shu et al., 2019), our model facilitates multi-domain state tracking and allows learning dialogue acts during response generation.

3 Method

The input consists of dialogue context of $t-1$ turns, each including a pair of user utterance U and system response R, $(U_1, R_1), ..., (U_{t-1}, R_{t-1})$, and the user utterance at current turn U_t. A task-oriented dialogue system aims to generate the next response R_t. The information for responses is typically queried from a database based on the user's provided information i.e. *inform* slots tracked by a DST. We assume access to a database of all domains with each column corresponding to a specific slot being tracked. We denote the intermediate output, including the dialogue state of current turn B_t and dialogue act as A_t. We denote the list of all domains $D = (d_1, d_2, ...)$, all slots $S = (s_1, s_2, ...)$, and all acts $A = (a_1, a_2, ...)$. We also denote the list of all (domain, slot) pairs as $DS = (ds_1, ds_2, ...)$. Note that $\|DS\| \leq \|D\| \times \|S\|$ as some slots might not be applicable in all domains. Given the current dialogue turn t, we represent each text input as a sequence of tokens, each of which is a unique token index from a vocabulary set V: dialogue context X_{ctx}, current user utterance X_{utt}, and target system response X_{res}. Similarly, we also represent the list of domains as X_D and the list of slots as X_S.

In DST, we consider the raw text form of dialogue state of the previous turn B_{t-1}, similarly as (Lei et al., 2018; Budzianowski and Vulić, 2019). In the context-to-text setting, we assume access to the ground-truth dialogue states of current turn B_t. The dialogue state of the previous and current turn can then be represented as a sequence of tokens $X_{\text{st}}^{\text{prev}}$ and $X_{\text{st}}^{\text{curr}}$ respectively. For a fair comparison with current approaches, during inference, we use the model predicted dialogue states $\hat{X}_{\text{st}}^{\text{prev}}$ and do not use $X_{\text{st}}^{\text{curr}}$ in DST and end-to-end tasks. Following (Wen et al., 2015; Budzianowski et al., 2018), we consider the delexicalized target response $X_{\text{res}}^{\text{dl}}$ by replacing tokens of slot values by their corresponding generic tokens to allow learning value-independent parameters.

Our model consists of 3 major components (See Figure 1). First, *Encoders* encode all text input into continuous representations. To make it consistent, we encode all input with the same embedding dimension. Secondly, our *Bi-level State Tracker (BDST)* is used to detect contextual dependencies to generate dialogue states. The DST includes 2 modules for slot-level and domain-level representation learning. Each module comprises attention layers to project domain or slot representations and incorporate important information from dialogue context, dialogue state of the previous turn, and current user utterance. The outputs are combined as a context-aware vector to decode the corresponding *inform* or *request* slots in each domain. Lastly, our *Joint Dialogue Act and Response Generator (DARG)* projects the target system response representations and enhances them with information from various dialogue components. Our response generator can also learn a latent representation to generate dialogue acts, which condition all target tokens during each generation step.

3.1 Encoders

An encoder encodes a text sequence X to a sequence of continuous representation $Z \in \mathbb{R}^{L_X \times d}$. L_X is the length of sequence X and d is the embedding dimension. Each encoder includes a token-level embedding layer. The embedding layer is a trainable embedding matrix $E \in \mathbb{R}^{\|V\| \times d}$. Each row represents a token in the vocabulary set V as a d-dimensional vector. We denote $E(X)$ as the embedding function that transform the sequence X by looking up the respective token index: $Z_{\text{emb}} = E(X) \in \mathbb{R}^{L_X \times d}$. We inject the positional attribute of each token as similarly adopted in (Vaswani et al., 2017). The positional encoding is denoted as PE. The final embedding is the element-wise summation between token-embedded representations and positional encoded representations with layer normalization (Ba et al., 2016): $Z = \text{LayerNorm}(Z_{\text{emb}} + PE(X)) \in \mathbb{R}^{L_X \times d}$.

The encoder outputs include representations of dialogue context Z_{ctx}, current user utterance Z_{utt}, and target response $Z_{\text{res}}^{\text{dl}}$. We also encode the dialogue states of the previous turn and current turn and obtain $Z_{\text{st}}^{\text{prev}}$ and $Z_{\text{st}}^{\text{curr}}$ respectively. We encode X_S and X_D using only token-level embedding layer: $Z_S = \text{LayerNorm}(E(X_S))$ and $Z_D = \text{LayerNorm}(E(X_D))$. During training, we shift the target response by one position to the left side to allow auto-regressive prediction in each generation step. We share the embedding matrix E to encode all text tokens except for tokens of target responses as the delexicalized outputs contain different semantics from natural language inputs.

3.2 Bi-level Dialogue State Tracker (BDST)

Slot-level DST. We adopt the Transformer attention (Vaswani et al., 2017), which consists of a dot-product attention with skip connection, to integrate dialogue contextual information into each slot representation. We denote $\text{Att}(Z_1, Z_2)$ as the attention operation from Z_2 on Z_1. We first enable models to process all slot representations together rather than separately as in previous DST models (Ramadan et al., 2018; Wu et al., 2019a). This strategy allows our models to explicitly learn dependencies between all pairs of slots. Many pairs of slots could exhibit correlation such as time-wise relation ("departure_time" and "arrival_time"). We obtain $Z_{SS}^{\text{dst}} = \text{Att}(Z_S, Z_S) \in \mathbb{R}^{\|S\| \times d}$.

We incorporate the dialogue information by learning dependencies between each slot representation and each token in the dialogue history. Previous approaches such as (Budzianowski and Vulić, 2019) consider all dialogue history as a single sequence but we separate them into two inputs because the information in X_{utt} is usually more important to generate responses while X_{ctx} includes more background information. We then obtain $Z_{S,\text{ctx}}^{\text{dst}} = \text{Att}(Z_{\text{ctx}}, Z_{SS}^{\text{dst}}) \in \mathbb{R}^{\|S\| \times d}$ and $Z_{S,\text{utt}}^{\text{dst}} = \text{Att}(Z_{\text{utt}}, Z_{\text{S,ctx}}^{\text{dst}}) \in \mathbb{R}^{\|S\| \times d}$.

Following (Lei et al., 2018), we incorporate dialogue state of the previous turn B_{t-1} which is a more compact representation of dialogue context. Hence, we can replace the full dialogue context to only R_{t-1} as the remaining part is represented in B_{t-1}. This approach avoids taking in all dialogue history and is scalable as the conversation grows longer. We add the attention layer to obtain $Z_{S,\text{st}}^{\text{dst}} = \text{Att}(Z_{\text{st}}^{\text{prev}}, Z_{S,\text{ctx}}^{\text{dst}}) \in \mathbb{R}^{\|S\| \times d}$ (See Figure 1). We further improve the feature representations by repeating the attention sequence over N_S^{dst} times. We denote the final output Z_S^{dst}.

Domain-level DST. We adopt a similar architecture to learn domain-level representations. The representations learned in this module exhibit global information while slot-level representations contain local dependencies to decode multi-domain dialogue states. First, we enable the domain-level DST to capture dependencies between all pairs of domains. For example, some domains such as "taxi" are typically paired with other domains such as "attraction", but usually not with the "train" domain. We then obtain $Z_{DD}^{\text{dst}} = \text{Att}(Z_D, Z_D) \in \mathbb{R}^{\|D\| \times d}$. We then allow models to capture dependencies between each domain representation and each token in dialogue context and current user utterance. By segregating dialogue context and current utterance, our models can potentially detect changes of dialogue domains from past turns to the current turn. Especially in multi-domain dialogues, users can switch from one domain to another and the next system response should address the latest domain. We then obtain $Z_{D,\text{ctx}}^{\text{dst}} = \text{Att}(Z_{\text{ctx}}, Z_{DD}^{\text{dst}}) \in \mathbb{R}^{\|D\| \times d}$ and $Z_{D,\text{utt}}^{\text{dst}} = \text{Att}(Z_{\text{utt}}, Z_{D,\text{ctx}}^{\text{dst}}) \in \mathbb{R}^{\|D\| \times d}$ sequentially. Similar to the slot-level module, we refine feature representations over N_D^{dst} times and denote the final output as Z_D^{dst}.

Domain-Slot DST. We combined domain and slot representations by expanding the tensors to identical dimensions i.e. $\|D\| \times \|S\| \times d$. We then apply Hadamard product, resulting in domain-slot joint features $Z_{DS}^{\text{dst}} \in \mathbb{R}^{\|D\| \times \|S\| \times d}$. We then apply a self-attention layer to allow learning of dependencies between joint domain-slot features: $Z^{\text{dst}} = \text{Att}(Z_{DS}^{\text{dst}}, Z_{DS}^{\text{dst}}) \in \mathbb{R}^{\|D\| \times \|S\| \times d}$. In this attention, we mask the intermediate representations in positions of invalid domain-slot pairs. Compared to previous work such as (Wu et al., 2019a), we adopt a *late fusion* method whereby domain and slot representations are integrated in deeper layers.

3.2.1 State Generator

The representations Z^{dst} are used as context-aware representations to decode individual dialogue states. Given a domain index i and slot index j, the feature vector $Z_{dst}[i, j, :] \in \mathbb{R}^d$ is used to generate value of the corresponding (domain, slot) pair. The vector is used as an initial hidden state for an RNN decoder to decode an *inform* slot value. Given the k-th (domain, slot) pair and decoding step l, the output hidden state in each recurrent step h_{kl} is passed through a linear transformation with softmax to obtain output distribution over vocabulary set V: $P_{\text{kl}}^{\text{inf}} = \text{Softmax}(h_{kl}W_{\text{inf}}) \in \mathbb{R}^{\|V\|}$ where $W_{\text{dst}}^{\text{inf}} \in \mathbb{R}^{d_{\text{rnn}} \times \|V\|}$. For *request* slot of k-th (domain,slot) pair, we pass the corresponding vector Z_{dst} vector through a linear layer with sigmoid activation to predict a value of 0 or 1. $P_{\text{k}}^{\text{req}} = \text{Sigmoid}(Z_k^{dst}W_{\text{req}})$.

Optimization. The DST is optimized by the cross-entropy loss functions of *inform* and *request* slots:

$$\mathcal{L}_{\text{dst}} = \mathcal{L}_{\text{inf}} + \mathcal{L}_{\text{req}} = \sum_{k=1}^{\|DS\|} \sum_{l=1}^{\|Y_k\|} -\log(P_{\text{kl}}^{\text{inf}}(y_{kl}))$$

$$+ \sum_{k=1}^{\|DS\|} -y_k \log(P_k^{\text{req}}) - (1 - y_k)(1 - \log(P_k^{\text{req}}))$$

3.3 Joint Dialogue Act and Response Generator (DARG)

Database Representations. Following (Budzianowski et al., 2018), we create a one-hot vector for each domain d: $x^d_{\text{db}} \in \{0,1\}^6$ and $\sum_i^6 x^d_{\text{db},i} = 1$. Each position of the vector indicates a number or a range of entities. The vectors of all domains are concatenated to create a multi-domain vector $X_{\text{db}} \in \mathbb{R}^{6 \times \|D\|}$. We embed this vector as described in Section 3.1.

Response Generation. We adopt a stacked-attention architecture that sequentially learns dependencies between each token in target responses with each dialogue component representation. First, we obtain $Z^{\text{gen}}_{\text{res}} = \text{Att}(Z_{\text{res}}, Z_{\text{res}}) \in \mathbb{R}^{L_{\text{res}} \times d}$. This attention layer can learn semantics within the target response to construct a more semantically structured sequence. We then use attention to capture dependencies in background information contained in dialogue context and user utterance. The outputs are $Z^{\text{gen}}_{\text{ctx}} = \text{Att}(Z_{\text{ctx}}, Z^{\text{gen}}_{\text{res}}) \in \mathbb{R}^{L_{\text{res}} \times d}$ and $Z^{\text{gen}}_{\text{utt}} = \text{Att}(Z_{\text{utt}}, Z^{\text{gen}}_{\text{ctx}}) \in \mathbb{R}^{L_{\text{res}} \times d}$ sequentially. To incorporate information of dialogue states and DB results, we apply attention steps to capture dependencies between each response token representation and state or DB representation. Specifically, we first obtain $Z^{\text{gen}}_{\text{dst}} = \text{Att}(Z^{\text{dst}}, Z^{\text{gen}}_{\text{utt}}) \in \mathbb{R}^{L_{\text{res}} \times d}$. In the context-to-text setting, as we directly use the ground-truth dialogue states, we simply replace Z^{dst} with $Z^{\text{curr}}_{\text{st}}$. Then we obtain $Z^{\text{gen}}_{\text{db}} = \text{Att}(Z_{\text{db}}, Z^{\text{gen}}_{\text{dst}}) \in \mathbb{R}^{L_{\text{res}} \times d}$. These attention layers capture the information needed to generate tokens that are towards task completion and supplement the contextual cues obtained in previous attention layers. We let the models to progressively capture these dependencies for N^{gen} times and denote the final output as Z^{gen}. The final output is passed to a linear layer with softmax activation to decode system responses auto-regressively: $P^{\text{res}} = \text{Softmax}(Z^{\text{gen}} W_{\text{gen}}) \in \mathbb{R}^{L_{\text{res}} \times \|V_{\text{res}}\|}$

Dialogue Act Modeling. We couple response generation with dialogue act modeling by learning a latent variable $Z_{\text{act}} \in \mathbb{R}^d$. We place the vector in the first position of Z_{res}, resulting in $Z_{\text{res+act}} \in \mathbb{R}^{(L_{\text{res}}+1) \times d}$. We then pass this tensor to the same stacked attention layers as above. By adding the latent variable in the first position, we allow our model to semantically condition all downstream tokens from second position, i.e. all tokens in the target response, on this latent variable. The output representation of the latent vector i.e. first row in Z^{gen}, incorporates contextual signals accumulated from all attention layers and is used to predict dialogue acts. We denote this representation as $Z^{\text{gen}}_{\text{act}}$ and pass it through a linear layer to obtain a multi-hot encoded tensor. We apply Sigmoid on this tensor to classify each dialogue act as 0 or 1: $P^{\text{act}} = \text{Sigmoid}(Z^{\text{gen}}_{\text{act}} W_{\text{act}}) \in \mathbb{R}^{\|A\|}$.

Domain	**#dialogues**		
	train	**val**	**test**
Restaurant	3,817	438	437
Hotel	3,387	416	394
Attraction	2,718	401	396
Train	3,117	484	495
Taxi	1,655	207	195
Police	245	0	0
Hospital	287	0	0

Table 2: Summary of MultiWOZ dataset (Budzianowski et al., 2018) by domain

Optimization. The response generator is jointly trained by the cross-entropy loss functions of generated responses and dialogue acts:

$$\mathcal{L}_{\text{gen}} = \mathcal{L}_{\text{res}} + \mathcal{L}_{\text{act}} = \sum_{l=1}^{\|Y_{\text{res}}\|} -\log(P^{\text{res}}_l(y_l))$$

$$+\sum_{a=1}^{\|A\|} -y_a \log(P^{\text{act}}_a) - (1-y_a)(1-\log(P^{\text{act}}_a))$$

4 Experiments

4.1 Dataset

We evaluate our models with the multi-domain dialogue corpus MultiWOZ 2.0 (Budzianowski et al., 2018) and 2.1 (Eric et al., 2019) (The latter includes corrected state labels for the DST task). From the dialogue state annotation of the training data, we identified all possible domains and slots. We identified $\|D\| = 7$ domains and $\|S\| = 30$ slots, including 19 *inform* slots and 11 *request* slots. We also identified $\|A\| = 32$ acts. The corpus includes 8,438 dialogues in the training set and 1,000 in each validation and test set. We present a summary of the dataset in Table 2. For additional information of data pre-processing procedures, domains, slots, and entity DBs, please refer to Appendix A.

4.2 Experiment Setup

We select $d = 256$, $h_{\text{att}} = 8$, $N^{\text{dst}}_S = N^{\text{dst}}_D = N^{\text{gen}} = 3$. We employed dropout (Srivastava et al., 2014) of 0.3 and label smoothing (Szegedy et al., 2016) on target system responses during training.

Table 4: Evaluation of context-to-text task on MultiWOZ2.0.

We adopt a teacher-forcing training strategy by simply using the ground-truth inputs of dialogue state of the previous turn and the gold DB representations. During inference in DST and end-to-end tasks, we decode system responses sequentially turn by turn, using the previously decoded state as input in the current turn, and at each turn, using the new predicted state to query DBs. We train all networks with Adam optimizer (Kingma and Ba, 2015) and a decaying learning rate schedule. All models are trained up to 30 epochs and the best models are selected based on validation loss. We used a greedy approach to decode all slots and a beam search with beam size 5. To evaluate the models, we use the following metrics: Joint Accuracy and Slot Accuracy (Henderson et al., 2014b), Inform and Success (Wen et al., 2017), and BLEU score (Papineni et al., 2002). As suggested by Liu et al. (2016), human evaluation, even though popular in dialogue research, might not be necessary in tasks with domain constraints such as MultiWOZ. We implemented all models using Pytorch and will release our code on github[1].

4.3 Results

DST. We test our state tracker (i.e. using only $\mathcal{L}_{\text{dst}}$) and compare the performance with the baseline models in Table 3 (Refer to Appendix B for description of DST baselines). Our model can outperform fixed-vocabulary approaches such as HJST and FJST, showing the advantage of generating unique slot values rather than relying on a slot ontology with a fixed set of candidates. DST Reader model (Gao et al., 2019) does not perform well and we note that many slot values are not easily expressed as a text span in source text inputs. DST approaches that separate domain and slot representations such as TRADE (Wu et al., 2019a) reveal competitive performance. However, our approach has better performance as we adopt a *late fusion* strategy to explicitly obtain more fine-grained contextual dependencies in each domain and slot representation. In this aspect, our model is related to TSCP (Lei et al., 2018) which decodes output state sequence auto-regressively. However, TSCP attempts to learn domain and slot dependencies implicitly and the model is limited by selecting the maximum output state length (which can vary significantly in multi-domain dialogues).

Context-to-Text Generation. We compare with existing baselines in Table 4 (Refer to Appendix B for description of the baseline models). Our model achieves very competitive Inform, Success, and BLEU scores. Compared to TokenMOE (Pei et al., 2019), our single model can outperform multiple domain-specific dialogue agents as each attention module can sufficiently learn contextual features of multiple domains. Compared to HDSA (Chen et al., 2019) which uses a graph structure to represent *acts*, our approach is simpler yet able to outperform HDSA in Inform score. Our work is related to Structured Fusion (Mehri et al., 2019) as we incorporate intermediate representations during decoding. However, our approach does not rely on pretraining individual sub-modules but simultaneously learning both act representations and predicting output tokens. Similarly, our stacked attention architecture can achieve good performance in BLEU score, competitively with a GPT-2 based model (Budzianowski and Vulić, 2019), while consistently improve other metrics. For completion, we tested our models on MultiWOZ2.1 and achieved similar results: 87.90% *Inform*, 72.70% *Success*, and 18.52 BLEU score. Future work may further improve *Success* by optimizing the models towards a higher success rate using strategies such as LaRL (Zhao et al., 2019). Another direction is a data augmentation approach such as DAMD (Zhang et al.,

Table 5: Evaluation on MultiWOZ2.1 in the end-to-end setting.

2019) which achieves significant performance gain in this task.

End-to-End. From Table 5, our model outperforms existing baselines in all metrics except the Inform score (See Appendix B for a description of baseline models). In TSCP (Lei et al., 2018), increasing the maximum dialogue state span L from 8 to 20 tokens helps to improve the DST performance, but also increases the training time significantly. Compared with HRED-TS (Peng et al., 2019), our single model generates better responses in all domains without relying on multiple domain-specific teacher models. We also noted that the performance of DST improves in contrast to the previous DST task. This can be explained as additional supervision from system responses not only contributes to learn a natural response but also positively impact the DST component. Other baseline models such as (Eric and Manning, 2017; Wu et al., 2019b) present challenges in the MultiWOZ benchmark as the models could not fully optimize due to the large scale entity memory. For example, following GLMP (Wu et al., 2019b), the *restaurant* domain alone has over 1,000 memory tuples of *(Subject, Relation, Object)*.

Ablation. We conduct a comprehensive ablation analysis with several model variants in Table 6 and have the following observations:

- The model variant with a single-level DST (by considering $S = DS$ and $N_D^{\text{dst}} = 0$) (Row A2) performs worse than the Bi-level DST (Row A1). In addition, using the dual architecture also improves the latency in each attention layers as typically $\|D\| + \|S\| \ll \|DS\|$. The performance gap also indicates the potential of separating global and local dialogue state dependencies by domain and slot level.

- Using B_{t-1} and only the last user utterance as the dialogue context (Row A1 and B1) performs as well as using B_{t-1} and a full-length dialogue history (Row A5 and B3). This demonstrates that the information from the last dialogue state is sufficient to represent the dialogue history up to the last user utterance. One benefit from not using the full dialogue history is that it reduces the memory cost as the number of tokens in a full-length dialogue history is much larger than that of a dialogue state (particularly as the conversation evolves over many turns).

- We note that removing the loss function to learn the dialogue act latent variable (Row B2) can hurt the generation performance, especially by the task completion metrics *Inform* and *Success*. This is interesting as we expect dialogue acts affect the general semantics of output sentences, indicated by BLEU score, rather than the model ability to retrieve correct entities. This reveals the benefit of our approach. By enforcing a semantic condition on each token of the target response, the model can facility the dialogue flow towards successful task completion.

- In both state tracker and response generator modules, we note that learning feature representations through deeper attention networks can improve the quality of predicted states and system responses. This is consistent with our DST performance as compared to baseline models of shallow networks.

- Lastly, in the end-to-end task, our model achieves better performance as the number of attention heads increases, by learning more high-resolution dependencies.

5 Domain-dependent Results

DST. For state tracking, the metrics are calculated for domain-specific slots of the corresponding domain at each dialogue turn. We also report the DST separately for multi-domain and single-domain dialogues to evaluate the challenges in multi-domain dialogues and our DST performance gap as compared to single-domain dialogues. From Table 7,

#	X_{ctx}	B_{t-1}	N_S^{dst}	$N_{\text{D}}^{\text{dst}}$	N^{gen}	$\mathcal{L}_{\text{act}}$	d	h_{att}	**Joint Acc.**	**Slot Acc.**	**Inform**	**Success**	**BLEU**

Table 6: Ablation analysis on the MultiWOZ2.1 in DST (top), context-to-text (middle), and end-to-end (bottom).

our DST performs consistently well in the 3 domains *attraction, restaurant*, and *train* domains. However, the performance drops in the *taxi* and *hotel* domain, significantly in the *taxi* domain. We note that dialogues with the *taxi* domain is usually not single-domain but typically entangled with other domains. Secondly, we observe that there is a significant performance gap of about 10 points absolute score between DST performances in single-domain and multi-domain dialogues. State tracking in multi-domain dialogues is, hence, could be further improved to boost the overall performance.

Domain	**Joint Acc**	**Slot Acc**
Multi-domain	48.40%	97.14%
Single-domain	59.63%	98.36%
Attraction	66.76%	98.94%
Hotel	47.86%	97.54%
Restaurant	65.11%	98.68%
Taxi	30.84%	96.86%
Train	63.77%	98.53%

Table 7: DST results on MultiWOZ2.1 by domains.

Context-to-Text Generation For this task, we calculated the metrics for single-domain dialogues of the corresponding domain (as Inform and Success are computed per dialogue rather than per turn). We do not report the *Inform* metric of the *taxi* domain because no DB was available for this domain. From Table 8, we observe some performance gap between *Inform* and *Success* scores on multi-domain dialogues and single-domain dialogues. However, in terms of BLEU score, our model performs better with multi-domain dialogues. This could be caused by the data bias in MultiWOZ corpus as the majority of dialogues in this corpus is multi-domain. Hence, our models capture the semantics of multi-domain dialogue responses better than single-domain responses. For domain-specific results, we note that our models perform not as well as other domains in *attraction* and *taxi* domains in terms of *Success* score.

Domain	**Inform**	**Success**	**BLEU**
Multi-domain	85.01%	68.86%	18.68
Single-domain	97.79%	85.84%	17.62
Attraction	91.67%	66.67%	19.17
Hotel	97.01%	91.04%	16.55
Restaurant	96.77%	88.71%	19.88
Taxi	-	78.85%	13.85
Train	99.10%	87.88%	18.14

Table 8: Context-to-text generation results on MultiWOZ2.1. by domains.

Additionally, we report qualitative analysis and the insights can be seen in Appendix C.

6 Conclusion

We proposed *UniConv*, a novel unified neural architecture of conversational agents for Multi-domain Task-oriented Dialogues, which jointly trains (1) a Bi-level State Tracker to capture dependencies in both domain and slot levels simultaneously, and (2) a Joint Dialogue Act and Response Generator to model dialogue act latent variable and semantically conditions output responses with contextual cues. The promising performance of UniConv on the MultiWOZ benchmark (including three tasks: DST, context-to-text generation, and end-to-end dialogues) validates the efficacy of our method.

Acknowledgments

A Data Pre-processing

First, we delexicalize each target system response sequence by replacing the matched entity attribute that appears in the sequence to the canonical tag $\langle domain\_slot \rangle$. For example, the original target response 'the train id is tr8259 departing from cambridge' is delexicalized into 'the train id is *train_id* departing from *train_departure*'. We use the provided entity databases (DBs) to match potential attributes in all target system responses. To construct dialogue history, we keep the original version of all text, including system responses of previous turns, rather than the delexicalized form. We split all sequences of dialogue history, user utterances of the current turn, dialogue states, and delexicalized target responses, into case-insensitive tokens. We share the embedding weights of all source sequences, including dialogue history, user utterance, and dialogue states, but use a separate embedding matrix to encode the target system responses.

We summarize the number of dialogues in each domain in Table 2. For each domain, a dialogue is selected as long as the whole dialogue (i.e. single-domain dialogue) or parts of the dialogue (i.e. in multi-domain dialogue) is involved with the domain. For each domain, we also build a set of possible *inform* and *request* slots using the dialogue state annotation in the training data. The details of slots and database in each domain can be seen in Table 9. The DBs of 3 domains *taxi, police*, and *hospital* are not available as part of the benchmark. On average, each dialogue has 1.8 domains and extends over 13 turns.

B Baselines

We describe our baseline models in DST, context-to-text generation, and end-to-end dialogue tasks.

B.1 DST

FJST and **HJST** (Eric et al., 2019). These models adopt a fixed-vocabulary DST approach. Both models include encoder modules (either bidirectional LSTM or hierarchical LSTM) to encode the dialogue history. The models pass the context hidden states to separate linear transformation to obtain final vectors to predict individual slots separately. The output vector is used to measure a score of each candidate from a predefined candidate set.

DST Reader (Gao et al., 2019). This model considers the DST task as a reading comprehension task and predicts each slot as a span over tokens within dialogue history. DST Reader utilizes attention-based neural networks with additional modules to predict slot type and carryover probability.

TSCP (Lei et al., 2018). The model adopts a sequence-to-sequence framework with a pointer network to generate dialogue states. The source sequence is a combination of the last user utterance, dialogue state of the previous turn, and user utterance. To compare with TSCP in a multi-domain task-oriented dialogue setting, we adapt the model to multi-domain dialogues by formulating the dialogue state of the previous turn similarly as our models. We reported the performance when the maximum length of the output dialogue state sequence L is set to 20 tokens (original default parameter is 8 tokens but we expect longer dialogue state in MultiWOZ benchmark and selected 20 tokens).

HyST (Goel et al., 2019). This model combines the advantage of fixed-vocabulary and open-vocabulary approaches. The model uses an open-vocabulary approach in which the set of candidates of each slot is constructed based on all word n-grams in the dialogue history. Both approaches are applied in all slots and depending on their performance in the validation set, the better approach is used to predict individual slots during test time.

TRADE (Wu et al., 2019a). The model adopts a sequence-to-sequence framework with a pointer network to generate individual slot token-by-token. The prediction is additionally supported by a slot gating component that decides whether the slot is "none", "dontcare", or "generate". When the gate of a slot is predicted as "generate", the model will generate value as a natural output sequence for that slot.

NADST (Le et al., 2020). The model proposes a non-autoregressive approach for dialogue state tracking which enables learning dependencies between domain-level and slot-level representations as well as token-level representations of slot values.

DSTQA (Zhou and Small, 2019). The model treats dialogue state tracking as a question answering problem in which state values can be predicted through lexical spans or unique generated values. It is enhanced with a knowledge graph where each node represent a slot and edges are based on overlaps of their value sets.

SOM-DST (Kim et al., 2020). This is the current state-of-the-art model on the MultiWOZ2.1 dataset. The model exploits a selectively overwriting mechanism on a fixed-sized memory of dialogue states.

Domain	Slots	#entities	DB attributes
Restaurant	inf_area, inf_food, inf_name, inf_pricerange, inf_bookday, inf_bookpeople, inf_booktime, req_address, req_area, req_food, req_phone, req_postcode	110	id, address, area, food, introduction, name, phone, postcode, pricerange, signature, type

Attraction	inf_area, inf_name, inf_type, req_address, req_area, req_phone, req_postcode, req_type	79	id, address, area, entrance, name, phone, postcode, pricerange, openhours, type
Train	inf_arriveBy, inform_day, inf_departure, inf_destination, inf_leaveAt, inf_bookpeople, req_duration, req_price	2,828	trainID, arriveBy, day, departure, destination, duration, leaveAt, price
Taxi	inf_arriveBy, inf_departure, inf_destination, inf_leaveAt, req_phone	-	-
Police	inf_department, req_address, req_phone, req_postcode	-	-
Hospital	req_address, req_phone, req_postcode	-	-

Table 9: Summary of slots and DB details by domain in the MultiWOZ dataset (Budzianowski et al., 2018)

At each dialogue turn, the mechanism involve decision making on whether to update or carryover the state values from previous turns.

B.2 Context-to-Text Generation

Baseline. (Budzianowski et al., 2018) provides a baseline for this setting by following the sequence-to-sequence model (Sutskever et al., 2014). The source sequence is all past dialogue turns and the target sequence is the system response. The initial hidden state of the RNN decoder is incorporated with additional signals from the dialogue states and database representations.

TokenMoE (Pei et al., 2019). TokenMoE refers to Token-level Mixture-of-Expert model. The model follows a modularized approach by separating different components known as expert bots for different dialogue scenarios. A dialogue scenario can be dependent on a domain, a type of dialogue act, etc. A chair bot is responsible for controlling expert bots to dynamically generate dialogue responses.

HDSA (Chen et al., 2019). This is the current state-of-the-art in terms of Inform and BLEU score in the context-to-text generation setting in MultiWOZ2.0. HDSA leverages the structure of dialogue acts to build a multi-layer hierarchical graph. The graph is incorporated as an inductive bias in a self-attention network to improve the semantic quality of generated dialogue responses.

Structured Fusion (Mehri et al., 2019). This approach follows a traditional modularized dialogue system architecture, including separate components for NLU, DM, and NLG. These components are pre-trained and combined into an end-to-end system. Each component output is used as a structured input to other components.

LaRL (Zhao et al., 2019). This model uses a latent dialogue action framework instead of handcrafted dialogue acts. The latent variables are learned using unsupervised learning with stochastic variational inference. The model is trained in a reinforcement learning framework whereby the parameters are trained to yield a better Success rate. The model is the current state-of-the-art in terms of Success metric.

GPT2 (Budzianowski and Vulić, 2019). Unsupervised pre-training language models have significantly improved machine learning performance in many NLP tasks. This baseline model leverages the power of a pre-trained model (Radford et al., 2019) and adapts to the context-to-text generation setting in task-oriented dialogues. All input components, including dialogue state and database state, are transformed into raw text format and concatenated as a single sequence. The sequence is used as input to a pre-trained GPT-2 model which is then fine-tuned with MultiWOZ data.

DAMD (Zhang et al., 2019). This is the current state-of-the-art model for context-to-text generation task in MultiWOZ 2.1. This approach augments training data with multiple responses of similar context. Each dialogue state is mapped to multiple valid dialogue acts to create additional state-act pairs.

B.3 End-to-End

TSCP (Lei et al., 2018). In addition to the DST task, we evaluate TSCP as an end-to-end dialogue system that can do both DST and NLG. We adapt the models to the multi-domain DST setting as described in Section B.1 and keep the original response decoder. Similar to the DST component, the response generator of TSCP also adopts a pointer network to generate tokens of the target system responses by copying tokens from source sequences. In this setting, we test TSCP with two settings of the maximum length of the output dialogue state sequence: $L = 8$ and $L = 20$.

HRED-TS (Peng et al., 2019). This model adopts a teacher-student framework to address multi-domain task-oriented dialogues. Multiple teacher networks are trained for different domains and intermediate representations of dialogue acts and output responses are used to guide a universal student network. The student network uses these representations to directly generate responses from dialogue context without predicting dialogue states.

C Qualitative Analysis

We examine an example of dialogue in the test data and compare our predicted outputs with the baseline TSCP ($L = 20$) (Lei et al., 2018) and the ground truth. From Figure 4, we observe that both our predicted dialogue state and system response are more correct than the baseline. Specifically, our dialogue state can detect the correct *type* slot in the *attraction* domain. As our dialogue state is correctly predicted, the queried results from DB is also more correct, resulting in better response with the right information (i.e. 'no attraction available'). In Figure 5, we show the visualization of domain-level and slot-level attention on the user utterance. We notice important tokens of the text sequences, i.e. 'entertainment' and 'close to', are attended with higher attention scores. Besides, at domain-level attention, we find a potential additional signal from the token 'restaurant', which is also the domain from the previous dialogue turn. We also observe that attention is more refined throughout the neural network layers. For example, in the domain-level processing, compared to the 2^{nd} layer, the 4^{th} layer attention is more clustered around specific tokens of the user utterance.

In Table 10 and 11, we reported the complete output of this example dialogue. Overall, our dialogue agent can carry a proper dialogue with the user throughout the dialogue steps. Specifically, we observed that our model can detect new domains at dialogue steps where the domains are introduced e.g. *attraction* domain at the 5^{th} turn and *taxi* domain at the 8^{th} turn. The dialogue agent can also detect some of the co-references among the domains. For example, at the 5^{th} turn, the dialogue agent can infer the slot *area* for the new domain *attraction* as the user mentioned 'close the restaurant'. We noticed that that at later dialogue steps such as the 6^{th} turn, our decoded dialogue state is not correct possibly due to the incorrect decoded dialogue state in the previous turn, i.e. 5^{th} turn.

In Figure 2 and 3, we plotted the Joint Goal Accuracy and BLEU metrics of our model by dialogue turn. As we expected, the Joint Accuracy metric tends to decrease as the dialogue history extends over time. The dialogue agent achieves the highest accuracy in state tracking at the 1^{st} turn and gradually reduces to zero accuracy at later dialogue steps, i.e. 15^{th} to 18^{th} turns. For response generation performance, the trend of BLEU score is less obvious. The dialogue agent obtains the highest BLEU scores at the 3^{rd} turn and fluctuates between the 2^{nd} and 13^{th} turn.

GraphDialog: Integrating Graph Knowledge into End-to-End Task-Oriented Dialogue Systems

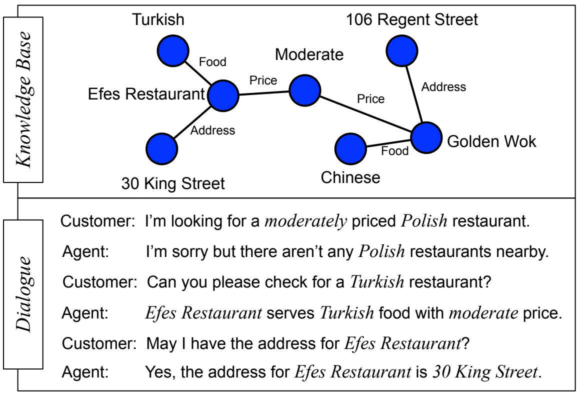
Shiquan Yang, Rui Zhang[*], Sarah Erfani
The University of Melbourne, Australia
{shiquan@student., rui.zhang@, sarah.erfani@}unimelb.edu.au

Abstract

End-to-end task-oriented dialogue systems aim to generate system responses directly from plain text inputs. There are two challenges for such systems: one is how to effectively incorporate external knowledge bases (KBs) into the learning framework; the other is how to accurately capture the semantics of dialogue history. In this paper, we address these two challenges by exploiting the graph structural information in the knowledge base and in the dependency parsing tree of the dialogue. To effectively leverage the structural information in dialogue history, we propose a new recurrent cell architecture which allows representation learning on graphs. To exploit the relations between entities in KBs, the model combines multi-hop reasoning ability based on the graph structure. Experimental results show that the proposed model achieves consistent improvement over state-of-the-art models on two different task-oriented dialogue datasets.

1 Introduction

Task-oriented dialogue systems aim to help user accomplish specific tasks via natural language interfaces such as restaurant reservation, hotel booking and weather forecast. There are many commercial applications of this kind (e.g. Amazon Alexa, Google Home, and Apple Siri) which make our life more convenient. Figure 1 illustrates such an example where a customer is asking for the information about restaurants. By querying the knowledge base (KB), the agent aims to provide the correct restaurant entities from the KB to satisfy the customer in a natural language form. Hence, the ability to understand the dialogue history, and to retrieve relevant information from the KB is essential in task-oriented dialogue systems.



Customer: I'm looking for a *moderately* priced *Polish* restaurant.
Agent: I'm sorry but there aren't any *Polish* restaurants nearby.
Customer: Can you please check for a *Turkish* restaurant?
Agent: *Efes Restaurant* serves *Turkish* food with *moderate* price.
Customer: May I have the address for *Efes Restaurant*?
Agent: Yes, the address for *Efes Restaurant* is *30 King Street*.

Figure 1: An example dialogue in the restaurant booking domain. The top part is knowledge base (KB) information that represented by a graph and the bottom part is the conversation between a customer and the agent. Our aim is to predict the agent responses given KB information and the customer utterances.

One approach for designing task-oriented dialogue systems is the pipeline approach (Williams and Young, 2007; Lee et al., 2009; Young et al., 2013), but it suffers from the difficulty in credit assignment and adaption to new domains. Another popular approach is the end-to-end models (Serban et al., 2016; Wen et al., 2017; Williams et al., 2017; Zhao et al., 2017; Serban et al., 2017), which directly map the dialogue history to the output responses. This approach has attracted more attention in the research community recently as it alleviates the drawbacks of the pipeline approach. However, end-to-end dialogue models usually suffer from ineffective use of knowledge bases due to the lack of appropriate framework to handle KB data.

To mitigate this issue, recent end-to-end dialogue studies (Eric et al., 2017; Madotto et al., 2018) employ memory networks (Weston et al., 2015; Sukhbaatar et al., 2015) to support the learning over KB, and have achieved promising results via integrating memory with copy mechanisms (Gulcehre et al., 2016; Eric and Manning, 2017). By using memory, they assume that the underlying structure of KB is linear since memory can be viewed as a

list structure. As a result, the relationships between entities are not captured. However, since KB is naturally a graph structure (nodes are entities and edges are relations between entities). By overlooking such relationships, the model fails to capture substantial information embedded in the KB including the semantics of the entities which may significantly impact the accuracy of results. Moreover, structural knowledge such as dependency relationships has recently been investigated on some tasks (e.g., relation extraction) (Peng et al., 2017; Song et al., 2018) and shown to be effective in the model's generalizability. However, such dependency relationships (essentially also graph structure) have not been explored in dialogue systems, again missing great potential for improvements.

With the above insight, we propose a novel **graph**-based end-to-end task-oriented **dialog**ue model (**GraphDialog**) aimed to exploit the graph knowledge both in dialogue history and KBs. Unlike traditional RNNs such as LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014), we design a novel recurrent unit (Section 3.1.2) that allows multiple hidden states as inputs at each timestep such that the dialogue history can be encoded with graph structural information. The recurrent unit employs a masked attention mechanism to enable variable input hidden states at each timestep. Moreover, We incorporate a graph structure (Section 3.2) to handle the external KB information and perform multi-hop reasoning on the graph to retrieve KB entities.

Overall, the contributions of this paper are summarized as follows:

- We propose a novel graph-based end-to-end dialogue model for effectively incorporating the external knowledge bases into task-oriented dialogue systems.
- We further propose a novel recurrent cell architecture to exploit the graph structural information in the dialogue history. We also combine the multi-hop reasoning ability with graph to exploit the relationships between entities in the KB.
- We evaluate the proposed model on two real-world task-oriented dialogue datasets (i.e., SMD and MultiWOZ 2.1). The results show that our model outperforms the state-of-the-art models consistently.

2 Related Work

Task-oriented dialogue system has been a long-standing studied topic (Williams and Young, 2007; Lee et al., 2009; Huang et al., 2020b) and can be integrated into many practical applications such as virtual assistant (Sun et al., 2016, 2017). Traditionally, task-oriented dialogue systems are built in the pipeline approach, which consists of four essential components: natural language understanding (Chen et al., 2016), dialogue state tracking (Lee and Stent, 2016; Zhong et al., 2018; Wu et al., 2019a), policy learning (Su et al., 2016; Peng et al., 2018; Su et al., 2018) and natural language generation (Sharma et al., 2017; Chen et al., 2019; Huang et al., 2020a). Another recent approach is the end-to-end models (Wu et al., 2018; Lei et al., 2018), which directly map the user utterances to responses without heavy annotations. Bordes et al. (2017) apply end-to-end memory networks (Sukhbaatar et al., 2015) for task-oriented dialogues and shown that end-to-end models are promising on the tasks. To produce more flexible responses, several generative models are proposed (Zhao et al., 2017; Serban et al., 2016). They formulate the response generation problem as a translation task and apply sequence-to-sequence (Seq2Seq) models to generate responses. Seq2Seq models have shown to be effective in language modeling but they struggle to incorporate external KB into responses. To mitigate this issue, Eric and Manning (2017) has enhanced the Seq2Seq model by adding copy mechanism. Madotto et al. (2018) combines the idea of pointer with memory networks and obtained improved performance. Wu et al. (2019b) incorporates global pointer mechanism and achieved improved performance. Our study differs from those works in that we exploit the powerful graph information both contained in the dialogue history and in the KBs to effectively incorporate KBs into dialogue systems.

3 Proposed Model

Our proposed model consists of three components: an encoder (Section 3.1), a decoder (Section 3.3) and a knowledge graph with multi-hop reasoning ability (Section 3.2). Formally, let $X = \{x_1,...,x_n\}$ be a sequence of tokens, where each token $x_i \in X$ corresponds to a word in the dialogue history. We first obtain a *dialogue graph* $\widehat{G}$ (Section 3.1.1), which is the dependency parsing graph of the sentences in the dialogue history X, as the input of the encoder. The encoder then learns a fixed-length

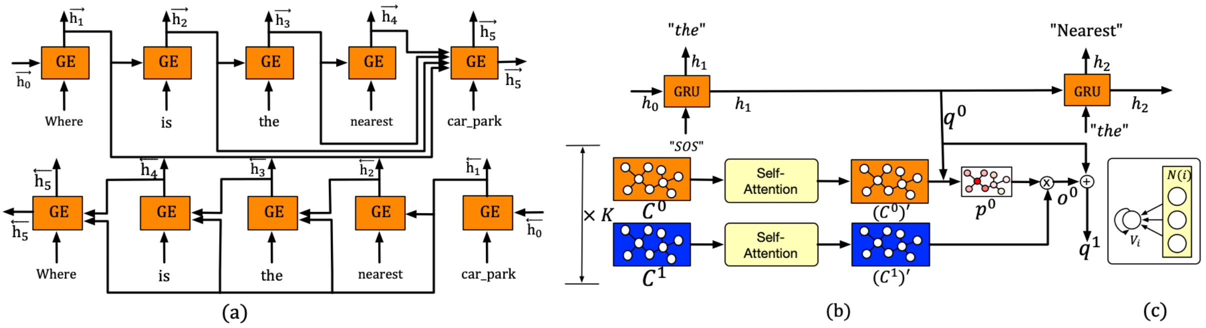

Figure 2: Overview of the proposed architecture. (a) Graph Encoder, top is forward graph and bottom is backward graph. (b) Decoder and Knowledge Graph with multi-hop reasoning mechanism. (c) Self-Attention Mechanism.

vector as the encoding of the dialogue history based on $\widehat{G}$, which is then fed to the decoder for hidden state initialization. The knowledge graph adopts another graph $G = \{V,E\}$ to store and retrieve the external knowledge data (Section 3.2.1), where V denotes the entities and E denotes the edges. The decoder generates the system response $Y = \{y_1,...,y_m\}$ token-by-token either by copying entities from graph G via querying the knowledge graph or by generating tokens from vocabularies. Figure 2 illustrates the overall architecture of the proposed model. In the following sections, we describe each component in detail.

3.1 Graph Encoder

3.1.1 Dialogue Graph

To enable learning semantic rich representations of words with various relationships, such as adjacency and dependency relations, we first use the off-the-shelf tool *spacy*[1] to extract the dependency relations among the words in the dialogue history X. Figure 3 gives an example of the dependency parsing result. The bi-directional edges among words allow information flow both from dependents to heads and from heads to dependents. The intuition is that the representation learning of the head words should be allowed being influenced by the dependent words and vice versa, thus allowing the learning process to capture the mutual relationships between the head words and the dependent words to provide richer representation.

We compose the dialogue graph by combining the obtained dependency relations with the sequential relations (i.e., *Next* and *Pre*) among words, which serves as the input to the graph encoder. To further support bi-directional representation learning, we split the obtained dialogue graph into two parts: the *forward graph* (from left to right) and the *backward graph* (from right to left).

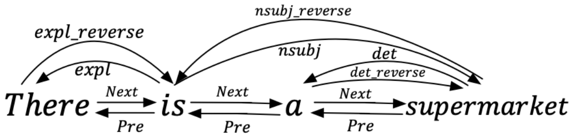

Figure 3: An example of dialogue graph.

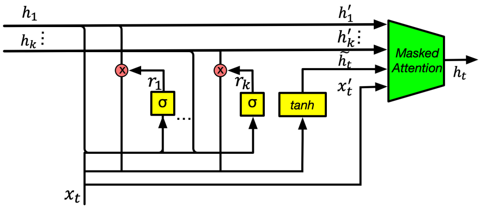

Figure 4: Overview of the proposed recurrent unit.

3.1.2 Recurrent Cell Architecture

The recurrent cell architecture (Figure 4) is the core computing unit of the graph encoder, and is used to compute the hidden state of each word in the obtained dialogue graph. The cell traverse the words in the dialogue graph sequentially according to the word order in the dialogue history. Next, we show how to compute the cell hidden state h_t at timestep t.

Let us define x_t as the input word representation at timestep t. $P(t) = \{p_1,p_2,\ldots,p_k\}$ is the set of precedent words for x_t where each $p_i \in P(t)$ denotes a word in the dialogue graph that connects to x_t, and k is the total number of the precedents of x_t. $H = \{h_1,h_2,\ldots,h_k\}$ is a set of hidden states where each element $h_j \in H$ denotes the hidden state of the j-th predecessor $p_j \in P(t)$.

The input of the cell consists of two parts: the input word vector x_t, and the predecessor hidden states H. First, we loop over the k hidden states

---

[1] `https://spacy.io/`

in H and compute a *reset gate* for each of them. Specifically, we compute r_j for the *j*-th hidden state using:

$$r_j = \sigma\left(W_r x_t + U_r h_j\right) \tag{1}$$

where σ is the logistic sigmoid function, x_t and h_j are the current input and the hidden state of the *j*-th predecessor at timestep *t* respectively. W_r and U_r are parameters which will be learned. We then compute a candidate hidden state $\widetilde{h}_t$ using:

$$\widetilde{h}_t = \phi\left(W_n x_t + \frac{1}{k}\sum_{j=1}^{k} r_j * (U_n h_j)\right) \tag{2}$$

where ϕ is the hyperbolic tangent function, *k* is the number of predecessors of word x_t, W_n and U_n are the learnable weight matrices. Intuitively, $\widetilde{h}_t$ is the contextualized representation of current input x_t.

Next, we combine the obtained candidate hidden state $\widetilde{h}_t$ with the predecessor hidden states *H*, and use an *masked attention mechanism* (Equation 6) to aggregate them together to yield the output hidden state h_t at timestep *t*. To obtain sufficient expressive power, we first apply linear transformations to the input x_t and the hidden states $h_j \in H$ using:

$$x_t^{'} = W_z x_t \tag{3}$$

$$h_j^{'} = U_z h_j \tag{4}$$

where W_z, U_z are parameters which are learned, *t* is the current timestep. We denote $H^{'}$=$\{h_1^{'}$,$h_2^{'}$,...,$h_k^{'}\}$ as the transformed set of hidden states. Then we add the previously obtained candidate hidden state $\widetilde{h}_t$ into the transformed set of hidden states $H^{'}$ and obtain $H^{''}$=$\{h_1^{'}$,$h_2^{'}$,...,$h_k^{'}$,$\widetilde{h}_t\}$. The intuition is that the output hidden state depends on both the history information ($h_1^{'}$ to $h_k^{'}$) and the current input ($\widetilde{h}_t$).

Then we perform attention mechanism by using the hidden states $H^{''}$ as keys and the current input x_t as query. Intuitively, different inputs (e.g. different predecessors in $H^{''}$) should have different impacts on the output hidden state h_t, and we expect our model to capture that. However, the inputs may have different number of predecessors at different timesteps. To handle this, inspired by (Vaswani et al., 2017), we employ an *masked attention mechanism* to learn the importance of each predecessor at every timestep, thus avoiding the pad information affecting the learning process. We compute the attention using:

$$e_j = v^T \phi\left(x_t^{'} + h_j^{'}\right) \tag{5}$$

$$\alpha_j = \mathit{softmax}\left([e_j]_m\right) \tag{6}$$

where v is a learnable parameter, $h_j^{'}$ is the *j*-th vector in $H^{''}$, $softmax(z_i)$=e^{z_i}/$\sum_j e^{z_j}$, α_j denotes the attention weight on the *j*-th vector in $H^{''}$, $[\cdot]_m$ denotes the mask operation. In our implementation, we simply set the number to negative infinity if the *j*-th hidden state corresponds to a pad token. Finally, we compute the weighted sum to obtain the cell output hidden state h_t at timestep *t* using:

$$h_t = \sum_{j=1}^{k+1} \alpha_j h_j^{'} \tag{7}$$

Intuitively, the *reset gate* controls the information flow from the multiple predecessors to the hidden state of current timestep. If a precedent word is more correlated to the current input word, then it is expected to let the information of the precedent word flow through the gate to affect the representation of current timestep.

3.1.3 Bi-directional Representation

To obtain a bi-directional representation for the dialogue history, we use the same cell architecture (Section 3.1.2) to loop over the *forward graph* and *backward graph* separately, and compute a forward representation $\overrightarrow{h}_n$ and a backward representation $\overleftarrow{h}_n$, respectively. Then we concatenate them together to serve as the final representation of dialogue history h_n^e=[$\overrightarrow{h}_n$;$\overleftarrow{h}_n$], which will become a part of the inputs to the decoder.

3.2 Multi-hop Reasoning Mechanism over Knowledge Graph

A straightforward way to explore the graph information in KB is to represent the KB as a graph structure, and then query the graph using attention mechanism with the decoder hidden states. However, our preliminary experiments didn't show a good performance using this approach. We conjecture that it may be due to the poor reasoning ability of this method. To address this issue, we extend the graph with multi-hop reasoning mechanism, which aimed to strengthen the reasoning ability over graph as well as to capture the graph structural information between entities via self-attention. We call it knowledge graph module in the following sections.

Formally, the knowledge graph module contains two sets of trainable parameters $C = \{C^1, C^2, \ldots, C^{K+1}\}$, where each C^k is an embedding matrix that maps tokens to vector representations, and $V = \{V^1, V^2, \ldots, V^{K+1}\}$, where each V^k is a weight vector for computing self-attention coefficients, and K is the maximum number of hops.

Now we describe how to compute the output vector of the knowledge graph. The model loops over K hops on an input graph. At each hop k, a query vector q^k is employed as the reading head. First, the model uses an embedding layer C^k to obtain the continuous vector representations of each node i in the graph as C_i^k, where $C_i^k = C^k(n_i)$ and n_i is the i-th node in the graph. Then we perform *self-attention mechanism* on the nodes and compute the attention coefficients using:

$$e_{ij} = \varphi\left(\left(V^k\right)^T [C_i^k || C_j^k]\right) \tag{8}$$

where φ is the LeakyReLU activation function (with negative input slope $\alpha = 0.2$), V^k is the parametrized weight vector of the attention mechanism at hop k, C_i^k and C_j^k are the node vectors for the i-th and j-th node in the graph at hop k, and $||$ is the concatenation operation. We then normalize the coefficients of each node i with respect to all its first-order neighbors using the softmax function:

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{k \in N_i} exp(e_{ik})} \tag{9}$$

where N_i is the first-order neighbors of node i (including i), *exp* is the exponential function.

Then we update the representation of each node i by a weighted sum of its neighbors in N_i using:

$$\left(C_i^k\right)' = \sum_{j \in N_i} \alpha_{ij} C_j^k \tag{10}$$

Next, the query vector q^k is used to attend to the updated nodes in the graph and compute the attention weights for each node i at hop k using:

$$p_i^k = softmax\left(\left(q^k\right)^T \left(C_i^k\right)'\right) \tag{11}$$

To obtain the output of the knowledge graph, we apply the same self-attention mechanism (Equations 8 and 9) and update strategy (Equation 10) to the node representation C_i^{k+1}. We use C^{k+1} here since the adjacent weighted tying strategy is adopted. The updated node representation for output is denoted as $\left(C_i^{k+1}\right)'$. Once obtained, the model reads out the graph o^k by the weighted sum over it using:

$$o^k = \sum_i p_i^k \left(C_i^{k+1}\right)' \tag{12}$$

Then the query vector q^k is updated for the next hop using $q^{k+1} = q^k + o^k$. The final output of the knowledge graph is o^K, which will become a part of the inputs to the decoder.

3.2.1 Graph Construction

In practice, dialogue systems usually use KBs (mostly in a relational database format) to provide external knowledge. We have converted the original relational database into a graph structure to exploit the relation information between KB entities. First, we find all the entities in the relational database as the nodes of the graph. Then we assign an edge to a pair of entities if there exists relationship between them according to the records in the relational database. Thus we can obtain the graph structured external knowledge.

3.3 Decoder

We use a standard Gated Recurrent Unit (GRU) (Cho et al., 2014) as the decoder to generate the system response word-by-word. The initial hidden state h_0 consists of two parts: the graph encoder output and the knowledge graph output. We take the output hidden state of the graph encoder h_n^e as the initial query vector q^0 to attend to the knowledge graph and obtain the output o^K. The initial hidden state h_0 is then computed using:

$$h_0 = [h_n^e || o^K] \tag{13}$$

At each decoder timestep t, the GRU takes the previously generated word $\hat{y}_{t-1}$ and the previous hidden state h_{t-1} as the input and generates a new hidden state h_t using:

$$h_t = GRU\left(\hat{y}_{t-1}, h_{t-1}\right) \tag{14}$$

Next, we follow (Wu et al., 2019b) that the decoder learns to generate a sketch response that the entities in the response are replaced with certain tags. The tags are obtained from the provided ontologies in the training data. The hidden state h_t are used for two purposes. The first one is to generate a vocabulary distribution P_{vocab} over all the words in the vocabulary using:

$$P_{vocab} = softmax\left(W_o h_t\right) \tag{15}$$

where W_o is the learnable parameter. The second one is to query the knowledge graph to generate a graph distribution P_{graph} over all the nodes in the graph. We use the attention weights at the last hop of the knowledge graph p_t^K as P_{graph}.

At each timestep *t*, if the generated word from P_{vocab} (the word has the maximum posterior probability) is a tag, then the decoder choose to copy from the graph entities that has the largest attention value according to P_{graph}. Otherwise, the decoder will generate the target word from P_{vocab}. During training, all the parameters are jointly learned via minimizing the sum of two cross-entropy losses: one is between P_{vocab} and $y_t \in Y$, and the other is between P_{graph} and G_t^{Label}, where G_t^{Label} is the node id that corresponds to the current output y_t.

4 Experiments

4.1 Dataset

To validate the efficacy of our proposed model, we evaluate it on two public multi-turn task-oriented diaglogue datasets: Stanford multi-domain dialogue (SMD) (Eric et al., 2017) and MultiWOZ 2.1 (Eric et al., 2019). The SMD is a human–human dataset for in-car navigation task. It includes three distinct task domains: *point-of-interest navigation*, *calendar scheduling* and *weather information retrieval*. The MultiWOZ 2.1 dataset is a recently released human–human dialogue corpus with much larger data size and richer linguistic expressions that make it a more challenging benchmark for end-to-end task-oriented dialogue modeling. It consists of seven distinct task domains: *restaurant*, *hotel*, *attraction*, *train*, *hospital*, *taxi* and *police*. We select four domains (*restaurant*, *hotel*, *attraction*, *train*) to test our model since the other three domains (*police*, *taxi*, *hospital*) lack KB information which is essential to our task. We will make our code and data publicly available for further study. To the best of our knowledge, we are the first to evaluate end-to-end task-oriented dialogue models on MultiWOZ 2.1. The train/validation/test sets of these two datasets are split in advance by the providers.

4.2 Training Details

We implement our model[2] in Tensorflow and is trained on NVIDIA GeForce RTX 2080 Ti. We use grid search to find the best hyper-parameters for our model over the validation set (use BLEU as criterion for both datasets). We randomly initialize all the embeddings in our implementation. The embedding size is selected between [16,512], which is also equivalent to the RNN hidden state (including the encoder and the decoder). We also use dropout for regularization on both the encoder and the decoder to avoid over-fitting and the dropout rate is set between [0.1,0.5]. We use Adam optimizer (Kingma and Ba, 2015) to accelerate the convergence with a learning rate chosen between [$1e^{-3}$,$1e^{-4}$]. We simply use a greedy strategy to search for the target word in the decoder without advanced techniques like beam-search.

Metrics	SMD	MultiWOZ 2.1
Avg. Turns per dialog	5.25	13.46
Avg. Tokens per turn	8.02	13.13
Total number of turns	12732	113556
Vocabulary	1601	23689
Train dialogs	2425	8438
Val dialogs	302	1000
Test dialogs	304	1000

Table 1: Dataset statistics for SMD and MultiWOZ 2.1.

4.3 Evaluation Metrics

We use two common evaluation metrics in dialogue studies including BLEU (Papineni et al., 2002) (using Moses `multi-bleu.perl` script) and Entity F1 (Eric et al., 2017; Madotto et al., 2018) for evaluations.

4.4 Effect of Models

We compare our model with several existing models: standard sequence-to-sequence (Seq2Seq) models with and without attention (Luong et al., 2015), pointer to unknown (Ptr-Unk, (Gulcehre et al., 2016)), GraphLSTM (Peng et al., 2017), BERT (Devlin et al., 2019), Mem2Seq (Madotto et al., 2018) and GLMP (Wu et al., 2019b). Note that the results we listed in Table 2 for GLMP is different from the original paper, since we reimplement their model in Tensorflow according to their released Pytorch code for fair comparison.

Stanford Multi-domain Dialogue. Table 2 has shown the results on SMD dataset. Our proposed model achieves a consistent improvement over all the baselines with the highest BLEU score 13.6 and 57.4% entity F1 score. The performance gain in BLEU score suggests that the generation error in the decoder has been reduced. The improvement on entity F1 indicates that our model can retrieve

Table 2: Evaluation on SMD dataset. Human, rule-based and KV Retrieval Net results are reported from (Eric et al., 2017), which are not directly comparable since the problem is simplified to canonicalized forms. K denotes the maximum number of hops for knowledge graph. Ours achieves highest BLEU and entity F1 score over baselines.

Model	S2S	S2S + Attn	Ptr-Unk	GraphLSTM	BERT	Mem2Seq	GLMP	GraphDialog		
								K=1	K=3	K=6
BLEU	2.5	3.0	2.3	3.4	3.9	4.1	4.3	5.47	**6.17**	5.14
Entity F1	1.3	2.1	2.5	4.7	4.1	3.2	6.7	9.56	**11.28**	8.74
Restaurant F1	1.6	2.2	2.3	9.8	7.3	2.9	11.4	15.27	**15.95**	13.25
Hotel F1	1.5	3.4	3.8	2.1	1.6	4.5	3.9	7.54	**10.79**	7.05
Attraction F1	0.8	1.4	1.7	7.2	8.4	2.1	9.4	5.78	**14.12**	7.89
Travel F1	0.2	0.7	0.9	1.8	2.1	1.5	3.5	3.41	**4.39**	3.53

Table 3: Evaluation on MultiWOZ 2.1 dataset. Ours achieves highest BLEU and entity F1 score over baselines.

entities from the external knowledge data more accurately than those baselines. We also conduct comparisons with BERT to validate the effectiveness of our proposed model. Specifically, we use the bert-base-uncased model (due to GPU memory limit) from huggingface library[3] as our encoder to encode the dialogue history and the remaining parts are the same as our model. We then fine-tune BERT on our dialogue dataset. We can find that our mode significantly outperforms the fine-tuned BERT by a large margin which further demonstrates the effectiveness of our proposed model. We conjecture that the reasons may lie in two aspects. First, the context of the corpus used for pretraining BERT differs from our dialogue dataset. Secondly, the model complexity of BERT may cause overfitting issue on small-scale datasets like SMD etc.

MultiWOZ 2.1. Table 3 shows the results on a more complex dataset MultiWOZ 2.1. Our model outperforms all the other baselines by a large margin both in entity F1 and BLEU score, which confirms our model has a better generalization ability than those baselines. One may find that the entity F1 and BLEU score has a huge gap between MultiWOZ 2.1 and SMD. This performance degradation phenomenon has also been observed by other dialogue works (Budzianowski et al., 2018) which implies that the MultiWOZ corpus is much more challenging than the SMD dataset for dialogue tasks.

Ablation Study. Table 4 shows the contributions of each components in our model. Ours without graph encoder means that we do not use the dependency relations information and the proposed recurrent cell architecture. We simply use a bidirectional GRU to serve as the encoder and the other parts of the model remain unchanged. We can observe that our model without the graph encoder has a 1.6% absolute value loss (over 25% in ratio) in BLEU score and a 1.1% absolute value loss (9.8% in ratio) in entity F1 on MultiWOZ 2.1, which suggests that the overall quality of the generated sentences are better improved by our graph encoder. On the other hand, ours without knowledge graph means that we do not use the graph structure to store and retrieve the external knowledge data. Instead we use memory networks (Sukhbaatar et al., 2015) that has been shown useful to handle the knowledge base similar to (Wu et al., 2019b). We can find a significant entity F1 drop (3.8% in absolute value and 33.9% in ratio) on MultiWOZ 2.1, which verifies the superiority of the proposed graph-based module with multi-hop reasoning ability in retrieving the correct entities, even compared to the strong memory-based baselines.

Model Training Time. We also compare the training time of GraphDialog with those baselines. GraphDialog is about 3 times faster than BERT since its model complexity is smaller. The number

Figure 5: Knowledge graph attention visualization when generating responses in the SMD navigation domain. Based on the question "Where is a nearby parking_garage?", the generated response of our model is "palo_alto_garage is 1_miles away". Specifically, the attention results at each generation timestep for the knowledge graph information of this example are shown in (a), (b), (c) and (d) respectively. The color and size of the nodes represent their attention weights. The darker and bigger the nodes are, the larger their attention weights are. Our model successfully learns to attend to the correct KB entities (i.e., *palo_alto_garage* and *1_miles* at generation timesteps 0 and 2) which have the highest attention, and the model copies them to serve as the output words. During timesteps 1 and 3, the model generates output words (i.e., *is* and *away*) from the vocabulary.

	SMD		MultiWOZ 2.1	
Model	BLEU	Entity F1(All)	BLEU	Entity F1(All)
GraphDialog	13.66(-)	57.42(-)	6.17(-)	11.28(-)
GraphDialog w/o Graph Encoder	12.35(-1.31)	56.61(-0.81)	4.57(-1.60)	10.13(-1.15)
GraphDialog w/o Knowledge Graph	13.13(-0.53)	55.28(-2.14)	5.35(-0.82)	7.41(-3.87)

Table 4: Model ablation study: Effects of Graph Encoder and Knowledge Graph. Number in the parentheses means the absolute value gap between the full version and the ablation one on corresponding metrics.

	Edge Path Distance			
Dataset	1	≥ 2	≥ 10	≥ 15
SMD	52.82%	33.68%	10.61%	2.89%
MultiWOZ 2.1	50.29%	35.41%	11.26%	3.04%

Table 5: Edge path distance distribution on different datasets.

of parameters for GraphDialog is almost 90% less than BERT, which also saves space for model storage. GraphDialog is slower than GLMP, which is expected as it needs to encode more information. However, the gap of the training time is up to 69%, and we can complete the whole training process within one day which seems reasonable.

4.5 Analysis and Discussion

Why does dependency relations help? We have conducted in-depth analyses from the edge path distance perspective. Table 5 shows the edge path distance distribution in the dialogue graph (Section 3.1.1) on both SMD and MultiWOZ 2.1. The edge path distance is defined as the the number of words between the head word and the tail word along the linear word sequence plus one. For example, for the sentence "There is a supermarket", the edge distance of the "Next" edge between "There" and "is" is 1, the edge path distance of the "nsubj" edge between "is" and "supermarket" is 2. We can find that although many edges have small edge path distances, there are still a considerable number of edges with relatively large distances, which could encourage more direct information flow between distant words in the input. This may partly explain the benefits of using information such as dependency relations in encoding the dialogue history.

Attention Visualization. To further understand the model dynamics, we analyze the attention weights of the knowledge graph module to show its reasoning process. Figure 5 has shown an example of the attention distribution over all the nodes at the last hop of the knowledge graph. Based on the question "Where is a nearby parking_garage?" asked by the user, the generated response of our model is "palo_alto_garage is 1_miles away", and the gold answer is "The nearest one is palo_alto_garage, it's just 1_miles away". We can find that our model has successfully learned to copy the correct entities (i.e., *palo_alto_garage* at timestep 0 and *1_miles* at timestep 2) from the knowledge graph.

Error Analysis. To inspire future improvements, we also inspect the generated responses manually. We find that the model tends to omit entities when the responses contain multiple KB entities. Besides, about 10% of the generated responses contain duplicate KB entities. For example, "*The temperature in New York on Monday is 100F, 100F*". This may be attributed to the training of GRU in the decoder, and we aim to solve the problem in future work.

5 Conclusion

In this work, we present a novel graph-based end-to-end model for task-oriented dialogue systems. The model leverages the graph structural information in dialogue history via the proposed recurrent cell architecture to capture the semantics of dialogue history. The model further exploits the relationships between entities in the KB to achieve better reasoning ability by combining the multi-hop reasoning ability with graph.

We empirically show that our model outperforms the state-of-the-art models on two real-world task-oriented dialogue datasets. Our model may also be applied to end-to-end open-domain chatbots since the goal is to generate responses given inputs and external knowledge, which is what our model can do. We will explore this direction in future work.

Abstract

Inducing a meaningful structural representation from one or a set of dialogues is a crucial but challenging task in computational linguistics. Advancement made in this area is critical for dialogue system design and discourse analysis. It can also be extended to solve grammatical inference. In this work, we propose to incorporate structured attention layers into a Variational Recurrent Neural Network (VRNN) model with discrete latent states to learn dialogue structure in an unsupervised fashion. Compared to a vanilla VRNN, structured attention enables a model to focus on different parts of the source sentence embeddings while enforcing a structural inductive bias. Experiments show that on two-party dialogue datasets, VRNN with structured attention learns semantic structures that are similar to templates used to generate this dialogue corpus. While on multi-party dialogue datasets, our model learns an interactive structure demonstrating its capability of distinguishing speakers or addresses, automatically disentangling dialogues without explicit human annotation.[1]

1 Introduction

Grammatical induction for capturing a structural representation of knowledge has been studied for some time (De la Higuera, 2010). Given the achievement in related areas like learning *Hidden Markov* acoustic models in speech recognition (Bahl et al., 1986) and sentence dependency parsing in language understanding (Covington, 2001), our work aims to explore a more sophisticated topic: learning structures in dialogues. Figure 1 shows the underlying semantic structure of conversations about bus information request from SimDial dataset (Zhao and Eskenazi, 2018), with one example dialogue as shown in Table 1. Another interesting type of dialogue structure is the interactive structure in multi-party dialogues. Figure 2 illustrates the interactive structure we learned from a dialogue sample in Ubuntu Chat Corpus (Lowe et al., 2015). Each node represents an utterance from different speakers in the dialogue with darker linkages represent stronger dependency relations between utterances. When speaker/addressee information is unavailable in the corpus, learning such a structure allows disentangling the conversation (Serban and Pineau, 2015) and estimating the speaker labels. Discovering dialogue structures is crucial for various areas in computational linguistics, such as dialogue system building (Young, 2006), discourse analysis (Grosz and Sidner, 1986), and dialogue summarization (Murray et al., 2005; Liu et al., 2010). Through looking into this topic, we can further improve the capability of machines to learn more generalized, interpretable knowledge representation from data.

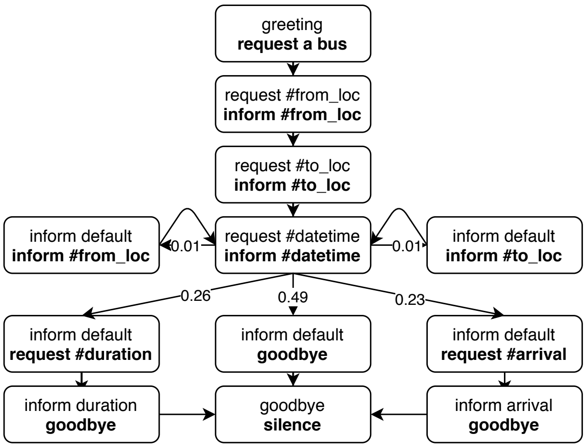

Figure 1: Original dialogue structure of the bus information request domain in SimDial (Zhao and Eskenazi, 2018). User intents are marked in bold.

However, capturing structure from the conversation is still much under-explored. The complexity of dialogues could range from several-round task-oriented dialogues to tens-round multi-party chitchat. It is unclear that for these different categories of dialogues, what types of inductive biases or constraints we could add to reduce the search space. It also remains an unsolved question for formally evaluating the performance of dialogue structure induction algorithms. In this paper, we propose to use a combination of structured attention and unsupervised generative model to infer the latent structure in a dialogue.

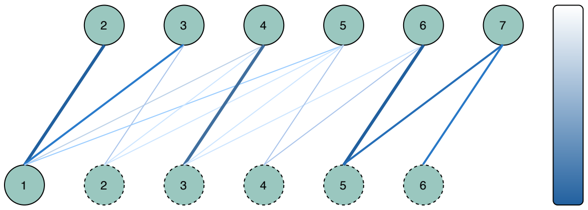

Figure 2: Learned interactive structure from a multi-party dialogue sample in Ubuntu Chat Corpus (Uthus and Aha, 2013).

Specifically, instead of simply applying a softmax function on potentials between a decoder query and encoder hidden states, dynamic programming algorithms like *Forward-Backward* (Devijver, 1985) and *Inside-Outside* (Lari and Young, 1990) could be used to efficiently calculate marginal probabilities from pairwise potentials with a structural constraint. Through embedding such structured attention layers in a *Variational Recurrent Neural Network* (VRNN) model, we can learn latent structures in dialogues by jointly re-generating training dialogues. Such a process requires no human annotation and is useful for dialogue analysis. In addition, by selecting appropriate structural biases or constraints, we can learn not only semantic structures but also interactive structures. A linear *Conditional Random Field* (CRF) attention layer is used in two-party dialogues to discover semantic structures. A non-projective dependency tree attention layer is embedded to learn an interactive structure that could help identify speaker/addressee information in multi-party dialogues that have tangled conversation threads, such as forum discussions.

This paper makes the following contributions. We propose to incorporate a structured attention layer in VRNN to learn latent structures in dialogues. To our knowledge, no work connecting structured attention with unsupervised dialogue structure learning has been done. We prove our proposed VRNN-LinearCRF learns better structures than the baseline VRNN on the SimDial dataset for semantic structure learning in two-party dialogues. For interactive structure learning in multi-party dialogues, we combine VRNN with a non-projective dependency tree attention layer. It achieves similar generation performance as the baseline GSN model (Hu et al., 2019) on Ubuntu Chat Corpus (Uthus and Aha, 2013; Lowe et al., 2015), while our model can identify the speaker/addressee information without trained on explicit labels. We release our code as well as the processed datasets to help stimulate related researches.

2 Related Work

Attention mechanism (Vaswani et al., 2017) has been widely adopted as a way for embedding categorical inference in neural networks for performance gain and interpretability (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019). However, for many tasks, we want to model richer structural dependencies without abandoning end-to-end training. *Structured Attention Networks* (Kim et al., 2017) can extend attention beyond the standard soft-selection approach by attending to partial segments or subtrees. People have proven its effectiveness on a variety of synthetic and real tasks: tree transduction, neural machine translation, question answering, and natural language inference (Rush, 2020). In this paper, we propose to utilize structured attention to explore dialogue structures. Specifically, we work on two types of dialogue structures, semantic structures (dialogue intent transitions), and interactive structures (addressee/speaker changes).

Semantic structures have been studied extensively. Some previous works, such as (Jurafsky, 1997), learned semantic structures relying on human annotations, while such annotations are costly and can vary in quality. Other unsupervised studies used *Hidden Markov Model* (HMM) (Chotimongkol, 2008; Ritter et al., 2010; Zhai and Williams, 2014). Recently, *Variational Autoencoders* (VAEs) (Kingma and Welling, 2013) and their recurrent version, *Variational Recurrent Neural Networks* (VRNNs) (Chung et al., 2015), connects neural networks and traditional Bayes methods. Because VRNNs apply a point-wise non-linearity to the output at every timestamp, they are also more suitable to model highly non-linear dynamics over the simpler dynamic Bayesian network models. Serban et al. (2017) proposed the VHRED model by combining the idea of VRNNs and *Hierarchical Recurrent Encoder-Decoder* (HRED) (Sordoni et al., 2015) for dialogue generation. Similarly, Zhao et al. (2018) proposed to use VAEs to learn discrete sentence representations. Shi et al. (2019) used two variants of VRNNs to learn the dialogue semantic structures and discussed how to use learned structure to improve reinforcement learning-based dialogue systems. But none of the previous work has tried to incorporate structured attention in VRNNs to learn dialogue structure.

Compared to semantic structures, the interactive structure of dialogues is not clearly defined. Elsner and Charniak (2008) initiated some work about dialogue disentanglement, which is defined as dividing a transcript into a set of distinct conversations. Serban and Pineau (2015) tested standard RNN and its conditional variant for turn taking and speaker identification. Both of the tasks are highly related to understanding the interactive structure but not identical. Our task, different from both of them, aims to construct an utterance dependency tree to represent a multi-party dialogue's turn taking. The tree can not only be used to disentangle the conversations but also label each utterance's speakers and addressees. We compare our model with *Graph Structured Network* (GSN), recently proposed by Hu et al. (2019). GSN builds a conversation graph utilizing explicit speaker/addressee information in Ubuntu Chat Corpus (Uthus and Aha, 2013) to improve the dialogue generation performance. Our model shows similar generation performance as them while demonstrating its capability of learning the utterance dependency tree.

3 Problem Formulations

We discuss the semantic and interactive dialogue structure learning separately. In task-oriented two-party dialogues (between system and user), we want to discover a semantic probabilistic grammar shared by dialogues in the same domain. While for multi-party dialogues, *e.g.*, conversations in a chatroom, which may have multiple conversations occur simultaneously, we are more interested in finding an interactive structure that could help disentangle the conversation and identify the speakers/addressees. Our method of structure learning is flexible to handle both problems with the formulations as shown below.

For semantic dialogue structure learning, we formulate the problem as labeling the dialogue with a sequence of latent states. Each conversational exchange x_i (a pair of system and user utterances at time step i) belongs to a latent state z_i, which has an effect on the future latent states and the words the interlocutors produce. The latent dialogue state is defined to be discrete, *i.e.*, $z_i \in \{1, 2, ..., N\}$, where N is the number of states predefined from experience. Our goal is to generate the current sentence pair x_i that maximizes the conditional likelihood of x_i given the dialogue history while jointly learning a latent state sequence $\mathbf{z} = [z_1, z_2, ..., z_n]$:

$$\hat{\mathbf{x}} = \operatorname*{argmax}_{\mathbf{x}} \sum_{i=1}^{|\mathbf{x}|} \log(P(\mathbf{z}_{<i}|\mathbf{x}_{<i})P(x_i|\mathbf{z}_{<i})). \tag{1}$$

Then, we can induce a probabilistic dialogue grammar by estimating the state transition probabilities through maximizing the likelihood of the parsed latent state sequences.

A multi-party dialogue session can be formulated as an utterance-level dependency tree $\mathbf{T}(V, E)$, where V is the set of nodes encoding the utterances, $E = \{e_{i,j}\}_{i<j}^{m} \in \{0, 1\}$ indicates whether utterance i is the parent of utterance j, and m is the maximum number of possible edges.

$$\begin{aligned}\hat{\mathbf{x}} &= \operatorname*{argmax}_{\mathbf{x}} \sum_{i=1}^{|\mathbf{x}|} \log(P(\mathbf{T}|\mathbf{x}_{<i})P(x_i|\mathbf{T})) \\ &= \operatorname*{argmax}_{\mathbf{x}} \sum_{i=1}^{|\mathbf{x}|} \log(\prod_{j<k}^{i-1} P(e_{j,k} = 1|\mathbf{x}_{<i}) \cdot \\ &\qquad P(x_i|\mathbf{T})) \\ &= \operatorname*{argmax}_{\mathbf{x}} \Big[\sum_{i=1}^{|\mathbf{x}|} \sum_{j<k}^{i-1} \log(P(e_{j,k} = 1|\mathbf{x}_{<i}) + \\ &\qquad \sum_{i=1}^{|\mathbf{x}|} \log(P(x_i|\mathbf{T}) \Big]\end{aligned} \tag{2}$$

Each path of the dependency tree represents a thread in the multi-party conversation in chronological order. Our goal is to generate the response $\hat{\mathbf{x}}$ that maximizes the conditional likelihood of the response given the dialogue history while jointly learning a latent utterance dependency tree as shown in Equation 2. The conditional likelihood is factorized into two parts, representing the encod-

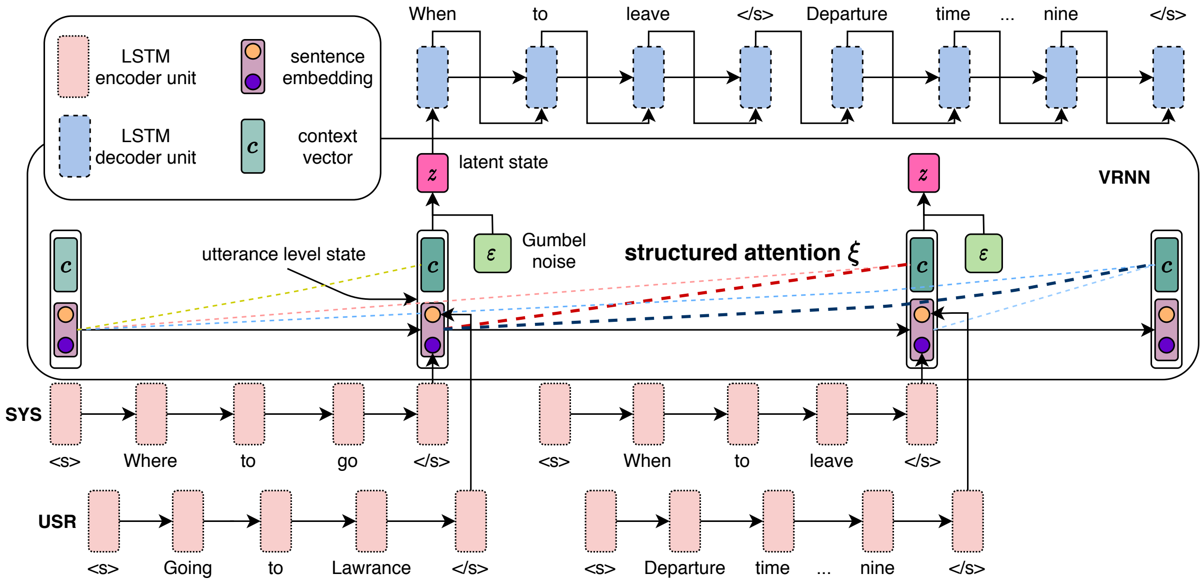

Figure 3: Structured-Attention Variational Recurrent Neural Network (SVRNN)

ing and decoding processes respectively. We can further reason about the speaker/addressee labels or disentangle the conversation by clustering the utterances from the learned tree.

4 Variational Recurrent Neural Network with Structured Attention

The overall architecture of Structured-Attention Variational Recurrent Neural Network (SVRNN) is illustrated in Figure 3. The LSTM (Hochreiter and Schmidhuber, 2001) word-level encoder marked in pink encodes each utterance into a sentence embedding. Then an utterance-level encoder VRNN with different structured attention layers encodes the dialogue history into a latent state z. A decoder marked in blue will decode the next utterances from the latent state. We describe more details about the key components of our model in the following subsections.

4.1 Variational Recurrent Neural Network

The pursuit of using an autoencoder like *Variational Recurrent Neural Network* (VRNN) is to compress the essential information of the dialogue history into a lower-dimensional latent code. The latent code z is a random vector sampled from a prior $p(z)$ and the data generation model is described by $p(x|z)$. The VRNN contains a *Variational Autoencoder* (VAE) at each time step. The VAE consists of an encoder $q_\lambda(z|x)$ for approximating the posterior $p(z|x)$, and a decoder $p_\theta(x|z)$ for representing the distribution $p(x|z)$. The variational inference attains its maximum likelihood by maximizing *evidence lower bound* (ELBO):

$$\mathbb{E}\left[\log p_\theta(x|z)\right] - \mathrm{KL}\left(q_\lambda(z|x) \| p(z)\right) \le \log p(x). \tag{3}$$

For sequential data, the parameterization of the generative model is factorized by the posterior $p\left(z_t|x_{<t}, z_{<t}\right)$ and the generative model $p\left(x_t|z_{\le t}, x_{<t}\right)$, *i.e.*,

$$p(x \le T, z \le T) = \prod_{t=1}^{T}\Big[p\left(x_t|z_{\le t}, x_{<t}\right) \cdot p\left(z_t|x_{<t}, z_{<t}\right)\Big]. \tag{4}$$

The learning objective function becomes maximizing the ELBO for all time steps

$$\mathbb{E}\Big[\sum_{t=1}^{T}\Big(- \mathrm{KL}\left(q(z_t|x_{\le t}, z_{<t}) \| p(z_t|x_{<t}, z_{<t})\right) + \log p(x_t|z_{\le t}, x_{<t})\Big)\Big]. \tag{5}$$

In addition, to mitigate the *vanishing latent variable problem* in VAE, we incorporate Bag-of-Words (BOW) loss and Batch Prior Regularization (BPR) (Zhao et al., 2017) with a tunable weight λ. By adjusting the λ, the VRNN based models can achieve a balance between clustering the utterance surface formats and attention on the context.

4.2 Linear CRF Attention

As we formulate the semantic structure learning in two-party dialogues as a state tagging problem, we find it suitable to use a linear-chain *Conditional Random Field* (CRF) attention layer with VRNN. Define $\boldsymbol{\xi}$ to be a random vector $\boldsymbol{\xi} = [\xi_1, ..., \xi_n]$ with $\xi_i \in \{0, 1\}$. n is the number of utterances in a dialogue. The context vector $\mathbf{c}_j$ given the current sentence hidden state $\mathbf{h}_j$ and hidden state history $\mathbf{h}$ can thus be written as:

$$\mathbf{c}_j = \sum_{i=1}^{j-1} p(\xi_i = 1 | \mathbf{h}, \mathbf{h}_j)\mathbf{h}_i. \tag{6}$$

We model the distribution over the latent variable $\boldsymbol{\xi}$ with a linear-chain CRF with pairwise edges,

$$p(\xi_1, ..., \xi_n | \mathbf{h}, \mathbf{h}_j) = softmax(\sum_{i=1}^{j-2} \theta_{i,i+1}(\xi_i, \xi_{i+1})), \tag{7}$$

where $\theta_{i,i+1}(k, l)$ is the pairwise potential for $\xi_i = k$ and $\xi_{i+1} = l$. The attention layer is a two-state CRF where the unary potentials at the j-th dialogue turn are:

$$\theta_i(k) = \begin{cases} \mathbf{h}_i \mathbf{W}_1 \mathbf{h}_j, k = 0 \\ \mathbf{h}_i \mathbf{W}_2 \mathbf{h}_j, k = 1 \end{cases}, \tag{8}$$

where $[\mathbf{h}_1, ..., \mathbf{h}_n]$ are utterance level hidden states and $\mathbf{W}_1, \mathbf{W}_2$ are parameters. The pairwise potentials can be parameterized as

$$\theta_{i,i+1}(\xi_i, \xi_{i+1}) = \theta_i(\xi_i) + \theta_{i+1}(\xi_{i+1}) + \mathbf{h}_i^\top \mathbf{h}_{i+1}. \tag{9}$$

The marginal distribution $p(\xi_i = 1|x)$ can be calculated efficiently in linear-time for all i using message-passing, *i.e.*, the *forward-backward* shown in Algorithm 1.

$\mathcal{C}$ denotes the state space and $\langle t \rangle$ is the special start/stop state. Typically the forward-backward with marginals is performed in the log-space semifield $\mathbb{R} \cup \{\pm\infty\}$ with binary operations $\oplus$ = logadd and $\otimes = +$ for numerical precision. These marginals allow us to calculate the context vector. Crucially, the process from vector softmax to *forward-backward* algorithm is a series of differentiable steps, and we can compute the gradient of the marginals with respect to the potentials (Kim et al., 2017). This allows the linear CRF attention layer to be trained end-to-end as a part of the VRNN.

Algorithm 1: Forward-Backward for LinearCRF Attention

```
Input: potential $\theta$
$\alpha[0, \langle t \rangle] \leftarrow 0$
$\beta[n+1, \langle t \rangle] \leftarrow 0$
for $i = 1, ..., n; c \in \mathcal{C}$ do
    $\alpha[i, c] \leftarrow \bigoplus_y \alpha[i-1, y] \otimes \theta_{i-1,i}[y, c]$
end for
for $i = n, ..., 1; c \in \mathcal{C}$ do
    $\beta[i, c] \leftarrow \bigoplus_y \beta[i+1, y] \otimes \theta_{i,i+1}[c, y]$
end for
$A \leftarrow \alpha[n+1, \langle t \rangle]$
for $i = 1, ..., n; c \in \mathcal{C}$ do
    $p(\xi_i = c|x) \leftarrow \exp(\alpha[i, c] \otimes \beta[i, c] \otimes -A)$
end for
return $p$
```

4.3 Non-projective Dependency Tree Attention

For interactive structure learning in multi-party dialogues, we want to learn an utterance dependency tree from each dialogue. Therefore, we propose to use a non-projective dependency tree attention layer with VRNN for this purpose. The potentials $\theta_{i,j}$, which reflect the score of selecting the i-th sentence being the parent of the j-th sentence (*i.e.*, $x_i \rightarrow x_j$), can be calculated by

$$\theta_{i,j} = \tanh(\mathbf{s}^\top \tanh(\mathbf{W}_1 \mathbf{h}_i + \mathbf{W}_2 \mathbf{h}_j + \mathbf{b})), \tag{10}$$

where $\mathbf{s}, \mathbf{b}, \mathbf{W}_1, \mathbf{W}_2$ are parameters, $\mathbf{h}_i, \mathbf{h}_j$ are sentence hidden states.

The probability of a parse tree ξ given the dialogue $x = [x_1, ..., x_n]$ is,

$$p(\xi|x) = \text{softmax}(\mathbb{1}\{\xi \text{ is valid}\} \cdot \sum_{i \neq j} \mathbb{1}\{\xi_{i,j} = 1\}\theta_{i,j}), \tag{11}$$

where the latent variable $\xi_{i,j} \in \{0, 1\}$ for all $i \neq j$ indicates that the i-th sentence is the parent of the j-th sentence; and $\mathbb{1}\{\xi \text{ is valid}\}$ is a special global constraint that rules out configurations of $\xi_{i,j}$'s that violate parsing constraints. In our case, we specify each sentence has one parent and that must precede the child sentence, i.e,

$$\sum_{i=1}^{n} \xi_{i,j} = 1 \quad \xi_{i,j} = 0 (i \geq j). \tag{12}$$

It is possible to calculate the marginal probability of each edge $p(\xi_{i,j} = 1|x)$ for all i, j in $O(n^3)$

time using the *inside-outside* algorithm with details explained in Appendix, which is a generalization of the *forward-backward* algorithm.

Then the soft-parent or the context vector of the j-th sentence is calculated using parsing marginals, *i.e.*,

$$\mathbf{c}_j = \sum_{i=1}^{n} p(\xi_{i,j} = 1|\mathbf{h}, \mathbf{h}_j)\mathbf{h}_i. \tag{13}$$

The original embedding is concatenated with its context vector to form the new representation

$$\hat{\mathbf{h}}_j = [\mathbf{h}_j; \mathbf{c}_j]. \tag{14}$$

4.4 Decoder

In order to generate a response to an utterance i, the decoder calculates a distribution over the vocabulary then sequentially predicts word w_k using a *softmax* function:

$$\begin{aligned} p(\mathbf{w}|\hat{\mathbf{h}}) &= \prod_{k=1}^{|\mathbf{w}|} P(w_k|\hat{\mathbf{h}}, \mathbf{w}_{<k}) \\ &= \prod_{k=1}^{|\mathbf{w}|} softmax(MLP(\mathbf{h}_k^{dec}, \mathbf{c}_k^{dec})) \\ \mathbf{h}_0^{dec} &= \hat{\mathbf{h}}_i \\ \mathbf{h}_k^{dec} &= LSTM(\mathbf{h}_{k-1}^{dec}, MLP(\mathbf{e}_{w_{k-1}}; \mathbf{c}_{k-1}^{dec})) \\ \mathbf{c}_k^{dec} &= \sum_{j=1}^{i} softmax(\mathbf{h}_k^{dec}\mathbf{W}_a\hat{\mathbf{h}}_j)\hat{\mathbf{h}}_j, \end{aligned} \tag{15}$$

where $\hat{\mathbf{h}}_i$ is the hidden state for utterance i with structured attention, $\mathbf{h}_k^{dec}$ is the hidden state of the decoder LSTM, $\mathbf{e}_{w_{k-1}}$ is the embedding of the predicted word at decoding time stamp $(k-1)$, and $\mathbf{c}_k^{dec}$ is the attention-based context vector at decoding time stamp k. Note that the context vector here is calculated with the simple attention different from the structured attention we described before. $\mathbf{W}_a$ is a matrix to learn the match degree of $\mathbf{h}_k^{dec}$ and $\hat{\mathbf{h}}_j$.

5 Experiments

We incorporate structured attention in VRNNs to explore two types of dialogue structure, semantic structure, and interactive structure.

5.1 Semantic Structure Learning in Two-party Dialogues

5.1.1 Datasets

We test the VRNN with Linear CRF Attention on the SimDial dataset (Zhao and Eskenazi, 2018) of simulated conversations. Dialogues are generated for information requests in four domains: bus, restaurant, weather, and movie. Table 1 shows an example dialogue in bus schedule request domain. Despite significant variations exist between dialogues of the same domain, we aim to explore a shared semantic structure among each dialogue domain. We validate our algorithm on this simulated dataset because these dialogues are generated using pre-defined templates that make recovering ground truth structures much easier. One recovered ground truth structure with transition probabilities is shown in Figure 1. We have 800 dialogue samples for training, 100 for validation, and 100 for testing in each dialog domain. The length of the dialogues ranges from 6 to 13 utterances. The maximum length of an utterance is 33 words.

From	Utterance
SYS:	Ask me about bus information. How can I help?
USR:	Hi. I need a bus.
SYS:	Where do you want to take off?
USR:	Going to Lawrance.
SYS:	What time do you need the bus?
USR:	Departure time is 9.
SYS:	Bus 137 can take you there. What else can I do?
USR:	Not done yet. How long will it take?
SYS:	The ride is 45 minutes long. What else can I do?
USR:	No more questions. Thank you.
SYS:	Goodbye.

Table 1: An example two-party bus information request dialogue in SimDial (Zhao and Eskenazi, 2018).

5.1.2 Evaluation Metrics

Since the number of states is unknown during unsupervised training, we set the state number empirically to 10. Then the learned structure is essentially a state transition matrix of size 10 × 10. However, the original structure could be another state transition matrix of any size depending on the domain complexity. This makes the model evaluation on the ground truth a problem because it requires us to measure the difference between two state transition matrices of different sizes. To alleviate this problem, we define two metrics: Structure Euclidean Distance (SED) and Structure Cross-Entropy (SCE). We first estimate a probabilistic mapping $P_{s_i,s_i'}$ between the learned states $\{s_i', i = 1, 2, ..., M\}$ and the true states $\{s_i, i = 1, 2, ..., N\}$, through dividing the number of utterances that have the ground truth state s_i and learned state s_i' by number of utterances with the ground truth state s_i. And we let the reversed mapping probability P_{s_i',s_i} be the normalized transpose of

$P_{s_i,s_i'}$. Then SED and SCE are defined as:

$$T'_{s_a,s_b} = \sum_{i,j\in\{1,2,\ldots,M\}} P_{s_a,s_i'} \cdot T_{s_i',s_j'} \cdot P_{s_j',s_b}$$
$$SED = \frac{1}{N}\sqrt{\sum_{a,b\in\{1,2,\ldots,N\}} (T'_{s_a,s_b} - T_{s_a s_b})^2}$$
$$SCE = \frac{1}{N}\sum_{a,b\in\{1,2,\ldots,N\}} -\log(T'_{s_a,s_b})T_{s_a s_b}, \tag{16}$$

where T'_{s_a,s_b} is the learned transition probability from state s_a to state s_b and T_{s_a,s_b} is the true transition probability.

5.1.3 Results and Analysis

We compare the proposed VRNN-LinearCRF against other unsupervised methods: K-means clustering, Hidden Markov Model, D-VRNN (Shi et al., 2019) and VRNN with vanilla attention. D-VRNN is similar to our work but without structured attention. We use a bidirectional LSTM with 300 hidden units as the sentence encoder and a forward LSTM for decoding. 300-dimensional word embeddings are initialized with GloVe word embedding (Pennington et al., 2014). A dropout rate of 0.5 is adopted during training. We set the BOW-loss weight λ to be 0.5. The whole network is trained with the Adam optimizer with a learning rate of 0.001 on GTX Titan X GPUs for 60 epochs. The training takes on average 11.2 hours to finish.

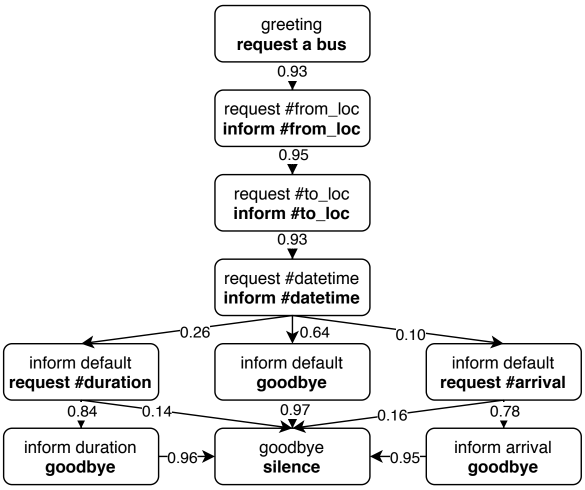

Figure 4: Learned semantic structure of SimDial bus domain (Zhao and Eskenazi, 2018). User intents are marked in bold. Transitions with $P < 0.1$ are omitted.

To evaluate the learned structure, we compare VRNN-LinearCRF's output in Figure 4 with the ground truth dialogue structure in Figure 1. A dialogue structure learned by VRNN without structured attention is also shown in the Appendix. We find our method generates similar structure compared to ground truth in the bus domain. Figure 5 shows all models' quantitative results. Having a lower value in SED and SCE indicates the learned structure is closer to the ground truth and better. Our method with BERT, VRNN-LinearCRF-BERT performs the best. K-means clustering performs worse than VRNN-based models because it only considers utterances' surface format and ignores the context information. Hidden Markov Model is similar to VRNN but lacks a continuous propagating hidden state layer. VRNN-LinearCRF observes the entire history of latent states but ignores the redundant transitions due to the structure attention. The model's performance further improves when replacing the vanilla LSTM encoder with a large scale pre-trained encoder like BERT (Devlin et al., 2019), as BERT provides better representations.

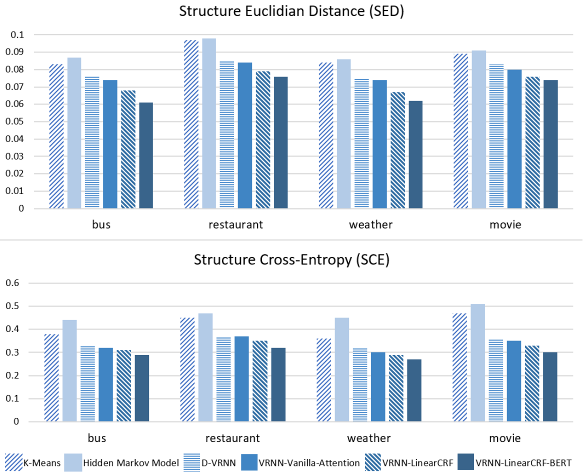

Figure 5: All models' performance in (a) Structure Euclidean Distance (SED) and (b) Structure Cross-Entropy (SCE) in four dialogue domains.

5.2 Interactive Structure Learning in Multi-party Dialogues

We extend our method to learn interactive structure in multi-party dialogues. Specifically, we detect each utterance's speaker and addressee by constructing an utterance dependency tree.

5.2.1 Datasets

We use Ubuntu Chat Corpus (Uthus and Aha, 2013) as the dataset to study interactive structure since

Model	BLEU1	BLEU2	BLEU3	BLEU4	METEOR	ROUGE$_L$
HRED	10.54	4.63	2.67	1.53	4.22	10.14
GSN No-speaker (1-iter)	9.23	3.32	1.89	1.24	3.57	8.12
GSN No-speaker (2-iter)	11.32	4.89	2.94	1.54	4.12	10.15
GSN No-speaker (3-iter)	11.42	4.81	3.11	1.87	4.51	10.29
GSN W-speaker (1-iter)	10.11	3.75	1.93	1.31	3.56	9.89
GSN W-speaker (2-iter)	11.43	4.90	2.99	1.63	4.32	10.34
GSN W-speaker (3-iter)	**11.52**	**4.93**	3.23	1.91	**4.77**	**11.21**
VRNN-Dependency-Tree	11.23	4.92	**3.24**	**1.92**	4.69	10.88

Table 2: Different methods' experiment results on Ubuntu dataset.

From	To	Utterance
p_1	p_2	I know upgrading always got hardon settings to new system..
p_3	–	And the description of the settings is even wrong
p_1	p_2	So these days i always clean install
p_2	p_1	Yeah, i think i will end up doing it
p_2	p_1	Do you happen to know if 12.10 install will let me install grub2 to partition instead of mbr without any extra tweaks?
p_1	p_2	I think default clean install will install grub2 on first section of your hd
p_4	p_2	No

Table 3: Multi-party dialogue example in Ubuntu Chat Corpus (Uthus and Aha, 2013).

it provides the ground-truth of speaker/addressee information for evaluation. Though every record of Ubuntu Chat Corpus contains clear speaker ID, only part of the data has implicit addressee ID, coming as the first word in the utterance. We select addressee ID that appeared in a limited context and extract dialogue sessions with all utterances having verified speaker ID and addressee ID. We extract 20k dialogues with length ranging from 7 to 8 turns. Table 3 shows an example dialogue.

5.2.2 Results and Analysis

Considering Ubuntu Chat Corpus have a large number of technical terminologies, we use a relatively larger vocabulary size of 30k. We use LSTMs and BERT as the sentence embedding encoder and two GRU (Chung et al., 2014) layers with 300 hidden units each as the decoder. The model converges after 100 epochs on GTX Titan X GPUs. The training procedure takes about 54 hours.

To evaluate the learned utterance dependency tree, we compare it with the annotated speaker-addressee relation and find 68.5% utterances are assigned the correct parents. This is a reasonable number because the dependency relationship does not fully rely on the speaker/addressee information in a chatroom. A different interlocutor could answer others' questions even when the questions were not addressed to him/her. Figure 2 visualizes the learned interactive structure from the example in Table 3. Specifically, utterance 4 largely depends on utterance 3, while utterance 6 and 7 are answering the question from utterance 5.

We also compare the model's generation performance with *Hierarchical Recurrent Encoder-Decoder* (HRED) and *Graph-Structured Network* (GSN) (Hu et al., 2019). The GSN model uses the annotated speaker/addressee information to construct a dialogue graph for utterance encoding iteration. However, this is not required by our VRNN-Dependency-Tree since we generate the original dialogues while learning a dependency structure. For consistent comparison with previous work, we evaluate all models with BLEU 1 to 4, METEOR, and ROUGE$_L$ with the package in (Chen et al., 2015). All results are shown in Table 2. We observe that the proposed VRNN-Dependency-Tree model without using any speaker annotation achieves similar generation performance compared to the state-of-the-art method, GSN with speaker annotation.

6 Conclusion

This paper proposed to inject structured attention into variational recurrent neural network models for unsupervised dialogue structure learning. We explored two different structure inductive biases: linear CRF for utterance-level semantic structure induction in two-party dialogues; and non-projective dependency tree for interactive structure learning in multi-party dialogues. Both models are proved to have a better structure learning performance over the state of the art algorithms. In the future, we will further explore how to explicitly incorporate linguistics information, such as named entities into the latent states.

Acknowledgments

We would like to thank Ziheng Xu for providing scripts to process dialogue datasets. We also thank the outstanding reviewers for their helpful comments to improve our manuscript.

Abstract

In the past few years, audiences from different fields witness the achievements of sequence-to-sequence models (e.g., LSTM+attention, Pointer Generator Networks and Transformer) to enhance dialogue content generation. While content fluency and accuracy often serve as the major indicators for model training, dialogue logics, carrying critical information for some particular domains, are often ignored. Take customer service and court debate dialogue as examples, compatible logics can be observed across different dialogue instances, and this information can provide vital evidence for utterance generation. In this paper, we propose a novel network architecture - Cross Copy Networks (**CCN**) to explore the current dialog context and similar dialogue instances' logical structure simultaneously. Experiments with two tasks, court debate and customer service content generation, proved that the proposed algorithm is superior to existing state-of-art content generation models.

1 Introduction

As an important task in Natural Language Generation **(NLG)**, dialogue generation empowers a wide spectrum of applications, such as chatbot and customer service automation. In the past few years, breakthroughs in dialogue generation technology focused on a series of sequence-to-sequence models (Sutskever et al., 2014). More recently, external knowledge is employed to enhance model performance. Wu et al. (2019); Liu et al. (2018) can assist dialogue generation by using knowledge triples. Similarly, Li et al. (2019); Rajpurkar et al. (2018); Huang et al. (2018); Reddy et al. (2019) explore document as knowledge discovery for dialogue generation, and Xia et al. (2017); Ye et al. (2020); Ghazvininejad et al. (2018); Parthasarathi and Pineau (2018) utilize unstructured knowledge to explore in the open-domain dialogue generation. However, unaffordable knowledge construction and defective domain adaptation restrict their utilization.

Copy-based generation models (Vinyals et al., 2015; Gu et al., 2016) have been widely adopted in content generation tasks and show better results compared to sequence-to-sequence models when faced with out-of-vocabulary problem. Thanks to their nature of leveraging vocabulary and context distributions for content copy, it enables to copy the aforementioned named entities (e.g., person names, locations, company names) appeared in the above context) from the upper context to improve the specificity of the generated text.

In the task of dialogue generation, we can often observe the phrases/utterance patterns across different ”similar dialogue” instances. For example, in customer service, the similar inquiries from the customers will get similar responses from the staff. It motivates us to build a model that can not only copy the content within the upper context of the target dialogue instance, but also learn the similar patterns across different similar cases of the target instance. Such external copy can be critical in some scenarios.

As shown in Figure.1, we propose two different kinds of copy mechanisms in this study: **vertical copy** context-dependent information within the target dialogue instance, and **horizontal copy** logic-dependent content across different 'Similar Cases' **(SC)**. This framework is labeled as Cross-Copy Networks **(CCN)**. As exemplar dialogue depicted, judges may repeat (horizontal copied) words, phrases or utterances from historical dialogues when those SCs sharing similar content, e.g., '*A sue B because of X and Y*'.

In order to validate the proposed model, we employ two different dialogue datasets from two orthogonal domains - *court debate* and *customer ser-*

Role	Utterance
Judge	What is the relationship between the plaintiff and the defendant ?
Plaintiff	A friend introduced to me.
Judge	What is the purpose of the defendant borrowing money ?
Plaintiff	Do business.
Judge	Who provides the loan contract ?
Plaintiff	I provided, I signed it and then signed the defendant.
Judge	Has anyone else seen this signing process ?
Plaintiff	Nobody.
	......

Role	Utterance
	......
Judge	What is the relationship between the plaintiff and the defendant ?
Plaintiff	He is my friend.
Judge	Why did defendant borrow money?
Plaintiff	The defendant said he wanted to build a brewery
Judge	How is the operation of the brewery ?
Defendant	It is under deficit, so have not money
Judge	Does the plaintiff have facts to add?
Plaintiff	No.
	......

Role	Utterance
	......
Judge	When was the debit note signed?
Plaintiff	One month after paying the defendant.
Judge	Why not sign a loan note while paying?
Plaintiff	He is my friends and we have good relationships. Later, the defendant kept making a loan.
Judge	Have you ever paid back the defendant ?
Defendant	No.
Judge	Does the plaintiff have facts to add?
Plaintiff	I don't need interest, just return the principal to me.
	......

Figure 1: An example from the court debate showing the intuition of utterance generation by leveraging its context and the information from its similar cases. We name the copy process from the context as *vertical copy* and the one copied from its neighbor cases as *horizontal copy*.

vice. We apply proposed **CCN** to both datasets for dialogue generation. Experiments show that our model achieves the best results. To sum up, our contributions are as follows:

- We propose a new end-to-end model, the Cross Copy Networks (**CCN**), which enables internal (vertical) copy from the target dialogue and external (horizontal) copy from similar cases in the dataset without employing any external resources.
- We validate the proposed model by leveraging two different datasets - court debate and customer service datasets. Experiments show that our model has achieved State-of-the-art results in both domain datasets.
- To motivate other scholars to investigate this novel but an important problem, we make the experimental datasets publicly available[1].

2 Model

In this section, we introduce the proposed model, the Cross Copy Network, which has three major components:

1. **Target Case Representation**: we obtain the target case representation with two attention distributions at the utterance layer and the dialogue layer, which contribute to the final attention distribution (Section 2.1);
2. **Similar Case Representation**: we fine-tune the pre-trained language model to obtain similar cases, and adopt the same method as the target case for encoding **SC** (Section 2.2);
3. **Cross Copy**: we learn two pointer distributions which are used to achieve internal (vertical) copy and external (horizontal) copy respectively (Section 2.3).

2.1 Target Case Representation

Given a dialogue $\mathbf{D} = \{(\mathbf{U}, \mathbf{R})^L\}$ containing L utterances, the $\mathbf{U}$ and $\mathbf{R}$ stand for utterance and role of speaker, respectively, where each utterances in the dialogue is expressed as $\mathbf{U_i} = \{w_{i1}, w_{i2}, ..., w_{il}\}$, and the l represents the length of the utterances. To distinguish **SC** and original context, we define the original context (historical dialogue) as **Target Case**.

Our encoder is shown in Figure 2. It is designed with hierarchical infrastructure consisting of three levels of components: utterance layer, dialogue layer and transformer layer.

2.1.1 Utterance Layer

In the dialogue, role information can make critical contribution to the task of dialogue generation, and different roles may not share consistent lexical spaces. For role information $\mathbf{R_i}$, we utilize a 100-dimensional vector to represent different roles which is randomly initialized, and updated via back propagation.

---

[1] https://github.com/jichangzhen/CCN

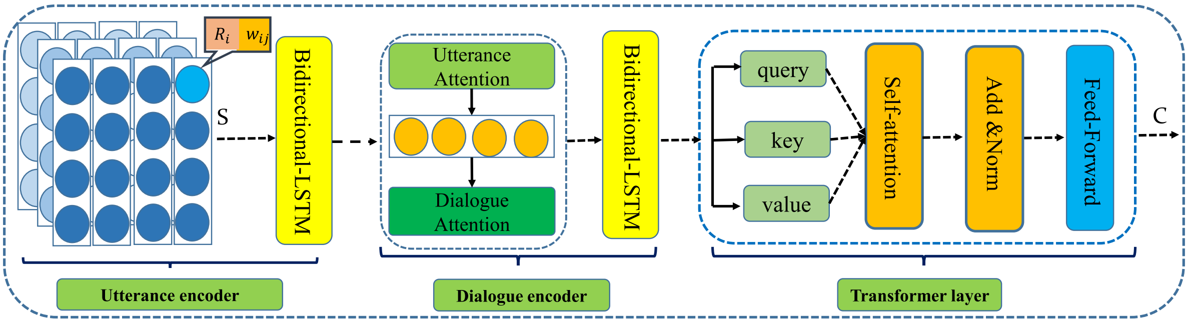

Figure 2: The encoder of **CCN** is divided into three levels: (1) **Utterance layer**: is used to encode role information and word level information; (2) **Dialogue layer**: is used to encode sentence level information; (3) **Transformer layer**: is used to capture long distance dependence for dialogue.

To take the role information into consideration for utterance representation learning, we concatenate the role information with each word of utterance expressed as $\mathbf{S_{ij}}$, and we use Bidirectional Long-Short Term Memory networks **(Bi-LSTM)** (Hochreiter and Schmidhuber, 1997) to encode the semantics of the utterance while maintaining its syntactic be expressed as $\mathbf{h^d}$.

In order to obtain the different importance of different historical dialogue information, we adopt the attention mechanism (Bahdanau et al., 2014) to obtain the utterance level's attention distribution in historical dialogue a_j^u and utterance context $\mathbf{h_i^U}$:

$$\mathbf{h_i^U} = \sum_{j=1}^{l} a_j^u \mathbf{h_{ij}^d} \tag{1}$$

$$a_j^u = \frac{exp(tanh(W^u \mathbf{h_{ij}^d} + b^u)^{\mathrm{T}} \mathbf{h_{ij}^d})}{\sum_{j=1}^{l} exp(tanh(W^u \mathbf{h_{ij}^d} + b^u)^{\mathrm{T}} \mathbf{h_{ij}^d})} \tag{2}$$

The a_j^u represents the word probability distribution for the target utterance[2].

2.1.2 Dialogue Layer

In order to represent the context information of the dialogue, we also use **Bi-LSTM** to encode the utterance dependency to obtain a global representation of an utterance as dialogue, denoted as $\mathbf{h^D}$.

We obtain the dialogue layer attention distribution a_i^d, which is a probability distribution over the prior utterances in the target dialogue. The a_i^d can be expressed as:

$$a_i^d = \frac{exp(tanh(W^d \mathbf{h_i^D} + b^d)^{\mathrm{T}} \mathbf{h_i^D})}{\sum_{i=1}^{L} exp(tanh(W^d \mathbf{h_i^D} + b^d)^{\mathrm{T}} \mathbf{h_i^D})} \tag{3}$$

The final context attention distribution A^d of target case can be expressed as the product of a_j^u and a_i^d:

$$A^d = a_j^u * a_i^d \tag{4}$$

2.1.3 Transformer Layer

To expand the model's ability to focus on different locations of long context, we adopt the self-attention with multi-heads (Vaswani et al., 2017) to explore an enhance representation, denoted as Transformer-Block. We feed $\mathbf{h^D}$ to a N-layer Transformer-Block to suppress the long distance dependency for dialogue. Following this strategy, the final target case representation is:

$$\mathbf{C^d} = \mathbf{Transformer^N}(\mathbf{h^D}) \tag{5}$$

2.2 Similar Case Representation

In this section, we introduce the approach of obtaining and representing similar cases.

2.2.1 Similar Case Finding

The similar cases (**SC**s) of the target case is discovered from the same dataset where the target case stays. To make it more efficient, we use ElasticSearch[3] to retrieve top 50 similar cases as candidates by leveraging the target case as a query and the all the other cases as documents. To make it more effective, we fine-tune the pre-trained **RoBERTa**[4] (Liu et al., 2019b) model. It uses a linear layer with sigmoid activation function on top of the pooled [CLS] representation from the

---

[2] The W^u and b^u are learnable parameters, the $tanh$ is hyperbolic tangent function.

[3] `https://www.elastic.co/products/elasticsearch`

[4] All the dialogues in the dataset are used to fine-tune RoBERTa. The average lengths of the candidate cases and the target case are both 106, so it can all fit within the RoBERTa model

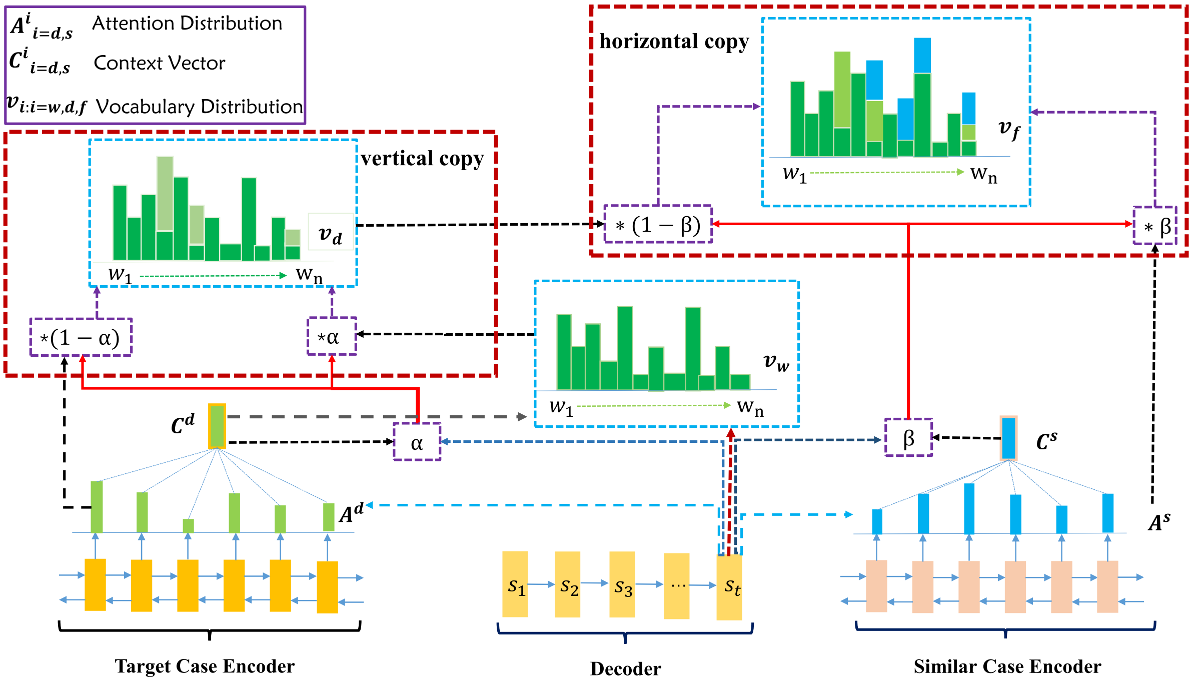

Figure 3: The decoder of **CCN** learns two pointer distribution to extend the original vocabulary twice. It learns the pointer distribution α to obtain the content to be copied from the context (vertical copy) as well as the pointer distribution β to determine the content to be copied from its similar cases (horizontal copy).

concatenation of the target case and each candidate retrieved above as a binary classifier, to obtain similarity score.

2.2.2 Similar Case Encoding

For **SC** encoding, we adopt the same method as the target case[5]. We fuse role information with each word of utterance in the **SC** and then use **Bi_LSTM** to obtain hidden state $\mathbf{h^s}$. Next, we adopt the attention mechanism to obtain the utterance layer distribution and dialogue layer distribution.

Therefore, we obtain attention distribution for different words a_j^{u*} of each utterance and different utterances a_i^{d*} of each **SC**. Then, we get final attention distribution A^s which can be expressed as the product of a_j^{u*} and a_i^{d*}.

Finally, we use the N-layer transformer-block to obtain the final **SC** representation $\mathbf{C^s}$.

2.3 Cross Copy

In this section, we learn two pointers distribution and to achieve internal (vertical) copy and external (horizontal) copy. The decoder's structure shown as Figure 3.

On the time step t, we concatenate target case context vector $\mathbf{C_t^d}$ with decoder states $\mathbf{s_t}$ to get the distribution of the current vocabulary:

$$v_w = softmax(W^v(W^w[\mathbf{C_t^d}, \mathbf{s_t}]+b^w)+b^v) \quad (6)$$

where the W^w, b^w, W^v and b^v are learnable parameters.

For the cross copy, the algorithm execution process is divided into two stages.

At the first stage, we perform **vertical copy**. With the target case encoder hidden state $\mathbf{h^d}$, context vector $\mathbf{C^d}$, and decoder hidden states $\mathbf{s}$ as mentioned above, on the time step t, we can learn **vertical copy** probability distribution α, it determines whether to copy the words from the historical dialogue. It can be expressed as Eq.7:

$$\alpha = \sigma(W^h * \mathbf{h_t^d} + W^c * \mathbf{C^d}_t + W^s * \mathbf{s_t} + b^d) \quad (7)$$

Combined with the attention distribution A^d, we can get the dynamic extended vocabulary v_d by pointer distribution α:

$$v_d = \alpha * v_w + (1-\alpha) * \sum_{i:w_i=w}^{l*L} A^d \qquad (8)$$

In the second stage, we learn the **horizontal copy** probability distribution β of **SC**. For **SC** context vector $\mathbf{C^s}$ and hidden state $\mathbf{h^s}$, on the time step

---

[5] We use two identical encoders to encode target case and similar case, while two encoders' parameters are not shared

Table 1: Statistics of the CDD and JDDC

Dataset	CCD		JDDC	
	Dialogue	Utterance	Dialogue	Utterance
train	208,152	2,869,794	261,282	3,135,377
dev	26,018	364,345	32,660	391,983
test	26,020	371,554	32,661	391,480
Total	**260,190**	**3,605,693**	**326,603**	**3,918,840**

t, we combine decoder hidden state $\mathbf{s}$, to get the **horizontal copy** pointer distribution β:

$$\beta = \sigma(W^{h*} * \mathbf{h_t^s} + W^{c*} * \mathbf{C_t^s} + W^{s*} * \mathbf{s_t} + b^s) \quad (9)$$

From the encoder, we get the attention distribution A^s of **SC**, we then perform a second expansion of the dynamic vocabulary to obtain the final vocabulary v_f:

$$v_f = (1 - \beta) * v_d + \beta * \sum_{i:w_i=w}^{l*L} A^s \qquad (10)$$

It should be noted, if w is not in original vocabulary but in **SC**, the β is 1. Model will copy the w from **SC**. One of the advantages of our model is that it can produce out-of-vocabulary word.

In the formula above, the σ is sigmoid function. The W^h, W^c, W^s, b^d,W^{h*}, W^{c*}, W^{s*} and b^s are learnable parameters.

2.4 Loss function

In this dialogue generation task, for each dialogue $\mathbf{D}$, the loss function is defined as:

$$\begin{aligned} loss &= -\log P(\mathbf{S} \mid \mathbf{D}) \\ &= -\sum_{j=1}^{l} \log P(w_{ij} \mid w_{i1:j-1}, \mathbf{D}) \end{aligned}$$

Denoting all the parameters in our model as δ, then we obtain the following optimized objective function:

$$\min_{\theta} loss = loss + \lambda \left\|\delta\right\|_2^2 \qquad (11)$$

To minimize the objective function, we use the diagonal variant of Adam (Zeiler, 2012).

3 Experimental Settings

3.1 Dataset

We employed two datasets for the experiment, Court Debate Dataset **(CDD)** from judicial field and Jing Dong Dialogue Corpus **(JDDC)** (Chen et al., 2019) from e-commerce field. The details of the dataset are illustrated in Table 1. During training, the data is divided into the training set, development set and test set[6].

3.1.1 Court Debate Dataset

For **CDD**, we collected $121,016$ court debate records of private lending dispute civil cases[7]. We take the judge and the historical conversation with the plaintiff and the defendant as the model input, and the judge's utterance as the model output. These records are divided into $260,190$ pairs of samples by experts with legal knowledge.

3.1.2 Jing Dong Dialogue Corpus

Jing Dong Dialogue Corpus **(JDDC)**[8] contains $1,024,196$ multi-turn dialogues, $20,451,337$ utterances, and 150 million words. The average number of tokens contained in per sentence is about 7.4. In the experiments, we adopted the top $326,603$ cases. The proposed algorithm and baselines are set to generate the utterances of the customer service, and the historical context between the customer service and the customer is set as input.

3.2 Evaluation Metrics

We adopt two evaluation methods to validate the proposed model: Automatic Evaluation and Human Evaluation.

3.2.1 Automatic Evaluation

To evaluate the effectiveness of the dialogue generated by **CCN**, we used ROUGE (Lin and Hovy, 2003) and BLEU (Papineni et al., 2002) scores to compare different models. We report ROUGE-1, ROUGE-L and BLEU to compare the advantages and disadvantages of each model.

3.2.2 Human Evaluation

In order to ensure the rationality/correctness of the generated utterance, we also conducted human evaluation. We randomly selected 300 samples from the test set. Then, we recruited five annotators[9] to judge the quality of generated utterance from two perspectives: (Ke et al., 2018; Zhu et al., 2019):

---

[6] The entire dataset is divided by a ratio of 8:1:1 for training, developing and testing, respectively.

[7] Private lending dispute cases are the most frequent cause of civil cases in China. This data set is provided by the High People's Court of a province in China. All the court transcripts are manually recorded by the court clerk.

[8] `http://jddc.jd.com/auth_environment`

[9] All annotators took basic annotation training before the experiment.

Table 2: Quantitative Evaluation. We report ROUGE-1, ROUGE-L and BLEU scores for each tested methods.

Table 3: Qualitative Evaluation. We report average score (Avg) and calculate the κ value in relevance and fluency. We recruited five annotators to evaluate the sentences generated by all the models. To be fair, for each input, we shuffled the output generated by all the models and then let the annotator to evaluate. The κ represents the consistency of evaluation by different annotators. And the κ coefficient between 0.48 and 0.82 means middle and upper agreement.

model	CCD				JDDC			
	Relevance		Fluency		Relevance		Fluency	
	Avg	κ	Avg	κ	Avg	κ	Avg	κ
LSTM(Hochreiter and Schmidhuber, 1997)	0.54	0.48	0.93	0.61	0.53	0.52	1.09	0.59
ByteNet(Gehring et al., 2017)	0.63	0.62	1.01	0.71	0.59	0.55	1.19	0.67

CCN$_{top-3}$	**1.12**	0.66	**1.69**	0.68	0.98	0.63	1.73	0.67

- **Relevance**: Generated utterance is logically relevant to the dialogue context and can provide meaningful information.
- **Fluency**: Generated utterance is fluent and grammatical.

The information on these two aspects are independently evaluated. For each aspect, we set three levels with scores: +2, +1, 0, in which 2 stands for excellent: for relevance, closely related to historical dialogue and be meaningful; for fluency, it has strong readability without grammatical error. 1 stands for good: for relevance, with some off-topic information; for fluency, sentence is readable, but with slight grammatical error. 0 means poor: for relevance, the sentence is off-topic or meaningless; for fluency, sentence has poor readability or serious grammatical errors. Finally, we obtain the weighted average score and kappa (κ) of each model to compare the effect of the model.

3.3 Training Details

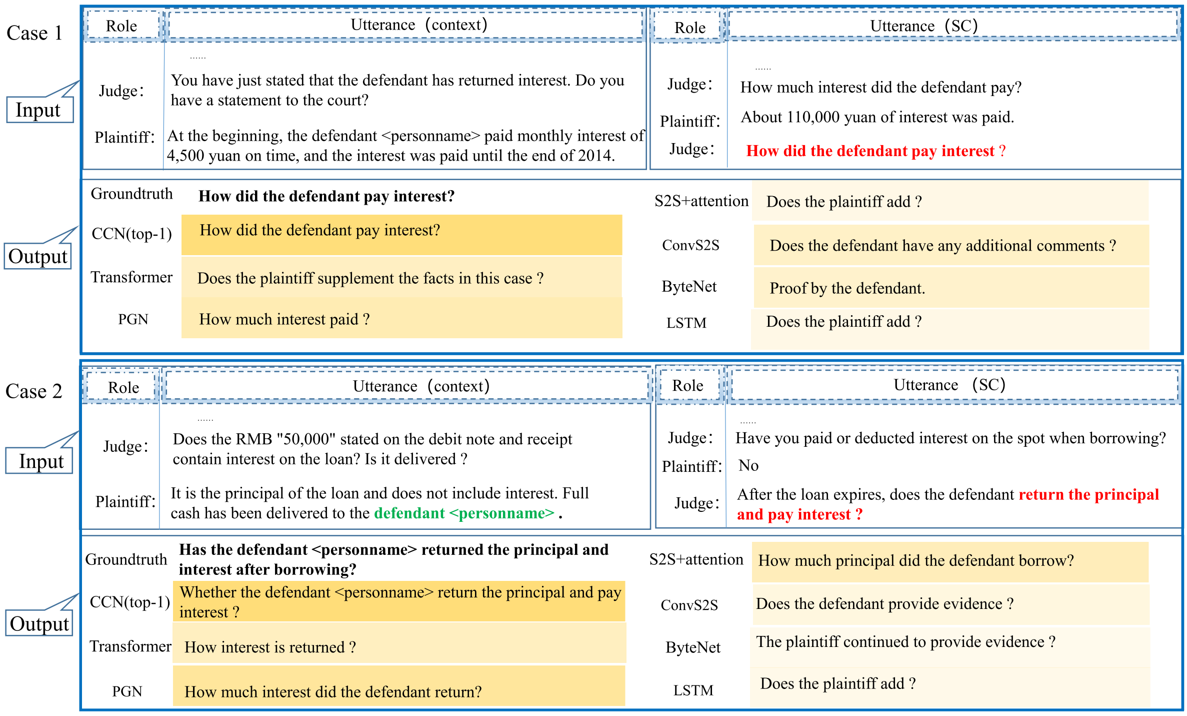
During the training process, we set the dimension of word embedding as 300 and use word2vec to build the initialization word vector. The dimention of role embedding is set to 100 with random initialization. The hidden size is set to 300, we use 4 layer Transformer, where the number of heads equals to 8. The dropout probability is set to 0.8. Based on these settings, we optimize the objective function with a learning rate of $5e-4$. We perform the mini-batch gradient descent with a batch size of 64. We set maximum utterance length as 40 in decoder during generation (the generated sentence might contain sub-utterances).

4 Result discussion

4.1 Overall Performance

In the experiments, we select up to three similar cases to validate the effectiveness of the CCN, i.e., leveraging the most similar case **(top-1)**, top two similar ones **(top-2)**, and top three similar ones **(top-3)**. In addition, we also test the variant of **CCN(vertical-only)** by only adopting vertical copy from the context, which is similar to the setting of the baseline **PGN** but with the proposed hierarchical dialogue encoders.

The performance of all the tested methods are reported in Table 2 and Table 3 in terms of quanti-



Case 1

Input

Role	Utterance (context)
	......
Judge:	You have just stated that the defendant has returned interest. Do you have a statement to the court?
Plaintiff:	At the beginning, the defendant <personname> paid monthly interest of 4,500 yuan on time, and the interest was paid until the end of 2014.

Role	Utterance (SC)
	......
Judge:	How much interest did the defendant pay?
Plaintiff:	About 110,000 yuan of interest was paid.
Judge:	**How did the defendant pay interest ?**

Output

Groundtruth	**How did the defendant pay interest?**
CCN(top-1)	How did the defendant pay interest?
Transformer	Does the plaintiff supplement the facts in this case ?
PGN	How much interest paid ?
S2S+attention	Does the plaintiff add ?
ConvS2S	Does the defendant have any additional comments ?
ByteNet	Proof by the defendant.
LSTM	Does the plaintiff add ?

Case 2

Input

Role	Utterance (context)
	......
Judge:	Does the RMB "50,000" stated on the debit note and receipt contain interest on the loan? Is it delivered ?
Plaintiff:	It is the principal of the loan and does not include interest. Full cash has been delivered to the **defendant <personname>** .

Role	Utterance (SC)
	......
Judge:	Have you paid or deducted interest on the spot when borrowing?
Plaintiff:	No
Judge:	After the loan expires, does the defendant **return the principal and pay interest ?**

Output

Groundtruth	**Has the defendant <personname> returned the principal and interest after borrowing?**
CCN(top-1)	Whether the defendant <personname> return the principal and pay interest ?
Transformer	How interest is returned ?
PGN	How much interest did the defendant return?
S2S+attention	How much principal did the defendant borrow?
ConvS2S	Does the defendant provide evidence ?
ByteNet	The plaintiff continued to provide evidence ?
LSTM	Does the plaintiff add ?

Figure 4: Case Study. We show two examples to intuitively illustrate the performance of all the tested models. The content in SC is the top 1 similar case used by our proposed method CCN. Note that the color indicates the BLEU score of each generated output. The darker the color, the higher the BLEU score is.

tative and qualitative evaluation, respectively. As Table 2 shows, the proposed approach **CCN** with its variants outperform all the baselines in Rouge and Bleu metrics over the two datasets. We can also observe the increasing performance as the number of referred similar cases increases. As for the two qualitative criteria, **CCN** also shows better performance by a big margin compared to the baselines. Note that the Kappa value (κ) indicates the agreement among the annotators.

As mentioned above, the increasing number of referred similar cases enables to bring about the improvement of performance, which demonstrates that the horizontal copy plays a critical role in dialogue generation without employing any external resources. However, in the training process, as the number of similar cases increases, the training speed is getting slower. Considering the time cost and memory limitation, only up to top three similar cases are utilized in this experiment to verify the proposed approach.

4.2 Case study

Figure 4 shows two examples to illustrate the performance of different tested methods. As depicted in case 1, comparing with the baselines, the **CCN** can learn dialogue logic from **SC**s and accurately locate the sentence to complete the horizontal copy. Another important finding is that we can use **SC**s to obtain more accurate representation information. It can identify specific entities from the context for vertical copy while capturing the discourse patterns from the similar cases for horizontal copy to finally synthesize the sentence to be generated.

On the other hand, the baseline models are more inclined to generate general expressions which appear more frequent in the training data without much attention to the specific information in the context and the logical discourse patterns appearing in certain circumstances.

4.3 Error analysis

In order to explore the algorithm limitation and model capability boundary, we summarize the samples with high error rate. The following observations should be highlighted to scope the limitation of current model and enlighten future investigation for this track of research.

In the **CDD**, 53% of errors[10] occur when generated sentence contains the information that does not appear in context or in similar cases (e.g., "According to the provisions of Articles 44 and 45 of

---

[10] the error refers to the generated text whose either relevance or fluency score equals 0.

the Civil Procedure Law of the People's Republic of China, if the parties find that the members of the collegiate bench and the clerk experienced any of the following circumstances, they have the right to apply for their evasion orally or in writing."). Similarly in **JDDC**, such problem caused 47% of errors (e.g., "Sorry, we cannot refund you with the product [#price, #style, #brand, #specification, #color] you required."). Such kind of law/product related information might need to leverage external expert knowledge. In addition, 23% and 36% of errors occur in **CDD** and **JDDC** respectively, when it comes to the long sentence to be generated (e.g., the sentence length is more than 30 words for the judge's inquiry or for customer service response).

To address these problems in the future research, enhancing the long dependence of language models and establishing relations between different entities can be promising approaches.

5 Related work

5.1 Pointer Network

Pointer network (Vinyals et al., 2015) is a special network structure. It solved the problem of generating sequence depending on the input sequence. Based on this basis, CopyNet (Gu et al., 2016) and PGN (See et al., 2017) were proposed, which can copy the words in the context and form output sequence to cope with Out-Of-Vocabulary (**OOV**) problem. Nowadays, pointer networks are increasingly popular in NLP applications. In text summarization, Miao and Blunsom (2016) used it to select only suitable words from context instead of the entire dictionary for sentence compression; Nallapati et al. (2016) used it to speed up model convergence; Sun et al. (2018) used it to generate text title; Wang et al. (2019a) generated new conceptual words; Eric and Manning (2017) used it to develop a recurrent neural dialogue system; Shen et al. (2019) used it to enhance power of capturing richer latent alignment. It was also widely used in many other tasks, such as dependency parsing (Fernández-González, 2019; Liu et al., 2019a), question answering (Kadlec et al., 2016; Golchha et al., 2019), machine reading comprehension (Wang and Jiang; Wang et al., 2017), machine translation (Gulcehre et al., 2016), and language models (Merity et al., 2016).

Unlike previous studies, on the basis of internal copy, we introduce external copy, to establish a cross-copy structure, and achieve significant improvement.

5.2 Dialogue System

As an important task of NLP, dialogue system, has achieved great success and is widely used in practical applications, including customer service systems and chatbots. In recent years, with the development of deep learning technology, the neural network model has made significant progress: Su et al. (2019) solved the problem of information omitting and quoting in multiple rounds of dialogue by rewriting sentences; Lu et al. (2019) solved the problem of selecting the reply sentence in the dialogue system by adding features of time sequence and space; Du and Black (2019) solved the problem of lack of diversity in replies by using the dichotomy function to judge whether the two responses are similar.

There exist a number of prior studies to assist the task of dialogue generation through external knowledge: Wu et al. (2019); Liu et al. (2018) leveraged the structured knowledge triples to assist dialogue generation. Similarly, Li et al. (2019); Rajpurkar et al. (2018); Huang et al. (2018); Reddy et al. (2019) used documents as knowledge discovery for dialogue generation, and Xia et al. (2017); Ye et al. (2020); Ghazvininejad et al. (2018); Parthasarathi and Pineau (2018) utilized unstructured knowledge to explore in the open-domain dialogue generation.

With the deepening of dialogue generation, various new tasks have been proposed: Le et al. (2019) generated the most appropriate response by given video content, video title, and existing dialogue sentences; Tang et al. (2019) introduced how to lead the conversation to a specific goal in an open conversation; Wang et al. (2019b) introduced how to use different persuasion strategies in the dialogue to persuade people to donate to charities; Cao et al. (2019) were concerned about the application of dialogue analysis in the psychotherapy.

In our model, the **CCN** approaches to solve the problem of defective domain adaptation without any costly external knowledge.

6 Conclusion and Outlook

In this paper, we proposed a novel neural network structure-Cross Copy Networks, enabling both vertical copy (from dialogue context) and horizontal copy (from similar cases). Unlike prior models, the proposed CCN doesn't need additional knowledge input, and it can be easily adopted to other domains. We conduct experiments on two different datasets with both quantitative and human evaluation to validate the proposed model. Experimental results proved CCN's superiority when comparing with a number of existing state-of-art text generation models, which tells the cross copy mechanism can successfully enhance the dialogue generation performance.

In future work, we will further investigate other content generation problems by leveraging multi-granularity copying mechanism. This study serves as the methodological foundation.

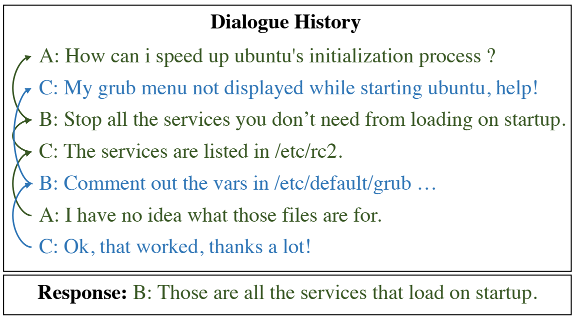
Abstract

Multi-turn response selection is a task designed for developing dialogue agents. The performance on this task has a remarkable improvement with pre-trained language models. However, these models simply concatenate the turns in dialogue history as the input and largely ignore the dependencies between the turns. In this paper, we propose a dialogue extraction algorithm to transform a dialogue history into threads based on their dependency relations. Each thread can be regarded as a self-contained sub-dialogue. We also propose Thread-Encoder model to encode threads and candidates into compact representations by pre-trained Transformers and finally get the matching score through an attention layer. The experiments show that dependency relations are helpful for dialogue context understanding, and our model outperforms the state-of-the-art baselines on both DSTC7 and DSTC8*, with competitive results on UbuntuV2.

1 Introduction

Dialogue system is an important interface between machine and human. An intelligent dialogue agent is not only required to give the appropriate response based on the current utterance from the user, but also consider the dialogue history. Dialogue context modeling has been a key point for developing such dialogue systems, including researches on state tracking (Eric et al., 2019; Ren et al., 2019), topic segmentation (Nan et al., 2019; Kim, 2019), multi-turn response selection (Tao et al., 2019; Gu et al., 2019), next utterance generation (Zhang et al., 2019; Chen et al., 2019), etc. In this paper, we target on the multi-turn response selection task, which is first proposed by Lowe et al. (2015) and is also a track in both DSTC7 (Gunasekara et al., 2019) and DSTC8 (Kim et al., 2019).



Dialogue History

A: How can i speed up ubuntu's initialization process ?

C: My grub menu not displayed while starting ubuntu, help!

B: Stop all the services you don't need from loading on startup.

C: The services are listed in /etc/rc2.

B: Comment out the vars in /etc/default/grub ...

A: I have no idea what those files are for.

C: Ok, that worked, thanks a lot!

Response: B: Those are all the services that load on startup.

Figure 1: An example of the tangled dialogue history. A, B and C are three participants. Texts in different colors represent different dialogue threads.

Given a dialogue history made up of more than one utterance, the selection task is to choose the most possible next utterance from a set of candidate responses. Previous work on this task can be roughly divided into two categories: sequential models and hierarchical models. The former ones, including (Lowe et al., 2015; Yan et al., 2016; Chen and Wang, 2019), concatenate the history utterances into a long sequence, try to capture the similarities between this sequence and the response and give a matching score. The latter ones, including (Tao et al., 2019; Wang et al., 2019; Gu et al., 2019), extract similarities between each history utterance and the response first. Then, the matching information is aggregated from each pair (mostly in a chronological way) to get a final score. There is little difference between the performance of these two kinds of architectures until the emergence of large pre-trained language models.

Work such as (Whang et al., 2019; Vig and Ramea, 2019) has shown the extraordinary performance of the pre-trained language models on dialogues. These pre-trained models are easily transferred to the response selection task by concatenating all of the utterances as the input. All of

the words in dialogue history can directly interact with each other via transformers like Bi-encoder, even the words both in the dialogue history and the candidate response if time permits, such as Cross-encoder (Humeau et al., 2019). However, since such models can be regarded as the ultimate architecture of the sequential-based models, the dialogue dependency information between the utterances is largely ignored due to the concatenation operation (Wu et al., 2017). An example is shown in Figure 1. The dependency relations can definitely help us to understand the two tangled dialogue threads. Besides, we always need to truncate the earlier dialogue history to limit the size of the model and make the computation efficient. However, it isn't always that the nearest utterances are more important. As we can see in Figure 1, several dialogue threads may be tangled especially in multi-party chat rooms, it's hard to tell which dialogue thread will be moving on.

In this paper, we propose to incorporate dialogue dependency information into the response selection task. We train a dialogue dependency parser to find the most probable parent utterance for each utterance in a session. We name such relation between utterances as "reply-to". Then, we empirically design an algorithm to extract dialogue threads, which is represented by a path of dependency relations according to the parsed trees. The extracted threads are sorted by the distance between the final utterance in each thread and the response in ascending order, following the intuition that the closer utterances are more relevant. After that, we propose the model named Thread-Encoder based on a pre-trained language model. Each encoder in the model can distill the critical information from each dialogue thread or the candidate response. Finally, another attention layer is used to calculate the matching score with thread representations and the candidate representation. The candidate with the highest matching score will be selected as the final response.

We collect the training data for dialogue dependency parser from a dialogue disentanglement dataset (Kummerfeld et al., 2019) in the technical domain. And we do response selection experiments among UbuntuV2, DSTC7 and DSTC8*. These datasets consist of dialogues in the same domain but under different settings, including two-party dialogues and multi-party dialogues. The results demonstrate our model's strong capability to represent multi-turn dialogues on all of these datasets.

Our main contributions are as follows:

- As far as we know, we are the first to incorporate dialogue dependency information into response selection task, demonstrating that the dependency relations in the dialogue history are useful in predicting dialogue responses (Sec 5).
- Based on the predicted dependencies, we design a straight-forward but effective algorithm to extract several threads from the dialogue history (Sec 2.1). The results show the algorithm is better than other simple segmentation methods on the response selection task.
- We propose the Thread-Encoder model, incorporating dialogue dependency information by threads and utilizing the pre-trained language model to generate corresponding representations (Sec 2.2). The experimental results show that our model outperforms the state-of-the-art baselines on DSTC7 and DSTC8* datasets, and is very competitive on UbuntuV2 (Sec 4).

2 Approach

The multi-turn response selection tasks represent each dialogue as a triple $T = \langle C, R, L \rangle$, where $C = \{t_1, t_2, ..., t_n\}$ represents the history turns. R is a candidate response and L is the $0/1$ label indicating whether R is the correct response or a negative candidate. To incorporate the dependency information between the history turns, we design a straight-forward algorithm to extract the dialogue history C into dialogues threads $\langle C_1, C_2, ..., C_M \rangle$ based on the predicted dependencies, along with an elaborately designed model to find the function $f(C_1, C_2, ..., C_M, R)$, which measures the matching score of each (C, R) pair. Both the extraction algorithm and the model will be explained as follows.

2.1 Dialogue Extraction Algorithm

Since it's impossible for the large pre-trained language models to take all of the dialogue history turns as the input under the computational power nowadays, these models usually set a truncate window and only consider the top-k most recent turns or tokens. However, several dialogue threads may exist concurrently in two-party (Du et al., 2017) or multi-party dialogues (Tan et al., 2019). Such coarse-grained truncating operation may not only bring in redundant turns from other dialogue threads, but also exclude the expected turns given earlier in the current dialogue thread, hurting the representation capability of pre-trained language models. Extracting the whole history into self-contained dialogue threads can help preserve more relevant turns and avoid the negative effects of encoding irrelevant turns by a single language model.

Motivated by the above, we aim to analyze the discourse structures in dialogue history at first. We utilize the discourse dependency parsing model for dialogues proposed by Shi and Huang (2019). It is a deep sequential model that achieves the state-of-the-art performance on the STAC corpus. Instead of predicting the predefined relation types between Elementary Discourse Units(EDUs), we borrow the proposed model in this work to find if there exist dependency relations between utterances in the given dialogue history. The model scans through the dialogue history and predicts the most likely parent turn for each turn. It finally constructs a dependency tree for each dialogue history with a confidence score on each edge.

Algorithm 1: The Dialogue Extraction Algorithm

```
Input  : The dependency tree $T$ with confidence scores on each edge
         $e_{ji} = (t_i, t_j, P_{ji})$, where $i.j = 1, 2, ..., n$ and $j > i$;
         The threshold for the confidence score $P$.
Output : The threads $C' = \langle C_1, C_2, ..., C_M \rangle$, and each is made up
         of a sequence of turns.
for $e_{ji}$ in $T$ do
    if $P_{ji} < P$ then
        delete $e_{ji}$ from $T$
    end
end
The forest $T' = T$
The set of threads $C' = \emptyset$
for each leaf node in $T'$ do
    $C_{tmp}$ = all the node from the leaf node to the corresponding
    root.
    $C' = C' \cup C_{tmp}$
end
Rank the threads in $C'$ based on the index of the leaf node in
descending order.
```

Then, the dialogue extraction algorithm is designed to extract original long history into dialogue threads according to dependency tree T and confidence scores. The algorithm is depicted in Algorithm 1. e_{ji} is a directed edge with head t_i and tail t_j, indicating that turn j is a reply of turn i with probability P_{ji}. The threshold P is a hyper-parameter. It is noteworthy that we still follow the intuition that the turns closer to the responses are more likely to be useful than others. As a result, the threads are returned in ascending order according to the distance between the last turns in each thread and the response. An illustration of the algorithm is shown in Figure 2. The 7-turn dialogue history is extracted into three threads.

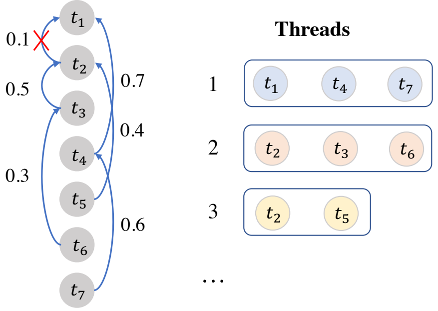

Figure 2: An example of the algorithm when the threshold $P = 0.2$. The figures are the confidence scores of corresponding predicted dependency relations.

2.2 Thread-based Encoder Model

In the work from Humeau et al. (2019), they use a pre-trained language model as the context encoder and generate the embedding for dialogue history. Inspired by this work, we also utilize pre-trained language models to encode natural texts into meaningful representations.

Given the extracted self-contained dialogue threads $\langle C_1, C_2, ..., C_M \rangle$, we utilize a pre-trained language model to encode the content of each dialogue thread in parallel and another pre-trained language model to encode the candidate respectively. If the candidate representation matches well with one or more thread representations, that candidate is probably the correct response.

The architecture of our model **Thread-Encoder** (shown in Figure 3) can be divided into two layers: Encoding Layer and Matching Layer.

2.2.1 Encoding Layer

We use the pre-trained language model released by Humeau et al. (2019). This large pre-trained Transformer model has the same architecture as BERT-base (Devlin et al., 2019). It has 12 layers, 12 attention heads and 768 hidden size. Different from the original one trained on BooksCorpus and Wikipedia, the new language model is further trained on Reddit (Henderson et al., 2019), a large dialogue dataset with around 727M context-response pairs. The pretraining tasks include masked language model and next utterance prediction [1]. Finally, the

---

[1] "Utterance" and "turn" are interchangeable in this paper.

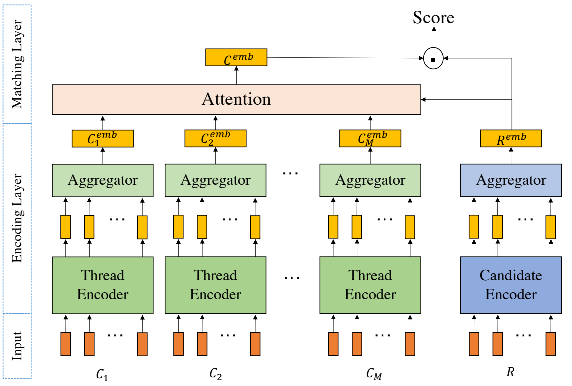

Figure 3: The architecture of Thread-Encoder model. All of the blocks in the same color share parameters.

pre-trained model can be used for a wide range of multi-sentence selection tasks with fine-tuning.

In our model, the encoder layer uses two Transformers, thread encoder $T_1(\cdot)$ and candidate encoder $T_2(\cdot)$, both initialized with the pre-trained weights. $T_1(\cdot)$ is used for encoding threads, and all of the turns in a thread are concatenated into a long sequence in reverse chronological order as the input. $T_2(\cdot)$ is used for encoding the candidate. The inputs to the Transformer encoder are surrounded by the special token $[S]$, consistent with the operations during pretraining.

Above the Transformer encoder is an aggregator $agr(\cdot)$ that aggregates a sequence of vectors produced by the encoder into one or more vectors. In a word, the threads and response can be encoded as follows:

$$\begin{aligned} C_m^{emb} &= agr_1(T_1(C_m)) \\ R^{emb} &= agr_2(T_2(R)), \end{aligned} \tag{1}$$

where $m = 1, 2, ...M$ and M is the number of dialogue threads. For $arg_1(\cdot)$, if we simply use ”average” function for the aggregator, only one representation will be encoded for each thread. We name this model as **Thread-bi**. If we use ”multi-head attention” as the aggregator, multiple representations will be encoded for each thread. We name this model as **Thread-poly**. The aggregator $agr_2(\cdot)$ for candidate representations is the average over input vectors.

2.2.2 Matching Layer

Given the encoded threads $\langle C_1^{emb}, C_2^{emb}, ..., C_M^{emb}\rangle$ and candidate R^{emb}, we further use an attention layer to distill the information from the threads by attending the query R^{emb} to each C_m^{emb}:

$$C^{emb} = \sum_{m=1}^{M} w_m C_m^{emb} \tag{2}$$

where

$$\begin{aligned} s_m &= (R^{emb})^\top \cdot C_m^{emb} \\ w_m &= \exp(s_m) / \sum_{k=1}^{M} \exp(s_k) \end{aligned} \tag{3}$$

The final matching score is given by:

$$S = F(C_1, C_2, ..., C_M, R) = (R^{emb})^\top \cdot C^{emb} \tag{4}$$

We consider the other correct responses in a mini-batch as the negative candidates to accelerate the training process (Mazaré et al., 2018). The whole model is trained to minimize the cross-entropy loss as follows:

$$loss = -\frac{1}{A}\sum_{a=1}^{A}\sum_{b=1}^{A} L_{ab}\log(S_{ab}) \tag{5}$$

where A is the batch size. L_{ab} equals 1 when $a = b$, otherwise 0. S_{ab} is the matching score in Eq. 4.

3 Experimental Setup

In this section, we introduce the datasets, baselines and implementation details of our model[2].

3.1 Datasets

Our experiments are performed on three datasets: UbuntuV2, DSTC 7 and DSTC 8*.

- **UbuntuV2** (Lowe et al., 2017) consists of two-party dialogues extracted from the Ubuntu chat logs.
- **DSCT7** (Gunasekara et al., 2019) refers to the dataset for DSTC7 subtask1 consisting of two-party dialogues.
- **DSCT8*** refers to the dataset for DSTC8 subtask 2, containing dialogues between multiple parties. We remove the samples without correct responses in the given candidate sets [3].

More details of these three datasets are in Table 1.

---

[2] The codes and data resources can be found in https://github.com/JiaQiSJTU/ResponseSelection.

[3] We do this to eliminate the controversy of solving no correct response in different ways and try to focus on dialogue context modeling.

	UbuntuV2	DSTC7	DSTC8*
Train	957,101	100,000	89,813
Valid	19,560	5,000	7,660
Test	18,920	1,000	7,174
#Candidates	10	10	100
#Correct Response	1	1	1
#Turns	3-19	3-75	1-99

Table 1: The statistics of the datasets used in this paper.

3.2 Baselines

We introduce several state-of-the-art baselines to compare with our results as follows.

- **DAM** (Zhou et al., 2018) is a hierarchical model based entirely on self and cross attention mechanisms.
- **ESIM-18** (Dong and Huang, 2018) and **ESIM-19** (Chen and Wang, 2019) are two sequential models, which are the modifications and extensions of the original ESIM (Chen et al., 2017) developed for natural language inference. The latter one ranked top on DSTC7.
- **IMN** (Gu et al., 2019) is a hybrid model with sequential characteristics at matching layer and hierarchical characteristics at aggregation layer.
- **Bi-Encoder** (Bi-Enc), **Poly-Encoder** (Poly-Enc) and **Cross-Encoder** (Cross-Enc) (Humeau et al., 2019) are the state-of-the-art models based on pre-trained model.

3.3 Implementation Details

According to Section 2.1, we firstly transform the dialogue disentanglement dataset (Kummerfeld et al., 2019). Turns are clustered if there exists a “reply-to” edge, and we obtain 4,444 training dialogues from the original training set and 480 test dialogues from the original valid set and test set. Only 7.3% of turns have multiple parents. Since the parsing model can only deal with dependency structure with a single parent, we reserve the dependency relation with the nearest parent in these cases. We trained a new parser on this new dataset. The results on the new test set are shown in Table 2. It shows that in-domain data are useful for enhancing the results for dialogue dependency prediction.

	Precision	Recall	F1
Trained on STAC	67.37	64.43	65.86
Trained on the new dataset	71.44	68.32	69.85

Table 2: The results of the dialogue dependency parser.

For the response selection task, we implemented our experiments based on ParlAI [4]. Our model is trained with Adamax optimizer. The initial learning rate and learning rate decay are $5e{-}5$ and 0.4 respectively. The candidate responses are truncated at 72 tokens, covering more than 99% of them. The last 360 tokens in the concatenated sequence of each thread are reserved. The BPE tokenizer was used. We set the batch size as 32. The model is evaluated on valid set every 0.5 epoch. The training process terminates when the learning rate is 0 or the hits@1 on validation no longer increases within 1.5 epochs. The threshold in the Algorithm 1 is set to 0.2 and we preserve at most top-4 threads for each sample, avoiding the meaningless single turns while ensuring the coverage of original dialogue contexts. The results are averaged over three runs. For UbuntuV2 and DSTC7 training set, we do data augmentation: each utterance of a sample can be regarded as a potential response and the utterances in the front can be regarded as the corresponding dialogue context.

Our experiments were carried out on 1 to 4 Nvidia Telsa V100 32G GPU cards. The evaluation metrics for response selection are hits@k and MRR, which are widely used and the codes can be found in ParlAI.

4 Results and Analysis

Here we show results on dialogue thread extraction and response selection of the three datasets, and give some discussions on our model design.

4.1 Extraction Results

We first evaluate the extraction results on UbuntuV2, DSTC7 and DSTC8* with three metrics: The average number of threads (**avg#thd**) is to show how many dialogue threads are discovered in each dialogue, which ranges from 1 to 4. We didn’t take all of the extracted threads into consideration, serving as a hard cut for the trade-off between information loss and memory usage of the model. The average number of turns in each thread (**avg#turn**) and the average standard deviation of the number

---

[4] https://github.com/facebookresearch/ParlAI

Dataset		avg#thd	avg#turn	std#turn	1-thd(%)	2-thd(%)	3-thd(%)	4-thd(%)
UbuntuV2	train	1.42	3.24	0.29	68.92	22.19	6.65	2.24
	valid	1.39	3.09	0.25	70.78	20.90	6.47	1.85
	test	1.39	3.13	0.25	70.69	20.89	6.18	2.23
DSTC7	train	1.40	4.45	0.38	67.75	25.37	5.48	1.40
	valid	1.39	4.42	0.37	67.76	25.74	5.44	1.06
	test	1.45	4.42	0.42	65.00	26.10	7.70	1.20
DSTC8*	train	3.82	24.70	5.39	2.96	2.59	3.85	90.61
	valid	3.80	24.46	5.37	3.32	3.09	3.64	89.95
	test	3.81	24.53	5.34	3.09	2.76	4.06	90.09

Table 3: Statistics on extraction results. avg#thd refers to the average number of threads per dialogue, avg#turn refers to the average number of turns in each thread, and std#turn refers to the average standard deviation of the number of turns in each thread per dialogue. 1-thd to 4-thd refers to the percentage of the number of dialogues with 1 to 4 threads in corresponding datasets.

of turns in each thread (**std#turn**) are to measure the length of each thread. Dialogues context is not well separated if the length of each thread varies a lot (i.e., the std#turn is too high).

We apply the dialogue extraction algorithm in Section 2.1 on the three datasets. The statistics of extracted threads are in Table 3. Firstly, we can find that the average number of threads is around 3.81 for DSTC8* dataset while around 1.40 for the other two datasets, which well aligns with the empirical observation that two-party dialogues tend to have more concentrated discussions with a smaller number of threads while multi-party dialogues usually contain more threads to accommodate conversation with high diversity. Also, as is listed in Table 1, the number of turns for DSTC8* dataset is usually larger than UbuntuV2 and DSTC7 dataset, which naturally leads to more leaf nodes hence a larger number of threads. Secondly, the average length of threads is around 24.50 for DSTC8* dataset while around 4.0 for DSTC7 dataset and UbuntuV2 and the standard deviation for DSTC8* dataset is also larger. It shows that when the number of dialogue threads increases, the standard deviation of the length of each thread also tends to increase since some dialogue threads may catch more attentions while others may be ignored. In summary, DSTC8* is a more challenging multi-party dialogue dataset for dialogue context modeling than two-party dialogue datasets, including UbuntuV2 and DSTC7.

4.2 Response Selection Results

The response selection results of our Thread-Encoder models, including Thread-bi and Thread-poly, are shown in Table 4 for UbuntuV2 and D-STC7 datasets, and in Table 6 for DSTC8*.

Since UbuntuV2 is too large, we only fine-tuned on this dataset for three epochs due to limited computing resources. The performance of our model is similar to Bi-Enc and Poly-Enc on UbuntuV2. Although the Cross-Enc rank top on UbuntuV2, it is too time-consuming and not practical (Humeau et al., 2019). It runs over 150 times slower than both Bi-Enc and Poly-Enc. Our model, Thread-bi, takes the top four threads (see Section 4.3.2 for more details) into consideration with the inference time overhead similar to Bi-Enc and Poly-Enc. Besides, the reason why our model seems slightly worse than Poly-Enc is that UbuntuV2 is an easier dataset with fewer turns and threads according to Table 1 and Table 3. Consequently, our model degenerates towards Bi-Enc and Poly-Enc, and all four models (Bi-Enc, Poly-Enc, Thread-bi, Thread-poly) actually yield similar results, with p-value greater than 0.05.

Due to the huge advancement of pre-trained models over other models shown on UbuntuV2 and DSTC7, we mainly compared the competitive state-of-the-art pre-trained models on DSTC8* dataset for through comparison as shown in Table 6. Our models achieve the new state-of-the-art results on both DSTC7 and DSTC8* dataset proving that threads based on dependency relation between turns are helpful for dialogue context modeling. We can see that using multiple vectors works much better than using only one representation. The gap between these two aggregation methods is not clear on UbuntuV2 and DSTC7, but much more significant on DSTC8* where the dialogues between multiple participants are much more complicated. This finding hasn't been shown in Humeau's work (2019). Besides, our model can enhance both kinds of pre-trained dialogue models on the multi-

	UbuntuV2				DSCT7

Thread-bi	83.8	92.4	98.5	90.0	**73.3***	92.5	99.3	80.2*
Thread-poly	83.6	**92.5**	98.5	90.0	73.2*	**93.6***	99.1	**80.4***

Table 4: Results on UbuntuV2 and DSTC7 dataset. Scores marked with $\star$ are statistically significantly better than the state-of-the-art with $p < 0.05$ according to t-test.

turn response selection task by comparing Thread-bi with Bi-enc and Thread-poly with Poly-enc.

It should be noted that the inherent properties of these three datasets are different according to Section 4.1. UbuntuV2 and DSTC7 datasets are dialogues between two parties, while DSTC8* dataset involves more complicated multi-party dialogue. This reveals that Thread-Encoder not only works under simple scenarios such as private chats between friends, but also acquires further enhancement under more interlaced scenarios such as chaos chat rooms.

Model	#Para	Train(h)	Test(#dialog/s)
Bi-Enc	256.08M	10.22	6.79
Poly-Enc	256.13M	12.34	4.78
Thread-bi	256.08M	16.36	4.73
Thread-poly	256.13M	17.09	4.77

Table 5: Total number of parameters, training time (h) and testing speed(#dialogues per second) on DSTC8* main models.

The number of parameters, training time and testing speed are shown in Table 5. It takes more epochs for our model to convergence, while the testing speed is similar to Poly-Enc.

4.3 Discussions on Model Design

To further understand the design of our full model, we did several ablations on DSTC8*. All of the ablation results as listed in Table 6. The descriptions and analysis are in following subsections.

4.3.1 Different ways to generate threads

We evaluate some reasonable alternative methods to extract dialogue threads from the history, i.e."Thread Type" in Table 6.

- **Full-hty** concatenate the full dialogue history in one thread. Our model degrades to Bi-Enc and Poly-Enc.
- **Dist-seg** segments the turns based on their distance to the next response. This idea is based on the intuition that the adjacent turns are possible to have strong connections. For example, if we use 4 threads, the dialogue in Figure 2 will be segmented into $\langle\langle t_6, t_7\rangle, \langle t_4, t_5\rangle, \langle t_2, t_3\rangle, \langle t_1\rangle\rangle$.
- **Dep-extr** refers to the threads extraction procedure as explained in Algorithm 1.

Comparing in group ID-$\{1, 5, 7\}$ and ID-$\{2, 11, 12\}$, we get the following observations: (1) Our extraction operations help with the response selection as both ID-5 and ID-11 have significant improvement despite the distance-based extraction method is a strong baseline. The dependency relations capture salient information in dialogue more accurately and yields better performance. (2) Segmenting dialogues simply based on distance may hurt the storyline for each sub dialogue as ID-7 is worse than ID-$\{1, 5\}$, which hurts the representation ability of language models. (3) The information loss caused by Dist-seg can be partially made up by "poly" settings as ID-12 lies between ID-2 and ID-11. Generating multiple representations by aggregators may help to get multiple focuses in each thread. Thus interleaved sub-dialogues can be captured more or less. The gap between Dist-seg and Dep-extr will definitely be widened by improving the performance of sub-dialogue extraction.

4.3.2 The number of threads to use

After deciding the way for extraction, the number of threads (i.e., #Thread in Table 6) to use is another key hyper-parameter for this model design.

We tested our model using the number of threads ranging from 1 to 4. The results are shown in

ID	Method	Aggregation Type	Thread Type	#Thread	hits@1	hits@5	hits@10	hits@50	MRR
1	Bi-Enc	Average	Full-hty	1	22.2	43.0	54.2	88.7	32.9
2	Poly-Enc	Attention	Full-hty	1	32.5	54.1	64.4	91.4	43.1
3	Thread-bi	Average	Dep-extr	1	20.2	39.6	51.1	86.1	30.5
4	Thread-bi	Average	Dep-extr	2	22.6	42.5	53.1	87.9	32.9
5	Thread-bi	Average	Dep-extr	3	23.4	43.0	54.9	88.2	33.8
6	Thread-bi	Average	Dep-extr	4	22.9	43.3	55.1	88.5	33.5
7	Thread-bi	Average	Dist-seg	3	21.7	43.2	55.2	88.8	32.8
8	Thread-poly	Attention	Dep-extr	1	29.4	49.1	59.4	88.7	39.5
9	Thread-poly	Attention	Dep-extr	2	32.0	53.2	63.2	91.1	42.5
10	Thread-poly	Attention	Dep-extr	3	33.1	54.1	64.2	92.0	43.5
11	Thread-poly	Attention	Dep-extr	4	**33.5***	**54.5***	**64.5**	91.7	**44.0***
12	Thread-poly	Attention	Dist-seg	4	33.2	53.5	63.6	**92.3***	43.4

Table 6: Main results of DSTC8* (underlined) and ablation tests on DSTC8*. Scores marked with * are statistically significantly better than Poly-Enc with $p < 0.05$ according to t-test.

ID-$\{3 \sim 6\}$ and ID-$\{8 \sim 11\}$ from Table 6, we draw following conclusions. First, by comparing the results with only 1 thread, we can see ID-3 and ID-8 are worse than Bi-enc and Poly-enc respectively. It shows that there does exist many cases that correct candidates that do not respond to the nearest dialogue threads. Considering only the nearest sub-dialogue is not enough. Second, with the increasing number of threads from 1 to 4, the results go up and down for Thread-bi. The peak value is achieved when #Thread equals 3. Although more than 90% of dialogues can be extracted into 4 threads according to Table 3, the results doesn't go up with one more thread. Some redundant dialogue threads far from the current utterances may bring noises for response selection. Also, the negative effects of redundant dialogue threads for Thread-poly reflect on the limited improvements and even decreases on hits@50 between ID-10 and ID-11. Designing a metric to filter the extracted dialogue threads automatically is our future work.

5 Related Work

Related work contains dialogue dependency parsing and multi-turn response selection.

5.1 Dialogue dependency parsing

Discourse parsing has been researched by scientists especially in linguistics for decades. Asher and Lascarides (2005) proposed the SDRT theory with the STAC Corpus (Asher et al., 2016) which made a great contribution to the discourse parsing on multi-party dialogues. Shi and Huang (2019) proposed a sequential neural network and achieved the state-of-the-art results on this dataset. Another similar task is dialogue disentanglement (Du et al., 2017). This task isn't focusing on developing discourse theories but trying to segment the long dialogues according to topics. It takes each turn in the dialogue as a unit, and only care about whether there is a relation between two turns, which is called "reply-to" relation. Due to the scarcity of annotated dialogues across domains under SDRT theory, the predicted dependency relations had never been used for down-streaming tasks, such as response selection and dialogue summarization. In this paper, we take advantage of both the simplicity of the "reply-to" relation and the sequential parsing methods (Shi and Huang, 2019) to do dialogue dependency parsing. Developing general discourse parsing with relations types and take relation types into consideration may be future work.

5.2 Multi-turn response selection

Multi-turn response selection task was proposed by Lowe et al. (2015) and the solutions for this task can be classified into two categories: the sequential models and the hierarchical models. To begin with, the sequential models (Lowe et al., 2015) were directly copied from the single-turn response selection task since we can regard the multiple history turns as a long single turn. Considering the multi-turn characteristic, Wu et al. (2017) proposed the sequential matching network (SMN), a new architecture to capture the relationship among turns and important contextual information. SMN beats the previous sequential models and raises a popularity of such hierarchical models, including DUA (Zhang et al., 2018), DAM (Zhou et al., 2018), IOI (Tao et al., 2019), etc. The ESIM (Dong and Huang, 2018), which is mainly based on the self and cross attention mechanisms and incorporates different kinds of pre-trained word embedding. It changed the inferior position of the sequential model, making it hard to say which kind of architecture is better.

Due to the popularity of the pre-trained language models such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2018), the state-of-the-art performance on this task was refreshed (Vig and Ramea, 2019). Work such as (Whang et al., 2019) and (Humeau et al., 2019) further shows that the response selection performance can be enhanced by further pretraining the language models on open domain dialogues such as Reddit (Henderson et al., 2019), instead of single text corpus such as BooksCorpus (Zhu et al., 2015). These models can be also regarded as the sequential models because they concatenate all the history turns as the input to the model while ignoring the dependency relations among the turns. Inspired by these works, we incorporate the dependency information in the dialogue history into the response selection model with the pre-trained language model on dialogue dataset.

In this work, we focus on the effectiveness of exploiting dependency information for dialogue context modeling and follow the data preprocessing steps in two-party dialogue datasets, including UbuntuV2 and DSTC7, which have no special designs for speaker IDs. In the papers for DSTC8 response selection track, such as (Gu et al., 2020), many heuristic rules based on speaker IDs are used for data preprocessing, which greatly helps to filter out unrelated utterances. However, they also definitely lead to losing some useful utterances. These hard rules will hurt the completeness of the meaning in each thread and are not suitable for us. As a result, the results on the response selection task for DSTC8 dataset are not comparable. We will take advantage of the speaker information into both extraction and dialogue understanding models as our future work.

6 Conclusion

As far as we know, we are the first work bringing the dependency information of dialogues into the multi-turn response selection task. We proposed the dialogue extraction algorithm and Thread-Encoder model, which becomes the state-of-the-art on several well-known ubuntu datasets. In the future, we will move on to develop a more general dialogue dependency parser and better incorporate dependency information into dialogue context modeling tasks.

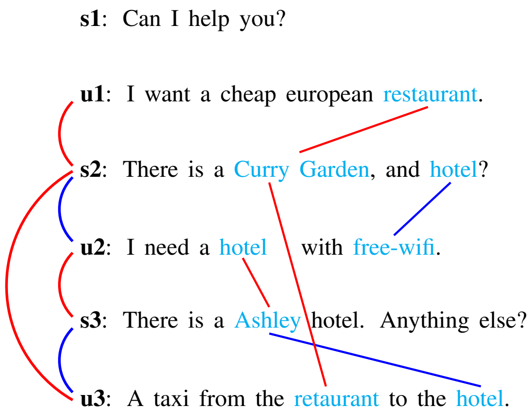
Abstract

The dependencies between system and user utterances in the same turn and across different turns are not fully considered in existing multi-domain dialogue state tracking (MDST) models. In this study, we argue that the incorporation of these dependencies is crucial for the design of MDST and propose Parallel Interactive Networks (PIN) to model these dependencies. Specifically, we integrate an interactive encoder to jointly model the in-turn dependencies and cross-turn dependencies. The slot-level context is introduced to extract more expressive features for different slots. And a distributed copy mechanism is utilized to selectively copy words from historical system utterances or historical user utterances. Empirical studies demonstrated the superiority of the proposed PIN model.

1 Introduction

Spoken dialogue system (SDS) is an application that can help users complete their goals efficiently. An SDS usually has a logic engine, called dialogue manager, which involves two main sub-tasks for determining how the system will respond to the users: dialogue state tracking and dialogue policy learning. The task we discuss in this paper is dialogue state tracking, which allows the system maintaining an internal representation of the state of the dialogue as the dialogue progress (Young et al., 2010).

Dialogue state tracking involving a single domain has been extensively studied and achieved much progress. As a more challenging task, Multi-domain dialogue state tracking (MDST) has been introduced in (Ramadan et al., 2018) and attracts much attention in the research community. Instead of only predicting the $(slot, value)$ pair, in MDST, a model is expected to predict the $(domain, slot, value)$ triplets for each slot in each domain. This task is a great challenge not only because of the large ontology involving 30 slots and exceeding 4500 values (Wu et al., 2019), but also the mixed-domain nature of the dialogues and some complex cases involving cross-turn inference.



s1: Can I help you?

u1: I want a cheap european restaurant.

s2: There is a Curry Garden, and hotel?

u2: I need a hotel with free-wifi.

s3: There is a Ashley hotel. Anything else?

u3: A taxi from the retaurant to the hotel.

Figure 1: The dependencies between the system utterances and user utterances in a multi-domain dialogue. The red lines imply cross-turn dependencies and the blue lines imply in-turn dependencies.

Several models have been proposed for MDST task and proven to be successful (Mrksic et al., 2015; Ramadan et al., 2018; Goel et al., 2019; Eric et al., 2020; Lee et al., 2019; Wu et al., 2019). Among these models, TRADE (Wu et al., 2019) achieves the state-of-the-art on the MultiWOZ 2.0 dataset (one of the standard MDST datasets) by encoding the entire dialogue history using a bidirectional GRU and incorporating soft-gated copy mechanism to generate the values. Inspired by

TRADE, we purpose to build a more accurate and robust state generator PIN. The motivations of proposing PIN is in two aspects.

One aspect is considering the interactive nature of the dialogues. The interaction of the user and the system is often organized by a question-answering style. It is common in dialogue state tracking that a domain or slot being specified by one of the user or system, then the value being answered by the other. For example, in the dialogue in Figure 1, the user specifies a *Restaurant* domain, and the system answers a restaurant name *Curry Garden*. As is shown in Figure 1, there are two types of dependencies, in-turn dependencies and cross-turn dependencies, both contribute to discovering slot-value pairs. It is worth noting that some hard cases involving inference actually rely on cross-turn dependencies (e.g., the dependency between utterance **s2** and **u3** in Figure 1). Thus a correctly modeling of these dependencies can improve slot-value extraction and cross-turn inference. In this work, we build an Interactive Encoder which completely accords with the dependencies expressed in Figure 1 to jointly model the in-turn dependencies and cross-turn dependencies.

The interactive nature of dialogues also implies that the value for a slot tends to be specified frequently either by a system or by a user. For example, the values for slots involving names, such as *Restaurant-name* and *Hotel-name* are likely to be provided by the system. And the values for the slots like *Hotel-stay* (the days to stay) and *Hotel-people* (the number of people booking for) are usually provided by the user. This observation inspires our designing of the distributed copy mechanism, which allows the state generator choosing to copy words from either the historical system utterances or the historical user utterances.

The other aspect is the slot overlapping problem in MDST. Unlike single-domain DST, slot overlapping is common in MDST, and these overlapping slots share similar values. For example, both the *Restaurant* and *Hotel* domain have a slot *price range* that shares the same values. Under this condition, a generator without considering slot-specific features may mistakenly extract the value of one slot as the value of some other slot. To overcome the slot overlapping problem, we introduce a slot-level context in the state generator.

In summary, we propose a generation-based MDST model which takes into consideration of the interactive nature of dialogues and slot overlapping problem in MDST. The contributions of this work are as follows.

- We propose an interactive encoding method with two parallel double-layer recurrent networks which can jointly model the in-turn dependencies and cross-turn dependencies.
- We introduce the slot-level context into the state generator to accurately generate the values for overlapping slots.
- We present a distributed copy mechanism to selectively copy words from either the historical system utterances or the historical user utterances.

2 Problem Statement

In multi-domain dialogue state tracking, the *state* is usually expressed as a set of $(domain, slot, value)$ triplets. The *domain* refers to the topics of the dialogue, such as the *Restaurant* domain, which indicates that the dialogue involves restaurant booking. The *slot* is an aspect of the user's goals, such as *food*, *area* and *pricerange* in the restaurant-booking dialogues. And the *value* is the user's specific interests, such as *chinese* value for *food* slot that indicates the user is interested in Chinese food. The dialogue state is maintained so as to track the progress of the dialogue. At each turn, the system generates a system utterance in natural language, and the user responds to the system with some sentences, referred to as user utterance. The objective of multi-domain dialogue state tracking is to predict the value of each $(domain, slot)$ pair at each turn given the historical system utterances and user utterances. In this paper, the multi-domain dialogue state tracking is treated as a sequence generation task, where each word of a value is generated from a state generator.

3 Methodology

In this section, we introduce the proposed PIN model. The model consists of four components: Interactive Encoder, Slot-level Context, Value Generator and Slot Gate. We next describe each component in detail.

3.1 Interactive Encoder

Our design of the Interactive Encoder is inspired by the dependencies between the system and user utterances. Specifically, we wish to propose a novel network structure that completely represents the dependencies expressed in Figure 1. A hierarchical recurrent networks with specific structures have been used to construct the Interactive Encoder, as shown in Figure 2. The Interactive Encoder consists of two parallel hierarchical recurrent networks, one for historical system utterance encoding and another for historical user utterance encoding. The lower layer of the hierarchical recurrent networks allow each word to capture the cross-turn dependencies; and the higher layer of the hierarchical recurrent networks allows each word to capture the in-turn dependencies. In this way, the cross-turn dependencies and in-turn dependencies are jointly modeled.

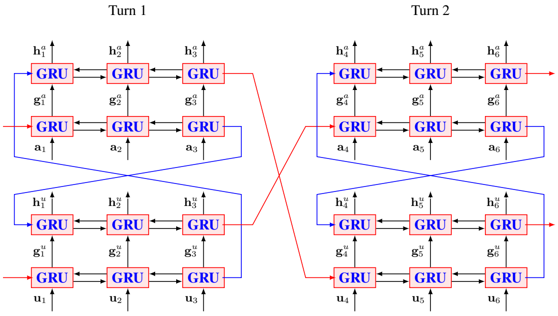

Figure 2: The structure of the Interactive Encoder. Due to space limitation, only two turns are shown. The red arrows emphasize modeling cross-turn dependencies and the blue arrows emphasize modeling in-turn dependencies.

We now present the details of the Interactive Encoder. Let $\mathbf{A}_l = \{\mathbf{a}_1, \mathbf{a}_2, \cdots, \mathbf{a}_m\}$ denotes the sequence of word embeddings for the l^{th} system utterance. And $\mathbf{U}_l = \{\mathbf{u}_1, \mathbf{u}_2, \cdots, \mathbf{u}_n\}$ denotes the sequence of word embeddings for the the l^{th} user utterance. Here m and n denote the number of words in the l^{th} system utterance and user utterance, respectively.

For later use, we introduce a notation $\mathrm{GRE}(\mathbf{X}, \mathbf{h}; \mathbf{W})$ to indicate the bi-directional GRU encoder (Chung et al., 2014) with inputs $\mathbf{X}$ (sequence of vector representations, such as word embeddings), parameters $\mathbf{W}$ and initialized hidden state $\mathbf{h}$. The Interactive Encoder jointly models the cross-turn dependencies and in-turn dependencies through the following recurrent process.

The Interactive Encoder first let the input word embedding sequences $\mathbf{A}_l$ and $\mathbf{U}_l$ interact with the historical context, allowing the words capturing cross-turn dependencies

$$\begin{aligned} \mathbf{G}^a_l, \mathbf{g}^a_l &= \mathrm{GRE}(\mathbf{A}_l, \mathbf{h}^u_{l-1}; \mathbf{W}_a) \\ \mathbf{G}^u_t, \mathbf{g}^u_l &= \mathrm{GRE}(\mathbf{U}_l, \mathbf{h}^a_{l-1}; \mathbf{W}_u) \end{aligned} \tag{1}$$

where $\mathbf{W}_a$ and $\mathbf{W}_u$ are the parameters of the GRUs, the initialized hidden states $\mathbf{h}^a_{l-1}$ and $\mathbf{h}^u_{l-1}$ are respectively the system context vector and the user context vector generated from the last turn. $\mathbf{G}^a_l$ and $\mathbf{g}^a_l$ denote the entire sequence of output vectors and the last output vector of the GRUs, respectively.

The outputs of the lower-layer GRUs, $\mathbf{G}^a_l$ and $\mathbf{g}^a_l$, are then feed into the higher-layer GRUs to interact with the current context for capturing in-turn dependencies

$$\begin{aligned} \mathbf{H}^a_l, \mathbf{h}^a_l &= \mathrm{GRE}(\mathbf{G}^a_l, \mathbf{g}^u_l; \mathbf{M}_a) \\ \mathbf{H}^u_l, \mathbf{h}^u_l &= \mathrm{GRE}(\mathbf{G}^u_t, \mathbf{g}^a_l; \mathbf{M}_u) \end{aligned} \tag{2}$$

where $\mathbf{M}_a$ and $\mathbf{M}_u$ are the parameters of the higher-layer GRUs, and $\mathbf{h}^a_l$ and $\mathbf{h}^u_l$ are the generated system context vector and user context vector of the current turn. $\mathbf{h}^a_l$ and $\mathbf{h}^u_l$ are then feed into the lower-layer GRUs as the initialized hidden states of the next turn.

With this recurrent architecture, the Interactive Encoder captures the dependencies of the entire dialogue history by rolling from the first turn to the current turn. At the beginning of a dialogue, we set the initialized hidden states as zero vectors, that is $\mathbf{h}^a_0 = \mathbf{h}^u_0 = \mathbf{0}$.

The outputs from each turn of the dialogue are then concatenated as the system context sequence $\mathbf{H}^a = \{\mathbf{h}^a_1, \mathbf{h}^a_2, \cdots, \mathbf{h}^a_M\}$ and user context sequence $\mathbf{H}^u = \{\mathbf{h}^u_1, \mathbf{h}^u_2, \cdots, \mathbf{h}^u_N\}$. Here M and N denote the total number of words in historical system utterance and historical user utterance, respectively.

3.2 Slot-level Context

The purpose of applying the slot-level context here is to strengthen the context representation with slot specific features and deal with the slot overlapping problem. We employ the attention mechanism to construct the slot-level context. Specifically, for each $(domain, slot)$ pair, we introduce an embedding vector $\mathbf{v}_s$. The slot-level system context $\mathbf{c}^a_s$

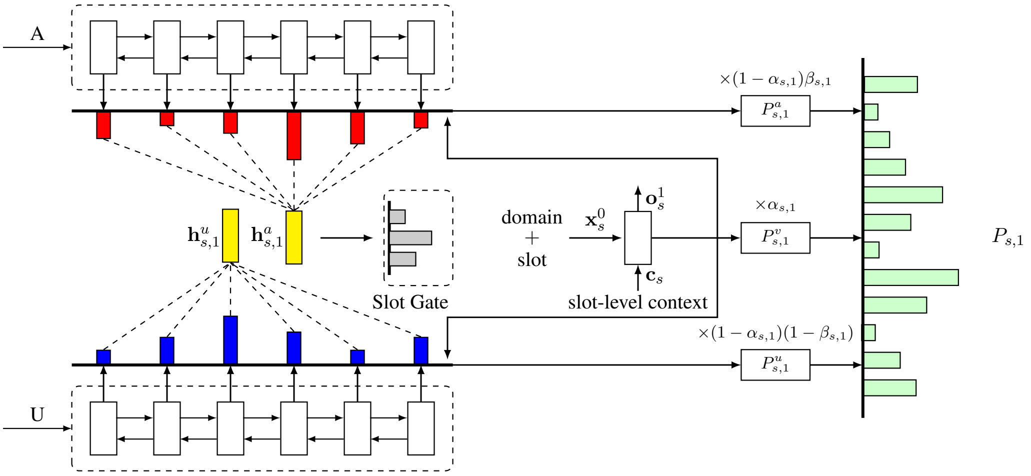

Figure 3: The architecture of the Value Generator and the Slot Gate.

and the slot-level user context $\mathbf{c}^u_s$ are computed by

$$\begin{aligned} \mathbf{c}^a_s &= \sum_{i=1}^{M} \mu_i \mathbf{h}^a_i, \quad \mu_i = \frac{\exp\left(\mathbf{v}_s^T \mathbf{h}^a_i\right)}{\sum_{k=1}^{M} \exp\left(\mathbf{v}_s^T \mathbf{h}^a_k\right)} \\ \mathbf{c}^u_s &= \sum_{j=1}^{N} \eta_j \mathbf{h}^u_j, \quad \eta_j = \frac{\exp\left(\mathbf{v}_s^T \mathbf{h}^u_j\right)}{\sum_{l=1}^{N} \exp\left(\mathbf{v}_s^T \mathbf{h}^u_l\right)} \end{aligned} \tag{3}$$

The slot-level context of the entire dialogue history is then simply the summation of the slot-level system context and the slot-level user context

$$\mathbf{c}_s = \mathbf{c}^a_s + \mathbf{c}^u_s \tag{4}$$

The slot-level context is then feed into the Value Generator as the initialized hidden state for the decoder GRU.

3.3 Value Generator

The Value Generator takes the slot-level context as input and uses a GRU decoder to generate the value sequence for each $(domain, slot)$ pair. Different from the copy mechanism applied in TRADE (Wu et al., 2019) that copying words from the entire dialogue history, in this paper, we propose a distributed copy mechanism that allows the state generator copying words from different sequences. The architecture of the Value Generator is shown in Figure 3. we now describe it in detail.

We use the abbreviation GRD to denote the GRU decoder. At the t^{th} decoding step, the hidden state of the GRU decoder for each $(domain, slot)$ pair s is

$$\mathbf{o}^t_s = \mathrm{GRD}(\mathbf{x}^t_s, \mathbf{o}^{t-1}_s, \mathbf{W}_d) \tag{5}$$

where $\mathbf{x}^t_s$ is the input at the t^{th} step, $\mathbf{o}^t_s$ is the hidden state at the t^{th} step and $\mathbf{W}_d$ is the parameters of the GRU decoder. The hidden state of GRD for each slot is initialized with corresponding slot-level context $\mathbf{c}_s$. The first input $\mathbf{x}^0_s$ is set as the summation of corresponding domain embedding and slot embedding.

We then introduce three distributions on the vocabulary: $P^v_{s,t}$, $P^a_{s,t}$ and $P^u_{s,t}$, for applying distributed copy mechanism. The three distributions represent the probabilities of generating a word from the vocabulary, copying a word from the historical system utterances and copying a word from the historical user utterances, respectively. Let $\mathbf{e}_i$ be the embedding of the i^{th} word in the vocabulary and $|V|$ be the vocabulary size. We use $P_{s,t}[i]$ to denote the i^{th} element in $P_{s,t}$. Then the three distributions are computed by

$$\begin{aligned} P^v_{s,t}[i] &= \frac{\exp\left(\mathbf{e}_i^T \mathbf{o}^t_s\right)}{\sum_{j=1}^{|V|} \exp\left(\mathbf{e}_j^T \mathbf{o}^t_s\right)} \\ P^a_{s,t}[i] &= \sum_{f(k)=i} \frac{\exp\left((\mathbf{h}^a_k)^T \mathbf{o}^t_s\right)}{\sum_{j=1}^{M} \exp\left((\mathbf{h}^a_j)^T \mathbf{o}^t_s\right)} \\ P^u_{s,t}[i] &= \sum_{f(k)=i} \frac{\exp\left((\mathbf{h}^u_k)^T \mathbf{o}^t_s\right)}{\sum_{j=1}^{N} \exp\left((\mathbf{h}^u_j)^T \mathbf{o}^t_s\right)} \end{aligned} \tag{6}$$

where the function f is used for mapping a distribution on the dialogue-history to corresponding distribution on the vocabulary.

The three distributions, $P^v_{s,t}$, $P^a_{s,t}$ and $P^u_{s,t}$ are then combined by learnable weights. We define $\alpha_{s,t}$ as the weight of generating from the vocabulary and $\beta_{s,t}$ as the weight of choosing to copy a word from the system utterances. For calculating the weights $\alpha_{s,t}$ and $\beta_{s,t}$, we first generate new feature vectors

$$\mathbf{h}^a_{s,t} = \sum_{i=1}^{M} q^a_{s,t}[i] \cdot \mathbf{h}^a_i, \quad \mathbf{h}^u_{s,t} = \sum_{j=1}^{N} q^u_{s,t}[j] \cdot \mathbf{h}^u_j \quad (7)$$

The weight $\alpha_{s,t}$ and $\beta_{s,t}$ are then computed by

$$\begin{aligned} \alpha_{s,t} &= \sigma(\mathbf{W}_v^T \cdot [\mathbf{x}^t_s, \mathbf{o}^t_s, \mathbf{h}^a_{s,t}, \mathbf{h}^u_{s,t}]) \\ \rho^a_{s,t} &= \mathbf{W}_c^T \cdot [\mathbf{x}^t_s, \mathbf{o}^t_s, \mathbf{h}^a_{s,t}] \\ \rho^u_{s,t} &= \mathbf{W}_c^T \cdot [\mathbf{x}^t_s, \mathbf{o}^t_s, \mathbf{h}^u_{s,t}] \\ \beta_{s,t} &= \frac{\exp(\rho^a_{s,t})}{\exp(\rho^a_{s,t}) + \exp(\rho^u_{s,t})} \end{aligned} \quad (8)$$

where $\mathbf{W}_v$ and $\mathbf{W}_c$ are the parameters of the linear functions, and σ denotes the logistic function.

The final distribution $P_{s,t}$ is then calculated as the weighted sum of distributions $P^v_{s,t}$, $P^a_{s,t}$ and $P^u_{s,t}$ as follows

$$P_{s,t} = \alpha_{s,t} P^v_{s,t} + (1-\alpha_{s,t})(\beta_{s,t} P^a_{s,t} + (1-\beta_{s,t}) P^u_{s,t}) \quad (9)$$

The t^{th} word of the value for $(domain, slot)$ pair s is then generated from distribution $P_{s,t}$. The embedding of the generated word is then used as the next input of the GRU decoder. This generation procedure allows the state generator to generate words from the vocabulary or copy words from either the historical system utterances or the historical user utterances.

3.4 Slot Gate

Following TRADE (Wu et al., 2019), we introduce the slot gate to predict the special values *none* (the value of the slot is not expressed yet) and *dontcare* (the user does not care about the slot) for each $(domain, slot)$ pair. Specifically, the slot gate is a three-class classifier, which aims to identify whether the value *none*, *dontcare* or other value is expressed from the context through a softmax classifier

$$P^c_s = \text{softmax}(\mathbf{W}_s^T \cdot [\mathbf{h}^a_{s,1}, \mathbf{h}^u_{s,1}]) \quad (10)$$

where $\mathbf{W}_s$ is the parameter of the softmax classifier. For a $(domain, slot)$ pair, if the output of the slot gate is *none* or *dontcare*, the generated word sequence from the state generator will be ignored and the corresponding predicted result of the slot gate will be chosen as the value. Otherwise, the generated word sequence from the state generator will be the predicted value for the $(domain, slot)$ pair.

3.5 Loss Function and Optimization

The cross-entropy loss is built for optimizing both the Value Generator and the Slot Gate, simultaneously. Let $\mathcal{S}$ be the total set of $(doamin, slot)$ pairs, and T_s be the number of words in the value for slot $s \in \mathcal{S}$. We define $\mathbf{y}^c_s$ as the ground-truth one-hot label vector of the slot gate and $\mathbf{y}^v_{s,t}$ as the one-hot representation of the t^{th} word in the value of s. The loss function is then defined as

$$\begin{aligned} \mathcal{L} = &\sum_{s\in\mathcal{S}} \sum_{i=1}^{3} -\mathbf{y}^c_s[i] \cdot \log P^c_s[i] \\ &+ \sum_{s\in\mathcal{S}} \sum_{t=1}^{T_s} \sum_{j=1}^{|V|} -\mathbf{y}^v_{s,t}[j] \cdot \log P_{s,t}[j] \end{aligned} \quad (11)$$

The loss function can be optimized by stochastic gradient descent(SGD) method.

4 Experiment

4.1 Datasets

MultiWOZ 2.0. The Multi-Domain Wizard-of-Oz (MultiWOZ 2.0) dataset, collected by (Budzianowski et al., 2018), with conversations spanning over multiple domains and topics, is used to train and evaluate the models. There are total 7 domains with 30 $(domain, slot)$ pairs in the ontology; these $(domain, slot)$ pairs involve $4,510$ values. The dataset contains $10,419$ dialogues with a a total $115,434$ turns; the average turns of dialogue is 13.46. The training, validation and test set contain $8,420$, $1,000$ and $1,000$ dialogues respectively. As is mentioned in (Wu et al., 2019) that *hospital* and *police* domain has very few dialogues and only appear in the training set. We thus follow the dataset setting in (Wu et al., 2019) that only keep five domains (*restaurant*, *hotel*, *attraction*, *taxi*, *train*) in the experiment.

MultiWOZ 2.1. As is pointed out in (Eric et al., 2020), the MultiWOZ 2.0 dataset is faulty in substantial errors in the state annotations and dialogue utterances. In order to clean the dataset, the authors of (Eric et al., 2020) ask crowd-source workers to fix the state annotations and utterances in the original data. As a result, over 32% of state annotations in 40% of the dialogue turns are changed and 146 utterances are fixed. The cleaned dataset is released as the MultiWOZ 2.1 dataset. We also evaluate our models on the MultiWOZ 2.1 dataset.

4.2 Implementation Details

The proposed model is implemented using the Pytorch framework. The code and data are released on the Github page[1]. All the word embeddings are initialized by the concatenation of the pre-trained GloVe embeddings (Pennington et al., 2014) and character n-gram embeddings (Hashimoto et al., 2017). The batch size is set as 32. The dimensions of hidden states in all GRUs are set as 400. The embedding dropout is used in the Interactive Encoder with a dropout rate 0.3. Following (Bowman et al., 2016; Wu et al., 2019), we also adopt the word dropout in the Interactive Encoder to improve the model generalization; and the dropout rate is set as 0.3. At training time, the Value Generator uses Teacher-forcing (Williams and Zipser, 1989) with a probability 0.5. The greedy search (Vinyals and Le, 2015) is used in the decoding process. We use the Adam optimizer (Kingma and Ba, 2015) to optimize the model with an initialized learning rate 0.001.

4.3 Evaluation Metrics

The standard metrics joint goal accuracy and goal accuracy are used to evaluate the multi-domain dialogue state tracking performance. The joint goal accuracy denotes the proportion of dialogue turns where the values of all the $(domain, slot)$ pairs are correctly predicted. While goal accuracy is the proportion of slots whose values are correctly predicted.

4.4 Baseline Models

The recently proposed dialogue state tracking models are used for comparison. The models dealing with dialogue state tracking through building classifiers on predefined ontology include the MDBT (Ramadan et al., 2018), GLAD (Zhong et al., 2018), GCE (Nouri and Hosseini-Asl, 2018), SUMBT (Lee et al., 2019), FJST (Eric et al., 2020), HJST (Eric et al., 2020) and SST (Chen et al., 2020). The models utilizing the copy system include PtrNet (Xu and Hu, 2018). The models incorporating both classifiers and copy system include HyST (Goel et al., 2019), DSTreader (Gao et al., 2019), TRADE (Wu et al., 2019), DST-Picklist (Zhang et al., 2019) and MERET (Huang et al., 2020).

To investigate how much the proposed interactive encoder and distributed copy mechanism contributes to the PIN model, we also report the results of two ablated version of the PIN model: PIN–inter and PIN–dcopy. The PIN–inter model removes the interaction between the two parallel encoders in PIN and allows them to be independent. And the PIN–dcopy model copies words from the entire dialogue history instead of applying the distributed copy.

Table 1: Evaluation on the MultiWOZ 2.0 dataset.

Model	**Joint Goal** (%)	**Goal** (%)
MDBT	15.57	89.53
PtrNet	30.28	93.85
GLAD	35.57	95.44
GCE	36.27	**98.42**
HJST	38.40	-
DSTreader	39.41	-
FJST	40.20	-
HyST	42.33	-
HyST(ensemble)	44.22	-
SUMBT	42.40	-
DSTreader+JST	47.33	-
TRADE	48.62	96.92
MERET	50.91	97.07
SST	51.17	-
PIN–inter	51.95	97.24
PIN–dcopy	50.57	97.06
PIN	**52.44**	97.28

4.5 Experimental Results

Evaluation on the MultiWOZ 2.0 dataset. The evaluation results on the MultiWOZ 2.0 dataset are shown in Table 1. We observe that most of the models building classifiers and the models using the copy system to generate the states are inferior to the models utilizing both the classifiers and the copy system. As mentioned in (Eric et al., 2020), the models building upon a copy system have an advantage in extracting values from the dialogue history but struggle to predict values that do not exist in the dialogue history. Thus it is reasonable that models combining copy systems with state classifiers achieve better performance. Compared with the baseline model TRADE and the previous state-of-the-art model SST, PIN achieves significant 3.82% and 1.27% performance gain. This fact demonstrates that the modeling of the interaction dependencies, the slot-level context and the distributed copy mechanism help improve state generation.

Table 2: Evaluation on the MultiWOZ 2.1 dataset.

Model	Joint Goal (%)	Goal (%)
HJST	35.55	-
DST Reader	36.40	-
FJST	38.00	-
HyST	38.10	-
TRADE	45.60	96.55
DST-Picklist	53.30	-
SST	**55.23**	-
PIN–inter	47.36	96.90
PIN–dcopy	47.29	96.91
PIN	48.40	**97.02**

Evaluation on the MultiWOZ 2.1 dataset. The evaluation results on the MultiWOZ 2.1 dataset are shown in Table 2. The consistent performance drop is caused by changing a value to a *dontcare* or *none* label as explained in (Eric et al., 2020). The PIN model outperforms the previous models except for the DST-Picklist and SST model, which indicates the effectiveness of the model design. Although DST-Picklist and SST achieve better performance than PIN, DST-Picklist takes a lot of human efforts in dividing the slots into span-based or picklist-based slots and SST requires extra relation information among the slots. PIN's performance drop in the ablated version (PIN-inter and PIN-dcopy) on both datasets demonstrates the necessity of encoder-interaction and distributed copy.

Table 3: The evaluation results of overlapping slots and non-overlapping slots on the MultiWOZ 2.1 dataset. 1:*Restaurant*, 2:*Hotel*, 3:*Attraction*, 4:*Train*, 5:*Taxi*.

Slot	Domains	TRADE	PIN
area	1,2,3	86.2	**86.4**
book people	1,2,3	92.0	**95.1**
price range	2,3	84.2	**89.7**
book day	2,3	96.4	**96.8**
departure	4,5	89.0	**90.9**
destination	4,5	91.6	**92.4**
leave at	4,5	65.1	**66.7**
arrive by	4,5	82.4	**84.7**
book time	1	**92.7**	91.8
food	1	**92.8**	92.6
parking	2	80.1	**81.2**
book stay	2	**96.4**	96.2
internet	2	78.8	**81.2**

4.6 Evaluation on the Overlapping Slots

In multi-domain dialogue state tracking, domains may have overlapping slots. One of the motivations for building the PIN model is to handle the slot overlapping problem with a slot-level context. Thus we report the goal accuracy on overlapping slots and non-overlapping slots in Table 3 for further analysis on PIN. Table 3 shows that slot overlapping (involve at least two domains) usually appears among similar domains, such as (*Restaurant*, *Hotel*, *Attraction*) and (*Train*, *Taxi*). The PIN model achieves much higher goal accuracy than TRADE on all overlapping slots, compared with non-overlapping slots. This result demonstrates the effectiveness of the slot-level context on extracting distinctive features for each slot so that the values for overlapping slots are correctly predicted.

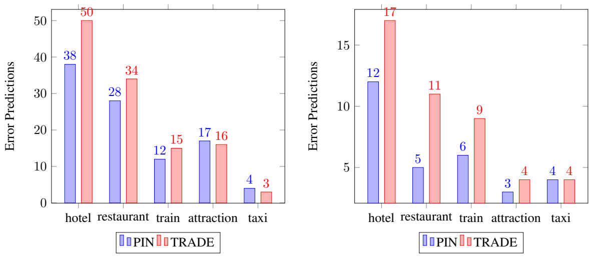

Figure 4: Error analysis on the dialogue turns involving in-turn dependencies (left) and cross-turn dependencies (right). We report the number of error predictions for TRADE and PIN on each domain.

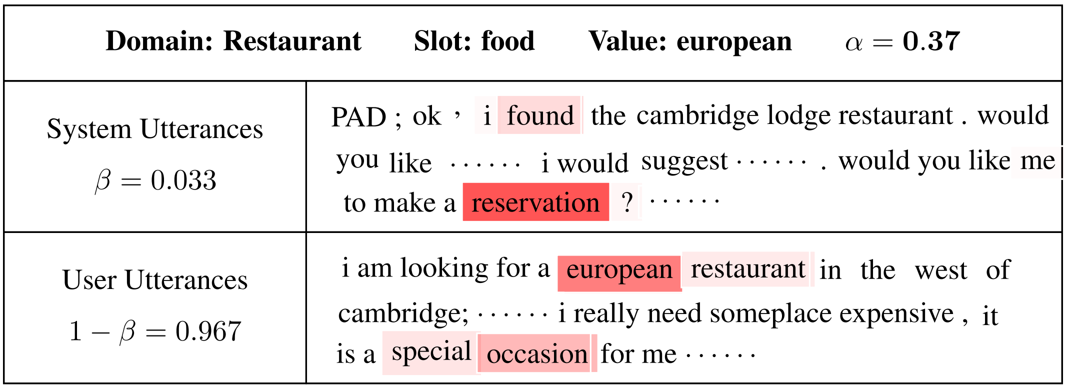
4.7 The Effectiveness of the Interactive Encoder

To study the Interactive Encoder in handling in-turn and cross-turn dependencies in MDST, we make a error analysis on a subset of the test data. We first sample 100 dialogue turns from the MultiWOZ 2.1 test set. Then the wrongly predicted $(domain, slot, value)$ triplets for TRADE and PIN are selected and each of the triplets is marked according to the dependencies (in-turn or cross-turn) involved. The statistics of these error predictions are shown in Figure 4. We observe that whether in the dialogue turns involving in-turn dependencies or cross-turn dependencies, the PIN model creates much fewer prediction errors than the TRADE model, especially on $hotel$ domain and $restaurant$ domain. These results demonstrate the effectiveness of the Interactive Encoder in capturing the in-turn and cross-turn dependencies.



Domain: Restaurant Slot: food Value: european $\alpha = 0.37$	
System Utterances $\beta = 0.033$	PAD ; ok ’ i found the cambridge lodge restaurant . would you like ⋯⋯ i would suggest ⋯⋯ . would you like me to make a reservation ? ⋯⋯
User Utterances $1 - \beta = 0.967$	i am looking for a european restaurant in the west of cambridge; ⋯⋯ i really need someplace expensive , it is a special occasion for me ⋯⋯

Figure 5: An example of dialogues and prediction of PIN. The red color represent the copy probability of the word. And the copy probability of the word *reservation* in system utterances is 0.668, the copy probability of the word *european* in the user utterances is 0.507.

4.8 The Function of the Distributed Copy Mechanism

Unlike the traditional copy mechanism that only copies words from one sequence, the distributed copy mechanism in the PIN model can copy words from two separate sequences considering the interactive nature of dialogues. The example in Figure 5 shows a case that the traditional copy mechanism will make a wrong prediction, but the distributed copy mechanism will correctly predict. The dialogue in Figure 5 is a sample from the Restaurant domain in the test set. In this example, we want to predict the value of the *food* slot. As the wight $\alpha = 0.37$, the generator has a higher probability of copying a word from the dialogue history. In the total dialogue history, if we ignore the wight β, which determines whether to copy from the historical system utterance or the historical user utterance, the generator will copy the wrong word *reservation* from the entire dialogue history because the word *reservation* has higher copy probability 0.668 than 0.507 of the word *european*. This wrong prediction will happen in the traditional copy-based model. But in PIN, the word to be copied also depends on the sequence-selection weight β. With a probability 0.967 to copy the word from the historical user utterance, the correct value *european* will be copied according to Equation 9. This case demonstrates the effectiveness of the distributed copy mechanism.

5 Related Works

The dialogue state tracking (DST) problem has attracted the research community for years. The traditional DST models focus on single domain dialogue state tracking (Thomson and Young, 2010; Wang and Lemon, 2013; Lee and Kim, 2016; Liu and Perez, 2017; Jang et al., 2016; Shi et al., 2016; Vodolán et al., 2017; Yu et al., 2015; Henderson et al., 2014; Zilka and Jurcícek, 2015; Mrksic et al., 2017; Xu and Hu, 2018; Zhong et al., 2018; Ren et al., 2018). Some of these models solve DST problem by incorporating a natural language understanding (NLU) module (Thomson and Young, 2010; Wang and Lemon, 2013) or jointly modeling NLU and DST (Henderson et al., 2014; Zilka and Jurcícek, 2015), which rely on hand-crafted features or delexicalisation features. Other models adopt the representation learning approach and incorporate neural networks to extract features and track the dialogue states (NBT (Mrksic et al., 2017), GLAD (Zhong et al., 2018), StateNet (Ren et al., 2018), PtrNet (Xu and Hu, 2018) and SUMBT (Lee et al., 2019)). Although these models have achieved remarkable success in single-domain DST , they can not be capable enough in multi-domain DST.

Recently, the multi-domain DST attracts more attention than the single-domain DST in the research community. The first work involving state tracking in multiple domains is (Mrksic et al., 2015). This work proposes a pre-training procedure to improve the performance on a new domain. The work of (Rastogi et al., 2017) uses bi-directional GRU to extract features and predict the value by a candidate scoring model. The MDBT (Ramadan et al., 2018) model applies multiple bi-directional-LSTM to jointly track the domain and states. It adopts semantic similarity between the ontology and utterances and allows parameter sharing across domains. The HyST (Goel et al., 2019) model combines a classification-based system and an n-gram copy-based system to deal with multi-domain dialogue state tracking problem. The FJST and HJST model presented in (Eric et al., 2020) employ flatten structured LSTM and hierarchical structured LSTM to encode the dialogue history respectively. The TRADE model (Wu et al., 2019) combines the soft-copy mechanism to generate states and a slot gate to classify special values for each slot. These models motivate our design of the PIN model.

Another idea related to our design of PIN is hierarchical recurrent networks. The hierarchical recurrent networks have been used for dialogue representation in HRED (Serban et al., 2016) and VHRED (Serban et al., 2017). Although our model has a slight flavor of a hierarchical structure (since a sentence-level encoding is sent to another GRU as its initial state), our model is very different from the hierarchical recurrent networks. Specifically, in PIN, the inputs and outputs for each GRU layer are both at the word level; and the GRU layers are parallel, albeit interacting. This is distinct from the hierarchical recurrent networks, where a GRU layer takes word-level inputs, and outputs at the sentence level; then the sentence-level representations are used as the inputs to the next GRU layer.

6 Conclusion

This paper studies the problem of state generation for multi-domain dialogues. Existing generation-based models fail to model the dialogue dependencies and ignore the slot-overlapping problem in MDST. To overcome the limitation of existing models, we present novel Parallel Interactive Networks (PIN) for more accurate and robust dialogue state generation. The design of the PIN model is inspired by the interactive nature of the dialogues and the overlapping slots in the ontology. The Interactive Encoder characterizes the cross-turn dependencies and the in-turn dependencies. The slot-overlapping problem is solved by introducing the slot-level context. Furthermore, a distributed copy mechanism is introduced to perform a selective copy from either the historical system utterances or the historical user utterances. Empirical studies on two benchmark datasets demonstrate the effectiveness of the PIN model.

Abstract

Slot filling and intent detection are two main tasks in spoken language understanding (SLU) system. In this paper, we propose a novel non-autoregressive model named SlotRefine for joint intent detection and slot filling. Besides, we design a novel two-pass iteration mechanism to handle the uncoordinated slots problem caused by conditional independence of non-autoregressive model. Experiments demonstrate that our model significantly outperforms previous models in slot filling task, while considerably speeding up the decoding (up to ×10.77). In-depth analyses show that 1) pretraining schemes could further enhance our model; 2) two-pass mechanism indeed remedy the uncoordinated slots.

1 Introduction

Slot filling (SF) and intent detection (ID) play important roles in spoken language understanding, especially for task-oriented dialogue system. For example, for an utterance like "*Buy an air ticket from Beijing to Seattle*", intent detection works on sentence-level to indicate the task is about purchasing an air ticket, while the slot filling focus on words-level to figure out the departure and destination of that ticket are "*Beijing*" and "*Seattle*".

In early studies, ID and SF were often modeled separately, where ID was modeled as a classification task, while SF was regarded as a sequence labeling task. Due to the correlation between these two tasks, training them jointly could enhance each other. Zhang and Wang (2016) propose a joint model using bidirectional gated recurrent unit to learn the representation at each time step. Meanwhile, a max-pooling layer is employed to capture the global features of a sentence for intent classification. Liu and Lane (2016) cast the slot filling task as a tag generation problem and introduce a recurrent neural network based encoder-decoder framework with attention mechanism to model it, meanwhile using the encoded vector to predict intent. Goo et al. (2018) and Haihong et al. (2019) dig into the correlation between ID and SF deeper and modeled the relationship between them explicitly. Qin et al. (2019) propagate the token-level intent results to the SF task, achieving significant performance improvement.

Briefly summarized, most of the previous works heavily rely on autoregressive approaches, *e.g.,* RNN based model or seq2seq architecture, to capture the grammar structure in an utterance. And conditional random field (CRF) is a popular auxiliary module for SF task as it considers the correlations between tags. Thus, several state-of-the-art works combine the autoregressive model and CRF to achieve the competitive performance, which therefore are set as our baseline methods.

However, for SF task, we argue that identifying token dependencies among slot chunk is enough, and it is unnecessary to model the entire sequence dependency in autoregressive fashion, which leads to redundant computation and inevitable high latency.

In this study, we cast these two tasks jointly as a non-autoregressive tag generation problem to get rid of unnecessary temporal dependencies. Particularly, a Transformer (Vaswani et al., 2017) based architecture is adopted here to learn the representations of an utterance in both sentence and word level simultaneously (Sec.§2.1). The slots and intent labels are predicted independently and simultaneously, achieving better decoding efficiency. We further introduce a two-pass refine mechanism (in Sec.§2.2) to model boundary prediction of each slots explicitly, which also handle the uncoordinated slots problem (*e.g., I-song* follows *B-singer*) caused by conditional independence attribute.

Experiments on two commonly-cited datasets

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1932–1937,
November 16–20, 2020.

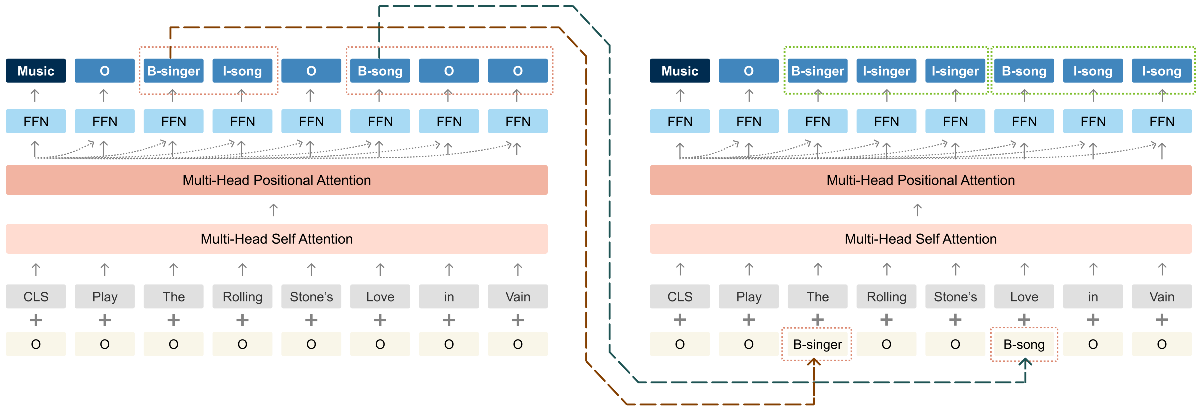

Figure 1: Illustration of SlotRefine, where the left and right part indicate the first and second iteration process respectively. In the first pass, wrong slot tagging results are predicted, as shown in the pink dotted box in the figure, and the "*B-tags*" (beginning tag of a slot) are feeded as additional information with utterance for second iteration. The slot results in the green dotted box are refined results by second pass. Note that the initial tag embedding "O" added to each inputting position is designed for the two-pass mechanism(Sec.§2.2).

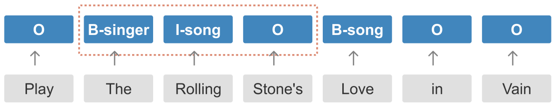

Figure 2: A example of uncoordinated slot tagging.

show that our approach is significantly and consistently superior to the existing models both in SF performance and efficiency (Sec.§3). Our contributions are as follows:

- We propose an fast non-autoregressive approach to model ID and SF tasks jointly, named SlotRefine[1], achieving the state-of-the-art on ATIS dataset.
- We design a two-pass refine mechanism to handle uncoordinated slots problem. Our analyses confirm it is a better alternative than CRF in this task.
