Table 2: Results on the test set for Urban, Oxford, Wikipedia, Cambridge, and Robert.

To compare the values obtained for each example across two models, we utilized t-tests and pair-wise bootstrap resampling tests with 10,000 samples (Koehn, 2004), controlling for the random seed (set to 2 in our experiments).

5 Results

Automatic Evaluation: Table 2 shows the results on the test set for each reported metric and dataset. Firstly, we note that the LSTM Baseline is able to consistently outperform LoG-CAD in terms of BERTScore, although with mixed results in terms of BLEU. We think this difference is mainly due to the n-gram matching nature of BLEU, which tends to give better scores for longer but incorrect generations, as the example in Table 3 shows, while also being unable to adequately handle cases where the definitions are expressed using words not present in the gold standard. We believe these results validate the usage of a metric such as BERTScore on this task, ultimately showing that tackling definition

Word	Frankenstein
Context	In arming the dictator, the US was creating a ***Frankenstein***
Reference	something that destroys or harms the person or people who created it

Generated	BL	P	R	F
something that you say or do that you think someone of something is ridiculous	**12.5**	83.41	84.78	84.09
an extremely frightening or offensive person	8.13	**87.00**	84.78	**85.88**

Table 3: An example from the CAMBRIDGE test set, showing an evaluation issue caused by BLEU. The generated outputs of the LoG-CAD baseline are shown above, and ours below. BL stands for sentence BLEU and P, R and F stand for P_{BERT}, R_{BERT}, and F_{BERT}.

Configuration	$\mathbf{F_{BERT}}$ **(Δ)**	**BLEU (Δ)**
VCDM	**87.70** (—)	**22.46** (—)
Decoder LSTM Cell	87.68 (-0.02)	22.27 (-0.19)
Frozen definition encoder	87.14 (-0.56)	20.70 (-1.76)
Tied encoders	87.14 (-0.56)	20.59 (-1.87)
Frozen encoders	86.35 (-1.35)	17.42 (-5.04)
Frozen context encoder	85.19 (-2.51)	13.49 (-8.97)

Table 4: Results of the ablation study performed on CAMBRIDGE.

modeling with a generative approach can lead to improved results, and suggesting that the incorporation of a latent variable that models the underlying definition space is beneficial for this task.

Results on Table 2 also show that the inclusion of BERT significantly improves generation quality in terms of BERTScore and BLEU on most datasets. This suggests that the inclusion of pretrained deep contextual word representations is beneficial for the task, which is expected given its contextual nature. We also see that VCDM is able to successfully leverage BERT, as our model is able to offer improved results compared to BERT baselines in all datasets except WIKIPEDIA. We think these results offer additional empirical evidence to support the effectiveness of our generative approach. Improvements provided by our model are particularly significant in the case of URBAN, a dataset which there are many rare words and the context is arguably less informative due to its noisy properties.

We surmise that the subpar performance of VCDM over BERT-ft in WIKIPEDIA is related to the properties of the dataset domain (i.e. description generation of named entities). With this in mind, it could be argued that a completely context- focused architecture (such as that of our finetuned BERT baseline) has properties that are more beneficial in this setting. Contrary to findings in Ishiwatari et al. (2019) which argue for the inclusion of a global context during generation, we find that a contextually-focused (local context) architecture with a strong context encoder (such as BERT) results in better performance within this domain.

Model	Model	p-value bootstrap	p-value t-test
VCDM	LoG-CAD	0.005	1.4×10^{-8}
BERT-ft	LoG-CAD	0.006	4.2×10^{-5}
VCDM	BERT-ft	0.797	1.6×10^{-2}

Table 5: Exact p-values of the performed statistical tests, to compare the scores obtained during our human evaluation.

Ablation Study: To further evaluate the contribution of each introduced component in our approach we performed an ablation study on CAMBRIDGE. Results of these experiments are summarized in Table 4, where it is possible to see that each of our introduced components is beneficial to the task. Note that the VCDM-Cell vs LSTM-Cell improvement is minimal on this dataset. The purpose of the integration of the latent variable in the decoder LSTM cell is for it to act as a ”global definition signal” so we can rely on the properties of the latent variable. As this property is especially useful in cases in which there is noisy context, we think it is reasonable to assume that as context here is more informative, the performance gain from including a global definition signal is relatively small. We also see that freezing the context encoder has a extremley negative impact on performance. We believe this is because the context-encoder hasn't effectively learned to use the *phrase-context pairs* (Sec. 3.1.1).

Human Evaluation: Average human scores obtained are 2.51 for LoG-CAD, 3.08 for BERT-ft and **3.31 for VCDM**. When tested for statistical significance (Table 5), we observed that both VCDM and BERT-ft were superior to LoG-CAD with 99% confidence, using both paired t-tests or pair-wise bootstrap resampling tests (Koehn, 2004), and that the difference between VCDM and BERT-ft was statistically significant at 95% for the t-test.

Qualitative Evaluation: Finally we provide a qualitative evaluation by showing an example of the output of our model and of two of our base-

Word:	Present(VB)	Present(NN)
Context:	Within a sexist ideology and a male-dominated cinema, the woman is ***presented*** as what she represents for man.	In addition to this, think of the ***presents***, the toys, gift sets, and most importantly, all that wrapping paper.
Reference:	To represent (someone or something) to others in a particular way	A thing given to someone as a gift
LoG-CAD:	a person who is present in a particular way	a person's mind
BERT-ft:	Portray or regard (someone) as a particular person, idea or action	An item of furniture presented to resemble a bride <unk>
VCDM:	To portray or describe (someone or something) in a particular context	A thing kept as a gift for children

Table 6: Example showing the generated definitions for two senses of the word "present", taken from OXFORD.

lines, in Table 6. In the OXFORD dataset, which this example is taken from there are 7 senses of the "present", showing VCDM's ability to effectively disambiguate between a large amount of senses.

6 Conclusion

In this paper we have introduced a generative model that directly combines distributional and lexical semantics via a continuous latent variable for the task of definition modeling. Empirical results on multiple corpora, including two new datasets released, show that our model is able to outperform previous work by a consistent margin, also successfully being able to leveraging contextualized word representations. For future work we are interested in exploring how definition modeling could be adapted to a multilingual or cross-lingual setting.

Acknowledgments

We are grateful for the support provided by the NVIDIA Corporation, donating two of the GPUs used for this research. We thank Victor Zhong for insightful discussions, and thank Pablo Loyola, Cristian Rodriguez-Opazo, and Jorge Balazs for proofreading the work and providing useful suggestions.

VCDM: Leveraging Variational Bi-encoding and Deep Contextualized Word Representations for Improved Definition Modeling

A Datasets

Tables 1, 2 and 3 provide a summary of the sizes of each partition for the datasets OXFORD, URBAN and WIKIPEDIA, respectively.

Partition	Count		Length		
	Phrases	Examples	Phrase	Context	Definition
Train	33,128	97,855	1.00	17.74	11.02
Valid	8,867	12,232	1.00	17.80	10.99
Test	8,850	12,232	1.00	17.56	10.95

Table 1: Statistics for OXFORD. The number of individual phrases, number of examples, and the mean lengths of each partition of the dataset are reported.

Partition	Count		Length		
	Phrases	Examples	Phrase	Context	Definition
Train	190,696	411,384	1.54	10.89	10.99
Valid	26,876	57,883	1.54	10.86	10.95
Test	26,875	38,371	1.68	11.14	11.50

Table 2: Statistics for URBAN. The number of individual phrases, number of examples, and the mean lengths of each partition of the dataset are reported.

Partition	Count		Length		
	Phrases	Examples	Phrase	Context	Definition
Train	151,995	887,455	2.10	18.79	5.89
Valid	8,361	44,003	2.11	19.21	6.31
Test	8,397	57,232	2.10	19.02	6.94

Table 3: Statistics for WIKIPEDIA. The number of individual phrases, number of examples, and the mean lengths of each partition of the dataset are reported.

B Evaluation

We make use of the `sentence-bleu.cpp`[1] script in the MOSES (Koehn et al., 2007) GitHub repository to compute sentence-level BLEU, and use the `bert-score` Python package[2] to calculate BERTScore, with hash `roberta-large_L17_no-idf_version=0.3.2 (hug_trans=2.8.0)` for the English datasets and hash `bert-base-multilingual-cased_L9_no-idf_version=0.3.3(hug_trans=2.10.0)` for ROBERT which is in French. For datasets where there are multiple examples for a given word sense, such as WIKIPEDIA, we note that results provided by (Ishiwatari et al., 2019) are obtained by first averaging the evaluation metrics for multiple examples for a given sense —although this is not reported on the paper— which tends to inflate the final values of the metrics. Instead, in this paper report example-wise metric averages, which provide more realistic values of the aggregated evaluation metrics.

C Model Details

We train each of our models using a batch size of 64, and set 1e-3 as the initial learning rate for the Adam optimizer. However, when finetuning BERT (or CamemBERT) in any circumstance, we set the initial learning rate for the BERT parameters to be 5e-5 and use a linear warmup schedule, warming up for the first epoch. We train all models in PyTorch (Paszke et al., 2019), and use the HuggingFace[3] (Wolf et al., 2019) implementation of CamemBERT-base and BERT-base-uncased.

Additionally, we re-implement LoG-CAD (Ishiwatari et al., 2019) using the authors' GitHub repository[4].

D Infrastructure and Environment

Experiments for different datasets were run in two different machines:

- A server machine with an Intel Xeon E5-2630 CPU, and two NVIDIA RTX-2080 (Driver 418.56, CUDA 10.1) GPUs, running Ubuntu 16.04
- An additional server machine with an Intel Core i7-6850K CPU and two NVIDIA Titan Xp (Driver 430.50, CUDA 10.1) GPUs, also running Ubuntu 16.04

E Additonal Output Examples

Word:	Yen
Context:	If Koizumi has enjoyed some economic success, say critics, it has been through a combination of good luck and what many believe has been an artificial weakens of they yen against the dollar.
Reference:	the basic monetary unit of japan.
LoG-CAD:	a longing or yearning
BERT-ft:	a monetary in a foreign country
VCDM:	the basic monetary unit of japan, equal to 100 cents.

Table 4: Descriptions for the rare word “yen"

Word:	doucheturd
Context:	Brad, you’re such a doucheturd.
Reference:	insulting noun, being both a douche or douchebag and a turd
LoG-CAD:	a person who is a douchebag
BERT-ft:	a person who is a douchebag
VCDM:	a person who is a mix of a douche and a turd

Table 5: Descriptions for the slang word “doucheturd"

Gold	(especially of a political party) sponsor (a candidate) in an election
LoG-CAD	a candidate or candidate in a race or election
VCDM	set (a person or team) in an election
Gold	(of a batsman) run from one wicket to the other in scoring or attempting to score a run .
LoG-CAD	a race or contest in which a race is run
VCDM	(of a sports team) run by hitting at the reach of the three runs
Gold	a large open stretch of land used for pasture or the raising of stock
LoG-CAD	(of a horse) be <unk>
VCDM	a specially <unk> area for cattle or cattle
Gold	a large open stretch of land used for pasture or the raising of stock
LoG-CAD	(of a horse) be <unk>
VCDM	a specially <unk> area for cattle or cattle
Gold	a preliminary test of a procedure or system
LoG-CAD	a person or thing that is <unk> or <unk>
VCDM	a continuous search or undertaking
Gold	a race between candidates for elective office
LoG-CAD	a series of people who are <unk>
VCDM	be the charge of
Gold	a row of unravelled stitches
LoG-CAD	a short , narrow <unk>
VCDM	a <unk> in a careless or <unk> way
Gold	a track made or regularly used by a particular animal
LoG-CAD	move or cause to move in a specified direction
VCDM	a <unk> or <unk> run over a tree
Gold	become undone
LoG-CAD	be <unk>
VCDM	become undone by being undone
Gold	cause something to pass or lead somewhere
LoG-CAD	move or move in a <unk>
VCDM	cause something to pass or lead somewhere by constant strength
Gold	cause to perform
LoG-CAD	make a series of facts or plans
VCDM	put in an area
Gold	diarrhoea .
LoG-CAD	a person 's <unk>
VCDM	a <unk> of <unk>
Gold	emit or exude a liquid
LoG-CAD	(of a person 's eyes) move or cause to move in a specified direction
VCDM	(of a person ' s <unk>) become <unk> with <unk>
Gold	extend or continue for a certain period of time
LoG-CAD	be a result of
VCDM	pass for a certain time of time
Gold	fail to stop at (a red traffic light)
LoG-CAD	(of a vehicle) move or move in a specified direction
VCDM	run at or at a particular <unk>
Gold	move about in a hurried and hectic way
LoG-CAD	be in a specified way
VCDM	go or run somewhere in a particular place
Gold	move or cause to move between the spools of a recording machine
LoG-CAD	move or move in a specified direction
VCDM	use or enable (a container) to a desired point in a specified direction
Gold	publish or be published in a newspaper or magazine
LoG-CAD	a <unk> or <unk>
VCDM	(of a newspaper or a public station) publish or broadcast (a television programme)
Gold	put (a form of public transport) in service
LoG-CAD	(of a vehicle) be <unk> or <unk>
VCDM	provide (an undertaking , train , or service) for a service
Gold	the act of running ; traveling on foot at a fast pace
LoG-CAD	a run in a race
VCDM	the act of running ; traveling on foot at a fast pace
Gold	the act of testing something
LoG-CAD	the act of <unk> something
VCDM	the act of testing something
Gold	travel a route regularly
LoG-CAD	move or move in a specified direction
VCDM	travel a route regularly
Gold	the after part of a ship 's bottom where it rises and narrows towards the stern .
LoG-CAD	a <unk> or <unk> .
VCDM	an act of <unk> a boat ' s foot
Gold	the average or usual type of person or thing
LoG-CAD	a person 's existence or belief
VCDM	the general aspects of something , especially a language

Abstract

More recently, Named Entity Recognition has achieved great advances aided by pre-training approaches such as BERT. However, current pre-training techniques focus on building language modeling objectives to learn a general representation, ignoring the named entity-related knowledge. To this end, we propose a NER-specific pre-training framework to inject coarse-to-fine automatically mined entity knowledge into pre-trained models. Specifically, we first warm-up the model via an entity span identification task by training it with Wikipedia anchors, which can be deemed as general-typed entities. Then we leverage the gazetteer-based distant supervision strategy to train the model extract coarse-grained typed entities. Finally, we devise a self-supervised auxiliary task to mine the fine-grained named entity knowledge via clustering. Empirical studies on three public NER datasets demonstrate that our framework achieves significant improvements against several pre-trained baselines, establishing the new state-of-the-art performance on three benchmarks. Besides, we show that our framework gains promising results without using human-labeled training data, demonstrating its effectiveness in label-few and low-resource scenarios.[1]

1 Introduction

Named Entity Recognition (NER) is the task of discovering information entities and identifying their corresponding categories, such as mentions of people, organizations, locations, temporal and numeric expressions (Freitag, 2004). It is an essential component in many applications including machine translation (Babych and Hartley, 2003), relation extraction (Yu et al., 2019), entity linking (Xue et al., 2019a), and so on.

Recently, NER has seen remarkable advances with the help of pre-trained representation models, such as BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019). Providing contextual representation, these pre-trained models could be easily applied to NER applications as an encoder by just fine-tuning it. Despite refreshing the state-of-the-art performance of NER, the current pre-training techniques are not directly optimized for NER. Typically, these models build unsupervised training objectives to capture dependency between words and learn a general language representation (Tian et al., 2020), while rarely considering incorporating named entity information which can provide rich knowledge for NER. Due to little knowledge connection between NER and general language modeling, how to adapt public pre-trained models to be NER-specific remains an open problem.

To this end, injecting named entity knowledge during pre-training is a possible solution. However, this process of knowledge acquisition may be inefficient and expensive. In fact, there are extensive weakly labeled annotations that naturally exist on the web yet to be explored for NER model pre-training, which are relatively easier to obtain compared with labeled data (Cao et al., 2019). One can collect them from online resources, such as the Wikipedia anchors and gazetteers (named entity dictionaries). Although automatically derived corpora usually contain massive noisy data, it still contains some extend the valuable semantic information required for NER (Peng et al., 2019).

In this paper, we propose a *Coarse-to-Fine Entity knowledge Enhanced* (CoFEE) pre-training framework for NER task, aiming to gather and utilize knowledge related to named entities. In particular, we first extract anchors from Wikipedia and use them as training corpora for entity span identification. While anchors have no entity type information, the model could get general-typed entity

knowledge from them and learn to distinguish entity words and non-entity words. In the second phase, we use gazetteers and anchors to generate weakly labeled data for specific entity types and use it to train the model for extracting entities with coarse-grained type. Furthermore, another observation is that entities with the same coarse-grained type may belong to different fine-grained types. According to the cluster hypothesis (Chapelle et al., 2009), the features of entities with the same latent fine-grained label will cluster together in the semantic space. Intuitively, mining these latent cluster structures provides auxiliary information about the coarse-grained entity type, which could be beneficial to improve the NER performance. Based on such motivation, we finally devise a self-supervised method to exploit fine-grained type knowledge and tap the potential of weakly labeled data, which effectively train the NER model with clustering-generated pseudo labels.

We conduct experiments on three realistic NER benchmarks in this paper. Experimental results show that the proposed CoFEE pre-training framework significantly outperforms other competitive baselines, often by large margins. We also demonstrate that CoFEE pre-training can work well in more challenging, label-free and low-resource scenarios. Further ablation studies show the impact of each pre-training task in achieving these strong performance. To the best of our knowledge, this is the first work that has tackled NER-specific representation during pre-training.

2 Related Work

Entity Knowledge for NER. Recently, neural networks have been used for NER and achieved great success (Collobert et al., 2011; dos Santos and Guimarães, 2015; Huang et al., 2015; Ma and Hovy, 2016). Specifically, various types of entity knowledge, including lexical words, gazetteers and anchors in Wikipedia have been proved to be useful for a wide range of sentiment analysis tasks.

For supervised NER task, some researchers utilize lattice structure to incorporate the lexical information into character-based NER and avoid the segmentation error propagation of word (Zhang and Yang, 2018; Gui et al., 2019a; Xue et al., 2019b; Gui et al., 2019b; Sui et al., 2019). Additionally, gazetteers have long been regarded as a piece useful knowledge for NER, previous methods commonly incorporated gazetteers by either using them as handcraft features (Alan et al., 2011; Dominic et al., 2018) or auxiliary structural information (Ding et al., 2019; Liu et al., 2019).

For weakly supervised NER, a typical line of methods centres around transfer learning to extract source knowledge for target, such as cross-domain (Yang et al., 2017; Lin and Lu, 2018; Jia et al., 2019) or cross-lingual (Ni et al., 2017; Xie et al., 2018; Zhou et al., 2019). There are also a lot of weak labels lying on the web or gazetteers, which have not been explored. Consequently, a number of works focus on distantly supervised methods, using anchors or gazetteers to generate data by distant supervision (Liu et al., 2015; Yang et al., 2018; Cao et al., 2019; Peng et al., 2019).

Task Specific Pre-training. Unsupervised language model pre-training and task-specific fine-tuning achieve SOTA results on many NLP tasks, including NER (Peters et al., 2018; Devlin et al., 2019; Li et al., 2020). Recently, with the help of automatically minded knowledge lying in the web, researchers devoted them to the pre-training models for specific tasks, including word sense disambiguation (Huang et al., 2019), word-in-context tasks (Levine et al., 2020), entity-linking and relation classification (Zhang et al., 2019), sentiment classification (Tian et al., 2020).

3 Background

In this section, we give a brief introduction to MRC-NER (Li et al., 2020), which achieves satisfying performance in NER and thus is chosen as the foundation of our work. Given an input paragraph $X = \{x_1, x_2, \cdots, x_n\}$ where x_i denotes the i-th character, NER aims at discovering each entity $x_{start,end}$ in X and identify its corresponding type $y \in Y$, where Y is the set of predefined tags(e.g., PER, LOC). $x_{start,end} = \{x_{start}, x_{start+1}, \cdots, x_{end-1}, x_{end}\}$ is a substring of X satisfying *start* $\leq$ *end*. Specifically, MRC-NER formulates NER as a machine reading comprehension (MRC) problem. Each entity type y is characterized by a natural language query $Q_y = \{q_1^y, q_2^y, ..., q_m^y\}$, and entities are extracted by answering these queries given the contexts. For example, the task of assigning the PER label to "[Washington] was born into slavery on the farm" is formalized as answering the question "Find person including fictional". This strategy naturally introduces the natural language query which encodes significant prior knowledge about the entity

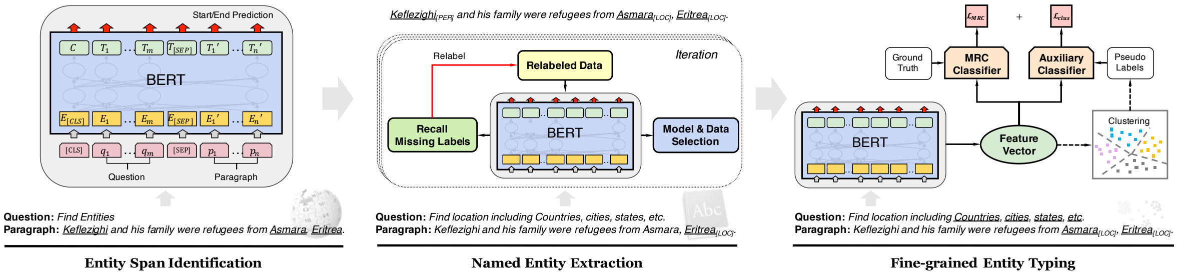

Figure 1: The overall architecture of CoFEE. In Fine-grained Entity Typing, the *solid line* represents the training phase and the *dotted line* represents the clustering phase. These two stages are iteratively done until the network converges.

category to extract.

Formally, MRC-NER model concatenates the query Q and paragraph X, forming string $\{[\text{CLS}], Q, [\text{SEP}], X\}$, where [CLS] and [SEP] are special tokens. Then BERT (Devlin et al., 2019) captures the contextual information for each token in the string via self-attention and produces the representation matrix $\mathbf{H} \in \mathbb{R}^{n \times d}$ of X, where d is the dimension of the last layer of BERT. To extract entity spans, the representation of each word is fed to two softmax layers to predict the probability of each token being a start or end index as follows:

$$P_{\text{start}}(\mathbf{y}_i^{\text{s}}|x_i) = softmax(\mathbf{W}_{\text{s}}\mathbf{h}_i + \mathbf{b}_{\text{s}}), \quad (1)$$

$$P_{\text{end}}(\mathbf{y}_i^{\text{e}}|\mathbf{x}_i) = softmax(\mathbf{W}_{\text{e}}\mathbf{h}_i + \mathbf{b}_{\text{e}}), \quad (2)$$

where $\mathbf{W}_{\text{s}}, \mathbf{W}_{\text{e}} \in \mathbb{R}^{d \times 2}$ and $\mathbf{b}_{\text{s}}, \mathbf{b}_{\text{e}} \in \mathbb{R}^2$ are trainable parameters. At training time, S associated with each question Q_y is paired with two label sequences $\mathbf{Y}_{\text{start}} = \{y_1^{\text{s}}, y_2^{\text{s}}, ..., y_n^{\text{s}}\}$ and $\mathbf{Y}_{\text{end}} = \{y_1^{\text{e}}, y_2^{\text{e}}, ..., y_n^{\text{e}}\}$, where y_i^{s} (y_i^{e}) is the ground-truth label of x_i being the start (end) index of a y-typed entity or not. The cross-entropy loss of start and end index predictions are therefore denoted as:

$$\mathcal{L}_{\text{start}}^{\mathcal{D}} = -\frac{1}{n}\sum_{i=1}^{n} y_i^{\text{s}} log(P_{\text{start}}(y_i^{\text{s}}|x_i)), \quad (3)$$

$$\mathcal{L}_{\text{end}}^{\mathcal{D}} = -\frac{1}{n}\sum_{i=1}^{n} y_i^{\text{e}} log(P_{\text{end}}(y_i^{\text{e}}|x_i)), \quad (4)$$

where $\mathcal{D}$ denotes the training dataset. Finally, the overall training objective to be minimized can be formulated as follows:

$$\mathcal{L}_{\text{MRC}}^{\mathcal{D}} = \mathcal{L}_{\text{start}}^{\mathcal{D}} + \mathcal{L}_{\text{end}}^{\mathcal{D}}. \quad (5)$$

4 Methodology

In this section, we introduce the overall framework of our coarse-to-fine pre-training. Figure 1 gives a brief illustration, which operates in three stages as follows: (1) Stage 1: identity entity span based on Wikipedia anchors; (2) Stage 2: extract coarse-grained entities based on gazetteers; (3) Stage 3: predict fine-grained entity types with a clustering-oriented self-supervised method.

4.1 Entity Span Identification

Pre-trained language Models such as BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019) have been proven to capture rich language information from text. However, as the entity information of a text is seldom explicitly studied, it is hard to expect such pre-trained general representations to capture entity-centric knowledge. In order to better capture entity information and learn NER-specific representation, we propose the first pre-training task named Entity Span Identification (ESI). The entity-centric knowledge is automatically mined from the large scale Wikipedia corpus. In Wikipedia, an anchor $\langle m, e \rangle$ links a mention m to an entity e. Therefore, we assign an "Entity" tag to each anchor in the sentence and construct a General-typed weakly labeled NER dataset $\mathcal{D}_{\text{g}}$ without considering the entity type. To align with MRC-NER, the question of the generated dataset is set as "*Find Entities*". With the general labeled data, the MRC-NER model can be warmed-up with loss $\mathcal{L}_{\text{MRC}}^{\mathcal{D}_{\text{g}}}$. By integrating the general-typed named entity knowledge into the pre-training process, the learned representation would be incorporated with the structural information of crucial importance for NER.

4.2 Named Entity Extraction

After the ESI pre-training, the model has learned to distinguish entity words and non-entity words. Then we step into the second phase (i.e., NEE) in which the model is trained to extract typed entities with gazetteer-labeled data. To alleviate human

Type	Question
PER	人名和虚构的人物形象
ORG	组织包括公司，政府党派，学校，政府，新闻机构
LOC	山脉，河流自然景观的地点
GPE	按照国家，城市，州县划分的地理区域
HP	找出文中的商标，包括公司，品牌
HC	找出文中的产品，包括商品，作品，食品，用品，设施，副产品，农产品，制成品，软件产品，硬件产品，资讯产品，通讯产品，通信产品，电信产品，电脑产品，手机产品，电子产品，科技产品，其他产品
ORG	organization entities are limited to named corporate, governmental, or other organizational entities.
PRR	person entities are named persons or family.
LOC	location entities are the name of politically or geographically defined locations such as cities, provinces, countries, international regions, bodies of water, mountains, etc.

Table 1: Neural language questions for each entity type used in our model.

effort, gazetteer-based distant supervision has been applied to automatically generate labeled data and has gained successes in NER (Yang et al., 2018; Peng et al., 2019). A standard strategy is to scan through the anchor text in $\mathcal{D}_{\text{g}}$ using the gazetteer of a given entity type y and treat anchors matched with entries of the given gazetteer as the entities with type y. In this way, we can obtain a specific-typed NER dataset $\mathcal{D}_{\text{s}}$, which is then exploited to train the MRC-NER model by optimizing $\mathcal{L}_{\text{MRC}}^{\mathcal{D}_{\text{s}}}$. Besides, in order to meet the paradigm of MRC-NER, we also generate a natural language query for each entity type. This procedure is critical since queries encode prior knowledge about labels. Inspired by (Li et al., 2020), we take annotation guideline notes as references to construct queries and illustrate all of the queries used in our model in Table 1. They are theoretical description of the tag categories, thus having the ability to make the model incorporate the information within the label categories unambiguously and completely.

However, as most existing gazetteers only cover part of entities, the automatically derived dataset usually contains massive noisy data including missing labels, incorrect boundaries and types. To address this issue, we propose an iterative self-picking strategy. At the beginning (iteration 0), the model starts with training from the original noisy label set. At the end of each iteration, the model determines the next label set by making predictions on $\mathcal{D}_{\text{s}}$. Concretely, a new entity will be extracted with type y if the probabilities of its start and end indices being predicted as y are both greater than a picking threshold δ. In the next iteration, we use the new derived dataset as input for the model training. Considering that we aim to recall the missing labels, we set $\delta < 0.5$. The model is trained until we find the best model w.r.t. the performance on the validation set. And the final derived dataset is denoted as $\mathcal{D}_{\text{s}}^{\text{best}}$.

4.3 Fine-grained Entity Typing

NEE pre-training focuses on teaching the model named entity knowledge about coarse-grained entity types. However, one coarse-grained entity type may be composed of a set of fine-grained entity types. For example, the coarse-grained type *Location* includes City, Country, Bodies of water, etc. These fine-grained types can provide auxiliary information to help us understand the meaning of *Location*. With this in mind, it is intuitive to group the extracted entities with a cluster miner, and use the subsequent cluster assignments as pseudo labels to mine the fine-grained NER knowledge. One of the most well-studied clustering algorithms is k-Means, and the simplicity and efficiency have established it as a popular means for performing clustering across different disciplines.

Formally, in order to partition the entity set $E = \{e_1, e_2, \cdots, e_M\}$ in $\mathcal{D}_{\text{s}}^{\text{best}}$ into pre-defined K distinct clusters $\{C_k\}_{k=1}^{K}$, k-Means minimizes the sum of the intra-cluster variances $\sum_{k=1}^{K} \mathcal{V}_k$, where $\mathcal{V}_k = \sum_{i=1}^{M} \delta_{ik} ||\mathbf{e}_i - \mathbf{m}_k||^2$ and $\mathbf{m}_k = \sum_{i=1}^{M} \delta_{ik} \mathbf{e}_i / \sum_{i=1}^{M} \delta_{ik}$ are the variance and the center of the k-th cluster, respectively, $\mathbf{e}_i = sumpool([\mathbf{h}_{start_i}, \mathbf{h}_{start_i+1}, ..., \mathbf{h}_{end_i}])$ denotes the representation of the i-th entity, and δ_{ik} is a cluster indicator variable with $\delta_{ik} = 1$ if $e_i \in C_k$

and 0 otherwise. Clustering proceeds by alternating between assigning instances to their closest center and recomputing the centers, until a local minimum is reached. The cluster assignments are used as pseudo labels to guide the transformation of $\mathcal{D}_{\mathrm{s}}^{\mathrm{best}}$ to a pseudo-labeled fine-grained dataset $\mathcal{D}_{\mathrm{c}} = \{(e_i, y_i^{\mathrm{c}})\}$, where y_i^{c} is the pseudo label of e_i Then we can take the negative log-likelihood of the pseudo-labeled tags as the training objective:

$$P_c(\mathbf{y}_i^{\mathrm{c}}|e_i) = softmax(\mathbf{W}_{\mathrm{c}}\mathbf{e}_i + \mathbf{b}_{\mathrm{c}}) \tag{6}$$

$$\mathcal{L}_{\mathrm{clus}} = -\frac{1}{M}\sum_{i=1}^{M} y_i^{\mathrm{c}} log(P_{\mathrm{c}}(y_i^{\mathrm{c}}|e_i)) \tag{7}$$

where $\mathbf{W}_{\mathrm{c}} \in \mathbb{R}^{K\times d}$ and $\mathbf{b}_{\mathrm{c}} \in \mathbb{R}^{K}$ are trainable parameters, $P_{\mathrm{c}}(y_i^{\mathrm{c}}|e_i)$ denotes the probability of entity e_i being predicted to the y_i^{c}-th cluster. Recall that our purpose is to pre-train the NER model to discover typed entities belonging to Y rather than fine-grained entities, so $\mathcal{L}_{\mathrm{clus}}$ can be deemed as an auxiliary task to assist the model to mine the fine-grained NER knowledge and regularize the optimization of $\mathcal{L}_{\mathrm{MRC}}^{\mathcal{D}_{\mathrm{s}}}$. So the training objective in this stage is defined as:

$$\mathcal{L}_{\mathrm{FET}} = \mathcal{L}_{\mathrm{MRC}}^{\mathcal{D}_{\mathrm{s}}^{\mathrm{best}}} + \gamma\mathcal{L}_{\mathrm{clus}}, \tag{8}$$

where γ is the trade-off parameter.

While optimizing with pseudo labels created by the cluster miner seems reasonable, the inevitable label noise caused by the clustering procedure is ignored. To this end, we propose a variance-weighted cross-entropy loss to alleviate the influence of noisy pseudo labels. Obviously, the inverse of $\mathcal{V}_k$ ($\mathcal{V}_k^{-1}$) represents the intra-cluster compactness of the k-th cluster. If the features of instances in the k-th cluster are close together, $\mathcal{V}_k^{-1}$ will be large, meantime the confidence of assigning pseudo label y_i to these instances should also be high and vice versa. Thus we re-formulate Equation 7 as:

$$\mathcal{L}_{\mathrm{clus}} = -\frac{1}{M}\sum_{i=1}^{M} \alpha_{y_i^{\mathrm{c}}} y_i^{\mathrm{c}} log(P_{\mathrm{c}}(y_i^{\mathrm{c}}|e_i)), \tag{9}$$

$$\alpha_{y_i^{\mathrm{c}}} = \frac{exp(\mathcal{V}_{y_i^{\mathrm{c}}}^{-1})}{\sum_{k=1}^{K} exp(\mathcal{V}_n^{-1})}. \tag{10}$$

Finally, we iterate the above clustering-optimizing process by putting back the model to output new representations, generate new pseudo labels $\mathcal{D}_{\mathrm{c}}$ and start the next iteration.

Algorithm 1 Coarse-to-fine Pre-training

```
Require: Wikipedia corpus;
Require: Specific typed gazetteers;
Require: Specific typed validation data $\mathcal{D}_s^{val}$;
Require: Initialize Model Parameters $\theta$ with BERT.

        $best\_score = score(\theta, \mathcal{D}_s^{val})$
    end if
    Re-cluster entities in $\mathcal{D}_s^{best}$ and construct new $\mathcal{D}_c$
end for
return $\theta_{best}$
```

4.4 Algorithm Workflow

In this subsection, we introduce the overall procedure of our framework. Algorithm 1 gives the scratch. First, we construct general-typed NER data $\mathcal{D}_{\mathrm{g}}$ based on Wikipedia anchors, and pre-train the model to extract general typed entities with loss $\mathcal{L}_{\mathrm{MRC}}^{\mathcal{D}_{\mathrm{g}}}$. Then we leverage the gazetteer-based distant supervision strategy to construct a specific-typed NER dataset $\mathcal{D}_{\mathrm{s}}$, and propose an iterative self-picking method to alleviate the data missing problem. In each iteration, the model is optimized to fit the data labeled by the previous iteration. When the performance on the validation set starts to decline, the iteration is ended and the best-performed model is passed to the third stage, where a cluster miner is deployed to group the entities extracted from the second stage into fine-grained types, and the model is trained to simultaneously distinguish fine-grained entities and extract specific-typed entities. Also, we iteratively cluster the features from the last iteration to gradually refine the fine-grained pseudo labels for current.

5 Experiments

We evaluate the CoFEE framework under two settings: (i) supervised setting (ii) weakly supervised setting. In the supervised setting, the pre-trained model is fine-tuned on human-labeled datasets while in the weakly-supervised setting, the model pre-trained with CoFEE is directly applied to perform NER without fine-tuning. Next, we describe these experiments in detail.

5.1 Datasets

Our experiments are conducted on three benchmarks. (1) **Chinese Ontonotes 4.0** consists of newswire text and published by Ralph et al. (2011). It is annotated by four types: PER (Person), ORG (Organization), GPE (Geo-Political Entity) and LOC (Location) for Chinese named entity. It contains 15.7k sentences for training and 4.3k for testing. (2) **E-commerce** is a Chinese NER dataset collected from the e-commerce domain and released by Ding et al. (2019). It is annotated by PROD (product) and BRAN (brand) types. The training and test datasets contain 273k and 53k lines, respectively. (3) **Twitter** is an English NER dataset (Qi et al., 2018), following (Peng et al., 2019), we only use textual information to perform NER and make entity detection on PER, LOC and ORG. It contains 4,000 tweets for training and 3,257 tweets for testing.

5.2 Pre-training Corpora

Wikipedia. We use 20200401 Chinese and English Wikipedia dumps[2][3] for data construction, where we set the max sentence length as 250 and remove the sentences which contain three or fewer anchors. The resulting Chinese corpora contains 1,116,514 sentences and 6,383,142 anchors (entity mentions), and the English corpora contains 3,911,059 sentences and 37,755,176 anchors.

Gazetteer. For Chinese PER, ORG, GPE, and LOC, we collect the gazetteers from the crowd-source dictionaries used by Chinese Input Method ”Sougou”[4], which contain 2,314 person names, 2,649 organization names, 895 geopolitical entities, and 628 location names. For Chinese PROD and BRAN, we use the gazetteers provided by Ding et al.(2019), which contain 628 brand names and 2,974 product names. For English PER, ORG and LOC, we collect the gazetteers using the method released by Peng et al.(2019), which contain 2,795 person names, 1,825 organization names and 1,408 location names.

5.3 Baselines

We chose two types of baselines: supervised methods and the weakly supervised methods. We call our proposed CoFEE pre-training framework with MRC-NER backbone as CoFEE-MRC. In addition, to demonstrate the model-agnostic and generic property of CoFEE, we also implemented another competitive baseline by replacing the MRC-NER backbone with a widely used BERT model (Devlin et al., 2019) without any change in the training procedure, denoted as CoFEE-BERT. We used open-source release of https://github.com/huggingface/transformers.

Supervised Setting. We fine-tune CoFEE-MRC and CoFEE-BERT on supervised NER data and compare with the following baselines to learn how improvement can be achieved for supervised models. **BiLSTM-CRF** (Huang et al., 2015) is a classical neural-network-based baseline for NER, which usually achieves competitive performance in supervised NER. **BERT-Tagger** (Devlin et al., 2019) uses the outputs from the last layer of model BERT$_{base}$ as the character-level enriched contextual representations to make sequence labeling. **MRC-NER** (Li et al., 2020) formulates NER as a machine reading comprehension task and uses BERT as the basic encoder.

Weakly Supervised Setting. We investigate the effect of CoFEE-MRC for solving the NER task without any human annotations, and compare the model to some weakly supervised NER models. For fair comparison, we implemented baselines with the same gazetteers constructed in Section 5.2. **Gazetteer Matching** applies the constructed gazetteers to the test set directly to obtain entity mentions with exactly the same surface name. By comparing with it, we can check the improvements of neural models over the distant supervision itself. **MRC-NER** uses the MRC-NER backbone to perform weakly supervised NER task with gazetteer labeled training data. Furthermore, we explore the influence of our proposed pre-training tasks by removing entity span identification pre-training (**-ESI**) and fine-grained entity typing pre-training (**-FTP**) from CoFEE-MRC.

Table 2: Model performance (%) for supervised NER on three benchmark datasets. Bold marks highest number among all models.

5.4 Hyper-parameter settings

We use the BertAdam as our optimizer, all of the models are implemented under PyTorch using a single NVIDIA Tesla V100 GPU, we use ”bertbase-chinese” and ”bert-base-cased” as our pretrained models for Chinese and English language, the number of parameters is same to these pretrained models in addition to two binary classifier. For each training stage, we vary the learning rate from $1e-6$ to $1e-4$. In NEE stage, we select the best trade-off from 0.1 to 0.5 with an incremental 0.1. In FET stage, we choose the number of clusters K from $\{K-2, K-1, K, K+1, K+2\}$ if we set K as the categories of fine-grained entity. For all these hyper-parameters, we select the best according to the F1-score on the dev sets.

5.5 Evaluation

Following the evaluation metrics in previous work (Li et al., 2020), we apply the entity-level (exact entity match) standard micro Precision (P), Recall (R), and F1 score to evaluate the results.

5.6 Overall Performance

Table 2 contains results for models tuned on human-labeled NER data. We can observe that our CoFEE-MRC pre-training performs remarkably better than MRC-NER, establishing an impressive new state-of-the-art for supervised NER on OntoNotes and Twitter of 82.64% and 73.86%, respectively. CoFEE-BERT also significantly improves the performance compared with BERT and achieves a new SOTA for supervised NER on E-commerce of 79.73%, which confirms the model-agnostic property of our CoFEE pre-training framework. Please note that the results of MRC-NER on OntoNotes have a few concerns need to be addressed. MRC-NER set the max sentence length as 77, which is far less than the true maximum length of the dataset. While in our method, we promise that the maximum length is more than 100.

Chinese OntoNotes 4.0

Table 3: Model performance (%) for weakly supervised NER on three benchmark datasets. Bold marks highest number among all models.

Table 3 reports the results of our models against to baselines under the weakly supervised setting. We can find that: **1)** Gazetteer Matching performs quite poorly and the capability of this method is strongly influenced by the size of the gazetteers. For OntoNotes, the coverage of the large scale gazetteer is almost 40%, but also its huge size causes the low precision. For Twitter, the recall value is about 14% due to its limited gazetteers. **2)** If we directly use MRC-NER to perform weakly supervised NER task with gazetteer labeled data, the model achieves a degree of improvement but is still inaccurate due to the distantly labeled data. **3)** CoFEE-MRC achieves the state-of-the-art F1 score on all three benchmarks, which confirms the validity of our proposed CoFEE pre-training framework. **4)** FET pre-training task brings performance improvements, which verifies the effective-

ness of the introducing fine-grained named entity knowledge. **5)** ESI pre-training further improves the performance, which demonstrates the necessity to warm-up the pre-trained language model using general-typed named entity knowledge.

6 Analysis

6.1 Impact of Data Size

We analyze the influence of reducing the amount of pre-training data and fine-tuning data. The results on the dev set of E-commerce are shown in Figure 2(a) and 2(b), respectively. From Figure 2(a), we can observe that increasing the size of the pre-training data will improve the performance generally, but the improvement tends to flatten out with $60\% \sim 80\%$ data. We suppose that this is because of the number of unique patterns, the influence of the training data size has its local minimum and maximum critical point. From Figure 2(b), we see that knowledge enhanced pre-training is more effective for low-resource cases, where there is a larger gap in performance between our CoFEE-MRC and MRC-NER. Besides, the performance of CoFEE pre-training is more stable as data scale changes. This further demonstrates that our CoFEE pre-training framework can significantly reduce human efforts to create NER taggers.

6.2 Impact of Picking Rate

We then evaluate the influence of the value and variation of our picking rate δ. From Figure 2(c), we can see that setting a lower picking rate to recall more named entities can indeed improve a great performance for the model and gives the highest result with $\delta_0 = 0.1$.

6.3 Impact of Gazetteer Size

We further explore the change of the training data and performance when we use gazetteers of different sizes. In particular, we used 20%, 40%, 60%, 80% and 100% of the original gazetteers to construct pre-training corpora. Statistical information of each resultant gazetteer is illustrated in Figure 3(a), and the model performance on the E-commerce dev set with these gazetteers is demonstrated in Figure 3(b). We can observe that increasing the size of gazetteers will generally improve the performance of our proposed CoFEE-MRC model and the performance growths in line with the performance of “Matching”, indicating that in addition to the gazetteer size, matching degree also has a crucial influence on the model performance.

6.4 Impact of Cluster Size

The proposed CoFEE framework does require a cluster size K as the scope for pseudo labels. One may wonder whether the choice of K has a significant influence on the final results. In this subsection, we vary K from 4 to 90 and report the F1 score of CoFEE-MRC on the E-commerce dev set. As shown in Figure 2(d), the best performance is obtained when K is exactly set as the number of fine-grained entity types described in the queries (23), indicating that our CoFEE pre-training can leverage this information as useful prior knowledge. Thanks to the self-supervised learning schema, when we very from 3 to 90, the model achieves stable F1 score and is not sensitive to the choice of K. The results also further indicate the applicability of the proposed framework when being applied to a new kind of named entity where the number of fine-grained entity types is not available in advance. We can safely assign a larger value than needed and the model is still robust.

7 Conclusion

We investigated coarse-to-fine entity knowledge enhanced pre-training for named entity recognition, which integrates three kinds of entity knowledge with different granularity levels. Though conceptually simple, our framework is highly effective and easy to implement. On three popular NER benchmarks, we found consistent improvements over both state-of-the-art supervised and weakly-supervised methods. Further analysis verifies the necessity of utilizing NER knowledge for pre-training models.

Abstract

Entity alignment (EA) aims at building a unified Knowledge Graph (KG) of rich content by linking the equivalent entities from various KGs. GNN-based EA methods present promising performance by modeling the KG structure defined by relation triples. However, attribute triples can also provide crucial alignment signal but have not been well explored yet. In this paper, we propose to utilize an attributed value encoder and partition the KG into subgraphs to model the various types of attribute triples efficiently. Besides, the performances of current EA methods are overestimated because of the name-bias of existing EA datasets. To make an objective evaluation, we propose a hard experimental setting where we select equivalent entity pairs with very different names as the test set. Under both the regular and hard settings, our method achieves significant improvements (5.10% on average Hits@1 in DBP15k) over 12 baselines in cross-lingual and monolingual datasets. Ablation studies on different subgraphs and a case study about attribute types further demonstrate the effectiveness of our method. Source code and data can be found at `https://github.com/thunlp/explore-and-evaluate`.

1 Introduction

The prosperity of data mining has spawned Knowledge Graphs (KGs) in many domains that are often complementary to each other. Entity Alignment (EA) provides an effective way to integrate the complementary knowledge in these KGs into a unified KG by linking equivalent entities, thus benefiting knowledge-driven applications such as Question Answering (Yang et al., 2017, 2018), Recommendation (Cao et al., 2019b) and Information Extraction (Kumar, 2017; Cao et al., 2018). However, EA is a non-trivial task that it could be formulated as a quadratic assignment problem (Yan et al., 2016), which is NP-complete (Garey and Johnson, 1990).

A KG comprises a set of triples, with each triple consisting of a *subject*, *predicate*, and *object*. There are two types of triples: (1) *relation triples*, in which both the subject and object are entities, and the predicate is often called *relation* (see Figure 1(a)); and (2) *attribute triples*, in which the subject is an entity and the object is a *value*, which is either a number or literal string (see Figure 1(c)), and the predicate is often called *attribute*.

Most of the previous EA models (Sun et al., 2017; Wang et al., 2018; Wu et al., 2019a) rely on the structure assumption that, the adjacencies of two equivalent entities in KGs usually contain equivalent entities (Wang et al., 2018) (see Figure 1(a)). These models mainly focus on modeling KG structure defined by the relation triples. However, we argue that attribute triples can also provide important clues for judging whether two entities are the same, based on the attribute assumption that: *equivalent entities often share similar attributes and values in KGs.* For example, in Figure 1(b), the equivalent entities e and e' share the attribute *Area* with similar values of $153,909$ and $154,077$. Therefore, we aim to improve EA using attribute triples. We have identified the challenges of attribute incorporation and dataset bias.

Attribute Incorporation Challenge. Modeling attribute triples together with relation triples is a more effective strategy than modeling attribute triples alone. In this way, the alignment signal from attribute triples can be propagated to an entity's neighbors via relation triples. Recently, some pioneer EA works (Zhang et al., 2019; Trisedya et al., 2019) have incorporated both attribute and relation triples. However, they learn relation and attribute triples in separate networks. In this case, the alignment signal from an entity's discriminative attributes and values will be reserved to the

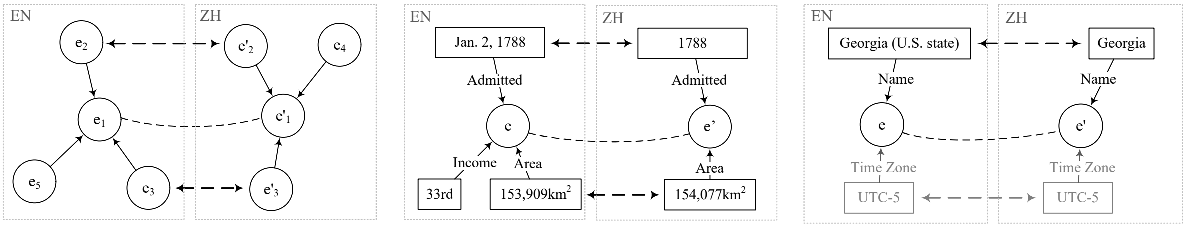
November 16–20, 2020.



(a) EA by the structure assumption.
(b) EA by the attribute assumption.
(c) EA with attribute importance.

Figure 1: Examples for EA using different assumptions and identifying the different importance of attributes. In Figure 1(a), we align e_1 and e'_1 for the equivalent entity pairs (e_2, e'_2) and (e_3, e'_3) in their neighbors. In Figure 1(b),1(c), we align e and e' for their similar attributes and values; e refers to the entity "Georgia (U.S. state)" from English Wiki and e' is the Chinese equivalent. In Figure 1(c), attribute *Time Zone* and its value is assigned less attention weight for being less discriminative for alignment. Chinese texts are translated. Dashed curves link the target equivalent entity pairs. Dashed bothway arrows indicate alignment signals.

entity itself and will not help align its neighbors. In addition, it is crucial to identify the different importance of attributes in discriminating whether two entities are equivalent. For example, the attribute *Time Zone* should be assigned less importance than *Name* since many cities can share the same *Time Zone* (Figure 1(c)). Previous works fail to consider the different importance of attributes.

Dataset Bias Challenge. The performance of EA is overestimated because the existing EA datasets are biased to the attribute *Name*: $60\% - 80\%$ of the released seed set of equivalent entities in DBP15k can be aligned via name matching. The reason is that the equivalent entities are collected using inter language links, which are labeled by a strategy that heavily relies on the translation of entity names[1]. In this way, the datasets contain many "easy" equivalent entities that have similar names. However, in the practical application of EA, the "easy" equivalent entities are often aligned already, and the challenge is to align the "hard" ones that have very different names. This discrepancy between datasets and practical situation causes overestimated EA performance.

To address the first challenge, we propose **Attr**ibuted **G**raph **N**eural **N**etwork (AttrGNN) to learn attribute triples and relation triples in a unified network, and learn importance of each attributes and values dynamically. Specifically, we propose an *attributed value encoder* to select and aggregate alignment signal from informative attributes and values. We further employ the mean aggregator (Hamilton et al., 2017) to propagate this signal to entity's neighbors. In addition, as different types of attributes have different similarity measurements, we partition the KG into four subgraphs by grouping attributes, *i.e.*, attribute *Name*, literal attribute, digital attribute, and structural knowledge. We apply separate channels to learn their representations. We present two methods to ensemble the outputs from all channels.

To alleviate the name-bias of EA datasets (second challenge), we propose a hard experimental setting. Specifically, we construct harder test sets from existing datasets by selecting equivalent entities that have the least similarity in their names. We further evaluate the models on these harder test sets to offer a more objective evaluation of EA models' performance. Under both the hard and regular settings, AttrGNN achieves the best result with significant performance improvement (5.10% Hits@1 on average in DBP15k) over 12 baselines on both the cross-lingual and monolingual datasets.

2 Related Work

Recent entity alignment methods can be classified into embedding-based methods and Graph Neural Network-based (GNN-based) methods.

2.1 Embedding-based Methods

Recent works utilize KG embedding methods, such as TransE (Bordes et al., 2013), to model the relation triples and further unifies two KG embedding spaces by forcing seeds to be close (Chen et al., 2017). Attribute triples has been introduced in this field. JAPE (Sun et al., 2017) computes attribute similarity to regularize the structure-based optimization. KDCoE (Chen et al., 2018) co-trains entity description and structure embeddings with a shared iteratively enlarged seed set. At-

---

[1] https://en.wikipedia.org/wiki/Help:Interlanguage_links

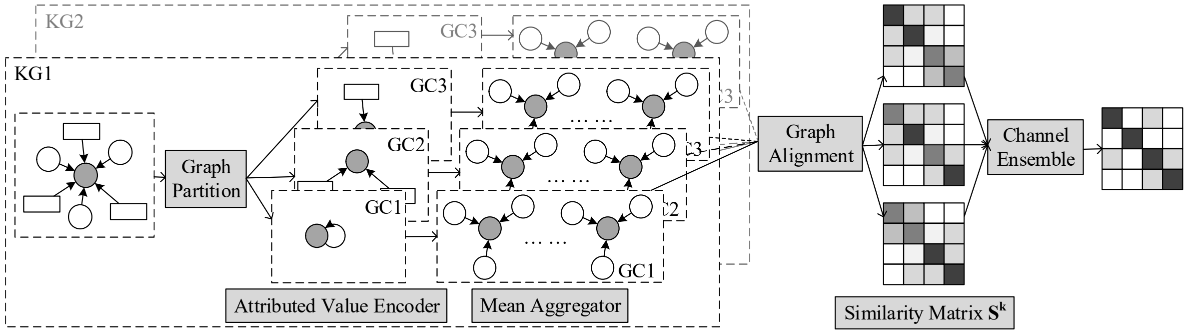


Figure 2: The framework of AttrGNN. Three GNN channels (GCs) are shown as an example. We do not use any attributes in GC1 to focus on the learning of structural knowledge (node degree distribution). $\mathbf{S}^k$ is the output similarity matrix of GCk. $\mathbf{S}^k_{e,e'}$ is the similarity between $e \in$ KG1 and $e' \in$ KG2 measured by GCk. For the KGs and its subgraphs, we use circles to denote entities and rectangles to denote values.

trE (Trisedya et al., 2019) and MultiKE (Zhang et al., 2019) encode values as extra entity embeddings. However, the diversity of attributes and uninformative values limit the performance of the above methods.

2.2 GNN-based Methods

Following Graph Convolutional Networks (Kipf and Welling, 2017), many GNN-based models are proposed because of GNN's strong ability to model graph structure. These methods present promising results on EA because GNN can propagate the alignment signal to the entity's distant neighbors. Previous GNN-based methods focus on extending GNN's ability to model relation types (Wu et al., 2019a,b; Li et al., 2019), aligning entities via matching subgraphs (Xu et al., 2019; Wu et al., 2020), and reducing the heterogeneity between KGs (Cao et al., 2019a). With the exception of Wang et al. (2018) that have incorporated attributes as the initial feature of entities, most of the current GNN-based methods fail to incorporate the attributes and values to further improve the performance of EA.

In this paper, we add values as nodes into graph and use an attributed value encoder to conduct attribute-aware value aggregation.

3 Methodology

The key idea of AttrGNN is to use graph partition and attributed value encoder to deal with various types of attribute triples. In this section, we first define KG and then introduce our graph partition strategy. Further, we design different GNN channels for different subgraphs and present two methods to ensemble all channels' outputs for final evaluation.

3.1 Model Framework

Knowledge Graph (KG) is formalized as a 6-tuple directed graph $G = (E, R, A, V, T^r, T^a)$ where E, R, A, and V refer to the set of entities, relations, attributes, and values, respectively. $T^r = \{(h, r, t) \mid h, t \in E, r \in R\}$ and $T^a = \{(e, a, v) \mid e \in E, a \in A, v \in V)\}$ is the set of relation triples and attribute triples.

Entity Alignment is to find a mapping between two KGs G and G', *i.e.*, $\psi = \{(e, e') \mid e \in E, e' \in E'\}$, where e and e' are equivalent entities. A seed set of equivalent entities ψ^s is used as training data.

Framework. The framework of our AttrGNN model is shown in Figure 2, which consists of four major components: (1) *Graph Partition*, which divides the input KG into subgraphs by grouping attributes and values. (2) *Subgraph Encoder*, which employs multiple GNN channels to learn the subgraphs separately. Each channel is a stack of L attributed value encoders and mean aggregators. The attributed value encoder aggregate attributes and values to generate the entity embeddings, and the mean aggregator propagates entity features to its neighbors following the graph structure. (3) *Graph Alignment*, which unifies the entity vector spaces of two KGs for each channel. (4) *Channel Ensemble*, which infers the entity similarity using each channel and ensemble all channels' results for final inference.

3.2 Graph Partition

Attributes and values have various types, *e.g.*, strings $\mathbb{S}$ and numbers $\mathbb{R}$. Different attributes have different similarity measurements, for example, the similarity between digital values should be numerical differences ($153,909$ *v.s.* $154,077$), while the similarity of literal values is often based on their semantic meanings. Therefore, we separately learn the similarity measurements of the KG's 4 subgraphs, defined as $G^k = (E, R, A^k, V^k, T^r, T^{ak})$, where $k \in \{1, 2, 3, 4\}$:

- G^1 includes attribute triples of *Name* only, *i.e.*, $A^1 = \{a_{name}\}$.
- G^2 includes attribute triples of literal values, *i.e.*, $A^2 = \{a \mid (e, a, v) \in T^a, v \in \mathbb{S}, a \neq a_{name}\}$.
- G^3 includes attribute triples of digital values, *i.e.*, $A^3 = \{a \mid (e, a, v) \in T^a, v \in \mathbb{R}\}$;
- G^4 has no attribute triples, *i.e.*, $A^4 = \emptyset$.

These subgraphs have mutually-exclusive attribute triples but share the same relation triples.

3.3 Subgraph Encoder

We design different GNN channels (GCs) to encode the above four subgraphs: *Name* channel for G^1, *Literal* channel for G^2, *Digital* channel for G^3, and *Structure* channel for G^4. The building blocks of these channels are two types of GNN layers: the attributed value encoder and the mean aggregator. Particularly, to select alignment signal from the informative attributes and values, we first stack one attributed value encoder and then mean aggregators in the *Literal* and *Digital* channels. We stack no attributed value encoder and only mean aggregators for the *Structure* and *Name* channels because they do not use various attribute triples. We add residual connections (He et al., 2016) between GNN layers for the *Name*, *Literal*, and *Digital* channels. Following previous EA works, all channels have two GNN layers. Next, we describe attributed value encoder and mean aggregator in details.

3.3.1 Attributed Value Encoder

Attributed value encoder can selectively gather discriminative information from the initial feature of attributes and values to the central entity. As an example, we show how to obtain e's first layer hidden state $\mathbf{h}_e^1$. The same method applies to all the entities. We obtain the sequence of attribute features $\{\mathbf{a}_1, \cdots, \mathbf{a}_n\}$ and value features $\{\mathbf{v}_1, \cdots, \mathbf{v}_n\}$ given the attribute triples $\{(e, a_1, v_1), \cdots, (e, a_n, v_n)\}$ of e as inputs. Specifically, we use BERT (Devlin et al., 2019) to obtain the features of both literal and digital values[2]. BERT is a language model that is pre-trained on a more than 3000M words corpora. It is popularly used as a feature extractor in NLP tasks. By adding values as nodes and attributes as edges, which connect values and the entity, into the graph, we then can apply attention from the entity to attributes and use the attention score to compute the weighted average of attributes and values. Following the Graph Attention Networks (Velickovic et al., 2018), we define $\mathbf{h}_e^1$ as follows:

$$\begin{aligned}\mathbf{h}_e^1 &= \sigma\Big(\sum_{j=1}^{n} \alpha_j \mathbf{W}_1 [\mathbf{a}_j; \mathbf{v}_j]\Big),\\ \alpha_j &= \operatorname{softmax}(o_j) = \frac{\exp(o_j)}{\sum_{k=1}^{n} \exp(o_k)},\\ o_j &= \operatorname{LeakyReLU}(\mathbf{u}^T [\mathbf{h}_e^0; \mathbf{a}_j]),\end{aligned} \tag{1}$$

where $j \in \{1, \cdots, n\}$, $\mathbf{W}_1 \in \mathbb{R}^{D_{h_1} \times (D_a + D_v)}$ and $\mathbf{u} \in \mathbb{R}^{(D_e + D_a) \times 1}$ are learnable matrices, σ is the $\mathrm{ELU}(\cdot)$ function, and $\mathbf{h}_e^0$ is the initial entity feature.

3.3.2 Mean Aggregator

Mean aggregator layer utilizes the features of the target entity and its neighbors to generate the entity embedding. The neighbor entities of e are defined by relation triples: $\mathcal{N}(e) = \{j \mid \forall (j, r, e) \in T^r \textit{ or } \forall (e, r, j) \in T^r, \forall r \in R\}$. We aggregate the features of e's neighbor entities to gather alignment signal and learn the structural knowledge. Given the hidden state $\mathbf{h}_e^{l-1}$ from the $l-1$ layer, the mean aggregator (Hamilton et al., 2017) is defined as:

$$\mathbf{h}_e^l = \sigma(\mathbf{W}_l\, \mathrm{MEAN}(\{\mathbf{h}_e^{l-1}\} \cup \{\mathbf{h}_j^{l-1}, \forall j \in \mathcal{N}(e)\})) \tag{2}$$

where $\mathbf{W}_l \in \mathbb{R}^{D_{h_l} \times D_{h_{l-1}}}$ is a learnable matrix, $\mathrm{MEAN}(\cdot)$ returns the mean vector of the inputs, and σ is the nonlinear function chosen as $\mathrm{ReLU}(\cdot)$.

3.4 Graph Alignment

Graph Alignment unifies the two KGs' representations of each channel into a unified vector space by reducing the distance between the seed equivalent entities. We separately train the four channels and ensemble their outputs afterward for final evaluation (see Section 3.5). Following Li et al. (2019), we generate negative samples of $(e, e') \in \psi^s$ by searching the nearest entities of e (or e') in the entity embedding space. We denote the final output $\mathbf{h}_e^L$ of the channel GC^k as the entity embedding $\mathbf{e}^k$. For each channel GC^k, we optimize the following objective function:

$$\begin{aligned}\mathcal{L}_k = \sum_{(e,e') \in \psi^s} \Big(&\sum_{e_- \in \mathrm{NS}(e)} [d(\mathbf{e}^k, \mathbf{e}'^k) - d(\mathbf{e}_-^k, \mathbf{e}'^k) + \gamma]_+ \\ &+ \sum_{e'_- \in \mathrm{NS}(e')} [d(\mathbf{e}^k, \mathbf{e}'^k) - d(\mathbf{e}, \mathbf{e}'^k_-) + \gamma]_+ \Big)\end{aligned} \tag{3}$$

---

[2] As shown by Andor et al. (2019), BERT embedding can be used for simple numerical computation.

where ψ^s is the seed set of equivalent entities, $\mathrm{NS}(e)$ denotes the negative samples of e; $[\cdot]_+ = \max\{\cdot, 0\}$, $d(\cdot,\cdot) = 1 - \cos(\cdot,\cdot)$ is the cosine distance, and γ is a margin hyperparameter.

3.5 Channel Ensemble

We use the entity embedding of each channel to infer the similarity matrices $\mathbf{S}^k \in \mathbb{R}^{|E|\times|E'|}$ ($k \in \{1,2,3,4\}$), where $\mathbf{S}^k_{e,e'} = \cos(\mathbf{e}^k, \mathbf{e'}^k)$ is the cosine similarity score between $e \in E$ and $e' \in E'$. We present two methods to ensemble the four matrices into a single similarity matrix $\mathbf{S}^*$ for final evaluation.

Average Pooling. Empirically, we assume that each channel has equal importance. We let $\mathbf{S}^* = \frac{1}{4}\sum_{k=1}^{4} \tilde{\mathbf{S}}^k$, where $\tilde{\mathbf{S}}^k$ is the standardized $\mathbf{S}^k$:

$$\tilde{\mathbf{S}}^k = \frac{\mathbf{S}^k - \mathrm{mean}(\mathbf{S}^k)}{\mathrm{std}(\mathbf{S}^k)} \tag{4}$$

SVM. We utilize LS-SVM (Suykens and Vandewalle, 1999) to learn the weights for each channel: $\mathbf{S}^* = \sum_{k=1}^{4} w_k \mathbf{S}^k$, where $\mathbf{w} = [w_1, w_2, w_3, w_4]$ is trained as follow:

$$\mathcal{L}_{\mathrm{svm}} = C\sum_{l=1}^{m}[y_l \cdot \max(0, 1 - \mathbf{w}^T\mathbf{x}_l) + (1 - y_l)\cdot \max(0, 1 + \mathbf{w}^T\mathbf{x}_l)] + \frac{1}{2}\mathbf{w}^T\mathbf{w} \tag{5}$$

where $\mathbf{x}_l = [\mathbf{S}^1_{e,e'}, \mathbf{S}^2_{e,e'}, \mathbf{S}^3_{e,e'}, \mathbf{S}^4_{e,e'}]$ is a vector of sampled similarity scores. If $(e, e') \in \phi_s$, label $y_l = 1$, otherwise $y_l = 0$.

4 Experiments

In this section, we compare AttrGNN with 12 baselines on the regular setting and our designed hard setting of EA. We also present an ablation study and a case study to evaluate attributes' and values' effects for EA.

4.1 Experimental Settings

Datasets. We test models on both cross-lingual and monolingual datasets: DBP15k (Sun et al., 2017) and DWY100k (Sun et al., 2018). DBP15k includes three cross-lingual datasets collected from DBpedia: Chinese and English (DBPZH-EN), Japanese and English (DBPJA-EN), French and English (DBPFR-EN). DWY100k contains two monolingual datasets: DBpedia and Wikidata (DBP-WD), DBpedia and YAGO (DBP-YG). The original DBP15k does not have attribute triples. Therefore we retrieve attribute triples from the DBpedia dump (2016-10). We then randomly sample 30% of gold entity alignments for training and use the rest for testing. For DWY100k, we use the released attribute triples and the train/valid/test split of Zhang et al. (2019). We show the number of relation/attribute triples for each dataset in Table 1.

Datasets	#Relation	#Digital	#Literal
DBPZH DBPEN	153k 237k	177k 203k	290k 292k
DBPJA DBPEN	164k 233k	152k 171k	227k 268k
DBPFR DBPEN	192k 278k	162k 227k	313k 323k
DWYWD DWYDB	463k 448k	362k 219k	628k 403k
DWYYG DWYDB	428k 502k	1147k 253k	712k 506k

Table 1: Triple numbers of datasets. #Relation indicates the number of relation triples. The numbers of attribute triples that have digital values and literal values are denoted by #Digital and #Literal.

Table 2: Characteristics of entity alignment models. The top part lists 8 models without utilizing entity names, and the bottom part lists 5 models with entity names. Attr and Value indicate the attributes and values from attribute triples; Name indicates entity names; and Iter indicates whether the model iteratively enlarge training set of equivalent entities.

Baselines. We compare AttrGNN with 12 baselines. We summarize four common characteristics of EA models and mark the employed characteristic for each method in Table 2. Among them, AttrE and MultiKE use the same information as AttrGNN. We also construct a baseline NameBERT that only uses the BERT embedding of entity names to measure the similarity. For each model, we list the reported performance if available; otherwise, we run the source code to get the result. Following ex-

Table 3: Overall performance on the regular setting of DBP15k. Models in the first part do not use *Names* while models in the second part use *Name*. * indicates results from our re-implementation using their source code.

isting works (Sun et al., 2018), we employ Hits@N (%, short as H@N) and Mean Reciprocal Rank (MRR) as the evaluation metrics. Higher Hits@N and MRR indicate better performance.

Training Details. We use BERT (Devlin et al., 2019) to initialize the feature vector for each value. Specifically, given a value v consisting of a sequence of tokens, we use the pre-trained *bert-base-cased*[3] to generate a sequence of hidden states and apply max-pooling to obtain a fixed length vector $\mathbf{v}$ as the initial value feature vector. We do not fine-tune the BERT so that the feature vectors can be cached for efficiency. Following Sun et al. (2017), we use Google Translate to translate all values to English for cross-lingual datasets. We initialize the four channels defined in Section 3.3 as follows. For the *Name* channel, we initialize the entity features using the BERT embedding of entity names. For the *Literal*, *Digital*, and *Structure* channels, we use randomly initialized the 128 dimensional vectors as the entity and attribute features. We use Adagrad (Duchi et al., 2011) as the optimizer. For each entity, we choose maximum 20 or 3 attribute triples based on GPU memory. For Graph Alignment, we choose 25 negative samples for each entity. We use 16 negative samples for each positive sample in the SVM ensemble model. We grid search the best parameters for each GNN channel on the valid set (if available) in the following range: learning rate $\{0.001, 0.004, 0.007\}$, L2 regularization $\{10^{-4}, 10^{-3}, 0\}$. We set $\gamma = 1.0$. We train each channel for 100 epochs. For the SVM in Channel Ensemble, we search for C in range $\{10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$. The experiments are conducted on a server with two 6-core 2.40ghz CPUs, one TITAN X, and 128 GB memory. On DBP15k, the *Literal/Digital/Name* channel costs less than 20 minutes for a grid search, and *Structure* channel costs less than 5 minutes.

4.2 Overall Performance

We report the results in two settings: *regular setting*, *i.e.*, the setting used in the previous entity alignment works; and *hard setting*, where we construct a harder test set for objective evaluation.

4.2.1 Regular Setting

Cross-lingual Dataset. Table 3 shows the overall performance on DBP15K. We can see that:

1. As compared to the second best model, AttrGNN achieves significant performance improvements of 5.10% for Hits@1 and 0.056 for MRR on average. This demonstrates the effectiveness of AttrGNN in integrating both attribute triples and relation triples.

2. NameBERT, which only uses entity names, performs better than models without using names in most cases. This demonstrates our observations that (1) the datasets are name-biased; and (2) the evaluation result cannot reflect true EA performance in real-world situation. Specifically, NameBERT performs better on DBPFR-EN than that on DBPJA-EN and DBPZH-EN, which indicates a higher name-bias on DBPFR-EN. The reason is the better translation quality between French and English.

3. AttrGNN's performance improvement over baselines is higher on DBPZH-EN (8.85%) than those on DBPJA-EN (1.59%) and DBPFR-EN (4.86%). The primary reason is that on DBPZH-EN, different chan-

---

[3] https://github.com/huggingface/transformers

nels of features complement each other better than those on DBP$_{\text{JA-EN}}$ and DBP$_{\text{FR-EN}}$. The ratios[4] of complementary features on DBP$_{\text{ZH-EN}}$/DBP$_{\text{JA-EN}}$/DBP$_{\text{FR-EN}}$ are $19\%/9\%/5\%$. Thus, we benefit the most on DBP$_{\text{ZH-EN}}$ from the ensemble.

4. The SVM ensemble strategy performs better than average pooling on DBP$_{\text{FR-EN}}$. On DBP$_{\text{FR-EN}}$, the performances of AttrGNN channels are imbalanced: the *Name* channel performs much better than other channels, as shown by the performance gap between NameBERT and baselines without names on these datasets. In these imbalanced cases, SVM performs better because it can adjust the weights of channels. However, we can not explain that the SVM strategy performs worse that average pooling on DBP$_{\text{ZH-EN}}$ and DBP$_{\text{JA-EN}}$. In fact, the integration of the various KG features is an open problem. We leave that as a future work.

Monolingual Dataset. We evaluate models on this monolingual setting to inspect the name-bias level when there is no translation error. Table 4 shows the performance on DWY100K. The overall performance is similar to that on DBP15k, on which AttrGNN achieves the best performance. There are three major observations:

1. NameBERT achieves nearly 100% Hits@1 on DBP-YG, which shows more severe name-bias than that on the cross-lingual dataset. The reason is that both DBpedia and YAGO are derived from Wikipedia, resulting in that 77.60% of the released equivalent entities have exactly the same names while the rest have very similar names, *e.g.*, *George B. Rodney* and *George B Rodney*. This results dose not indicate that EA is solved because EA is still challenging when integrating KGs from different domains, where entity names can be very different.

2. AttrE and MultiKE, which use entity names, do not perform well because of their agnostic of attribute importance. The crucial alignment signal from *Name* is thus averaged away by other attribute triples (in DBpedia, each entity has 7-8 attribute triples in average).

3. MultiKE performs better than AttrE because it particularly sets a "Name View" to incorporate names. However, MultiKE performs worse than NameBERT on DBP-YG and DBP15k (Table 3), indicating that its inefficient combination of "Name View" and other views harms the performance.

Methods	DBP-WD			DBP-YG		
	H@1	**H@10**	**MRR**	**H@1**	**H@10**	**MRR**

Table 4: Overall performance on DWY100K. The performance of AttrE is reported in Zhang et al. (2019).

4.2.2 Hard Setting

In the hard setting, we aim to carry out a more objective evaluation of EA models on a harder test set. We first introduce how to construct the test set and then present the results and discussion.

Build Harder Test Set. Let E_s and E'_s be the set of known aligned entities in G and G'. First, we compute the similarity matrix $\mathbf{S}$ via NameBERT; each element $\mathbf{S}_{e,e'}$ denotes the similarity between the entity pair $e \in E_s$ and $e' \in E'_s$. Second, we sort each row of $\mathbf{S}$ in descending order, by ranking (e, e') higher when there is less similarity in their names. Finally, we pick the highest-ranked 60% of equivalent entity pairs as the test set. The train set (30%) and the valid set (10%) are then randomly selected from the remaining set of data. We construct harder test set for the cross-lingual dataset only, because it is impractical to find equivalent entity pairs whose entities have very different names on the monolingual dataset, as shown by the performance of NameBERT in Table 4.

Discussion. We implement AttrGNN and eight best-performed baselines with their source codes on the hard setting. Table 5 shows the overall performance. We observe general performance drop in Hit@1 on DBP15k for all models, as shown in Figure 3. There are three major observations:

1. AttrGNN still achieves the best performance, demonstrating the effectiveness of our model. However, the performance of AttrGNN has degraded by around 6% for Hits@1. This degradation indicates that the practical application of EA is still challenging and worth exploration.

2. RDGCN shows the lowest degradation in performance among all the models with entity names

---

[4] We test the ratios of two models', *i.e.*, the *Name* channel and the ensemble of the other three channels, complementary correct predictions.

AttrGNN$_{\text{avg}}$	**66.21**	**81.81**	**0.719**	75.72	88.76	0.805	86.41	94.67	0.894
AttrGNN$_{\text{svm}}$	65.90	81.16	0.716	**77.39**	**90.33**	**0.821**	**88.64**	**95.64**	**0.912**

Table 5: Overall performance on the hard setting of DBP15k.

because RDGCN utilizes the feature of relation type within a GNN framework. This stable performance suggests that incorporating relation type into GNN is crucial for EA and worth exploration.

3. Except for the iterative model, *i.e.*, BootEA, the performance of models without using entity names exhibits less performance drop than the models with names. The iterative model's performance degrades more because the harder dataset weakens the snowball effect [5] when iteratively enlarging the seed set of equivalent entities.

4.3 Ablation Study

We conduct an ablation study on the performance of each AttrGNN channel, AttrGNN$_{\text{avg}}$ without using the *Name* channel (A w/o Name), AttrGNN without using relation triples (A w/o Relation), and AttrGNN without graph partition (MixAttrGNN) (Figure 4). A w/o Relation is to ensemble NameBERT and one-layer Literal and Digital channels. There are three major observations:

1. The *Literal* and *Structure* channels' performances are close to the *Name* channel under the hard setting. This demonstrates the importance to explore non-name features, including other attributes and relation, for practical EA.

2. Compared to MixAttrGNN, our simple graph partition strategy achieves promising improvement. The reason is that graph partition enables model to measure the similarity of different attributes differently.

3. The *Digital* channel's performance is poor because it is challenging to learn the numerical calculation with the supervision of entity alignment. We thus leave it as future work.

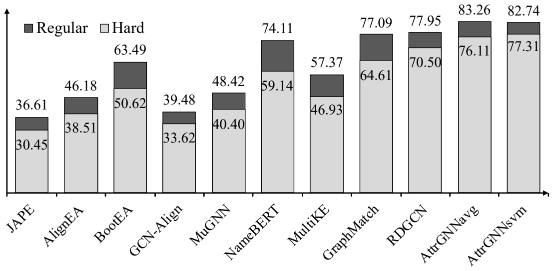

Figure 3: Average Hits@1 (%) of models under the regular setting and the hard setting on DBP15k.

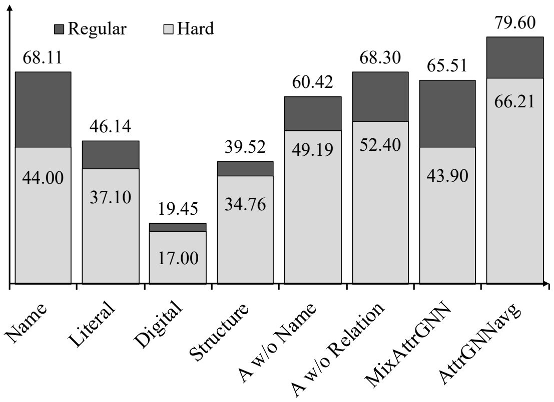

Figure 4: Ablation study on DBP$_{\text{ZH-EN}}$ (Hits@1 %).

4. Our full model significantly outperforms the Structure channel and the A w/o relation, which are the models with only relation/attribute features. This demonstrates the necessity of considering both relation and attribute triples for EA.

4.4 Case Study of Attributes and Values

We give a qualitative analysis of how attribute triples contribute to EA in this case study. Table 6 shows an equivalent entity pair that NameBERT fails to align, but AttrGNN aligns it by taking alignment signal from attributes and values. We observe

.019	motto	Wisdom, Justice...
Chinese Entity: Georgia		
.144	postalabbreviation	GA
.048	flag	Flag of Georgia.svg
.041	fullZhName	Georgia
.037	arearank	24
...		
.026	officiallang	English
.026	admittancedate	1788
.025	totalarea	154077

Table 6: Attributes and values for the entity "Georgia (U.S. state)" from the English and Chinese DBpedia. Attributes are sorted in descending order according to the attention score. Chinese texts are translated.

that most of the top-ranked attributes have similar values between two KGs. In this case, the similar values include three literal strings, *e.g.*, *GA*, *Flag of Georgia* and *Seal of Georgia*, and a number, *e.g. 24*. Meanwhile, the values that are not shared in both KGs are assigned low attention weights and filtered out. As similar cases are commonly observed, we conclude that – attributes determine the importance of values, and values provide discriminative signals. In other words, the attributes whose values are unique are ranked higher, *e.g.*, *postalabbreviation* that denotes the unique postal abbreviation of provinces. The value of the lowest-ranked attributes may have different forms in different KGs. For example, the attention weight of *totalarea* is small, because English KG and Chinese KG use different units of area (square mile in English DBpedia and square kilometer in Chinese DBpedia).

5 Conclusion and Future Work

We propose a novel EA model (AttrGNN) and contribute a hard experimental setting for practical evaluation. AttrGNN can integrate both attribute and relation triples with varying importance for better performance. Experimental results under the regular and hard settings present significant improvements of our proposed model, and the severe dataset bias can be effectively alleviated in our proposed hard setting.

In the future, we are interested in replacing BERT with knowledge enhanced and number sensitive text representations models (Cao et al., 2017; Geva et al., 2020).

Abstract

We present a simple few-shot named entity recognition (NER) system based on nearest neighbor learning and structured inference. Our system uses a supervised NER model trained on the source domain, as a feature extractor. Across several test domains, we show that a nearest neighbor classifier in this feature-space is far more effective than the standard meta-learning approaches. We further propose a cheap but effective method to capture the label dependencies between entity tags without expensive CRF training. We show that our method of combining structured decoding with nearest neighbor learning achieves state-of-the-art performance on standard few-shot NER evaluation tasks, improving F1 scores by 6% to 16% absolute points over prior meta-learning based systems.

1 Introduction

Named entity recognition (NER) aims at identifying and categorizing spans of text into a closed set of classes, such as people, organizations, and locations. As a core language understanding task, NER is widely adopted in several domains, such as news (Tjong Kim Sang and De Meulder, 2003), medical (Stubbs and Uzuner, 2015), and social media (Derczynski et al., 2017). However, one of the primary challenges in adapting NER to new domains is the mismatch between the different domain-specific entity types. For example, only two out of the twenty-three entity types annotated in the I2B2 2014 (Stubbs and Uzuner, 2015) data can be found in the OntoNotes 5 (Weischedel et al., 2013) annotations. Unfortunately, obtaining NER annotations for a novel domain can be quite expensive, often requiring domain knowledge.

Few-shot classification (Vinyals et al., 2016; Bao et al., 2020) models aim at recognizing new classes based on only few labeled examples (support set) from each class. In the context of NER, these few-shot classification methods can enable rapid building of NER systems for a new domain by labeling only a few examples per entity class. Several previous studies (Fritzler et al., 2019; Hou et al., 2020) propose using prototypical networks (Snell et al., 2017), a popular few-shot classification algorithm, to address the few-shot NER problem. However, these approaches only achieve 10 $\sim$ 30% F1 scores on average, when transferring knowledge between different NER datasets with one or five shot examples, warranting more effective methods for the problem.

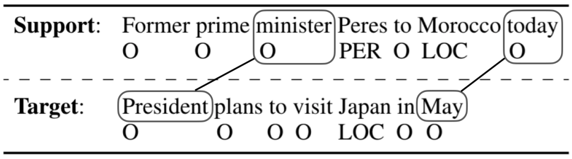

Figure 1: An few-shot NER example. Professions (e.g., 'minister' and 'president') and dates (e.g., 'today' and 'tomorrow') are part of the `O` class. Nearest neighbor classifier is better at predicting the `O` class using an instance-based metric compared to methods using class-based metric.

The direct adaption of existing few-shot *classification* methods to few-shot NER is challenging for two reasons. First, NER is essentially a structured learning problem. It is crucial to model label dependencies as shown in Lample et al. (2016) instead of directly classifying each token independently using the existing few-shot classification approaches. Second, few-shot classification models (Snell et al., 2017) typically learn to represent each semantic class by a prototype based on the labeled examples in its support set. However, for NER, unlike the entity classes, the `Outside` (`O`) class does not represent any unified semantic meaning. In fact, tokens labeled with `O` in a dataset actually correspond to different semantic spaces that should be separately represented in a metric-based learning

---

framework. Consider, for example, in Fig. 1, semantic classes such as professions (e.g., 'minister') and dates (e.g., 'today') may also belong to the `O` class for some NER datasets. Thus, previous approaches end up learning a noisy prototype for representing `O` class in this low-resource setting.

In this paper, we propose a simple, yet effective method STRUCTSHOT for few-shot NER. Instead of learning a prototype for each entity class, we represent each token in the labeled examples of the support set by its contextual representation in the sentence. We learn these contextual representations from training a standard supervised NER model (Lample et al., 2016; Devlin et al., 2019), on the source domain. Whereas meta-learning approaches (Snell et al., 2017; Vinyals et al., 2016) simulate few-shot evaluation setup during training, our approach does not need to do so. This makes it possible to deploy a unified NER system supporting both classical and emerging types of entities, without the overhead of maintaining a separate few-shot system. During evaluation, STRUCTSHOT uses a nearest neighbor (NN) classifier and a Viterbi decoder for prediction. As shown in Fig. 1, for each token ("president") in the target example, the NN classifier finds its nearest token ("minister") from the support examples, instead of relying on an erroneous class-level (`Outside`) prototypical representation. We also improve our nearest neighbor predictions by using Viterbi decoder (Forney, 1973) to capture label dependencies.

We perform extensive in-domain and out-of-domain experiments for this problem. We test our systems on both identifying new types of entities in the source domain as well as identifying new types of entities in various target domains in one-shot and five-shot settings. In addition to the previous evaluation setup followed by Hou et al. (2020), we propose a more standard and reproducible evaluation setup for few-shot NER by using standard test sets and development sets from benchmark datasets of several domains. In particular, we sample support sets from the standard development set and evaluate our models on the standard test set. For all our experiments, we find that our proposed systems outperform previous meta-learning systems by 6% to 16% absolute F1 score.

2 Problem Statement and Setup

In this section, we formalize the task of few-shot NER and propose a standard evaluation setup to facilitate meaningful comparison of results for future research.

2.1 Few-shot NER

NER is a sequence labeling task, where each token in a sentence is either labeled as part of an entity class (e.g., `Person`, `Location`, and `Organization`) or `O` class if it does not belong to an entity. In practice, tagging schemes such as BIO or IO are adopted to represent if a token is at the beginning (`B-X`) or inside (`I-X`) of an entity `X`. Few-shot NER focuses on a specific NER setting where a system is trained on annotations of one or more source domains $\{\mathcal{D}_S^{(i)}\}$ and then tested on one or more target domains $\{\mathcal{D}_T^{(i)}\}$ by only providing a few labeled examples per entity class. It is a challenging problem since the target tag set $\mathcal{C}_T^{(i)}$ can be different from any source tag set $\mathcal{C}_S^{(j)}$. To this end, few-shot NER systems need to learn to generalize to unseen entity classes using only a few labeled examples.

Formally, the task of K-shot NER is defined as follows: given an input sentence $\mathbf{x} = \{x_t\}_{t=1}^T$ and a K-shot support set for the target tag set $\mathcal{C}_\mathcal{T}$, find the best tag sequence $\mathbf{y} = \{y_t\}_1^T$ for $\mathbf{x}$. The K-shot support set contains K entity examples (not tokens) for each entity class given by $\mathcal{C}_\mathcal{T}$.

2.2 A standard evaluation setup

Prior work (Fritzler et al., 2019; Hou et al., 2020) on few-shot NER followed few-shot classification literature and adopted the episode evaluation methodology. Specifically, a NER system is evaluated with respect to multiple evaluation episodes. An episode includes a sampled K-shot support set of labeled examples and a few sampled K-shot test sets. In addition to these prior practices, we propose a more realistic evaluation setting by sampling only the support sets and testing the model on the standard test sets from NER benchmarks.

Test set construction In the episode evaluation setting, test sets are sampled such that the different entity classs are equally distributed. This evaluation setup clearly does not account for the entity distributions in the real data.[1] As a result, the reported performance scores do not reflect the effectiveness of these models when adapting to a new domain.

---

[1] In the I2B2 test data, more frequent `DATE` entity occurs 4,983 times, whereas less frequent `EMAIL` entity occurs only once.

Algorithm 1: Greedy sampling

```
Require: # of shot $K$, labeled set $\mathbf{X}$ with tag set $\mathcal{C}$
Sort classes in $\mathcal{C}$ based on their freq. in $\mathbf{X}$
$\mathcal{S} \leftarrow \phi$ //Initialize the support set
$\{\text{Count}_i \leftarrow 0\}$ //Initialize counts of entity classes in $\mathcal{S}$
while $i < |\mathcal{C}|$ do
    while $\text{Count}_i < K$ do
        Sample $(\mathbf{x}, \mathbf{y}) \in \mathbf{X}$ s.t. $\mathcal{C}_i \in \mathbf{y}$, w/o replacement
        $\mathcal{S} \leftarrow \mathcal{S} \cup \{(\mathbf{x}, \mathbf{y})\}$
        Update $\{\text{Count}_j\}$ $\forall \mathcal{C}_j \in \mathbf{y}$
    end while
end while
return $\mathcal{S}$
```

We propose to use the original test sets of the standard NER datasets to evaluate the performance of our models. Our evaluation setup does not need to randomly sample test sets, thus, improving its reproducibility for future research.

Support set construction In order to test our models in the few-shot setting, we sample support sets from the standard development set of the benchmark dataset. We account for the variance of our model performance by sampling multiple support sets and reporting the average performance on the test set for these sampled support sets. We plan to release the different support sets used for evaluation in our experiments for reproducibility.

Unlike classification tasks, a sentence in NER may contain multiple entity classes. Thus, simply sampling K sentences for each entity class will result in many more entities of frequent classes than those of less frequent classes, as sampling entities of infrequent classes is more likely to also bring in entities of frequent classes than the other way around. Because of this, we utilize a greedy sampling strategy to build support sets as shown in Alg. 1. In particular, we sample sentences for entity classes in an increasing order with respect to their frequencies.

3 Model

In this section, we present our few-shot NER algorithm based on structured nearest neighbor learning (STRUCTSHOT). Our method uses a NER model (Lample et al., 2016; Devlin et al., 2019) trained on the source domain, as a token embedder to generate contextual representations for all tokens. At inference, these *static* representations are simply used for nearest neighbor token classification. We also use a Viterbi decoder to capture label dependencies by leveraging tag transitions estimated from the source domain.

3.1 Nearest neighbor classification for few-shot NER

The backbone of STRUCTSHOT is a simple token-level nearest neighbor classification system (NNShot). At inference, given a test example $\mathbf{x} = \{x_t\}_1^T$ and a K-shot entity support set $\mathcal{S} = \{(\mathbf{x}_n^{(sup)}, \mathbf{y}_n^{(sup)}\}_{n=1}^N$ comprising of N sentences, NNShot employs a token embedder $f_\theta(x) = \hat{x}$ to obtain contextual representations for all tokens in their respective sentences. NNShot simply computes a similarity score between a token x in the test example and all tokens $\{x'\}$ in the support set. It assigns the token x a tag c corresponding to the most similar token in the support set:

$$y^* = \arg \min_{c \in \{1, \cdots, C\}} d_c(\hat{x}) \tag{1}$$

$$d_c(\hat{x}) = \min_{x' \in \mathcal{S}_c} d(\hat{x}, \hat{x'}),$$

where $\mathcal{S}_c$ is the set of support tokens whose tags are c. In this work, we use the squared Euclidean distance, $d(\hat{x}, \hat{x'}) = ||\hat{x} - \hat{x'}||_2^2$ for computing similarities between tokens in the nearest neighbor classification. We also perform L2-normalization on the features before computing these distances.

Pre-trained NER models as token embedders Most meta-learning approaches (Snell et al., 2017; Hou et al., 2020) simulate the test time setup during training. Hence, these approaches sample multiple support sets and test sets from the training data and learn representations to minimize their corresponding few-shot loss on the source domain. In this paper, we instead use a NER model trained on the source domain to learn token-level representations that minimizes the supervised cross-entropy loss. Supervised NER models typically consist of a token embedder $f_\theta(\cdot)$ followed by a linear classifier $\mathbf{W} \in \mathbb{R}^{D \times L}$ where D is the token embedding size and L represents the number of tags.

We consider two popular neural architectures for our supervised NER model: a BiLSTM NER model (Lample et al., 2016) and a BERT-based NER model (Devlin et al., 2019).[2] For training these models on the source domain, we follow the setting from their original papers. These models are trained to minimize the cross-entropy loss $\ell(\mathbf{W} f_\theta(x), y)$ on the training data in the source domain. [3] At inference time, NNShot uses the BiL-

---

[2] We fine-tune the cased BERT-base model.

[3] If training data from more source domains is available, a similar multitask loss can be adopted.

STM and Transformer encoders just before the final linear classification layers as token embedders.

3.2 Structured nearest neighbor learning

Conditional random field (CRF) (Lafferty et al., 2001) is the de facto method to model label dependencies for NER. Lample et al. (2016) use BiLSTM embedder followed by a classification layer to represent token-tag emission scores and learn tag-tag transition scores by joint training a CRF layer. Adopting a similar method is challenging in the context of few-shot learning. The mismatch between the tags in the source domain and the target domain does not allow learning tag-tag transition scores of the target domain by only training on the source domain.

STRUCTSHOT addresses this challenge by using an abstract tag transition distribution estimated on the source domain data. Additionally, STRUCTSHOT discards training phase in CRF and only makes use of its Viterbi decoder during inference. In particular, similar to Hou et al. (2020), we utilize a transition matrix that captures transition probabilities between three abstract NER tags: `O`, `I`, `I-Other`[4]. For instance, $p(\texttt{O}|\texttt{I})$ and $p(\texttt{I}|\texttt{O})$ correspond to the transition probabilities between an entity tag and `O`, whereas $p(\texttt{I}|\texttt{I})$ and $p(\texttt{I-Other}|\texttt{I})$ correspond to the probabilities of transitioning from an entity tag to itself and to a different entity tag respectively. As depicted in Fig. 2, we can extend these abstract transition probabilities to an arbitrary target domain tag set by evenly distributing the abstract transition probabilities into corresponding target transitions. Our simple extension method guarantees that the resulting target transition probabilities still lead to a valid distribution. Hou et al. (2020) copy these abstract transition scores to multiple specific transitions such that the resulting target transition probabilities no longer correspond to a distribution.

The key idea in STRUCTSHOT is that it estimates the abstract transition probabilities by counting the number of times a particular transition was observed in the training data. The transition probability from `X` to `Y` is

$$p(\texttt{Y}|\texttt{X}) = \frac{N(\texttt{X} \to \texttt{Y})}{N(\cdot \to \texttt{Y})}, \tag{2}$$

where $N(\texttt{X} \to \texttt{Y})$ and $N(\cdot \to \texttt{Y})$ are the frequencies of the transition from `X` to `Y` and the transition from any tag to `Y` respectively. In practice, these abstract transitions can also be drawn from a prior distribution given domain knowledge.

For Viterbi inference, we obtain the emission probabilities $p(y = c|x)$ for each token in the test example from NNShot.

$$p(y = c|x) = \frac{e^{-d_c(\hat{x})}}{\sum_{c'} e^{-d_{c'}(\hat{x})}}. \tag{3}$$

Given this abstract transition distribution $p(y'|y)$ and the emission distribution $p(y|x)$, we use Viterbi decoder to solve the following the structured inference problem:

$$\mathbf{y}^* = \arg\max_{\mathbf{y}} \prod_{t=1}^{T} p(y_t|x) \times p(y_t|y_{t-1}). \tag{4}$$

As the emission and transition probabilities are estimated independently, we introduce a temperature hyper-parameter τ that re-normalizes the transition probabilities to align the emission and transition scores to a similar scale.

4 Experiments

In this section, we compare STRUCTSHOT against existing methods on two few-shot NER scenarios: tag set extension and domain transfer. We adopt several benchmark NER corpora in different domains for the few-shot experiments.[5]

4.1 Data

We experiment with standard NER datasets in four important domains: OntoNotes 5.0 (Weischedel et al., 2013) (General), CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003) (News), I2B2

---

[4] We demonstrate the transitions with the IO tagging scheme and ignore `START` and `END` tags for simplicity.

[5] When ready, the code will be published at `https://github.com/asappresearch/structshot`.

Dataset	Domain	# Class	# Sent	# Entity
OntoNotes	General	18	76,714	104,151
CoNLL'03	News	4	20,744	35,089
I2B2'14	Medical	23	140,817	29,233
WNUT'17	Social	6	5,690	3,890

Table 1: Data statistics. # Class corresponds to the number of entity classes labeled in a dataset.

2014 (Stubbs and Uzuner, 2015) (Medical), and WNUT 2017 (Derczynski et al., 2017) (Social). To the best of our knowledge, these are the largest annotated NER corpora in their respective domains. These datasets are labeled with diverse and representative named entity types. Table 1 presents detailed statistics of these datasets. We use the OntoNotes train/development/test splits released for the CoNLL 2012 shared task.[6] Standard train/development/test splits also come with other dataset distributions.

4.2 Evaluation tasks

We evaluate few-shot NER systems on two real world scenarios. For both scenarios, we experiment with both one-shot and five-shot settings.

Tag set extension Our first set of experiments are motivated by the fact that new types of entities often emerge in some domains such as medical and social media. Thus, we evaluate the performance of our systems on recognizing new entity types as they emerge in the source domain. We mimic this scenario by splitting the entity classes of a dataset into a source set and a target set. Specifically, we randomly split the eighteen entity classes of the OntoNotes dataset into three target entity class sets:

- Group A: {`ORG`, `NORP`, `ORDINAL`, `WORK_OF_ART`, `QUANTITY`, `LAW`}
- Group B: {`GPE`, `CARDINAL`, `PERCENT`, `TIME`, `EVENT`, `LANGUAGE`}
- Group C: {`PERSON`, `DATE`, `MONEY`, `LOC`, `FAC`, `PRODUCT`}

We evaluate our systems on each target entity set. For each experiment, we modify the training set by replacing all the entity tags corresponding to the target test group with the `O` tag. Hence, these target tags are no longer observed during training. Similarly, we modify the test set to only include annotations corresponding to the target test group such that we only evaluate our models based on the unseen tags during training. As discussed in § 2, we sample multiple support sets from the development set to simulate the few-shot setting at the test time.

Domain transfer The second set of experiments address a common scenario of adapting a NER system to a novel domain. For our experiments, we use General (OntoNotes) as the source domain and test our models on News (CoNLL), Medical (I2B2) and Social (WNUT) domains. We train our supervised NER models on the standard OntoNotes training set, whereas we evaluate the few-shot systems on standard test sets of CoNLL, I2B2, and WNUT. The support sets are sampled from the corresponding development sets of the three corpora.

4.3 Experimental settings

We have provided details of our proposed evaluation setup for few-shot NER in § 2. We report the standard evaluation metrics for NER: micro averaged F1 score. For each experiment, we sample five support sets and report the mean and standard deviation of the corresponding F1 scores. In order to establish a comprehensive comparison with prior work, we also report episode evaluation results in the Appendix.

Competitive systems We consider five competitive approaches in our experiments. We build BERT-based systems for all the methods and BiLSTM-based systems for three of them. *Prototypical Network* (Snell et al., 2017) is a popular few-shot classification algorithm that has been adopted in most state-of-the-art (SOTA) few-shot NER systems (Fritzler et al., 2019). *Prototypical-Net+P&D* (Hou et al., 2020) improves upon Prototypical Network by using the pair-wise embedding and dependency transfer mechanism.[7] *SimBERT* is a nearest neighbor classifier based on the pre-trained BERT encoder without fine-tuning on any NER data. Finally, we include our proposed *NNShot* and STRUCTSHOT described in § 3. We use the IO tagging scheme for all of the experiments, as we find that it performs much better than BIO scheme for all the considered methods.

Parameter tuning We adopt the best hyperparameter values reported by (Yang et al., 2018) for the BiLSTM-NER models and use the default

---

BERT hyper-parameter values provided by Hugging Face[8]. Specifically, our BiLSTM-NER models adopt one-layer word-level BiLSTM model and one-layer character-level uni-directional LSTM model. LSTM hidden sizes are 50 and 200 and input embedding sizes are 30 and 100 for the character-level and word-level models respectively. We use the pre-trained 100-dimensional GloVe vectors (Pennington et al., 2014) to initialize the word embeddings for all BiLSTM-NER models. SGD and Adam (Kingma and Ba, 2014) are utilized to optimize the BiLSTM-based and BERT-based models with learning rates 0.015 and 5×10^{-5} respectively. We tune other parameters required by different few-shot learning methods on the source domain development sets. The transition re-normalizing temperature τ is chosen from $\{0.01, 0.005, 0.001\}$.

4.4 Results

The results for one-shot NER and five-shot NER are summarized in Table 2 and Table 3 respectively. As shown, our NNShot and StructShot perform significantly better than all previous methods across all evaluation settings. By modeling label dependencies with a simple Viterbi decoder, StructShot boosts the performance of NNShot by 2.4% and 4% F1 scores on five-shot tag set extension and domain transfer tasks on average respectively. These performance gains are greater than the ones obtained by joint CRF training with the prototypical network (PrototypicalNet+P&D), suggesting that independently modeling transition and emission scores is a cheap but effective way to capture label dependencies. StructShot achieves new SOTA results on the two few-shot NER tasks, outperforming the previous SOTA system (PrototypicalNet+P&D) by 6% to 9% F1 score on one-shot setting and 11% to 16% F1 score on five-shot setting.

BiLSTM vs. BERT as token embedder The BERT-based systems considerably outperform BiLSTM-based systems on few-shot NER. Language model pre-training is critical for low-

---

[8] `https://huggingface.co/`

resource natural language processing including few-show transfer learning (Cherry et al., 2019). However, task-specific knowledge is usually more important than the general information learned via unsupervised training. For example, the top-performing BiLSTM-based systems can beat SimBERT by up to 15% F1 score on some few-shot NER settings. With fine-tuning on the OntoNotes data, NNShot outperforms SimBERT by 20% to 35% F1 scores across different settings, demonstrating the effectiveness of injecting task-specific information into pre-trained language models.

Tag set extension vs. Domain transfer The one-shot NER systems generally perform better on domain transfer than on tag set extension, while the five-shot systems work better on the tag set extension task. On the domain transfer task, the source entity classes overlap with some entity classes in the target domain, which benefits NER systems built under the extremely low-resource condition. However, in general, domain transfer is more challenging than tag set extension due to language variation across different domains. Not surprisingly, our five-shot NER systems are not only more accurate but also more robust than the one-shot systems. The standard deviations reported with multiple five-shot support sets are much lower than those obtained with one-shot support sets. This indicates that we can build more reliable few-shot NER systems given more few-shot examples in the support sets.

Episode evaluation Finally, as shown in the Appendix, the results obtained on episode evaluation are generally better than the ones reported with our proposed evaluation setup. However, the performance trend is the same, i.e., STRUCTSHOT significantly outperforms all competitors. It implies that previous studies (Fritzler et al., 2019; Hou et al., 2020) overestimate the performance of their few-shot NER systems.

Few-shot NER in practice Although the average F1 scores of the few-shot NER systems are relatively low, we believe that few-shot NER systems are still very useful in practice. First, the few-shot NER results are reasonably good if the source and target domains are close to each other. For example, the five-shot NER system trained on the OntoNotes training set can achieve 75% F1 score on the CoNLL test set. Second, given the few-shot NER system, we are able to provide immediate support to emerging entity types without retraining and redeploying the NER model. At the same time, a more accurate NER model can be trained in parallel after collecting sufficient annotations for the new types.

4.5 Analysis

We perform analysis to investigate the impact of various tagging schemes and BERT fine-tuning objectives on few-shot NER.

Tagging scheme When only a few entities are available in the support sets, the conventional BIO tagging scheme can harm the performance of few-shot NER systems, as it further reduces the number of labeled instances per tag class. We experiment with both BIO and IO tagging schemes for all the few-shot NER models. The systems equipped with IO tagging scheme always outperform those with BIO scheme. In particular, STRUCTSHOT and NNShot benefit from switching from BIO scheme to IO scheme by an average of 3.2% and 3.8% F1 scores on the five-shot tag set extension and domain transfer tasks respectively.

Fine-tuning objective STRUCTSHOT exploits the standard cross-entropy loss for NER used in the original paper (Devlin et al., 2019) to fine-tune BERT on OntoNotes data. We also experiment with fine-tuning BERT using the prototypical network objective, and then utilize the encoder in STRUCTSHOT. The results show that BERT fine-tuned with the standard NER loss performs much better than the one fine-tuned with the prototypical network loss by 12% and 9% on the five-shot tag set extension and domain transfer tasks respectively. This suggests that the popular meta-learning methods fall short in capturing effective representations for few-shot NER task.

5 Discussion

In this section, we investigate two questions: 1) why STRUCTSHOT is so effective? and 2) why few-shot NER is so difficult?

t-SNE visualization We project token-level representations obtained from the BERT embedders onto a 2-dimensional space using t-SNE (Maaten and Hinton, 2008). Fig. 3 presents the visualization results on the CoNLL and WNUT test sets (we exclude I2B2 as it includes too many classes for visualization). Fine-tuning BERT on OntoNotes clearly improves the task-awareness with respect to both

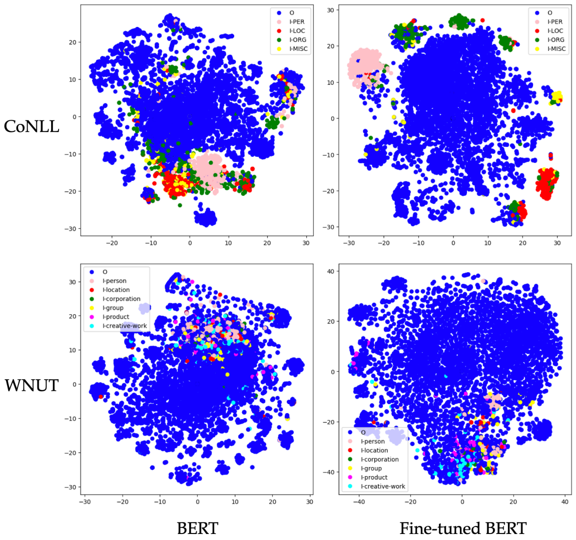

Figure 3: t-SNE visualizations of the CoNLL and WNUT test sets. The representations are obtained from the pre-trained BERT-base model and the BERT-base model fine-tuned on the OntoNotes training data.

I2B2			WNUT		
Class	F1	# Entity	Class	F1	# Entity
`DATE`	66.1	4,983	`person`	57.8	429
`CITY`	61.1	260	`loc.`	49.6	150
`DOCTOR`	51.1	1,945	`c-work`	30.1	142
`AGE`	29.3	768	`corp.`	16.7	66
`MED-REC`	14.4	428	`product`	10.9	127
`PATIENT`	14.0	920	`group`	5.0	165
`HOSPITAL`	10.1	874	-	-	-
`PHONE`	7.9	224	-	-	-
`IDNUM`	7.0	201	-	-	-

Table 4: Best per-class five-shot domain transfer results obtained from StructShot on the I2B2 and WNUT test sets, in which `MED-REC`, `loc.`, `c-work`, and `corp.` correspond `MEDICAL-RECORD`, `location`, `creative-work`, and `corporation` respectively.

CoNLL and WNUT datasets, as instances of the same class are much closer compared to those obtained from the non-fine-tuned BERT model. The separation of different entity classes is more evident on CoNLL due to the greater tag set overlap with OntoNotes. Instances labeled with `O` are spread across the space, regardless of fine-tuning. This explains the effectiveness of StructShot. First, fine-tuning BERT in a conventional NER setting is able to learn a good entity specific metric space. Second, the nearest neighbor classifier that emphasizes more on local distance is more appropriate for assigning `O` to an instance.

Per-class performance analysis We attempt to shed some light on the second question by analyzing outputs from the best five-shot StructShot systems on the domain transfer task. The per-class F1 scores are shown in Table 4, where we exclude I2B2 classes with less than 200 instances in the test set. StructShot achieves reasonable performance on less ambiguous entity classes such as `DATE`, `CITE`, `person`, and `location`. However, it struggles to distinguish between highly ambiguous classes. For example, `AGE`, `MEDICAL-RECORD`, `PHONE`, and `IDNUM` are all numbers. It is still challenging for our system to differentiate different numerical types without any domain specific knowledge. Similarly, StructShot often predicts a `PATIENT` entity as `DOCTOR` and it nearly always assigns the `corporation` label to entities of `group`. We believe that domain specific cues like 'Dr.' and 'MD.' can be useful in resolving these ambiguities and enable few-shot NER systems to generalize better.

6 Related Work

Meta learning Meta learning is widely studied in the computer vision community, as the low-level features in images are transferable across classes that enables learning from only a few examples from the unseen class. The existing approaches (Snell et al., 2017; Vinyals et al., 2016) typically focus on metric learning. Snell et al. (2017) learn a prototype representation for each class and classifies test points based on the nearest prototypes. Vinyals et al. (2016) compute support set aware similarities between a test point and the target classes. These methods have been adapted with some success to NLP tasks including text classification (Yu et al., 2018; Geng et al., 2019; Bao et al., 2020), machine translation (Gu et al., 2018), and relation classification (Han et al., 2018). Recently, Wang et al. (2019) show that simple feature transformations followed by nearest neighbor search can perform competitively with the state-of-the-art meta-learning methods on standard computer vision classification datasets. Inspired by this approach, we evaluate the performance of nearest neighbor based classification against meta-learning methods.

Few-shot NER A few approaches have been proposed for few-shot NER. Hofer et al. (2018) explore different pre-training and fine-tuning strategies to recognize entities in medical text with a few examples. Fritzler et al. (2019) and Hou et al. (2020) exploit popular few-shot classification methods such as prototypical networks and matching network, where Hou et al. (2020) also jointly learn transition scores that improve performance. These approaches require complex episode training and only achieve unsatisfactory results. STRUCTSHOT does not require meta-training. With a simple nearest neighbor classifier and a structured decoder, it is much more accurate than other existing meta-learning based systems.

7 Conclusion

We introduce STRUCTSHOT, a simple few-shot NER system that achieves SOTA performance without any few-shot specific training. We identify two weaknesses of previous systems related to their handling of `O` class and modeling label dependencies. Our systems overcomes these challenges with nearest neighbor learning and structured decoding. We further propose a standard evaluation setup for few-shot NER and show that STRUCTSHOT significantly outperforms prior SOTA systems on popular benchmarks across multiple domains. In the future, we want to extend our system to other few-shot sequence tagging problems such as part-of-speech tagging and slot filling.

Learning Structured Representations of Entity Names using Active Learning and Weak Supervision

Kun Qian, Poornima Chozhiyath Raman, Lucian Popa, Yunyao Li
IBM Research
qian.kun@ibm.com, {pchozhi, lpopa, yunyaoli}@us.ibm.com

Abstract

Structured representations of entity names are useful for many entity-related tasks such as entity normalization and variant generation. Learning the implicit structured representations of entity names without context and external knowledge is particularly challenging. In this paper, we present a novel learning framework that combines active learning and weak supervision to solve this problem. Our experimental evaluation show that this framework enables the learning of high-quality models from merely a dozen or so labeled examples.

1 Introduction

Entity normalization and variant generation are fundamental for a variety of other tasks such as semantic search and relation extraction (Bhutani et al., 2018; Arasu and Kaushik, 2009). Given an entity name E, the goal of entity normalization is to convert E to a canonical form (e.g., "*Jordan, Michael*" → "*Michael Jordan*"), while the goal of entity variant generation is to convert E to a set of different textual representations that refer to the same entity as E (e.g., "*Michael Jordan*" → {"*Jordan, Michael*", "*MJ*", "*M. Jordan*", . . .}).

Typically, entity normalization and variant generation are done by first performing entity linking (Moro et al., 2014; Zhao et al., 2019; Li et al., 2017), i.e., matching entity names appearing in some context (e.g., free text) to named entities in curated knowledge bases (KBs), then use the canonical form or variations (of the linked entities) residing in the KBs to complete the tasks. Unfortunately, in some scenarios, such as search (Thompson and Dozier, 1997), entity names are not surrounded by context. Furthermore, for specialized domain-specific applications, there may not be a knowledge base to govern the names of the relevant entities. Thus, entity linking is not always applicable. In this paper, we take the view that entity normalization and variant generation can be done without contextual information or external KBs if we understand the internal structures of entity names.

As observed in (Campos et al., 2015; Bhutani et al., 2018; Arasu and Kaushik, 2009; Katiyar and Cardie, 2018; Finkel and Manning, 2009), entity names often have implicit structures that can be exploited to solve entity normalization and variant generation. Table 1 shows how we can manipulate such structured representations of entity names to generate different variations without help from context or external knowledge.

Declarative frameworks are proposed in (Arasu and Kaushik, 2009; Campos et al., 2015) to allow developers to manually specify rules that parse entity names into a structured representation. To avoid such low-level manual effort, (Katiyar and Cardie, 2018; Finkel and Manning, 2009) used fully supervised methods for identifying nested entities embedded in flat named entities. Unfortunately, labeled data are rarely available to leverage these methods in the real-world. To mitigate the need for training data, (Bhutani et al., 2018; Qian et al., 2018) proposed an active learning system, LUSTRE, to semi-automatically learn rules for mapping entity names to their structured representations. By using regex-based extractors and a list of comprehensive dictionaries that capture crucial domain vocabularies, LUSTRE can generate rules that achieve SoTA results. However, for more complex and realistic scenarios, dictionaries may not be available and regex-based extractors alone are not expressive enough. Moreover, as shown in Section 3, LUSTRE cannot handle long entities such as machine logs.

In this paper, we present a framework that learns high-quality BERT-CRF models for parsing entity names into structured representations in low-resource settings, namely, when no labeled data is

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6376–6383,

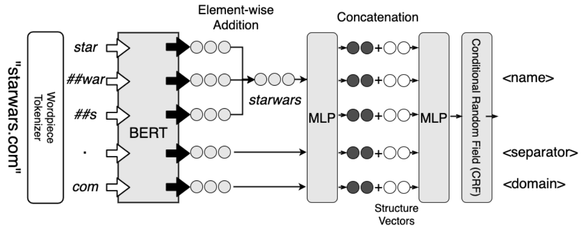

Figure 1: BERT-CRF based model

available. The proposed framework is essentially an active learning-based approach that learns from human interactions. We believe that comprehensible user interfaces are essential for active learning-based approaches, especially for labeling tasks that require non-trivial human labels (e.g., sequence labels in our approach). Therefore, we developed a system named PARTNER (Qian et al., 2020) that implements this framework. We designed the interface of PARTNER similar to that of LUSTRE, but we also made major modifications so that it is more user friendly. Interested readers can find a video demo of PARTNER at `http://ibm.biz/PARTNER`. Our main contributions include:

- A hybrid framework combining active learning and weak supervision to effectively learn BERT-CRF-based models with low human effort.
- A full-fledged system, with intuitive UI, that implements the framework.
- Comprehensive experimental results showing that the framework learns high-quality models from merely a dozen or so labeled examples.

Related work. Our problem is related to both flat and nested named entity recognition (NER). However, as discussed in (Finkel and Manning, 2009), NER focuses on identifying the outermost flat entities and completely ignores their internal structured representations. (Katiyar and Cardie, 2018; Ju et al., 2018; Finkel and Manning, 2009; Dinarelli and Rosset, 2012) identify nested entities within some context using fully supervised methods that require large amounts of labeled data, whereas our goal is to learn from very few labels (e.g., < 15) in a contextless fashion. Active learning (Settles, 2009) and weak supervision have been widely adopted for solving many entity-centric problems, such as entity resolution (Kasai et al., 2019; Qian et al., 2019, 2017; Gurajada et al., 2019), NER (Lison et al., 2020; Shen et al., 2018; He and Sun, 2017; Nadeau, 2007), and entity linking (Chen and Ji, 2011). While the power of the combination of the two techniques has been demonstrated in other domains (e.g., computer vision (Brust et al., 2020)), to the best of our knowledge, the two approaches are usually applied in isolation in prior entity-related work.

Recently, data programming approaches (e.g., (Ratner et al., 2017; Safranchik et al., 2020)) use labeling functions/rules to generate weak labels to train machine learning models in low-resource scenarios. Data programming approaches like Snorkel usually assume that labeling functions are manually provided by users, indicating that their target users must have programming skills in order to provide such labeling functions. In contrast, our goal is to minimize both human effort (i.e., minimize labeling requests) and lower human skills (no programming skills are needed).

2 Methodology

Given a set $E = \{\mathcal{E}_1, \ldots, \mathcal{E}_m\}$ of isolated entity mentions (name strings) of a particular type, where $\mathcal{E}_i$ is a sequence $\mathcal{E}_i = (t_i^1, \ldots, t_i^n)$ of tokens. Assume that the input set E of entity names contain a set $C = \{\mathcal{C}_1, \ldots, \mathcal{C}_k\}$ of semantic components (i.e., labels such as ⟨`first`⟩, ⟨`middle`⟩ in person names). Our goal is to learn a labeling model $\mathcal{M} : \mathcal{E}_i = (t_i^1, \ldots, t_i^n) \rightarrow (y_1, \ldots, y_n)$, where $y_k \in C$. The labeling model $\mathcal{M}$ is a BERT-CRF based model (see Fig. 1) with several key modifications, which we elaborate next.

Tokenization & vectorization. An input entity name is tokenized with BERT's wordpiece tokenizer, which may result in sub-words for out-vocabulary tokens, e.g., "*starwars*" $\rightarrow$ {"*star*", "*##war*", "*##s*"}. In this case, we combine these sub-words' embeddings (from BERT) into one vector using element-wise addition (see Fig. 1). We then feed the sequence of token embeddings to a multi-layer perceptron (MLP), the goal of which is to condense the BERT embeddings to smaller embeddings (e.g., 50), so that they are somewhat comparable to the size of the *structure vectors* (to be discussed next), which are crucial for our active learning and weak supervision approach. It is not hard to see that the pre-trained BERT model can be replaced with any other seq2seq models with pre-trained static word embeddings such as BiLSTM + fastText (Bojanowski et al., 2016).

Structure vectors. We predefined a set of boolean predicates where each of them verifies whether or not a token satisfies a specific syntactic pattern. In our experiments, we defined a list of 15 predicates, which can be easily extended, as shown below:

```
hasAllCapsTokens()
hasAllLowerTokens()
hasAllAlphbeticalToken()
hasPunctuationOnly()
isAlphanumToken()
containsNumber()
containsPunctuation()
isFirstLetterCapitalized()
isTwoDigitNumber()
isFourDigitNumber()
isSingleDigitNumber()
isInteger()
isNumericToken()
appearAtBegining()
appearAtEnd()
```

Each token is then converted to a boolean vector using the predefined boolean predicates, and is concatenated with the corresponding condensed token embedding emitted from the first MLP (see Fig 1). Intuitively, condensed token embeddings can capture semantic information and structure vectors can capture structural information.

CRF layer. Each of the concatenated vector are fed to another MLP, which condense them into a vector of size $|C|$ (i.e., the number of label classes). Finally, the final CRF layer uses viterbi algorithm to find out the most likely sequence of labels using the emission vectors (i.e., embeddings from the last MLP layer) and learned transition matrix.

2.1 Weak Supervision with Structure Vectors

Recall that each token is associated with a binary structure vector that carries its "structure" information. Consider the following company names:

- **"Apple Inc." = {*"Apple"*, *"Inc."*}**
- **"Microsoft Corp." = {*"Microsoft"*, *"Corp."*}**
- **"Coca Cola Co." = {*"Coca"*, *"Cola"*, *"Co."*}**

Although textually dissimilar, they are structurally identical. Concretely, "*Apple*", "*Microsoft*", "*Coca*", and "*Cola*" all contain only alphabetical letters with the first one capitalized; Tokens "*Inc.*", "*Corp.*", and "*Co.*" all are alphabetical letters with first letter capitalized, and they all end with a dot. Therefore, "*Apple Inc.*" and "*Microsoft Corp.*" have the same sequence of structure vectors. Moreover, for consecutive tokens with identical structure vectors, we combine them into one and hence "*Coca Cola*" shares the same structure vectors with the other two. Therefore, if one of the three is labeled as $\langle$`name`$\rangle\langle$`suffix`$\rangle$, we can apply the same sequence of labels to the other two examples as weak labels without actual human annotation.

To some extend, the structure vector-based weak supervision approach adopted in our framework is similar to the labeling functions/rules adopted in data programming approaches (e.g., (Ratner et al., 2017)). In our framework, predefined boolean predicates can be viewed as token-level labeling functions, which are later automatically combined as entity-level labeling functions (together with condensed BERT embeddings) used by the second MLP in our architecture (see Figure 1). Moreover, in our framework, the labeling functions are transparent to the user, thus no programming skills are needed.

2.2 Active Sampling Strategy

The model learning process has multiple iterations, where each starts with requesting the user to label the entity with highest *informative score* (to be defined shortly). Based on the user labeled entity, a set k of other entities with identical sequence of structure vectors will be automatically labeled and used for incrementally updating the model being learned. Then, unlabeled entities are annotated by the refined model and ranked according to the probability scores produced by the CRF layer. Subsequently, both top-p high-confidence and bottom-q low-confidence machine-label entities are sent to the user for verification (i,e, correct or incorrect). We also update the unlabeled entity set by removing user labeled entities and weakly labeled entities. We repeat the process until either user's labeling budget is completed or most (e.g, $\geq 90\%$) of the low-confidence labeled entities are correct.

Informative Score. The informativeness of an entity is measured according to its *representativeness* and *uncertanty*. Let $\mathcal{S}(\mathcal{E}_i)$ denote the sequence of structure vectors of entity $\mathcal{E}_i$, then we define the representativeness of $\mathcal{E}_i$ with respect to the current

Type	# entities	Components
PER	1302	⟨`title`⟩⟨`first`⟩⟨`middle`⟩⟨`last`⟩ ⟨`suffix`⟩⟨`degree`⟩
ORG	2209	⟨`corename`⟩⟨`type`⟩⟨`suffix`⟩⟨`location`⟩
DATE	1190	⟨`Year`⟩⟨`MonthOfYear`⟩⟨`Day`⟩
LOG	1323	⟨`host`⟩⟨`time`⟩⟨`filename`⟩⟨`operation`⟩ ⟨`requesttype`⟩⟨`errormsg`⟩⟨`remainder`⟩

Table 2: Statistics of datasets

set E^u of unlabeled entity as follows:

$$\text{Rep}(\mathcal{E}_i) = \mid \{\mathcal{E}_k \mid \mathcal{S}(\mathcal{E}_k) = \mathcal{S}(\mathcal{E}_i), \forall \mathcal{E}_k \in E^u\} \mid$$

Intuitively, the representativeness of an entity is the total number of entities in the unlabeled data that have the same sequence of structure vectors. The uncertainty score of an entity $\mathcal{E}_i$ is defined as:

$$\text{Uncertain}(\mathcal{E}_i) = \frac{1}{Pr(\mathcal{M}(\mathcal{E}_i))/|\mathcal{E}_i|}$$

where $Pr(\mathcal{M}(\mathcal{E}_i))$ is the probability score of the most likely sequence of labels for $\mathcal{E}_i$ produced by the final CRF layer, and $|\mathcal{E}_i|$ is the number of tokens in $\mathcal{E}$ (divided by this term to normalize the probability score wrt the length of the entities). Then, the informative score of an entity $\mathcal{E}_i$ is:

$$\text{Info}(\mathcal{E}_i) = \text{Rep}(\mathcal{E}_i) \times \text{Uncertain}(\mathcal{E}_i).$$

Thus, informative examples are the ones that are structurally highly representative and for which the current model is highly uncertain.

3 Experimental Evaluation

We implemented the system with Pytorch (Paszke et al., 2019) and pytorch-transformer (Wolf et al., 2019). Four different entity types were considered (see Table 2). Sample mentions of each entity type and corresponding expected structured representations are given in Table 3. Two baselines: (1) **CRF-AW** (Okazaki, 2007): linear-chain conditional random field using our structure vectors as features (2) **LUSTRE**: the prior SoTA active learning system for learning structured representations of entity names (Bhutani et al., 2018). More details about datasets, the implementation of the system, best-performing hyperparameter settings, and evaluation metrics can be found at `https://github.com/System-T/PARTNER`.

For our system, we ask the user to label the example with highest informative score (e.g., label "*Michael*" as ⟨`first`⟩ and "*Jordan*" as ⟨`last`⟩) in each active learning iteration. Then, $k = 50$ (a hyperparameter) structurally similar examples will be automatically labeled. In each iteration, 51 new labeled examples (or less, since there may not be 50 structurally similar examples) will be collected and used to incrementally refine the model. Since CRF-AW is fully supervised, we give it the sets of labels we iteratively accumulated during the active learning of our model. Hence, CRF-AW is not vanilla CRF models, they are enhanced by our structure vectors, our active learning, and our weak supervision strategies.

Metrics. We report F1-scores at *entity-level*, *token-level*, and *component-level*. Entity-level measures how well the model correctly labels individual entities (all tokens of an entity must be correctly labeled). For token and component-level results, we apply models to make predictions for each token in the given set of test entities. Each token prediction is credited as correct if it matches the true label. The difference between the token and component-level evaluation is that the former accumulates the credits over all tokens regardless the actual classes they belong to, whereas the latter evaluation accumulates the credits with respect to the actual classes.

Results. Figure 2 reports entity-level and token-level results for all methods at different iterations. As can be seen, our approach consistently outperforms the baselines, requiring only 7 to 13 actual user annotations per task. Moreover, as the active learning goes, the F1-score curves of our method in all tasks increase monotonically, showing stable performance. Supported by the weak labels obtained by our active sampling strategy, CRF-AW gives the suboptimal results (except for the entity-level performance for LOG), but there are still noticeable gaps between CRF-AW and ours, indicating that pre-trained BERT still plays an essential role. LUSTRE fails to match our performance except for DATE. This finding is not surprising: since LUSTRE learns highly precise rules from user labeled examples, its recall is largely determined by its sampling strategy, which is less effective to find a variety of structurally diverse examples. Since our method always make a prediction, recall is trivially 100%, but the overall precision for entity-level and token-level is relatively low initially. Then, whether or not our sampling strategy can keep finding the most informative examples to "complete" the training set is crucial for enhancing the overall precision. The monotonically increasing F1 curves indicate confirm the effectiveness of our method.

The LOG dataset consists of entities with long text and complex structures. For this dataset, CRF-AW performs well at token level but bad at entity

Table 4: Final F1-scores for different components

level, indicating that it can correctly label most tokens in an entity name, but makes minor mistakes leading to entity-level errors. LUSTRE outperforms CRF-AW since it learns very precise rules. However, LUSTRE terminated quickly as it runs out of memory when trying to learn a rule with over 70 regex primitives to capture a long log message.

Regarding the component-level results, as shown in Table 4, our methods significantly outperform other baselines, which is not a surprise given that our method gives the best token-level results.

4 Concluding Remarks

We proposed a framework for learning structured representation of entity names under low-resource settings. In particular, we focus on a challenging scenario, where entity names are given as textual strings without context. Experiments show the efficacy of our approach. One immediate future work is to generate explanations for model predictions using structured vector.

A Appendix

In the appendix, we provide more details about the experimental evaluation presented in the main paper. Other useful materials are also included in the github repository at `https://github.com/System-T/PARTNER`.

A.1 Datasets

We studied four different datasets, which will be made publicly available in the github repo mentioned earlier after we finish the open source approval process.

In our experiments, each dataset contains a training set and a held-out test set, which we will release. The datasets are manually annotated, and we adopted the 70%-30% splitting convention. Concretely, we first label all examples, and then 70% of them became the "unlabeled" data that is going to be provided to our system, and the rest 30% became a held-out test set.

Input Representation	
BERT-CRF word embeddings size	768
Input dropout rate	0
Structure Vectors	
size of predicates	15
Multilayer Perceptron Layer	
MLP-1 (after BERT) (input, output)	(768,50)
MLP-2 (after Concatenation) (input, output)	(50, # labels)
Activation function	relu
Training	
Optimization	SGD
# epochs	30
Learning rate	0.01
Learning rate decay	1×10^{-4}
Loss function	Negative log likelihood
Active Learning & Weak Supervision Parameters	
# structurally similar examples	50
# high-confidence examples	15
# low-confidence examples	15

Table 5: Architecture, hyperparameters, and training

A.2 Model Implementation

Table 5 lists the hyperparameters of the best-performing model that we reported in the main paper. As mentioned earlier, we used huggineFace pytorch-transformer (Wolf et al., 2019) to implement our BERT-CRF model. In particular, we used the pretrained `BertModel`, and we obtained the tokenizer and pretrained weights using the `bert-base-cased` configuration.

The Bert embedding size (i.e., 768) is predefined by the Bert model, and the size of predicates for structural vectors are predefined by us. The input-output dimension size of MLP-1 (bounds are determined by the embedding size of Bert and number of labels) and learning rate are determined using random sampling (using the DATE dataset).

A.3 Evaluation Metrics

We used three metrics in the main paper: *entity-level*, *token-level*, *component-level*. Here we give a concrete example for computing the three metrics. Consider a test set consisting of a single DATE entity string: **June 3rd, 2020**. Assume that we have three models: m_1, m_2, and m_3. The predictions of the three models over the single test date entity is shown in Table 6, and the F1-scores of these models at entity-level, token-level, and component-level are shown Table 7.

Given that m_1 correctly predict all the tokens (thus the entire entity), it is easy to see that it's F1-scores are all 1.0's. Similar argument can also show that m_3's F1-scores are all 0's. For m_2, since it does not correctly label all the three tokens of the

	June	**3rd**	**2020**
Ground truth	**month**	**day**	**year**
m_1's predictions	month	day	year
m_2's predictions	month	month	year
m_3's predictions	none	none	none

Table 6: Predictions of three dummy models (none means the model does not make a prediction)

	Entity-level	**Token-level**	**Component-level**	
m_1	1.0	1.0	month	1.0
			day	1.0
			year	1.0
m_2	0.0 (precision = 0) (recall = 1.0)	0.80 (precision = 0.67) (recall = 1.0)	month	0.67 (precision=0.5) (recall = 1.0)
			day	0 (precision=1.0) (recall = 0.0)
			year	1.0
m_3	0.0	0.0	month	0.0
			day	0.0
			year	0.0

Table 7: F1-scores of the three dummy models at entity-level, token-level, and component-level

entity string, so the entity-level is 0. However, it does correctly labeled two tokens (i.e., "June" and "3rd") out of the three tokens, so the precision is $0.67 = 2/3$. Moreover, since m_2 makes predictions for all the three tokens, thus the recall is trivially 100%, which means it's token-level F1 is 0.80. In fact, DL-based approaches such as ours that takes a sequence of tokens as input, will trivially achieve 100% recall. For component-level evaluation, m_2 predicted two tokens as **month**, where only one of them is correct, so the precision for month component is 50%. Since m_2 identified all the true **month** tokens, the recall is 100%. For **day** component, m_2 does not predict any token as **day**, but the second token "3rd" has true label **day**, so the recall is 0%, which leads to an F1-score of 0. We do not discuss its **year** component performance because it is obvious 100%.

A.4 Training

Unlike typical deep learning-based supervised learning approaches, where there are a lot of labeled examples, we have limited training data in each active learning iteration. It does not make sense to split the limited number of labeled examples (e.g., about 30) into a training set and a development set, and use the development set to choose the best-performing model. First, the number of examples is too small to make the splitting meaningful. Second, we could potentially perform k-fold cross validation, but that would require much more time, which makes the user experience bad (i.e., the user has to wait for a long time before the training is done).

To make the system as interactive as possible, we used a simple heuristic, that is, we simply train the model with a fixed number of epoch (with random shuffling after each epoch), in our experiments, we set the number to 30 epochs. However, we would terminate the training early if the difference between the total loss of two consecutive epochs is less than a certain threshold, which is set to 10^{-3} in our experiments. The main intuition is that we want to let the model somewhat overfit the training data as they are considered to be "informative" based on our active learning strategy, but we do need to avoid "extreme" overfitting.

A.5 Environment and Runtime

We have run our experiments both on a CPU machine (Apple Macbook Pro 2019 model) and on a GPU machine (with 1 Tesla V100 GPU). Recall that our framework is active learning-based, where each active learning iteration contains three steps: (1) user labeling, (2) model updating, and (3) user feedback. The most time-consuming part is the model updating phase. For the experiments reported in this paper, depending on the sizes of labeled data, the model updating phase takes 10 to 70 seconds with the GPU machine, and 30 seconds to 10 mins with the CPU machine.

Entity Enhanced BERT Pre-training for Chinese NER

Abstract

Character-level BERT pre-trained in Chinese suffers a limitation of lacking lexicon information, which shows effectiveness for Chinese NER. To integrate the lexicon into pre-trained LMs for Chinese NER, we investigate a semi-supervised entity enhanced BERT pre-training method. In particular, we first extract an entity lexicon from the relevant raw text using a new-word discovery method. We then integrate the entity information into BERT using Char-Entity-Transformer, which augments the self-attention using a combination of character and entity representations. In addition, an entity classification task helps inject the entity information into model parameters in pre-training. The pre-trained models are used for NER fine-tuning. Experiments on a news dataset and two datasets annotated by ourselves for NER in long-text show that our method is highly effective and achieves the best results.

1 Introduction

As a fundamental task in information extraction, named entity recognition (NER) is useful for NLP tasks such as relation extraction (Zelenko et al., 2003), event detection (Kumaran and Allan, 2004) and machine translation (Babych and Hartley, 2003). We investigate Chinese NER (Gao et al., 2005), for which the state-of-the-art methods use a character-based neural encoder augmented with lexicon word information (Zhang and Yang, 2018; Gui et al., 2019a,b; Xue et al., 2019).

NER has been a challenging task due to the flexibility of named entities. There can be a large number of OOV named entities in the open domain, which poses challenges to supervised learning algorithms. In addition, named entities can be ambiguous. Take Figure 1 for example. The term “老妇人(the old lady)” literally means “older woman”. However, in the context of football news, it means the nickname of a football club Juventus F.C.. Thus entity lexicons that contain domain knowledge can be useful for the task (Radford et al., 2015; Xu et al., 2019).

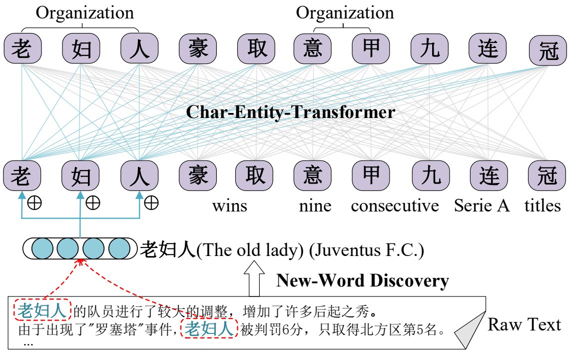

Figure 1: Entity enhanced pre-training for NER. “老妇人(The old lady)”, the nickname of a football club Juventus F.C., is extracted by new-word discovery and integrated into the Transformer structure. After pre-training, the embedding of “老妇人(The old lady)” has the global information and correctly classifies itself as an ORG, which also helps recognize “意甲(Serie A)” as an ORG.

Intuitively, such lexicons can be collected automatically from a set of documents that are relevant to the input text. For example, in the news domain, a set of news articles in the same domain and concurrent with the input text can contain highly relevant entities. In the finance domain, the financial report of a company over the years can serve as a context for collecting named entities when conducting NER for a current-year report. In the science domain, relevant articles can mention the same technological terms, which can facilitate recognition of the terms. In the literature domain, a full-length novel itself can serve as a context for mining entities.

There has been work exploiting lexicon knowledge for NER (Passos et al., 2014; Zhang and Yang,

---

[*] Equal contribution.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6384–6396,
November 16–20, 2020.

2018). However, little has been done integrating entity information into BERT, which gives the state-of-the-art for Chinese NER. We consider enriching BERT (Devlin et al., 2019) with automatically extracted domain knowledge as mentioned above. In particular, We leverage the strength of new-word discovery on large documents by calculating point-wise mutual information to identify entities in the documents. Information over such entities is integrated into the BERT model by replacing the original self-attention modules (Vaswani et al., 2017) with a Char-Entity-Self-Attention mechanism, which captures the contextual similarities of characters and document-specific entities, and explicitly combines character hidden states with entity embeddings in each layer. The extended BERT model is then used for both LM pre-training and NER fine-tuning.

We investigate the effectiveness of this semi-supervised framework on three NER datasets, including a news dataset and two annotated datasets (novels and financial reports) by ourselves, which aims to evaluate NER for long-text. We make comparisons with two groups of state-of-the-art Chinese NER methods, including BERT and ERNIE (Sun et al., 2019a,b). For more reasonable comparison, we also complement both BERT and ERNIE with our entity dictionary and further pre-train on the same raw text as ours.

Results on the three datasets show that our method outperforms these methods and achieves the best results, which demonstrates the effectiveness of the proposed Char-Entity-Transformer structure for integrating entity information in LM pre-training for Chinese NER. To our knowledge, we are the first to investigate how to make use of the scale of the input document text for enhancing NER. Our code and NER datasets are released at `https://github.com/jiachenwestlake/Entity_BERT`.

2 Related Work

Chinese NER. Previous work has shown that character-based approaches perform better for Chinese NER than word-based approaches because of the freedom from Chinese word segmentation errors (He and Wang, 2008; Liu et al., 2010; Li et al., 2014). Lexicon features have been applied so that the external word-level information enhances NER training (Luo et al., 2015; Zhang and Yang, 2018; Gui et al., 2019a,b; Xue et al., 2019). However, these methods are supervised models, which cannot deal with a dataset with relatively little labeled data. We address this problem by using a semi-supervised method by using a pre-trained LM.

Pre-trained Language Models. Pre-trained language models have been applied as an integral component in modern NLP systems for effectively improving downstream tasks (Peters et al., 2018; Radford et al., 2019; Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019b). Recently, there is an increasing interest to augment such contextualized representation with external knowledge (Zhang et al., 2019; Liu et al., 2019a; Peters et al., 2019). These methods focus on augmenting BERT by integrating KG embeddings such as TransE (Bordes et al., 2013). Different from the line of work, our model dynamically integrates document-specific entities without using any pre-trained entity embeddings. A more similar method is ERNIE (Sun et al., 2019a,b), which enhances BERT through knowledge integration. In particular, instead of masking individual subword tokens as BERT does, ERNIE is trained by masking full entities. The entity-level masking trick for ERNIE pre-training can be seen as an implicit way to integrate entity information through error backpropagation. In contrast, our method uses an explicit way to encode the entities to the Transformer structure.

3 Method

As shown in Figure 2, the overall architecture of our method can be viewed as a Transformer structure with multi-task learning. There are three output components, namely masked LM, entity classification and NER. With only the masked language model component, the model resembles BERT without the next sentence prediction task, and the entity classification task is added to enhance pre-training. While only NER outputs are yielded, the model is a sequence labeler for NER. We integrate entity-level information by extending the standard Transformer.

3.1 New-Word Discovery

In order to enhance a BERT LM with document-specific entities, we adopt an unsupervised method by Bouma (2009) to discover candidate entities automatically, which calculates the Mutual Information (MI) and Left and Right Entropy Measures between consecutive characters, respectively, and

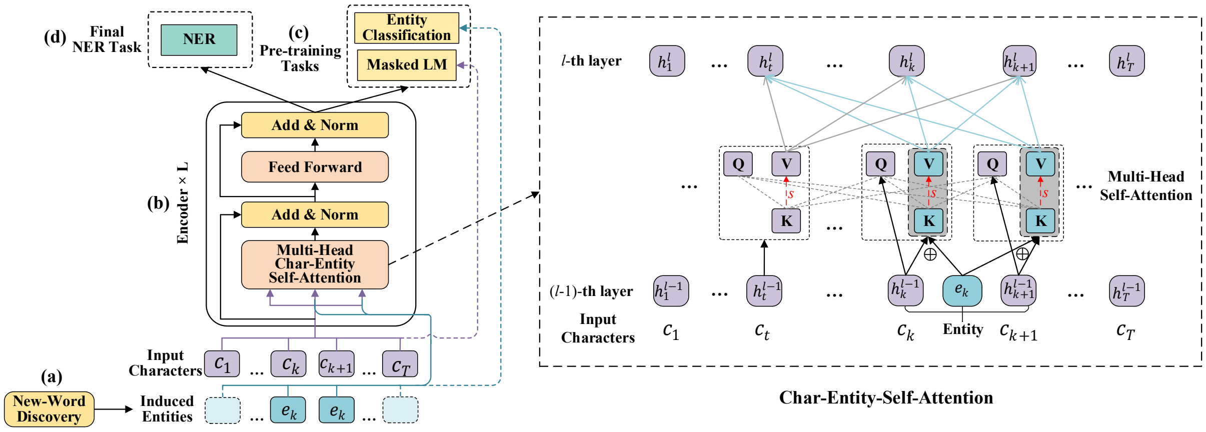

Figure 2: Overall model structure. The semi-supervised pre-training method has four main components: (a) New-word discovery based on information entropy; (b) A Char-Entity-Transformer component to enhance the character-level contextual representation with the acquired entities; (c) Output layers for masked language modeling and entity classification; (d) NER output layer.

adds these three values as the validity score of possible entities. The specific induction process is shown in Appendix A.

3.2 Char-Entity-Transformer

We construct models based on the Transformer structure of $\mathrm{BERT}_{\mathrm{BASE}}$ for Chinese (Devlin et al., 2019). In order to make use of the extracted entities, we extend the baseline Transformer to Char-Entity-Transformer, which consists of a stack of multi-head Char-Entity-Self-Attention blocks. We denote the hidden dimension of characters and the hidden dimension of new-words (entities) as H_c and H_e, respectively. L is the number of layers, and A is the number of self-attention heads.

Baseline Transformer. The Transformer encoder (Vaswani et al., 2017) is constructed with a stacked layer structure. Each layer consists of a multi-head self-attention sub-layer. In particular, given the hidden representation of a sequence $\{\mathbf{h}_1^{l-1}, ..., \mathbf{h}_T^{l-1}\}$ for the $(l-1)$-th layer and packed together as a matrix $\mathbf{h}^{l-1} \in \mathbb{R}^{T \times H_c}$, the self-attention function of the l-th layer is a linear transformation on the *Value* $\mathbf{V}^l$ space by means of *Query* $\mathbf{Q}^l$ and *Key* $\mathbf{K}^l$ mappings, represented as:

$$\begin{aligned}&\{\mathbf{Q}^l, \mathbf{K}^l, \mathbf{V}^l\} = \{\mathbf{h}^{l-1}\mathbf{W}_q^l, \mathbf{h}^{l-1}\mathbf{W}_k^l, \mathbf{h}^{l-1}\mathbf{W}_v^l\}\\ &\mathrm{Atten}(\mathbf{Q}^l, \mathbf{K}^l, \mathbf{V}^l) = \mathrm{softmax}\left\{\frac{\mathbf{Q}^l {\mathbf{K}^l}^\top}{\sqrt{d_k}}\right\}\mathbf{V}^l,\end{aligned} \tag{1}$$

where d_k is the scaling factor and $\mathbf{W}_q^l, \mathbf{W}_k^l, \mathbf{W}_v^l \in \mathbb{R}^{H_c \times H_c}$ are trainable parameters of the l-th layer. The result of $\mathrm{Atten}(\mathbf{Q}^l, \mathbf{K}^l, \mathbf{V}^l)$ is further fed to a feed-forward network sub-layer with layer normalization to obtain the final representation $\mathbf{h}^l$ of the l-th layer.

Algorithm 1 Maximum entity matching.

```
Input: Entity dictionary $\mathcal{E}_{ent}$; input character sequence $\boldsymbol{c} = \{c_1, \dots, c_T\}$.
Output: Entity labeled sequence $\boldsymbol{e} = \{e_1, \dots, e_T\}$.
Initialize: $i \leftarrow 1$; $\{e_1, ..., e_T\} \leftarrow \{0, ..., 0\}$.
# Maximum entity matching process
while $i \leq T - 1$ do
    for $j \in \{i+1, \dots, T\}$ do
        if $(\boldsymbol{c}_{i \sim j} \leftarrow \{c_i, \dots, c_j\}) \in \mathcal{E}_{ent}$ then
            $\{e_i, \dots, e_j\} \leftarrow \{\mathcal{E}_{ent}(\boldsymbol{c}_{i \sim j}), ..., \mathcal{E}_{ent}(\boldsymbol{c}_{i \sim j})\}$
            $k \leftarrow j$
        end if
        $i \leftarrow \max\{k+1, i+1\}$
    end for
end while
```

Char-Entity matching. Given a character sequence $\boldsymbol{c} = \{c_1, \dots, c_T\}$ and an extracted entity dictionary $\mathcal{E}_{ent}$[1], we use the maximum entity matching algorithm to obtain the corresponding entity-labeled sequence $\boldsymbol{e} = \{e_1, ..., e_T\}$. In particular, we label each character with the index of the longest entity in $\mathcal{E}_{ent}$ that includes the character, and label characters with no entity matches with 0. The process is summarized in Algorithm 1.

Char-Entity-Self-Attention. The Char-Entity-Self-Attention structure is shown in Figure 2 (right). Following BERT (Devlin et al., 2019), given a character sequence $\boldsymbol{c} = \{c_1, \dots, c_T\}$, the representation of the t-th ($t \in \{1, \dots, T\}$) character in the input layer is the sum of character, segment and

---

[1] Entities extracted by new-word discovery in Sec 3.1.

position embeddings, represented as:

$$\mathbf{h}_t^1 = \mathbf{E}_c[c_t] + \mathbf{E}_s[0] + \mathbf{E}_p[t] \tag{2}$$

where $\mathbf{E}_c$, $\mathbf{E}_s$, $\mathbf{E}_p$ represent character embedding lookup table, segment embedding lookup table and position embedding lookup table, respectively. In particular, the segment index $s \in \{0, 1\}$ is used to distinguish the order of input sentences for the next sentence prediction task in BERT (Devlin et al., 2019), which is not included in our method. Thus we set the segment index s as a constant 0.

Given the $(l-1)$-th layer character hidden sequence $\{\mathbf{h}_1^{l-1}, \dots, \mathbf{h}_T^{l-1}\}$, the l-th layer *Query* matrix $\mathbf{Q}^l = \{\mathbf{q}_t^l\}_{t=1}^T \in \mathbb{R}^{T \times H_c}$ is computed as the baseline self-attention, but for the *Key* matrix $\mathbf{K}^l = \{\mathbf{k}_t^l\}_{t=1}^T \in \mathbb{R}^{T \times H_c}$ and the *Value* matrix $\mathbf{V}^l = \{\mathbf{v}_t^l\}_{t=1}^T \in \mathbb{R}^{T \times H_c}$, we compute the combination of the character hidden and its corresponding entity embedding as:

$$\begin{aligned}
&\mathbf{q}_t^l = \mathbf{h}_t^{l-1\top}\mathbf{W}_{h,q}^l;\\
&\mathbf{k}_t^l = \begin{cases} \mathbf{h}_t^{l-1\top}\mathbf{W}_{h,k}^l & \text{if } e_t = 0,\\ \frac{1}{2}\left(\mathbf{h}_t^{l-1\top}\mathbf{W}_{h,k}^l + \mathbf{E}_{ent}^\top[e_t]\mathbf{W}_{e,k}^l\right) & \text{else;} \end{cases}\\
&\mathbf{v}_t^l = \begin{cases} \mathbf{h}_t^{l-1\top}\mathbf{W}_{h,v}^l & \text{if } e_t = 0,\\ \frac{1}{2}\left(\mathbf{h}_t^{l-1\top}\mathbf{W}_{h,v}^l + \mathbf{E}_{ent}^\top[e_t]\mathbf{W}_{e,v}^l\right) & \text{else,} \end{cases}
\end{aligned} \tag{3}$$

where $\mathbf{W}_{h,q}^l, \mathbf{W}_{h,k}^l, \mathbf{W}_{h,v}^l \in \mathbb{R}^{H_c \times H_c}$ are trainable parameters of the l-th layer, and $\mathbf{W}_{e,k}^l, \mathbf{W}_{e,v}^l \in \mathbb{R}^{H_e \times H_c}$ are trainable parameters for the corresponding entities. $\mathbf{E}_{ent}$ is the entity embedding lookup table.

As shown in Eq. (3), if there is no corresponding entity for a character, the representation is equal to the baseline self-attention. To show how a character and its corresponding entity are encoded jointly, we denote a pack of entity embeddings $\{\mathbf{E}_{ent}[e_1], \dots, \mathbf{E}_{ent}[e_T]\}$ as $\mathbf{e} \in \mathbb{R}^{T \times H_e}$. The attention score of the i-th character in the l-th layer $\mathbf{S}_i^l$ is computed as:

$$\begin{aligned}
\mathbf{S}_i^l &= \text{softmax}\left\{\frac{\mathbf{q}_i^l \mathbf{K}^{l\top}}{\sqrt{d_k}}\right\}\\
&= \text{softmax}\left\{\frac{\mathbf{q}_i^l \left(\mathbf{h}^{l-1}\mathbf{W}_{h,k}^l + \mathbf{e}\mathbf{W}_{e,k}^l\right)^\top}{2\sqrt{d_k}}\right\}\\
&= \left\{\frac{\sqrt{s_t^c s_t^e}}{\sum_j \sqrt{s_j^c s_j^e}}\right\}_{t=1}^T\\
s.t.\quad s_t^c &= \exp\left(\frac{\mathbf{q}_i^l(\mathbf{h}_t^{l-1\top}\mathbf{W}_{h,k}^l)^\top}{\sqrt{d_k}}\right);\\
s_t^e &= \exp\left(\frac{\mathbf{q}_i^l(\mathbf{e}_t{}^\top\mathbf{W}_{e,k}^l)^\top}{\sqrt{d_k}}\right),
\end{aligned} \tag{4}$$

where a char-to-char attention score s_t^c is computed equally to the baseline self-attention. A char-to-entity attention score s_t^e represents the similarity between a character and the corresponding entity.

Before normalization, the attention score of the i-th character and t-th character $\{\mathbf{S}_i^l\}_t$ is $\sqrt{s_t^c s_t^e}$, which is the geometric mean of s_t^c and s_t^e. This shows that the similarity between two characters by Char-Entity-Self-Attention is computed as a combination of the char-to-char geometric distance and the char-to-entity geometric distance.

Given the attention score $\mathbf{S}_i^l$, $\text{Atten}(\mathbf{q}_i^l, \mathbf{K}^l, \mathbf{V}^l)$ is computed as a weighted sum of the *Value* $\mathbf{V}^l$, which is a combination of character values and entity values.

$$\begin{aligned}
\text{Atten}(\mathbf{q}_i^l, \mathbf{K}^l, \mathbf{V}^l) &= \mathbf{S}_i^l \mathbf{V}^l\\
&= \mathbf{S}_i^l \frac{1}{2}\left(\mathbf{h}^{l-1}\mathbf{W}_{h,v}^l + \mathbf{e}\mathbf{W}_{e,v}^l\right)
\end{aligned} \tag{5}$$

3.3 Masked Language Modeling Task

Following Devlin et al. (2019), we use the masked LM (MLM) task for pre-training. In particular, given a character sequence $\boldsymbol{c} = \{c_1, \dots, c_T\}$, we randomly select 15% of input characters and replace them with [MASK] tokens.

Formally, given the the hidden outputs of the last layer $\{\mathbf{h}_1^L, \dots, \mathbf{h}_T^L\}$, for each masked character c_t in a character sequence, the prediction probability of MLM $p(c_t|\boldsymbol{c}_{<t} \cup \boldsymbol{c}_{>t})$ is computed as:

$$p(c_t|\boldsymbol{c}_{<t} \cup \boldsymbol{c}_{>t}) = \frac{\exp(\mathbf{E}_c^\top[c_t]\mathbf{h}_t^L + b_{c_t})}{\sum_{c \in \mathcal{V}} \exp(\mathbf{E}_c^\top[c]\mathbf{h}_t^L + b_c)}, \tag{6}$$

where $\mathbf{E}_c$ is the character embedding lookup table. $\mathcal{V}$ is the character vocabulary.

3.4 Entity Classification Task

In order to further enhance the coherence between characters and their corresponding entities, we propose an entity classification task, which predicts the specific entity that the current character belongs to. A theoretical explanation of this task is to maximize the mutual information $\mathcal{I}(e; c)$ between the character $c \sim p(c)$ and the corresponding entity $e \sim p(e)$, where $p(c)$ and $p(e)$ represent the probability distributions of c and e, respectively.

$$\begin{aligned}
\mathcal{I}(e; c) &= H(e) - H(e|c)\\
&= H(e) + \mathbb{E}_{c \sim p(c)}\left[\mathbb{E}_{e \sim p(e|c)}\left[\log p(e|c)\right]\right]\\
&= H(e) + \mathbb{E}_{c \sim p(c), e \sim p(e|c)}\left[\log p(e|c)\right],
\end{aligned} \tag{7}$$

where $H(e)$ indicates the entropy of $e \sim p(e)$, represented as $H(e) = -\mathbb{E}_{e \sim p(e)}[\log p(e)]$, which is a constant corresponding to the frequency of entities in a document. Thus the maximization of the mutual information $\mathcal{I}(e;c)$ is equivalent to the maximization of the expectation of $\log p(e|c)$.

Considering the computational complexity due to the excessive number of candidate entities, we employ sampling softmax for output prediction (Jean et al., 2015). Formally, given the hidden outputs of last layer $\{\mathbf{h}_1^L, \dots, \mathbf{h}_T^L\}$ and its corresponding entity labeled sequence $\boldsymbol{e} = \{e_1, \dots, e_T\}$, we compute the probability of each character c_t (s.t. $e_t \neq 0$) aligning with its corresponding entity e_t as:

$$\begin{aligned} p(e_t|c_t) &= \frac{1}{Z}\exp\left(\mathbf{E}_{ent}^{\top}[e_t]\mathbf{h}_t^L + b_{e_t}\right) \\ s.t. \quad Z &= \sum_{e \in \{e_t \cup \mathcal{R}^-\}} \exp\left(\mathbf{E}_{ent}^{\top}[e]\mathbf{h}_t^L + b_e\right), \end{aligned} \tag{8}$$

where $\mathcal{R}^-$ represents the randomly sampled negative set from the candidate entities of the current input document. $\mathbf{E}_{ent}$ is the entity embedding lookup table and b_e is the bias of entity e.

3.5 NER Task

Given the hidden outputs of the last layer $\{\mathbf{h}_1^L, \dots, \mathbf{h}_T^L\}$, the output layer for NER is a linear classifier $f : \mathbb{R}^{H_c} \rightarrow \mathcal{Y}$, where $\mathcal{Y}$ is a $(m-1)$-simplex and m is the number of NER tags. The probability that the character c_t aligns with the k-th NER tag is computed using softmax:

$$p(k|c_t) = \frac{\exp(\mathbf{w}_k{}^{\top}\mathbf{h}_t^L + b_k)}{\sum_{j \in \{1,\dots,m\}} \exp(\mathbf{w}_j{}^{\top}\mathbf{h}_t^L + b_j)}, \tag{9}$$

where $\mathbf{w}_k \in \mathbb{R}^{H_c}$ and b_k are trainable parameters specific to the k-th NER tag. We adopt the B-I-O tagging scheme for NER.

3.6 Training Procedure

Our model is initialized using a pre-trained BERT model[2], and the other parameters are randomly initialized. During training, we first pre-train an LM over all of the raw text to acquire the entity-enhanced model parameters and then fine-tune the parameters using the NER task.

Pre-training. Given raw text with induced entities $\mathcal{D}_{lm} = \{(\boldsymbol{c}^n, \boldsymbol{e}^n)\}_{n=1}^N$, where $\boldsymbol{c}^n$ is a character sequence and $\boldsymbol{e}^n$ is its corresponding entity sequence detected by Algorithm 1, we feed each training character sequence and its corresponding entities into the Char-Entity-Transformer to obtain last layer character hiddens.

Algorithm 2 Pre-training and fine-tuning.

Input: Raw text $\mathcal{D}_{lm}$, entity dict $\mathcal{E}_{ent}$, NER dataset $\mathcal{D}_{ner}$
Parameters: Entity embeddings $\mathbf{E}_{ent}$, Transformer layers $\mathbf{W}_T$, MLM output layer $\mathbf{W}_{MLM}^o$, entity classification output layer $\mathbf{W}_{ENC}^o$, NER output layer $\mathbf{W}_{NER}^o$.
Output: Target NER model

```
while LM pre-training stopping condition is not met do
    $\boldsymbol{x} \leftarrow \mathcal{D}_{lm}$; $\boldsymbol{e} \leftarrow$ Entity-Match($\boldsymbol{x}; \mathcal{E}_{ent}$)
    $\mathbf{h}^L \leftarrow$ Char-Entity-Transformer($\boldsymbol{x}, \boldsymbol{e}; \mathbf{W}_T, \mathbf{E}_{ent}$)
    $\mathcal{L}_{MLM} \leftarrow$ MLM($\mathbf{h}^L, \boldsymbol{x}; \mathbf{W}_{MLM}^o$)    [MLM loss]
    $\mathcal{L}_{ENC} \leftarrow$ ENC($\mathbf{h}^L, \boldsymbol{e}; \mathbf{W}_{ENC}^o$)  [Ent. class. loss]
    $\mathcal{L}_{LM} \leftarrow \mathcal{L}_{MLM} + \mathcal{L}_{ENC}$
    Update $\{\mathbf{W}_T, \mathbf{E}_{ent}, \mathbf{W}_{MLM}^o, \mathbf{W}_{ENC}^o\}$ by $\mathcal{L}_{LM}$
end while
while NER fine-tuning stopping condition is not met do
    $\{\boldsymbol{x}, \boldsymbol{y}\} \leftarrow \mathcal{D}_{ner}$; $\boldsymbol{e} \leftarrow$ Entity-Match($\boldsymbol{x}; \mathcal{E}_{ent}$)
    $\mathbf{h}^L \leftarrow$ Char-Entity-Transformer($\boldsymbol{x}, \boldsymbol{e}; \mathbf{W}_T, \mathbf{E}_{ent}$)
    $\mathcal{L}_{NER} \leftarrow$ NER($\mathbf{h}^L, \boldsymbol{y}; \mathbf{W}_{NER}^o$)  [NER loss]
    Update $\{\mathbf{W}_T, \mathbf{E}_{ent}, \mathbf{W}_{NER}^o\}$ by $\mathcal{L}_{NER}$
end while
```

We denote the masked subset of $\mathcal{D}_{lm}$ as $\mathcal{D}_{lm}^+ = \{(n,t)|\boldsymbol{c}_t^n = \text{[MASK]}, \boldsymbol{c}^n \in \mathcal{D}_{lm}\}$, the loss of the masked LM task is:

$$\mathcal{L}_{MLM} = -\sum_{(n,t) \in \mathcal{D}_{lm}^+} \log p(\boldsymbol{c}_t^n | \boldsymbol{c}_{<t}^n \cup \boldsymbol{c}_{>t}^n) \tag{10}$$

We denote the entity prediction subset of $\mathcal{D}_{lm}$ as $\mathcal{D}_{lm}^e = \{(n,t)|e_t^n \neq 0, \boldsymbol{c}^n \in \mathcal{D}_{lm}\}$, the loss of the entity classification task is:

$$\mathcal{L}_{ENC} = -\sum_{(n,t) \in \mathcal{D}_{lm}^e} \log p(\boldsymbol{e}_t^n | \boldsymbol{c}_t^n) \tag{11}$$

To jointly train the masked LM task and the entity classification task in pre-training, we minimize the overall loss:

$$\mathcal{L}_{LM} = \mathcal{L}_{MLM} + \mathcal{L}_{ENC} \tag{12}$$

Fine-tuning. Given an NER dataset $\mathcal{D}_{ner} = \{(\boldsymbol{c}^n, \boldsymbol{y}^n)\}_{n=1}^N$, we train the NER output layer and fine-tune both the pre-trained LM and entity embeddings by the NER loss:

$$\mathcal{L}_{NER} = -\sum_{n=1}^{N}\sum_{t=1}^{T} \log p(\boldsymbol{y}_t^n | \boldsymbol{c}_t^n) \tag{13}$$

The overall process of pre-training and fine-tuning is summarized in Algorithm 2.

4 Experiments

We empirically verify the effectiveness of entity enhanced BERT pre-training on different NER datasets. In addition, we also investigate how different components in the model impact the performance of NER with different settings.

---

Table 1: Statistics of the three datasets.

4.1 Datasets

We conduct experiments on three datasets, including one public NER dataset, CLUENER-2020 (Xu et al., 2020), and two datasets annotated by ourselves, which are also contributions of this paper. The statistics of the datasets are listed in Table 1.

News dataset. We use the CLUENER-2020 (Xu et al., 2020) dataset. Compared with OntoNotes (Weischedel et al., 2012) and MSRA (Levow, 2006) datasets for Chinese news NER, CLUENER-2020 is constructed as a fine-grained Chinese NER dataset with 10 entity types, and its labeled sentences belong to different news domains rather than one domain. We randomly sample 5.2K, 0.6K and 0.7K sentences from the original CLUENER-2020 dataset as the training[3], dev and test sets, respectively. The corresponding raw text is taken from THUCNews (Sum et al., 2016) in four news domains[4], namely GAM (game), ENT (entertainment), LOT (lottery) and FIN (finance), with a total number of about 100M characters. The detailed entity statistics are shown in Appendix **B.1**.

Novel dataset. We select three Chinese Internet novels, titled "天荒神域(*Stories in Myth*)", "道破天穹(*Taoist Stories*)" and "茅山诡术师(*Maoshan Wizards*)", respectively, and manually label around 0.9K sentences for each novel as the development and test sets. We also label around 6.7K sentences from six other novels for the training set. Considering the literature genre, we annotate six types of entities. Besides, we use the original text of the nine novels with about 48M characters for pre-training. The details of annotation and entity statistics are shown in Appendix **B.2**.

Hyperparameter	Pre-train	Fine-tune
Epoch number	3	10
Max sentence length	180	-
Batch size	32	32
Entity sample number	5	-
Optimizer	Adam	Adam
Learning rate	$3e^{-5}$	$5e^{-5}$
Lr decay rate	0.01	-
Warmup proportion	0.1	-

Table 2: Hyperparameters.

Financial report dataset. We collect annual financial reports of 12 banks in China for five years and select about 2k sentences to annotate as the test set. The annotation rules follow the MSRA dataset (Levow, 2006), and the annotation process follows the novel dataset. In addition, we use the MSRA training and dev sets as our training and dev data. The unannotated annual reports of about 26M characters are used in LM pre-training. The detailed entity statistics are shown in Appendix **B.3**.

4.2 Experimental Settings

Model size. Our model is constructed using $\mathrm{BERT}_{\mathrm{BASE}}$ (Devlin et al., 2019), with the number of layers $L = 12$, the number of self-attention heads $A = 12$, the hidden size of characters $H_c = 768$ and the hidden size of entities $H_e = 64$. The total amount of non-embedding model parameters is about 86M. The total amount of non-embedding parameters of $\mathrm{BERT}_{\mathrm{BASE}}$ is about 85M. The entity integration module occupies only a small proportion in the whole model. Therefore, it has little impact on training efficiency.

Hyperparameters. For pre-training, we largely follow the default hyperparameters of BERT (Devlin et al., 2019). We use the Adam optimizer with an initial learning rate of $5e^{-5}$ and a maximum epoch number of 10 for fine-tuning. We list the details about pre-training and fine-tuning hyperparameters in Table 2.

Baselines. We compare our methods with three groups of state-of-the-art methods to Chinese NER.

BERT baselines. BERT (Devlin et al., 2019) directly fine-tunes a pre-trained Chinese BERT on

---

[3] In practice, a little manual labeling can be performed on each news domain separately for the best results. However, considering the expense of performing experiments to study the influence of training data scale, we use a single set of training data for all the news domains. This setting is also used for the novel dataset.

[4] The original CLUENER-2020 dataset has no domain divisions, but our method aims to leverage domain-specific entity information for NER. Thus we select some specific news domains according to raw text from THUCNews and construct an entity dictionary for each domain. We also released a smaller version of CLUENER-2020 with domain divisions.

Methods	**News Dataset**					**Novel Dataset**				**Financial Report Dataset**

Table 3: Overall results on the three datasets. † indicates statistical significance with $p < 0.01$ by t-test.

NER. BERT+Fur uses the same raw text as ours to further pre-train the BERT with only the masked LM task. BERT+Fur+Ent uses the sum of character embeddings and the corresponding entity embeddings by the same entity matching algorithm as ours only in the input layer, and then further pre-trains BERT on the same raw text as ours.

ERNIE baselines. ERNIE[5] (Sun et al., 2019a,b) enhances BERT through knowledge integration using a entity-level masked LM task and more raw text from the Web resources, which achieves the currently best results on Chinese NER. ERNIE+Fur+Ent is a stronger baseline, which uses the same entity dictionary as ours for entity-level masking and further pre-trains ERNIE on the same raw text as ours.

LSTM baselines. We compare character-level BiLSTM (Lample et al., 2016) and BiLSTM+Ent, which concatenates the character embeddings and its corresponding entity embeddings as inputs. We also compare a gazetteer based method Lattice (Zhang and Yang, 2018) and Lattice (ReEnt), which replaces the word gazetteer of Lattice with our entity dictionary for fair comparison. We use the same embeddings as (Zhang and Yang, 2018), which are pre-trained on Giga-Word[6] using Word2vec (Mikolov et al., 2013). The entity embeddings are randomly initialized and fine-tuned during training.

4.3 Overall Results

The overall F_1-scores are listed in Table 3.

Comparison with BERT baselines. BERT+Fur achieves a slightly better result than BERT on the news dataset **All** (75.14% F_1 v.s. 74.22% F_1), but similar results on the novel dataset **All** and the financial report dataset. This shows that simply further pre-training BERT on document-specific raw text can hardly improve the performances. After using a naive method to integrate entity information, BERT+Fur+Ent achieves significantly better results on the novel dataset **All** (76.23% F_1 v.s. 73.22% F_1) compared to BERT+Fur, but lower F_1 on the news and the financial report datasets, which shows that this naive method cannot effectively benefit from the entities of arbitrary text genre.

Compared with BERT, **Ours** achieves more significantly better results on the novel dataset and the fiancial report dataset than the news dataset (at least over 4% F_1 v.s. 2.4% F_1), indicating the effectiveness of **Ours** for long-text genre. Compared with all of the BERT baselines, **Ours** achieves significant improvement (over at least 1.5% F_1 on the news dataset **All**, over 1.3% F_1 on the novel dataset **All** and over 4% F_1 on the financial report dataset), which shows that the Char-Entity-Transformer structure effectively integrates the document-specific entities extracted by new-word discovery and benefits for Chinese NER.

Comparison with the state-of-the-art. We make comparisons with ERNIE baselines. Even though ERNIE uses more raw text and entity information from the Web resources for pre-training, **Ours** outperforms ERNIE significantly (about 1% F_1 on the news dataset **All**, over 4% F_1 on both the novel dataset **All** and the financial report dataset), which shows the importance of document-specific entities for pre-training.

Using the same entity dictionary as **Ours** to further pre-train ERNIE on the same raw text as **Ours**, ERNIE+Fur+Ent achieves better results on the novel dataset and the financial report dataset

[6] `https://catalog.ldc.upenn.edu/LDC2011T13`

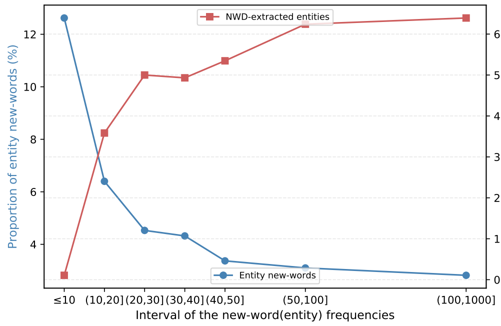

Figure 3: Performances of new-word discovery against word frequency on the news dataset. We ignore the interval >1000, because it occupies less than 5% new-words or entities.

than ERNIE, but suffers a decrease on the news dataset **All**, which shows that integrating document-specific entity dictionary benefits ERNIE for Chinese NER in long-text genre. Compared with ERNIE+FUR+ENT, **Ours** achieves significant improvements, which shows that our explicit method of integrating entity information by the Char-Entity-Transformer structure is more effective than entity-level masking for Chinese NER.

Finally, BERT and ERNIE outperform the LSTM baselines on all of the three datasets, indicating the effectiveness of LM pre-training for Chinese NER.

4.4 Analysis

MI-based new-word discovery. Figure 3 illustrates the relationships between new-words extracted by the MI-based new-word discovery (NWD) and the named entities with the scope of the news dataset.

On the one hand, within the scope of the news dataset, the proportion of entities extracted by the MI-based NWD is relatively higher when they are more frequently appearing n-grams in the raw text (overall 31.04% of the named entities are extracted by the NWD), as shown by the red line in Figure 3. On the other hand, within the n-grams in the news dataset, new-words with lower frequencies extracted by the MI-based NWD are more likely to be named entities (overall 3.86% of new words within the news dataset are named entities), as shown by the blue line in Figure 3.

Fine-grained comparison. In order to study the performances of our method on different entity types, we make fine-grained comparisons on the news dataset, which has plenty of entity types in different news domains. Figure 4 illustrates F_1-scores of several typical entity types, including GOV (government), BOO (book), MOV (movie) and ADD (address), for fine-grained comparison on the news dataset with BERT and ERNIE. The trends are consistent with the overall results. The full table is shown in Appendix C.

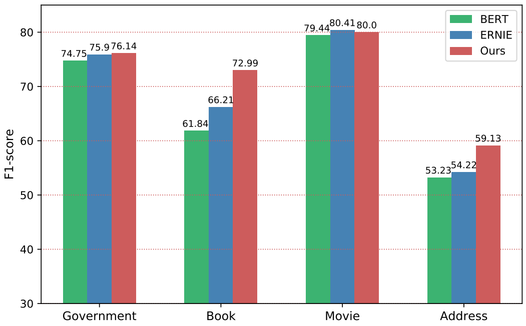

Figure 4: Detailed comparison on the news dataset.

Method	P	R	F_1	ΔF_1
FINAL	**81.19**	**74.27**	**77.58**	-
NO-ENT-CLASS	79.24	72.65	75.80	−1.78
HALF-RAW	78.37	72.75	75.46	−2.12
NO-PRETRAIN	78.17	72.51	75.23	−2.35
HALF-ENT	74.53	67.29	70.72	−6.86
N-GRAMS	73.92	63.48	68.30	−9.28
OPEN-DOMAIN	70.23	61.86	65.78	−11.80

Table 4: Ablation study on the novel dataset.

Ablation study. As shown in Table 4, we use two groups of ablation study to investigate the effect of entity information.

(1) *Entity prediction task.* We consider (i) NO-ENT-CLASS, which does not use the entity classification task in pre-training; and (ii) NO-PRETRAIN, which does not use entity enhanced pre-training. Results of these methods suffer significantly decreases compared to **FINAL**, which shows that pre-training, especially with the entity classification task, plays an important role in integrating the entity information. In addition, we also explore the effect of raw text quantity. The result of (iii) HALF-RAW shows that a larger amount of the raw text is helpful.

(2) *Entity dictionary.* We consider (i) HALF-ENT, which uses 50% randomly selected entities from the original entity dictionary; (ii) *N*-GRAMS, which uses randomly selected n-grams from the raw text; (iii) OPEN-DOMAIN, which uses an open-domain dictionary from Jieba[7]. The results of these methods decrease significantly (at least over 6% F_1) compared to **FINAL**, which shows that document-

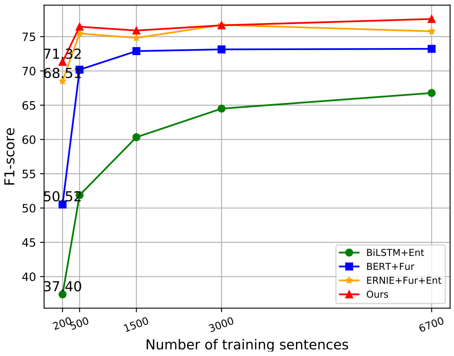

Figure 5: Influence of the amount of training data.

Sentence	我们可以运用花旗中国的全球经验和知识。 We can leverage Citi China 's global experience and knowledge. 核战的点子已经被《辐射》系列拿去用了。 The idea of nuclear warfare has been used for the *Radiation* series.
BERT	我们可以运用 花旗 COM 中国的全球经验和知识。 核战的点子已经被 《辐射》 GAM 系列拿去用了。
ERNIE	我们可以运用 花旗中国 COM 的全球经验和知识。 核战的点子已经被 《辐射》 GAM 系列拿去用了。
Ours	我们可以运用 花旗中国 COM 的全球经验和知识。 核战的点子已经被 《辐射》 MOV 系列拿去用了。

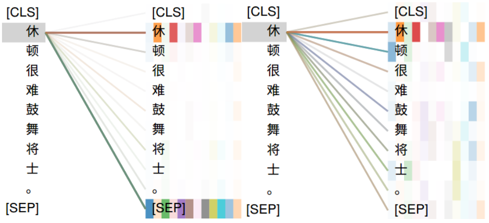
Table 5: Examples from the news test set. Green (Yellow) represents correct (incorrect) entities.

specific entity dictionary benefits the performance, and the new-word discovery method is effective for collecting entity dictionary.

The amount of NER training data. To compare performances of different models under different numbers of labeled training sentences, we randomly select different numbers of training sentences for training on the novel dataset.

As shown in Figure 5, in nearly unsupervised settings, **Ours** gives the largest improvements (33.92% F_1 over BiLSTM+Ent, 20.80% F_1 over BERT+Fur and 2.81% F_1 over ERNIE+Fur+Ent). With only 500 training sentences, **Ours** achieves competitive result, which shows the effectiveness of our LM pre-training method for the few-shot setting.

Case study. Table 5 shows a case study on the news dataset. “花旗中国(Citi China)” is a COM (company) and “《辐射》(*Radiation*)” is a MOV (movie). Since the text genre and entities in the news are so different from Wikipedia, BERT does not recognize the company name “花旗中国(Citi China)” and misclassifies “《辐射》(*Radiation*)” as a GAM (game). Benefiting from integrating entity information into LM pre-training, both ERNIE and **Ours** recognize “花旗中国(Citi China)”.



(a) BERT.

(b) Ours.

Figure 6: Visualization of last layer attention scores. We use an example in the news dataset, “休顿很难鼓舞将士。(It is difficult for Hughton to encourage team members.)”.

Ours uses document-specific entities to pre-train on raw news text. So with the global information, **Ours** also classifies “《辐射》(*Radiation*)” accurately as a MOV.

Visualization. Figure 6 uses BertViz (Vig, 2019) to visualize the last-layer attention patterns of “休(Hugh)” in a news example. BERT only has a higher attention score to itself, while **Ours** has relatively higher attention scores to all the tokens in the current entity “休顿(Hughton)”, especially for the first attention head (in blue). This shows that **Ours** enables entity information to enhance the contextual representation.

5 Conclusion

We investigated an entity enhanced BERT pre-training method for Chinese NER. Results on a news dataset and two long-text NER datasets show that it is highly effective to explicitly integrate the document-specific entities into BERT pre-training with a Char-Entity-Transformer structure, and our method outperforms the state-of-the-art methods for Chinese NER.

Acknowledgments

We thank the anonymous reviewers for their helpful comments and suggestions. Chen Jia proposes the method. Chen Jia and Yuefeng Shi jointly conduct the experiments and write the paper. A New-Word Discovery

First, we calculate Mutual Information using this formula:

$$\mathrm{MI}\,(\boldsymbol{x},\boldsymbol{y}) = \log_2 \frac{p(\boldsymbol{x}\oplus\boldsymbol{y})}{p(\boldsymbol{x})p(\boldsymbol{y})}, \tag{14}$$

where $\boldsymbol{x}$ and $\boldsymbol{y}$ represent two continual characters or words. $\oplus$ represents string concatenation. The notation $p(\cdot)$ represents the probability of a string occurs. Higher MI indicates that two sub-strings are more likely to form a new phrase.

Then we calculate the Left and Right Entropy Measures to distinguish the independence and boundary of candidate multi-word expressions (Hoang et al., 2009):

$$\begin{aligned} \mathrm{E}_{L}(\boldsymbol{w}) &= -\sum_{a\in\mathcal{A}} \{p\,(a\oplus\boldsymbol{w}|\boldsymbol{w})\log_2 p\,(a\oplus\boldsymbol{w}|\boldsymbol{w})\}; \\ \mathrm{E}_{R}(\boldsymbol{w}) &= -\sum_{b\in\mathcal{B}} \{p\,(\boldsymbol{w}\oplus b|\boldsymbol{w})\log_2 p\,(\boldsymbol{w}\oplus b|\boldsymbol{w})\}, \end{aligned} \tag{15}$$

Table 7: Entity statistics of the novel dataset and the financial report dataset. We use the gray scale to represent the proportion of different entities in four test sets, respectively.

where E_L and E_R represent the left and right entropy, respectively. $\boldsymbol{w}$ represents an N-gram substring. $\mathcal{A}$ and $\mathcal{B}$ are the sets of words that appear to the left or right of $\boldsymbol{w}$, respectively.

Finally, we add the three values MI, E_L and E_R as the validity score of possible new entities, remove the common words based on an open-domain dictionary from Jieba[8], and save the top 50% of the remaining words as the potential input document-specific entity dictionary.

B Details of the Datasets

B.1 News Dataset

Entity statistics. As listed in Table 6, the fine-grained news dataset consists of 10 entity types, including GAM (game), POS (position), MOV (movie), NAM (name), ORG (organization), SCE (scene), COM (company), GOV (government), BOO (book) and ADD (address). The four test domains have obvious different distributions of entity types, which are visualized by the gray scale of color in Table 6.

B.2 Novel Dataset

Data collection. We construct our corpus from a professional Chinese novel reading site named Babel Novel[9]. Unlike news, the novel dataset covers a mixture of literary style including historical novels, and martial arts novels in the genre of fantasy, mystery, romance, military, etc. Therefore, unique characteristics of this dataset such as novel-specific types of named entities present challenges for NER.

Annotation. Considering the literature genre, we annotate three more entity types other than PER (person), LOC (location) and ORG (organization) in MSRA (Levow, 2006), namely (i) TIT (title), which represents the appellation or nickname of a person, such as "冥界之主(Load of Underworld)" and "无极剑圣(Sward Master)"; (ii) WEA (weapon), which represents weapons or objects with special-purpose (e.g. "天龙战戟(Dragon Spear)" and "星辰法杖(Stardust Wand)"); and (iii) KUN (kongfu), which represents the name of martial arts such as "太极(Tai Chi)" and "忍术(Ninjutsu)". The annotation work is undertaken by five undergraduate students and two experts. All of the annotators have read the whole novels before annotation, which aims to prevent the labeling inconsistent problem. In terms of annotation progress, each sentence is first annotated by at least two students, and then the experts select the examples with inconsistent annotations and modify the mistakes. The inter-annotator agreement exceeded a Cohen's kappa value (McHugh, 2012) of 0.915 on the novel dataset.

Table 8: Fine-grained comparisons on the news dataset.

Entity statistics. The statistics for the above six entity types are listed in Table 7. We can see that the entity distributions on the three test novels are similar with only a few differences, which are because of the differences in the topics of novels.

B.3 Financial Report Dataset

Annotation. The annotation process is similar to that of the novel dataset. The inter-annotator agreement exceeded a Cohen's kappa value (McHugh, 2012) of 0.923 on the financial report dataset.

Entity statistics. The detailed statistics for the financial report dataset are listed in Table 7.

C Fine-grained Comparison

The total results of fine-grained comparisons on the news dataset are listed in Table 8. The news dataset has a total of 10 entity types, including Gam (game), Pos (position), Mov (movie), Nam (name), Org (organization), Sce (scene), Com (company), Gov (government), Boo (book) and Add (address).

Scalable Zero-shot Entity Linking with Dense Entity Retrieval

Abstract

This paper introduces a conceptually simple, scalable, and highly effective BERT-based entity linking model, along with an extensive evaluation of its accuracy-speed trade-off. We present a two-stage zero-shot linking algorithm, where each entity is defined only by a short textual description. The first stage does retrieval in a dense space defined by a bi-encoder that independently embeds the mention context and the entity descriptions. Each candidate is then re-ranked with a cross-encoder, that concatenates the mention and entity text. Experiments demonstrate that this approach is state of the art on recent zero-shot benchmarks (6 point absolute gains) and also on more established non-zero-shot evaluations (e.g. TACKBP-2010), despite its relative simplicity (e.g. no explicit entity embeddings or manually engineered mention tables). We also show that bi-encoder linking is very fast with nearest neighbour search (e.g. linking with 5.9 million candidates in 2 milliseconds), and that much of the accuracy gain from the more expensive cross-encoder can be transferred to the bi-encoder via knowledge distillation. Our code and models are available at `https://github.com/facebookresearch/BLINK`.

1 Introduction

Scale is a key challenge for entity linking; there are millions of possible entities to consider for each mention. To efficiently filter or rank the candidates, existing methods use different sources of external information, including manually curated mention tables (Ganea and Hofmann, 2017), incoming Wikipedia link popularity (Yamada et al., 2016), and gold Wikipedia entity categories (Gillick et al., 2019). In this paper, we show that BERT-based models set new state-of-the-art performance levels for large scale entity linking when used in a zero shot setup, where there is no external knowledge and a short text description provides the only information we have for each entity. We also present an extensive evaluation of the accuracy-speed trade-off inherent to large pre-trained models, and show is possible to achieve very efficient linking with modest loss of accuracy.

More specifically, we introduce a two stage approach for zero-shot linking (see Figure 1 for an overview), based on fine-tuned BERT architectures (Devlin et al., 2019). In the first stage, we do retrieval in a dense space defined by a bi-encoder that independently embeds the mention context and the entity descriptions (Humeau et al., 2019; Gillick et al., 2019). Each retrieved candidate is then examined more carefully with a cross-encoder that concatenates the mention and entity text, following Logeswaran et al. (2019). This overall approach is conceptually simple but highly effective, as we show through detailed experiments.

Our two-stage approach achieves a new state-of-the-art result on TACKBP-2010, with an over 30% relative error reduction. By simply reading the provided text descriptions, we are able to outperform previous methods that included many extra cues such as entity name dictionaries and link popularity. We also improve the state of the art on existing zero-shot benchmarks, including a nearly 6 point absolute gain on the recently introduced Wikia corpus (Logeswaran et al., 2019) and more than 7 point absolute gain on WikilinksNED Unseen-Mentions (Onoe and Durrett, 2019).

Finally, we do an extensive evaluation of the accuracy-speed trade-off inherent in our bi- and cross-encoder models. We show that the two stage methods scales well in a full Wikipedia setting, by linking against all the 5.9M Wikipedia entities for TACKBP-2010, while still outperforming existing model with much smaller candidate sets. We

November 16–20, 2020.

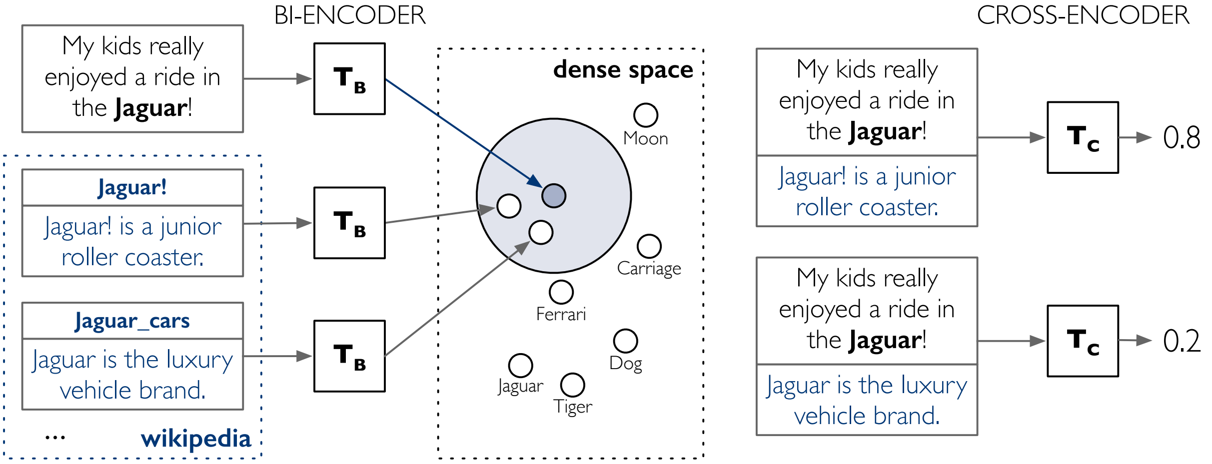

Figure 1: High level description of our zero-shot entity linking solution. From the top-left, the input gets encoded in the same dense space where all entities representations lie. A nearest neighbors search is then performed (depicted with a blue circle), k entities retrieved and supplied to the cross encoder. The latter attends over both input text and entities descriptions to produce a probability distribution over the candidates.

also show that bi-encoder linking is very fast with approximate nearest neighbor search (e.g. linking over 5.9 million candidates in 2 milliseconds), and that much of the accuracy gain from the more expensive cross-encoder can be transferred to the bi-encoder via knowledge distillation. We release our code and models, as well as a system to link entity mentions to all of Wikipedia (similar to TagME (Ferragina and Scaiella, 2011)).[1]

2 Related Work

We follow most recent work in studying entity linking with gold mentions.[2] The entity linking task can be broken into two steps: candidate generation and ranking. Prior work has used frequency information, alias tables and TF-IDF-based methods for candidate generation. For candidate ranking, He et al. (2013), Sun et al. (2015), Yamada et al. (2016), Ganea and Hofmann (2017), and Kolitsas et al. (2018) have established state-of-the-art results using neural networks to model context word, span and entity. There is also recent work demonstrating that fine-grained entity typing information helps linking (Raiman and Raiman, 2018; Onoe and Durrett, 2019; Khalife and Vazirgiannis, 2018).

Two recent results are most closely related to our work. Logeswaran et al. (2019) proposed the zero-shot entity linking task. They use cross-encoders for entity ranking, but rely on traditional IR-techniques for candidate generation and did not evaluate on large scale benchmarks such as TACKBP. Gillick et al. (2019) show that dense embeddings work well for candidate generation, but they did not do pre-training and included external category labels in their bi-encoder architectures, limiting their linking to entities in Wikipedia. Our approach can be seen as generalizing both of these lines of work, and showing for the first time that pre-trained zero-shot architectures are both highly accurate and computationally efficient at scale.

Humeau et al. (2019) studied different architectures to use deep pre-trained bidirectional transformers and performed detailed comparison of three different architectures, namely bi-encoder, poly-encoder, cross-encoder on tasks of sentence selection in dialogues. Inspired by their work, we use similar architectures to the problem of entity linking, and in addition, demonstrate that bi-encoder can be a strong model for retrieval. Instead of using the poly-encoder as a trade-off between cross-encoder and bi-encoder, we propose to train a bi-encoder model with knowledge distillation (Buciluundefined et al., 2006; Hinton et al., 2015) from a cross-encoder model to further improve the bi-encoder's performances.

3 Definition and Task Formulation

Entity Linking Given an input text document $\mathbf{D} = \{w_1, ..., w_r\}$ and a list of entity mentions $\mathbf{M_D} = \{m_1, ..., m_n\}$, the output of an entity

---

[1] Our code and models are available at `https://github.com/facebookresearch/BLINK`

[2] Kolitsas et al. (2018) study end-to-end linking. Our techniques should be applicable to this setting as well, but we leave this exploration to future work.

linking model is a list of mention-entity pairs $\{(m_i, e_i)\}_{i \in [1,n]}$ where each entity is an entry in a knowledge base (KB) (e.g. Wikipedia), $e \in \mathcal{E}$. We assume that the title and description of the entities are available, which is a common setting in entity linking (Ganea and Hofmann, 2017; Logeswaran et al., 2019). We also assume each mention has a valid gold entity in the KB, which is usually referred as *in-KB* evaluation. We leave the out-of-KB prediction (i.e. *nil* prediction) to future work.

Zero-shot Entity Linking We also study zero-shot entity linking (Logeswaran et al., 2019). Here the document setup is the same, but the knowledge base is separated in training and test time. Formally, denote $\mathcal{E}_{train}$ and $\mathcal{E}_{test}$ to be the knowledge base in training and test, we require $\mathcal{E}_{train} \cap \mathcal{E}_{test} = \emptyset$. The set of text documents, mentions, and entity dictionary are separated in training and test so that the entities being linked at test time are unseen.

4 Methodology

Figure 1 shows our overall approach. The bi-encoder uses two independent BERT transformers to encode model context/mention and entity into dense vectors, and each entity candidate is scored as the dot product of these vectors. The candidates retrieved by the bi-encoder are then passed to the cross-encoder for ranking. The cross-encoder encodes context/mention and entity in one transformer, and applies an additional linear layer to compute the final score for each pair.

4.1 Bi-encoder

Architecture We use a bi-encoder architecture similar to the work of Humeau et al. (2019) to model (mention, entity) pairs. This approach allows for fast, real-time inference, as the candidate representations can be cached. Both input context and candidate entity are encoded into vectors:

$$\boldsymbol{y_m} = \mathrm{red}(T_1(\tau_m)) \quad (1)$$

$$\boldsymbol{y_e} = \mathrm{red}(T_2(\tau_e)) \quad (2)$$

where τ_m and τ_e are input representations of mention and entity respectively, T_1 and T_2 are two transformers. $\mathrm{red}(.)$ is a function that reduces the sequence of vectors produced by the transformers into one vector. Following the experiments in Humeau et al. (2019), we choose $\mathrm{red}(.)$ to be the last layer of the output of the `[CLS]` token.

Context and Mention Modeling The representation of context and mention τ_m is composed of the word-pieces of the context surrounding the mention and the mention itself. Specifically, we construct input of each mention example as:

`[CLS]` ctxt$_l$ `[M`$_s$`]` mention `[M`$_e$`]` ctxt$_r$ `[SEP]`

where mention, ctxt$_l$, ctxt$_r$ are the word-pieces tokens of the mention, context before and after the mention respectively, and `[M`$_s$`]`, `[M`$_e$`]` are special tokens to tag the mention. The maximum length of the input representation is a hyperparameter in our model, and we find that small value such as 32 works well in practice (see Appendix A).

Entity Modeling The entity representation τ_e is also composed of word-pieces of the entity title and description (for Wikipedia entities, we use the first ten sentences as description). The input to our entity model is:

`[CLS]` title `[ENT]` description `[SEP]`

where title, description are word-pieces tokens of entity title and description, and `[ENT]` is a special token to separate entity title and description representation.

Scoring The score of entity candidate e_i is given by the dot-product:

$$s(m, e_i) = \boldsymbol{y_m} \cdot \boldsymbol{y_{e_i}} \quad (3)$$

Optimization The network is trained to maximize the score of the correct entity with respect to the (randomly sampled) entities of the same batch (Lerer et al., 2019; Humeau et al., 2019). Concretely, for each training pair (m_i, e_i) in a batch of B pairs, the loss is computed as:

$$\mathcal{L}(m_i, e_i) = -s(m_i, e_i) + \log \sum_{j=1}^{B} \exp\left(s(m_i, e_j)\right) \quad (4)$$

Lerer et al. (2019) presented a detailed analysis on speed and memory efficiency of using batched random negatives in large-scale systems. In addition to in-batch negatives, we follow Gillick et al. (2019) by using hard negatives in training. The hard negatives are obtained by finding the top 10 predicted entities for each training example. We add these extra hard negatives to the random in-batch negatives.

Inference At inference time, the entity representation for all the entity candidates can be precomputed and cached. The inference task is then reduced to finding maximum dot product between mention representation and entity candidate representations. In Section 5.2.3 we present efficiency/accuracy trade-offs by exact and approximate nearest neighbor search using FAISS (Johnson et al., 2019) in a large-scale setting.

4.2 Cross-encoder

Our cross-encoder is similar to the ones described by Logeswaran et al. (2019) and Humeau et al. (2019). The input is the concatenation of the input context and mention representation and the entity representation described in Section 4.1 (we remove the `[CLS]` token from the entity representation). This allows the model to have deep cross attention between the context and entity descriptions. Formally, we use $y_{m,e}$ to denote our context-candidate embedding:

$$\boldsymbol{y_{m,e}} = \mathrm{red}(T_{\mathrm{cross}}(\tau_{m,e})) \tag{5}$$

where $\tau_{m,e}$ is the input representation of mention and entity, T_{cross} is a transformer and $red(.)$ is the same function as defined in Section 4.1.

Scoring To score entity candidates, a linear layer $\boldsymbol{W}$ is applied to the embedding $\boldsymbol{y_{m,e}}$:

$$s_{\mathrm{cross}}(m, e) = \boldsymbol{y_{m,e}} \boldsymbol{W} \tag{6}$$

Optimization Similar to methods in Section 4.1, the network is trained using a softmax loss to maximize $s_{\mathrm{cross}}(m_i, e_i)$ for the correct entity, given a set of entity candidates (same as in Equation 4).

Due to its larger memory and compute footprint, we use the cross-encoder in a re-ranking stage, over a small set (≤ 100) of candidates retrieved with the bi-encoder. The cross-encoder is not suitable for retrieval or tasks that require fast inference.

4.3 Knowledge Distillation

To better optimize the accuracy-speed trade-off, we also report knowledge distillation experiments that use a cross-encoder as a teacher for a bi-encoder model. We follow Hinton et al. (2015) to use a softmax with temperature where the target distribution is based on the cross-encoder logits.

Concretely, let z be a vector of logits for set of entity candidates and T a temperature, and $\sigma(z, T)$ a (tempered) distribution over the entities with

$$\sigma(z, T) = \frac{\exp(z_i/T)}{\sum_j \exp(z_j/T)}. \tag{7}$$

Then the overall loss function, incorporating both distillation and student losses, is calculated as

$$\mathcal{L}_{dist} = \mathcal{H}(\sigma(z_t; \tau), \sigma(z_s; \tau)) \tag{8}$$

$$\mathcal{L}_{st} = \mathcal{H}(e, \sigma(z_s; 1)) \tag{9}$$

$$\mathcal{L} = \alpha \cdot \mathcal{L}_{st} + (1 - \alpha) \cdot \mathcal{L}_{dist} \tag{10}$$

where e is the ground truth label distribution with probability 1 for the gold entity, $\mathcal{H}$ is the cross-entropy loss function, and α is coefficient for mixing distillation and student loss $\mathcal{L}_{st}$. The student logits z_s are the output of the bi-encoder scoring function $s(m, e_i)$, the teacher logits the output of the cross-encoder scoring funcion $s_{\mathrm{cross}}(m, e)$.

5 Experiments

In this section, we perform an empirical study of our model on three challenging datasets.

5.1 Datasets

The Zero-shot EL dataset was constructed by Logeswaran et al. (2019) from Wikia.[3] The task is to link entity mentions in text to an entity dictionary with provided entity descriptions, in a set of domains. There are 49K, 10K, and 10K examples in the train, validation, test sets respectively. The entities in the validation and test sets are from different domains than the train set, allowing for evaluation of performance on entirely unseen entities. The entity dictionaries cover different domains and range in size from 10K to 100K entities.

TACKBP-2010 is widely used for evaluating entity linking systems Ji et al. (2010).[4] Following prior work, we measure *in-KB* accuracy (P@1). There are 1,074 and 1,020 annotated mention/entity pairs derived from 1,453 and 2,231 original news and web documents on training and evaluation dataset, respectively. All the entities are from the TAC Reference Knowledgebase which contains 818,741 entities with titles, descriptions and other meta info.

Method	**Train**	**Validation**	**Test**
BM25	76.86	76.22	69.13
Ours (bi-encoder)	93.12	91.44	82.06

Table 1: Recall@64 (%) on Zero-shot EL dataset, for the BM25 approach and our dense space bi-encoder based retrieval. Results on Train/Valideation/Test set reported.

WikilinksNED Unseen-Mentions was created by Onoe and Durrett (2019) from the original WikilinksNED dataset (Eshel et al., 2017), which contains a diverse set of ambiguous entities spanning a variety of domains. In the Unseen-Mentions version, no mentions in the validation and test sets appear in the training set. The train, validation and test sets contain 2.2M, 10K, and 10K examples respectively. In this setting, the definition of unseen-mentions is different from that in zero-shot entity linking: entities in the test set can be seen in the training set. However, in both definitions no (mention, entity) pairs from test set are observed in the training set. In the unseen-mentions test set, about 25% of the entities appear in training set.

5.2 Evaluation Setup and Results

We experiment with both BERT-base and BERT-large (Devlin et al., 2019) for our bi-encoders and cross-encoders. The details of training infrastructure and hyperparameters can be found in Appendix A. All models are implemented in PyTorch[5] and optimizied with Adam (Kingma and Ba, 2014). We use (base) and (large) to indicate the version of our model where the underlying pretrained transformer model is BERT-base and BERT-large, respectively.

5.2.1 Zero-shot Entity Linking

First, we train our bi-encoder on the training set, initializing each encoder with pre-trained BERT base. Hyper-parameters are chosen based on Recall@64 on validation datase. For specifics, see Appendix A.2. Our bi-encoder achieves much higher recall than BM25, as shown in Figure 2. Following Logeswaran et al. (2019), we use the top 64 retrieved candidates for the ranker, and we report Recall@64 on train, validation and test in Table 1.

After training the bi-encoder for candidate generation, we train our cross-encoder (initialized with pre-trained BERT) on the top 64 retrieved candidates from bi-encoder for each sample on the training set, and evaluate the cross-encoder on the test dataset. Overall, we are able to obtain a much better end-to-end accuracy, as shown in Table 2, largely due to the improvement on the retrieval stage.

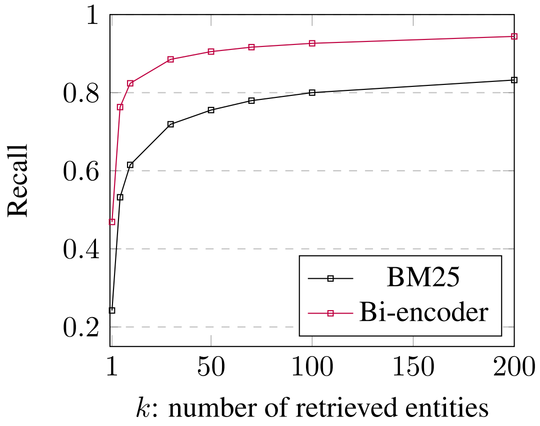

Figure 2: Top-k entity retrieval recall on validation dataset of Zero-shot EL dataset

Method	**U.Acc.**
Logeswaran et al. (2019)	55.08
Logeswaran et al. (2019)(domain)†	56.58
Ours (base)	61.34
Ours (large)	63.03

Table 2: Performance on test domains on the Zero-shot EL dataset. U.Acc. represents the unnormalized accuracy. † indicates model trained with domain adaptive pre-training on source and target domain. Average performance across a set of worlds is computed by macro-averaging.

We also report cross-encoder performance on the same retrieval method (BM25) used by Logeswaran et al. (2019) in Table 3, where the performance is evaluated on the subset of test instances for which the gold entity is among the top 64 candidates retrieved by BM25. We observe that our cross-encoder obtains slightly better results than reported by Logeswaran et al. (2019), likely due to implementation and hyper-parameter details.

5.2.2 TACKBP-2010

Following prior work (Sun et al., 2015; Cao et al., 2018; Gillick et al., 2019; Onoe and Durrett, 2019), we pre-train our models on Wikipedia[6] data. Data and model training details can be found in Appendix A.1.

---

[6] `https://www.wikipedia.org/`

Method	Valid	Test
TF-IDF†	26.06	
Ganea and Hofmann (2017)†	26.96	-
Gupta et al. (2017)†	27.03	-
Logeswaran et al. (2019)	76.06	75.06
Ours (base)	78.24	76.58

Table 3: Normalized accuracy on validation and test set on Zero-shot EL, where the performance is evaluated on the subset of test instances for which the gold entity is among the top-k candidates retrieved during candidate generation. † indicates methods re-implemented by Logeswaran et al. (2019).

After training our model on Wikipedia, we fine-tune the model on the TACKBP-2010 training dataset. We use the top 100 candidates retrieved by the bi-encoder as training examples for the cross-encoder, and chose hyper-parameters based on cross validation. We report accuracy results in Table 4. For ablation studies, we also report the following versions of our model:

1. bi-encoder only: we use bi-encoder for candidate ranking instead of cross-encoder.
2. Full Wikipedia: we use 5.9M Wikipedia articles as our entity Knowlegebase, instead of TACKBP Reference Knowledgebase.
3. Full Wikipedia w/o finetune: same as above, without fine-tuning on the TACKBP-2010 training set.

As expected, the cross-encoder performs better than the bi-encoder on ranking. However, both models exceed state-of-the-art performance levels, demonstrating that the overall approach is highly effective. We observe that our model also performs well when we change the underlying Knowledgebase to full Wikipedia, and even without fine-tuning on the dataset. In Table 5 we show that our bi-encoder model is highly effective at retrieving relevant entities, where the underlying Knowledgebase is full Wikipedia.

There are however many other cues that could potentially be added in future work. For example, Khalife and Vazirgiannis (2018) report 94.57% precision on the TACKBP-2010 dataset. However, their method is based on the strong assumption that a gold fine-grained entity type is given for each mention (and they do not attempt to do entity type prediction). Indeed, if fine-grained entity type information is given by an oracle at test time, then Raiman and Raiman (2018) reports 98.6% accuracy on TACKBP-2010, indicating that improving fine-grained entity type prediction would likely improve entity linking. Our results is achieved without gold fine-grained entity type information. Instead, our model learns representations of context, mention and entities based on text only.

5.2.3 WikilinksNED Unseen-Mentions

Similarly to the approach described in Section 5.2.2, we train our bi-encoder and cross-encoder model first on Wikipedia examples, then fine-tune on the training data from this dataset. We also present our model trained on Wikipedia examples

Method	**Training**	**Test**
MOST FREQUENT	Wiki	54.1
COSINE SIMILARITY	Wiki	21.7
GRU+ATTN (Mueller and Durrett, 2018)	in-domain	41.2
GRU+ATTN	Wiki	43.4
CBoW+WORD2VEC	in-domain	43.0
CBoW+WORD2VEC	Wiki	38.0
Onoe and Durrett (2019)	Wiki	62.2
Ours	in-domain	74.7
Ours	Wiki	75.2
Ours	Wiki (bi-encoder)	71.5
Ours	Wiki and in-domain	76.8

Table 6: Accuracy on the WikilinksNED Unseen-Mentions test set. The numbers of baseline models are from (Onoe and Durrett, 2019). The column **Training** indicates the source of data used in training: *Wiki* means Wikipedia examples; *in-domain* means examples in the training set.

and applied directly on the test set as well as our model trained on this dataset directly without training on Wikipedia examples. We report our models' performance of accuracy on the test set in Table 6, along with baseline models presented from Onoe and Durrett (2019). We observe that our model out-performs all the baseline models.

Inference time efficiency To illustrate the efficiency of our bi-encoder model, we profiled retrieval speed on a server with Intel Xeon CPU E5-2698 v4 @ 2.20GHz and 512GB memory. At inference time, we first compute all entity embeddings for the pool of 5.9M entities. This step is resource intensive but can be paralleled. On 8 Nvidia Volta v100 GPUs, it takes about 2.8 hours to compute all entity embeddings. Given a query of mention embedding, we use FAISS (Johnson et al., 2019) IndexFlatIP index type (exact search) to obtain top 100 entity candidates. On the WikilinksNED Unseen-Mentions test dataset which contains 10K queries, it takes 9.2 ms on average to return top 100 candidates per query in batch mode.

We also explore the approximate search options using FAISS. We choose the IndexHNSWFlat index type following Karpukhin et al. (2020). It takes additional time in index construction while reduces the average time used per query. In Table 7, we see that $HNSW_1$[7] reduces the average query time to 2.6 ms with less than 1.2% drop in accuracy and recall, and $HNSW_2$[8] further reduce the query time to 1.4 ms with less than 2.1% drop.

Method	Acc	R@10	R@30	R@100	ms/q
Ex. Search	71.5	92.7	95.4	96.7	9.2
$HNSW_1$	71.1	91.6	94.2	95.5	2.6
$HNSW_2$	70.7	91.0	93.9	94.6	1.4

Table 7: Exact and approximate candidate retrieval using FAISS. Last column: average time per query (ms).

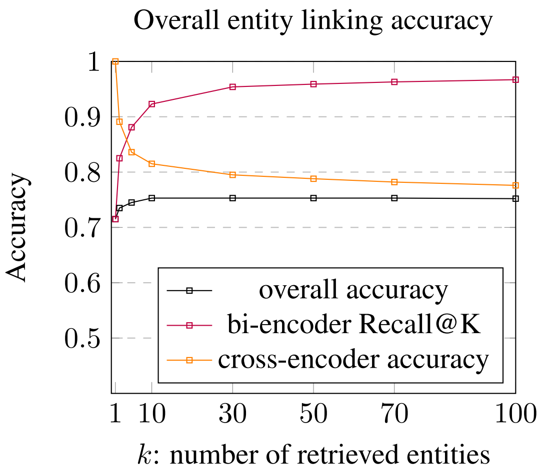

Figure 3: Overall model accuracy based on different choices of k (number of retrieved entities from bi-encoder), on the Unseen-Mentions dataset.

Influence of number of candidates retrieved In a two-stage entity linking systems, the choice of number of candidates retrieved influences the overall model performance. Prior work often used a fixed number of k candidates where k ranges from 5 to 100 (for instance, Yamada et al. (2016) and Ganea and Hofmann (2017) choose $k = 30$, (Logeswaran et al., 2019) choose $k = 64$). When k is larger, the recall accuracy increases, however, the ranking stage accuracy is likely to decrease. Further, increasing k would often increase the run-time on the ranking stage. We explore different choices of k in our model, and present the $recall@K$ curve, ranking stage accuracy and overall accuracy in Figure 3. Based on the overall accuracy, we found that $k = 10$ is optimal.

5.3 Knowledge Distillation

In this section, we present results on knowledge distillation, using our cross-encoder as a teacher model and bi-encoder as a student model.

---

[7] Neighbors to store per node: 128, construction time search depth: 200, search depth: 256; construction time: 2.1h.

[8] Neighbors to store per node: 128, construction time search depth: 200, search depth: 128; construction time: 1.8h.

Mention	Bi-encoder	Cross-encoder
But surely the biggest surprise is **Ronaldo**'s drop in value, despite his impressive record of 53 goals and 14 assists in 75 appearances for Juventus.	Ronaldo (Brazilian footballer)	**Cristiano Ronaldo**
... they spent eleven days in the United Kingdom and Spain, photographing things like **Gothic** statues, bricks, and stone pavements for use in textures.	Gothic fiction	**Gothic art**
To many people in many cultures, music is an important part of their way of life. **Ancient Greek** and Indian philosophers defined music as tones ...	**Acient Greek**	Ancient Greek philosophy

Table 8: Examples of top entities predicted by Bi-encoder model and Cross-encoder model. Mentions in the examples are written in **ornage** and the correct entity prediction in **bold**.

We experiment knowledge distillation on the TACKBP-2010 and the WikilinksNED Unseen-Mentions dataset. We use the bi-encoder pretrained on Wikipedia as the student model, and fine-tune it on each dataset with knowledge distillation from the teacher model, which is the best performing cross-encoder model pretrained on Wikipedia and fine-tuned on the dataset.

We also fine-tune the student model in our experiments on each dataset, without the knowledge distillation component, as baseline models. As we can see in Table 9, the bi-encoder model trained with knowledge distillation from cross-encoder outperforms the bi-encoder without knowledge distillation, providing another point in the accuracy-speed trade-off curve for these architectures.

Dataset	bi-encoder	teacher	bi-encoder-KD
Unseen	74.4	76.8	75.7
TAC2010	92.9	94.5	93.5

Table 9: Knowledge Distillation Results. The teacher model is the cross-encoder, and bi-encoder-KD is the bi-encoder model trained with knowledge distillation.

6 Qualitative Analysis

Table 8 presents some examples from our bi-encoder and cross-encoder model predictions, to provide intuition for how these two models consider context and mention for entity linking.

In the first example, we see that the bi-encoder mistakenly links "Ronaldo" to the Brazilian football player, while the cross-encoder is able to use context word "Juventus" to disambiguate. In the second example, the cross-encoder is able to identify from context that the sentence is describing art instead of fiction, where the bi-encoder failed. In the third example, the bi-encoder is able to find the correct entity "Ancient Greek,"; where the cross-encoder mistakenly links it to the entity "Ancient Greek philosophy," likely because that the word "philosophers" is in context. We observe that cross-encoder is often better at utilizing context information than bi-encoder, but can sometimes make mistakes because of misleading context cues.

7 Conclusion

We proposed a conceptually simple, scalable, and highly effective two stage approach for entity linking. We show that our BERT-based model outperforms IR methods for entity retrieval, and achieved new state-of-the-art results on recently introduced zero-shot entity linking dataset, WikilinksNED Unseen-Mentions dataset, and the more established TACKBP-2010 benchmark, without any task-specific heuristics or external entity knowledge. We present evaluations of the accuracy-speed trade-off inherent to large pre-trained models, and show that it is possible to achieve efficient linking with modest loss of accuracy. Finally, we show that knowledge distillation can further improve bi-encoder model performance. Future work includes:

- Enriching entity representations by adding entity type and entity graph information;
- Modeling coherence by jointly resolving mentions in a document;
- Extending our work to other languages and other domains;
- Joint models for mention detection and entity linking.

A Training details and hyper-parameters Optimization

- Computing infrastructure: we use 8 Nvidia Volta v100 GPUs for model training.
- Bounds for each hyper parameter: see Table 10. In addition, for our bi-encoders, we use a max number of tokens of $[32, 64, 128]$ for context/mention encoder and 128 for candidate encoder. In our knowledge distillation experiments, we set $\alpha = 0.5$, and T in $[2, 5]$. We use grid search for hyperparameters, for a total number of 24 trials.
- Number of model parameters: see Table 11.
- For all our experiments we use accuracy on validation set as criterion for selecting hyper-parameters.

Parameter	Bounds
Learning rate	[2e^{-6}, 5e^{-6}, 1e^{-5}, 2e^{-5}]
Bi-encoder batch size	$[128, 256]$
Cross-encoder batch size	$[1, 5]$

Table 10: Bounds of hyper-parameters in our models

Model	Number of parameters
Bi-encoder (base)	220M
Cross-encoder (base)	110M
Bi-encoder (large)	680M
Cross-encoder (large)	340M

Table 11: Number of parameters in our models

A.1 Training on Wikipedia data

We use Wikipedia data to train our models first, then fine-tune it on specific dataset. This approach is used in our experiments on TACKBP-2010 and WikilinksNED Unseen-Mentions datasets.

We use the May 2019 English Wikipedia dump which includes 5.9M entities, and use the hyperlinks in articles as examples (the anchor text is the mention). We use a subset of all Wikipedia linked mentions as our training data for the bi-encoder model (A total of 9M examples). We use a holdout set of 10K examples for validation. We train our cross-encoder model based on the top 100 retrieved results from our bi-encoder model on Wikipedia data. For the training of the cross-encoder model, we further down-sample our training data to obtain a training set of 1M examples.

Bi-encoder (large) model Hyperparameter configuration for best model: learning rate=1e^{-5}, batch size=128, max context tokens=32. Average runtime for each epoch: 17.5 hours/epoch, trained on 4 epochs.

Cross-encoder (large) model Hyperparameter configuration for best model: learning rate=2e^{-5}, batch size=1, max context tokens=32. Average runtime for each epoch: 37.2 hours/epoch, trained on 1 epoch.

A.2 Zero-shot Entity Linking Dataset

Dataset available at `https://github.com/lajanugen/zeshel`. There are 49K, 10K, and 10K examples in the train, validation, test sets respectively. Training details:

Bi-encoder (base) model Hyperparameter configuration for best model: learning rate=2e^{-5}, batch size=128, max context tokens=128. Average runtime: 28.2 minutes/epoch, trained on 5 epochs.

Bi-encoder (large) model Hyperparameter configuration for best model: learning rate=1e^{-5}, batch size=128, max context tokens=128. Average runtime: 38.2 minutes/epoch, trained on 5 epochs.

Cross-encoder (base) model Hyperparameter configuration for best model: learning rate=1e^{-5}, batch size=1, max context tokens=128. Average runtime: 2.6 hours/epoch, trained on 2 epochs.

Cross-encoder (large) model Hyperparameter configuration for best model: learning rate=1e^{-5}, batch size=1, max context tokens=128. Average runtime: 8.5 hours/epoch, trained on 2 epochs.

A.3 TACKBP-2010 Dataset

Dataset available at `https://catalog.ldc.upenn.edu/LDC2018T16`. There are 1,074 and 1,020 annotated examples in the train and test sets respectively. We use a 10-fold cross-validation from training set. Training details:

Bi-encoder (large) model Hyperparameter configuration for best model: learning rate=2e^{-6}, batch size=128, max context tokens=32. Average runtime: 9.0 minutes/epoch, trained on 10 epochs.

Bi-encoder (large) model with Knowledge Distillation Hyperparameter configuration for best model: learning rate=2e^{-5}, batch size=128, max context tokens=32, $T = 2, \alpha = 0.5$. Average runtime: 11.2 minutes/epoch, trained on 10 epochs.

Cross-encoder (large) model Hyperparameter configuration for best model: learning rate=1e^{-5}, batch size=1, max context tokens=128. Average runtime: 20.4 minutes/epoch, trained on 10 epochs.

A.4 WikilinksNED Unseen-Mentions Dataset

The train, validation and test sets contain 2.2M, 10K, and 10K examples respectively. We use a subset of 100K examples to fine-tune our model on this dataset, as we found more examples do not help. Training details:

Bi-encoder (large) model Hyperparameter configuration for best model: learning rate=2e^{-6}, batch size=128, max context tokens=32. Average runtime for each epoch: 3.2 hours/epoch, trained on 1 epochs.

Bi-encoder (large) model with Knowledge Distillation Hyperparameter configuration for best model: learning rate=5e^{-6}, batch size=128, max context tokens=32, $T = 2, \alpha = 0.5$. Average runtime: 6.5 hours/epoch, trained on 1 epochs.

Cross-encoder (large) model Hyperparameter configuration for best model: learning rate=2e^{-6}, batch size=5, max context tokens=128. Average runtime: 4.2 hours/epoch, trained on 1 epochs.

A Dataset for Tracking Entities in Open Domain Procedural Text

Abstract

We present the first dataset for tracking state changes in procedural text from arbitrary domains by using an *unrestricted* (open) vocabulary. For example, in a text describing fog removal using potatoes, a `car window` may transition between being *foggy, sticky, opaque*, and *clear*. Previous formulations of this task provide the text and entities involved, and ask how those entities change for just a small, pre-defined set of attributes (e.g., location), limiting their fidelity. Our solution is a new task formulation where given just a procedural text as input, the task is to generate a set of state change tuples *(entity, attribute, before-state, after-state)* for each step, where the entity, attribute, and state values must be predicted from an open vocabulary. Using crowdsourcing, we create OPENPI[1], a high-quality (91.5% coverage as judged by humans and completely vetted), and large-scale dataset comprising 29,928 state changes over 4,050 sentences from 810 procedural real-world paragraphs from WikiHow.com. A current state-of-the-art generation model on this task achieves 16.1% F1 based on BLEU metric, leaving enough room for novel model architectures.

1 Introduction

By one estimate, only about 12% of what we understand from text is expressed explicitly (Graesser, 1981). This is especially apparent in text about actions where the effects of actions are left unstated. Humans fill that gap easily with their commonsense but machines need to model these effects in the form of state changes. For example, when a potato is rubbed on a car window (to defog it), then the unstated effects of this action are the following state changes: *windows becomes sticky, opaque, and the potato becomes dirty*, etc. These changes can be tracked across the paragraph. An exemplary use case of text with actions is procedural text (recipes, how-to guides, etc.) where modeling such state changes helps in various reasoning-based end tasks, e.g. automatic execution of biology experiments (Mysore et al., 2019), cooking recipes (Bollini et al., 2012) and everyday activities (Yang and Nyberg, 2015).

	`1. Rub the cut side of potato on the window.`	...	`4. Leave to dry without touching.`
`location`	unknown → at car		no change
`existence`	exists		exists
`cleanliness`	clean → dirty		
`transparency`	fogged → partially clear		
`clarity`	opaque → translucent		
`texture`	smooth → sticky		
`moisture`			wet → dry
`...`	...	...	...
`open attr.`			touched → untouched

Figure 1: Previous formulations of the state tracking task are restricted to a small, fixed set of pre-defined state change types that limits its fidelity to model real-world procedures (they cannot cover the blue part in this procedure comprising four steps). Our solution is a new task formulation to track an unrestricted (open) set of state changes (additionally covering blue).

While there has been great progress in tracking entity states in scientific processes (Dalvi et al., 2018), tracking ingredients in cooking recipes (Bosselut et al., 2018), and tracking the emotional reactions and motivations of characters in simple stories (Rashkin et al., 2018), prior tasks are restricted to a fixed, small set of state change types thus covering only a small fraction of the entire world state. Figure 1 illustrates this for a real-world procedure "How to Keep Car Windows Fog Free Using a Potato". Existing datasets such as ProPara (Dalvi et al., 2018) only model the *existence* and *location* attributes, limiting the fidelity with which they model the world. Specifically:

- Attributes from domain-specific datasets such

---

as ProPara (Dalvi et al., 2018) and Recipes (Bosselut et al., 2018) together, only cover ∼40% of the state changes that people typically mention when describing state changes in real-world paragraphs from WikiHow (§2.1).

- The set of attributes that people naturally use to describe state changes is large, and hence hard to pre-enumerate ahead of time (especially when the target domain is unknown). Even a comprehensive list of popular attributes failed to cover 20% of those used in practice (§4.2).
- The dominant approach in existing datasets is to assume that changing entities are mentioned as spans in the procedural text. However, in unconstrained human descriptions of changes, ∼40% of the referred-to entities were unmentioned in the text (e.g., the knife and cutting board in several cooking recipes) (§4.4).

Addressing these limitations, our solution is a new task formulation to track an unrestricted (open) set of state changes: Rather than provide the text and entities, and ask how those entities change for a pre-defined set of attributes at each step, we instead provide just the input text, and ask for the set of state changes at each step, each describing the before and after values of an attribute of an entity in the form ($attribute$ *of* $entity$ *was* $value_{\text{before}}$ *before and* $value_{\text{after}}$ *afterwards.*). Importantly, the vocabularies for attributes, entities, and values is open (not pre-defined). Our contributions are:

(i) we introduce a novel task of tracking an unrestricted (open) set of state change types (§2).

(ii) we create a large-scale (∼30K state changes), high-quality ∼ 91.5% coverage and human vetted) crowdsourced annotated dataset OPENPI, from a general domain text serving as training dataset for this task (§4).

(iii) we establish a strong generation baseline demonstrating the difficulty of this task (§5), and present an error analysis suggesting avenues for future research (§6.3).

2 Proposed Task: OPENPI

From a procedural paragraph with sentences (i.e., steps) $step_1 \ldots step_K$, construct K data points, one per step.

Input: As input we are given a procedural text comprising current step $step_i$ as query and all past step as context $step_1 \cdots step_{i-1}$. We denote the input as $x = (x_q, x_c)$, where x_q is the step for which we need the state changes (i.e. the query) and x_c is the context.

Here, we use the common assumption (Dalvi et al., 2018) that the steps in procedural text are ordered such that the context required for $step_i$ is mentioned in $step_1 \cdots step_{i-1}$.

Output: The output is a set of zero or more state changes $\boldsymbol{y}= \{y_i\}$. A state change y_i is of the form:

$attr$ *of* ent *was* val_{pre} *before and* val_{post} *afterwards*

Here, $attr$ is the attribute or state change type, and ent is the changed entity. val_{pre} is the precondition (i.e., the state value before), and val_{post} is the postcondition (i.e., the state value afterwards). Pre/ postcondition $adj\_or\_relp(y_i^{pre})$ can be an adjectival phrase or a relational phrase. In this task, $attr$, ent, val_{pre} and val_{post} are open form text i.e. they are not tied to any fixed, constrained vocabulary.

Example: Consider the running example: x=(context: *The window of your car is foggy*, query: *Rub half potato on the window*). Then, $\{y\}$ = { *transparency of window was fogged before and partially clear afterwards*, *stickiness of window was smooth before and sticky afterwards* }. In y_1, $attr$ = *transparency*, ent = `window`, val_{pre} = *fogged* and val_{post} = *partially clear*

2.1 Unique Challenges

OPENPI has two unique challenges that are not found in any existing state change dataset.

- **Variable size, low-specificity output**: (Jas and Parikh, 2015) introduce the notion of image specificity which measures the amount of variance in multiple viable descriptions of the same image (typically, each image has exactly K descriptions from K annotators). Low specificity implies very different descriptions that are not mere re-phrasings. In OPENPI the output $\boldsymbol{y}$ has low-specificity (low specificity is also called high complexity output). To achieve low specificity outputs, existing methods learn to generate diverse responses by sampling different keywords and using a reinforcement learning approach for training (Gao et al., 2019) or use a diverse beam search (Vijayakumar et al., 2018) based approach on a typical encoder to decode diverse outputs. However, they all assume that the output set size is fixed to K (typically each

Input x	**Output** $\boldsymbol{y}$
Apply insecticide to peonies.	*the location of insecticide was in bottle before and on peonies afterwards.* *the health of bugs were healthy before and dying afterwards.*
Dip the peony flowers in water.	*the moisture of flowers was dry before and wet afterwards.* *the cleanliness of peonies were dirty before and clean afterwards.*
Stop ants from climb.. use trap	*the organization of trap was disassembled before and assembled after..* *the well being of plants were troubled before and healthy afterwards.*
Combine apricots, .. in blender.	*the location of apricots was on counter before and in blender afterwards.* *the state of ingredients were separate before and combined afterwards.* *the weight of blender was light before and heavy afterwards.*
Add oil until dressing thick.	*the state of ingredients were separate before and combined afterwards.* *the location of oil was on counter before and in blender afterwards.*
Stir in the basil.	*the location of dressing was in blender before and on serving plate..* *the location of basil was outside blender before and in blender afterwards.* *the weight of blender was heavy before and light afterwards.*

Table 1: Examples of the task based on our dataset. The input x comprises a ***query*** x_q and a context x_c (past sentences before this step in the paragraph– not shown due to limited space). The output is a set $\boldsymbol{y}$ of pre and postconditions. The paragraphs in this table are: above (how to clean oven) and below (cooking recipe).

sample is annotated by exactly K annotators). In our case, however, the number of items in $\boldsymbol{y}$ is variable, making these existing solutions inapplicable.

- **Open vocabulary**: In OPENPI $attr$, ent, val_{pre} and val_{post} are not restricted to any fixed, small vocabulary. Previous task formulations such as (Bosselut et al., 2018; Dalvi et al., 2018), made the assumption that ent is given, $attr$ is from a vocabulary of less than 10 classes, and val_{pre} or val_{post} are either from a small external vocabulary or a span in x[2]. In contrast, in OPENPI, the entities may not be present in the sentence or even the context, and the state change types and values can come from a rather open vocabulary. This openness brings a variety of challenges: (i) presupposed entities: these are entities that are not present in x and perceived through background knowledge, (ii) zero shot learning: during inference on a previously unseen domain, there are previously unseen attributes, entities, and state change types. This makes the problem very challenging and places this task in a novel setting (see §3.1)

Task	Vocab.	Specificity	Output size
Story CSK	open	high	fixed
ProPara	closed	high	fixed
Recipes Task	closed	low	fixed
ALFRED	closed	high	fixed
VirtualHome	closed	high	fixed
OpenPI	open	low	variable

Table 2: Comparison of our dataset to existing datasets

3 Related Work

Tracking state changes: Procedural text understanding addresses the task of tracking entity states throughout the text (Bosselut et al., 2018; Henaff et al., 2017). This ability is an important part of

---

[2] We matched an exhaustive list of synonyms of existing attributes from existing datasets ProPara and Recipes: *existence, location, temperature, composition, cleanliness, cookedness, shape, rotation, accessibility* and found that only ∼40% of the attributes in OPENPI are covered by these (however, these datasets cannot cover the open vocabulary of entities and attribute values)

text understanding. While syntactic parsing methods such as AMR (abstract meaning representation) (Banarescu et al., 2013) represent "who did what to whom" by uncovering stated facts, tracking entity states uncovers unstated facts such as how ingredients change during a recipe.

Datasets with closed state changes: The bAbI dataset (Weston et al., 2015) includes questions about objects moved throughout a paragraph, using machine-generated language over a deterministic domain with a small lexicon. The SCoNE dataset (Long et al., 2016) contains paragraphs describing a changing world state in three synthetic, deterministic domains. However, approaches developed using synthetic data often fail to handle the inherent complexity in language when applied to organic, real-world data (Hermann et al., 2015; Winograd, 1972). The ProPara dataset (Dalvi et al., 2018) contains three state changes *(create, destroy, move)* for natural text describing scientific procedures. Other domain specific datasets include recipe domain (Bosselut et al., 2018), and biology experiments (Mysore et al., 2019). These datasets contain a small, closed set of state change types that are relevant to a specific domain. Our dataset is general domain, and to accommodate this generality we have an open vocabulary of state changes.

Datasets with open state changes: (Isola et al., 2015) propose manually defined antonymous adjective pairs (big, small) to define transformations in images, and this was an inspiration for us to use adjectives as open state changes in OPENPI Knowledge bases such as ConceptNet (Speer and Havasi, 2013) and ATOMIC (Sap et al., 2019) contain (open) pre-conditions and post-conditions but they are agnostic to context. Context plays a role when dealing with a large number of state changes types e.g., if "a stone hits a glass" then the glass would break but this is not the case if "a soft toy or a sound wave hits the glass". Our dataset contains context information, an important training signal for neural models.

Current knowledge bases (such as ATOMIC) contain social rather than physical effects. As a result, generation models trained on these knowledge bases incorrectly force the effects to be social. For example, COMET (Bosselut et al., 2019), trained on ATOMIC data, when applied on "Cans are tied together and transported to a recycling center", incorrectly predicts[3] *person goes to recycle center, Person needs to be arrested → Person is arrested, gets dirty*.

3.1 Positioning OPENPI

Figure 2.1 projects existing tasks and models along two different dimensions (open vocabulary, and variable-size low-specificity). We find that models bottom-left quadrant represents majority of the existing work on state changes such as ProPara (Dalvi et al., 2018) and bAbI (Weston et al., 2016)) in NLP community, and ALFRED (Shridhar et al., 2019) and VirtualHome (Puig et al., 2018) in Computer Vision. Correspondingly many models exist in that space ((Tandon et al., 2018), (Bosselut et al., 2018), (Henaff et al., 2017)). Very few models exist that can predict either open vocab (Rashkin et al., 2018), or variable size output (Bosselut et al., 2018). However, no existing task has both open vocabulary and variable-size low specificity– placing OPENPI in a novel space.

4 Dataset

4.1 Data Collection

We set up a crowdsourcing task on Amazon Mechanical Turk where the annotators author the $\boldsymbol{y}= \{y_i\}$ for every sentence of a wikihow.com article, filling in a sentence template for each y_i as a guide. WikiHow contains a wide variety of goals (e.g., *how to wash dishes*) broken down into steps with detailed descriptions and pictorial illustrations, spanning across 19 categories. We selected a diverse subset of six popular categories and focus on action-oriented articles[4].

For a given WikiHow article, annotators were asked to describe up to six state changes for each step ($0 \leq |\boldsymbol{y}| \leq 6$), and were paid fairly[5]. Each state change description consists of precondition (y_i^{pre}), postcondition (y_i^{post}), and the (physical) attribute. Restricting the annotators to a template for state change described in §2, yields much better quality than free-form. This was a pragmatic

---

[3] Manually inspecting the 45 predictions made by COMET on this sentence, we found only one partially correct prediction that the human has to get to the recycle center before.

[4] We exclude WikiHow articles with steps containing stative verbs such as *know, see, want*, etc., and remove articles with too few (less than 4) or too many steps (7 or more). The selected categories are in Table 3.

[5] We set the reward to be \$0.07 for each of the first three state changes, and \$0.14 for each of the additional three state changes in order to encourage workers to write as many state changes as possible. All annotators met the following prerequisites as a minimum qualification: (1) 5K previous HITs approvals, (2) 99% or higher approval rate, (3) location is US, UK, CA, AU, or NZ.

choice, to encourage Turkers to give a complete description but not add extra noise. In an earlier pilot, we tried upto 10 changes but Turkers found the task too difficult and complained. Six empirically resulted in the best level of agreement and completeness among annotations, while also retaining diversity.

The annotators were encouraged (but not required) to pick from a pre-defined vocabulary of 51 WordNet derived attributes.

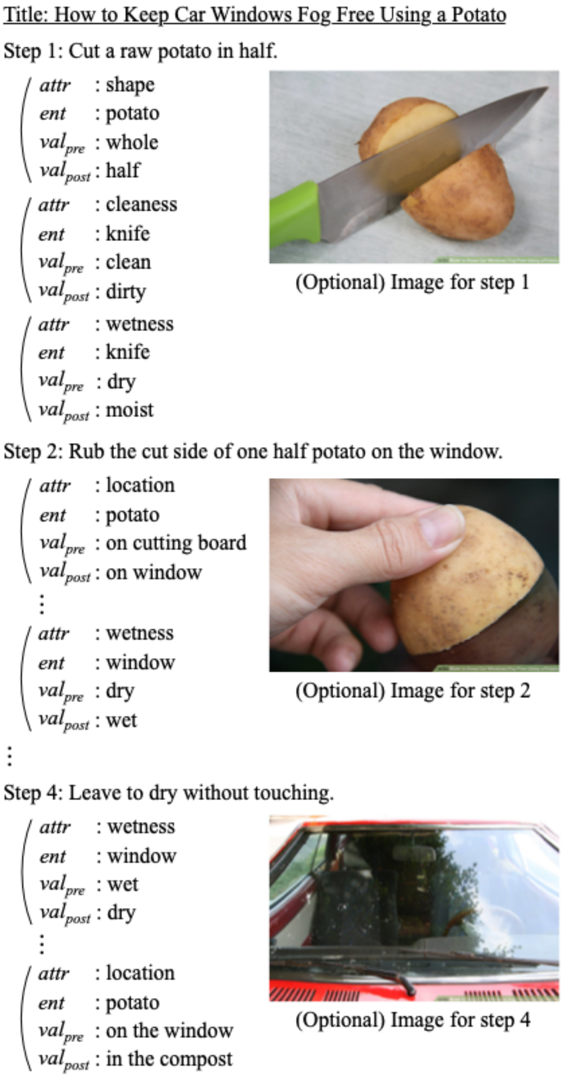

Figure 2: Data collection procedure: Crowdworkers are shown the article title, step descriptions and optionally the corresponding image, and asked to write up to six state changes (y_i^{pre}, y_i^{post}, *attr*) per step. See the appendix for a sample of the annotation task.

We performed two sets of annotations for every article, one where the annotators see the pictorial illustration of a step and one without. Visuals helped the annotators to provide more state changes (e.g., the color of cut potato turns gray). In total, one article is annotated four times (two turkers each for with and without images)– making the cost of annotation \$3.6 in average per article. See Figure 2 for an example of the annotation procedure.

After collecting the data, we cleaned up the state changes by asking three crowd workers if each state change is valid or not with the same annotation setting as data collection (e.g., with or without visual illustration). We discarded state changes that did not get the agreement by the majority (2 or more workers). With this cleaning step, the total number of state changes changed from 33,065 to 29,928.

The small number of errors encountered during vetting fell into five categories:

- (∼45% of the errors) Obscure attributes/ values, e.g., *state of clubhouse was spoken of before.*
- (∼20%) State change of future steps, e.g., *Prepare the pot* → *location of veggies in pot*
- (∼15%) Mismatch of attribute and value: *shape of lemon was solid*
- (∼10%) State change of the reader, not the actor: *knowledge of you becomes aware*
- (∼10%) Factual errors: annotated change does not occur or tautologously refers to the action.

4.2 Dataset statistics

The resulting OPENPI dataset comprises 29,928 state changes over 4,050 sentences from 810 WikiHow articles. Of these, 15,445 (4.3 per step) state changes were obtained from the *with images* setting and 14,483 (3.8 per step) from *without images*, indicating that the additional visual modality helped workers to come up with more state changes (e.g., the color of cut potato turns gray). These WikiHow articles were from six categories, see Table 3. The number of state changes in a category depends on the density of entities and their changes e.g., cooking related articles include multiple ingredients and instruments that undergo state changes.

Two thirds of the state changes are adjective phrases (avg. length 1.07 words) and the remaining one third are relational phrases (avg. length 2.36 words). Attributes, entities, adjective phrases, relational phrases all follow a power-law like distribution. The most popular adjectives were {*dry, empty, clean, wet, dirty, full, heavier, lighter, hot, whole, cool, cold*}, and the most popular relational phrases were location-indicating prepositions. About 20% of the attributes are present in 80% of the data.

WikiHow cat.	# para	$\|\boldsymbol{y}\|$	w/ img	w/o
Food & Entertain	197	9942	5399	4543
Home & Garden	199	6961	3758	3203
Hobbies & Craft	193	4766	2375	2391
Sports & Fitness	95	3361	1662	1699
Cars & Vehicles	43	1656	818	838
Health	77	3036	1433	1603
All	858	29928	15445	14483

Table 3: Basic statistics of the OPENPI dataset: the articles' WikiHow category, the number of WikiHow articles (i.e., paragraphs) in each category and number of state changes $|\boldsymbol{y}|$ (total), and data collected using with, and without image setting).

The long tail of the remaining 80% attributes indicates why open attributes are important. As similar attributes can be expressed differently in text e.g., *wetness* and *moisture*, we analyzed a few data points to observe a large agreement between annotators in choosing attributes (the average size of attribute clusters was only 1.2).

We split the data into training, development, and test sets. To evaluate model generalization, all the annotated articles in the Health category are marked as out-of-domain and placed (only) in the test set. All the remaining annotated articles are randomly assigned to one of the splits. The resulting training set has 23,869 state changes (3,216 instances because one instance comprises $|\boldsymbol{y}|$ state changes), dev set has 1,811 (274 instances), and test set has 4,248 (160 instances in domain, and 394 instances out-of-domain "Health").

4.3 Dataset quality

We measure the quality (coverage) of the dataset by asking a human judge whether there is any new state change they can add. The judge added only 8.5% new state changes. This suggests that OPENPI has a high coverage of ~91.5%, and a very high precision because of vetting.

These additions fell into four categories:

- (~40% of additions) Indirect effect was missed, e.g., *Place in freezer* → (existing) *food cooler*, (added) *food container cooler*
- (~35%) Extra dimension of change (attribute) missed, e.g., (added) Change in texture, organization, open/closed state.
- (~20%) Addition is a rewording hence not helpful e.g., *cleanliness of windshield*, (added) *clarity of windshield*
- (~5%) Addition is incorrect/obscure.

4.4 Quantifying the reasoning challenges

Presupposed entities: About 61% of the entities in our development set are mentioned as spans in the context and paragraph, while the remaining 40% are unmentioned entities. About 35% of the unmentioned entities were derivatives of mentioned entities, i.e. synonym, hypernym-hyponym, or part-whole. The remaining 65% were presupposed (assumed) entities, e.g., containers of mentioned entities, surfaces, cooking instruments.

Open attributes: 78.9% of the examples contain the 51 predefined attributes that the annotators were supplied. The remaining examples contain 577 Turk authored open attributes and many of these are difficult to anticipate, e.g., cookedness, tightness, saltiness. This makes up a long tail distribution of an open vocabulary of attributes.

Zero-shot learning: The test-set contains: 1) paragraphs from five categories covered in the training set, 2) paragraphs from `Health` category for which there is no training data, to test zero-shot learning. `Health` test-subset is particularly challenging with 55% unmentioned entities (40% otherwise) and 33% unseen attributes (18% otherwise).

Variable size, low specificity output: A system needs to decide relevant entities and attributes would be relevant and generate possibly varying number of state changes for different steps. The dev set has on average seven state changes per step, and 3% of the steps have no state change.

5 Model

OPENPI dataset poses unique challenges including presupposed entities, open attributes, zero-shot learning and variable-size, low specificity output (see Section 4.4). These challenges make it difficult to apply existing entity tracking methods like ProStruct (Tandon et al., 2018), EntNet (Henaff et al., 2017), NPN (Bosselut et al., 2018) without making significant changes to either the model or the task. E.g., the commonsense constraints in ProStruct do not scale with a large number of attributes, and EntNet is not suitable for a set output.

OPENPI is well-suited for a generation model because the output *$attr$ of ent was val_{pre} before and val_{post} afterwards* must be predicted using an open vocabulary. Therefore, as our baseline, we use the state-of-the-art pre-trained language model, GPT-2 (Radford et al., 2019), and fine-tune it for

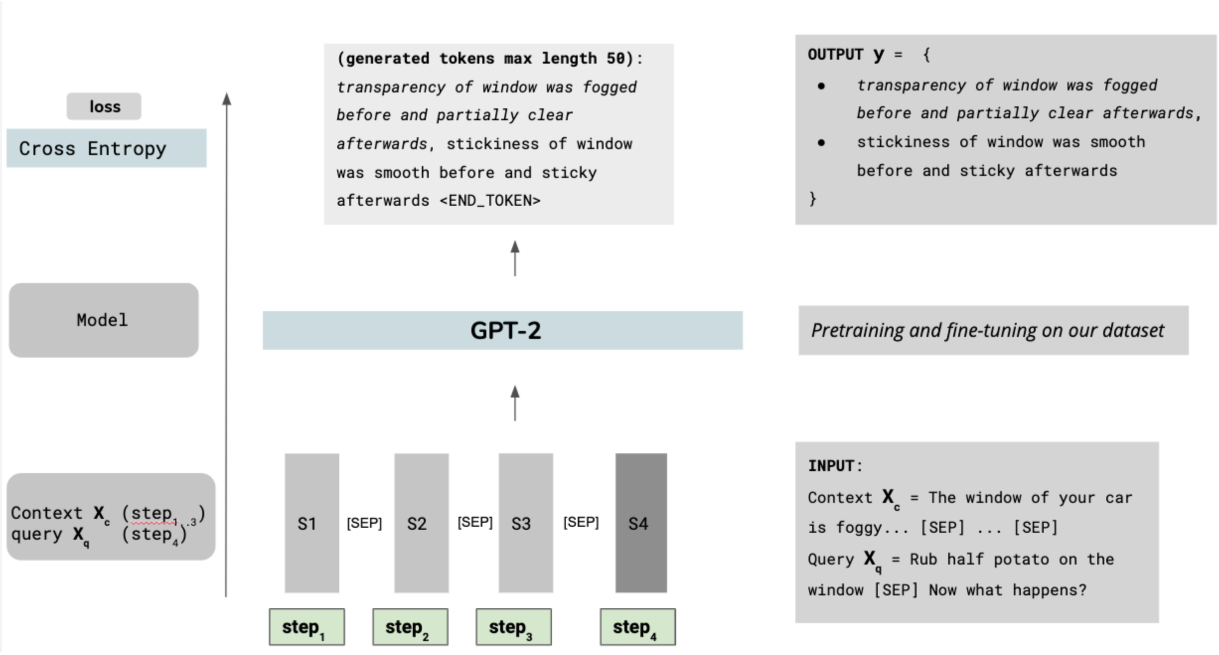

Figure 3: Our GPT-2 based model for OPENPI

OPENPI task. The model takes as input a special [SEP] token separated x_c and x_q. The output is expected to be a set $\boldsymbol{y}$ of variable size. As noted in §2.1, existing methods do not produce a variable size, low-specificity output. Instead we train the model to generate a long sequence of comma separated y_i. If there are no changes i.e., $|\boldsymbol{y}| = 0$, then we set $\boldsymbol{y} = \{\textit{there will be no change}\}$.

Figure 3 shows the model architecture. During decoding, we sample y_i as a sequence of output tokens generated by the model. The generation output accounts for all aspects of the state change - the attribute, entity, and before, after values.

6 Experiments

6.1 Metrics

To measure the performance on OPENPI we compare the predicted set $\boldsymbol{y}$ and gold set $\boldsymbol{y}*$, for every point x. Precision for a data point x is computed based on the best matching gold state change for each predicted state change i.e., $P(x) = \frac{1}{2} \sum_{y \in \boldsymbol{y}} max_{y*}\, O(y*^{pre}, y^{pre}) + O(y*^{post}, y^{post})$. Similarly, recall is based on the best matching predicted state change for each gold state change i.e. $R(x) = \frac{1}{2} \sum_{y* \in \boldsymbol{y}*} max_{y}\, O(y*^{pre}, y^{pre}) + O(y*^{post}, y^{post})$. The string overlap function $O(.)$ can use any of the standard generation metrics: exact match, BLEU, METEOR or ROUGE[6]. We report micro-averaged precision, recall, F1 scores for different choices of $O(.)$.

We remove template words before string comparison to avoid inflating scores for template words. We did not perform facet-based evaluation of the templated output for two reasons. Firstly, while it might seem when computing overlaps of gold and predicted state changes as two long strings, BLEU or ROUGE may accidentally see an overlap when there was none. That is unlikely in practice because the entities, attributes, and values are quite distinct and scoring accidental overlaps is uncommon. Secondly, our evaluation metric (F1, precision, recall) matches a list of predictions against a list of gold references. It is unclear how to compute F1 over individual facets that requires the best match based on all facets as tuple.

We also found that when manually evaluating on $\sim$200 dev datapoints, the score was systematically a few ($\sim$10%) points higher than BLEU, while the trends and model rankings remained the same, indicating robustness of the automatic metric.

Therefore, the proposed metric aligns with human evaluation, and is able to use existing generation metrics thereby simplifying evaluation, allowing easier reproducibility.

6.2 Evaluation

We evaluate state of the art generation model GPT-2 on OPENPI dataset. As mentioned in Section 4.2,

---

[6] github.com/allenai/abductive-commonsense-reasoning

OpenPI consists of two kinds of annotations: with-images (turkers were shown images along with text for each step of the procedure) and without-image (turkers looked at only text to predict state changes). GPT-2 gets to see only text as input but the state changes it has to predict are different depending on the setting. Table 4 reports P, R and F1 when GPT-2 model is tested on different subsets.

The GPT-2 model struggles to predict the right set of state changes indicating that the task is hard. Challenges include lexical variation on entities (in context vs. in gold), unseen categories, limited context for the initial sentences in the paragraph an so on. Detailed error analysis is presented in §6.3.

	F1 based on		
	Exact	BLEU	ROUGE
with-image	5.1	14.3	29.1
without-image	3.6	13.4	28.2
Entire dataset	4.3	16.1	32.4

Table 4: GPT-2 on OpenPI, and its sub-categories.

Models	BLEU scores		
	P	R	F1
seen category	25.1	18.4	17.1
unseen categories	24.4	17.4	15.7

Table 5: GPT-2 on topics seen, unseen during training.

OpenPI testset comprises of both unseen and seen categories, and we report BLEU separately on these subsets. Results from table 5 presents an encouraging result that GPT-2 generalizes to unseen topics even though the scores on seen categories is understandably a little higher (F1 of 17.1 for seen category vs 15.7 for unseen categories).

6.3 Error analysis

To better understand model shortcomings, the error types in dev predictions are illustrated (Table 6).

1. Wrong attribute ($attr(y_i)$): In 51% state changes produced by the GPT-2 model, predicted attribute is incorrect. Often (∼20% of cases) predicted attribute is *state*, i.e. the model couldn't name the attribute.

   Gold: wetness of potatoes was wet before, and dry after
   Pred: state of potatoes was wet before, and dry after

Error type	freq	%
Wrong attribute	826	51
Wrong entity	964	59
Wrong adjective	989	41
Wrong relation phrase	456	17
Any of the above	1,622	100

Table 6: Error types in 1,811 dev predictions. One state change prediction can have multiple error types.

2. Wrong entity ($ent(y_i^{pre})$): The model predicted incorrect entity 59% of the times. For 32% of the entity errors, the gold entity was unmentioned in the input text.

   (i) Entities present as span (68%): Typically, a related but not same entity is predicted:

   G: ..furniture was worn out before, and renewed after
   P: ..chairs was dirty before, and clean after

   (ii) Derivable entities: (3%) These entities are typically a lexical variation of the entities in the paragraph. E.g., *spray paint silk floral arrangement to change color or freshen its hue*, the model predicted

   G: ..plant was dry before, and wet after
   P: ..cloth was dry before, and wet after

   The following example also mentions a derivable entity and both gold and prediction are imply the same but it is difficult to automatically check that. E.g., *Keep the craft steady as others board.*

   G: stability of boat was rocking ... steadied after
   P: stability of craft was wobbling ... steady after

   (iii) Unmentioned entities: (29%). These types of errors are very difficult to overcome because the entities are typically not mentioned at all in the generated output. For instance in the following, loser and rider both refer to the same person in the text,

   G: ..loser was alive before, and dead after
   P: ..rider was alive before, and killed after

   In about 20% of such erroneous predictions, the model predicted the $adj(y_i^{pre})$ correctly. This may be because attribute is a good indicator of the adjectives.

3. Wrong $adj(y_i^{pre})$: (41%) The model pre-

dicts incorrect adjectives, such that in some cases the erroneous adjectives might not apply to the given entity, or the adjective values are swapped between pre and post condition. An example is shown below:

G ..curtains was white before, and painted after
P: ..double curtains was colorless ... colorful after

4. Wrong $relp(y_i^{pre})$ (17%): We find that relational phrases are very hard for the model currently. 184 out of 210 relational state changes predicted by the model have incorrect relational phrase. We believe that this poses a challenging research problem for future models.

G: knowledge of animals was absent ... present after
P: details afterwards was ignored ... discussed after

5. Length of the context plays an important role. Without any context (e.g., for the first step), the model gets a low accuracy of 8.3%.

7 Conclusion

We presented the first dataset to track entities in open domain procedural text. To this end, we crowdsourced a large, high-quality dataset with examples for this task. We also established a strong generation baseline highlighting the difficulty of this task. As future work, we will explore more sophisticated models that can address the highlighted shortcomings of the current model. An exciting direction is to leverage visuals of each step to deal with unmentioned entities and indirect effects.

Abstract

Cross-lingual Entity Linking (XEL), the problem of grounding mentions of entities in a foreign language text into an English knowledge base such as Wikipedia, has seen a lot of research in recent years, with a range of promising techniques. However, current techniques do not rise to the challenges introduced by text in low-resource languages (LRL) and, surprisingly, fail to generalize to text not taken from Wikipedia, on which they are usually trained. This paper provides a thorough analysis of low-resource XEL techniques, focusing on the key step of identifying candidate English Wikipedia titles that correspond to a given foreign language mention. Our analysis indicates that current methods are limited by their reliance on Wikipedia's interlanguage links and thus suffer when the foreign language's Wikipedia is small. We conclude that the LRL setting requires the use of outside-Wikipedia cross-lingual resources and present a simple yet effective zero-shot XEL system, `QuEL`, that utilizes search engines query logs. With experiments on 25 languages, `QuEL` shows an average increase of **25%** in gold candidate recall and of **13%** in end-to-end linking accuracy over state-of-the-art baselines.[1]

1 Introduction

Cross-lingual Entity Linking (XEL) aims at grounding mentions written in a foreign (source) language (SL) into entries in a (target) language Knowledge Base (KB), which we consider here as the English Wikipedia following Pan et al. (2017); Upadhyay et al. (2018a); Zhou et al. (2020). In Figure 1, for instance, an Odia (an Indo-Aryan language in India) mention ("Chilika Lake") is linked to the corresponding English Wikipedia entry. The XEL task typically involves two main steps: (1) candidate generation, retrieving a list of candidate KB entries for the mention, and (2) candidate ranking, selecting the most likely entry from the candidates.

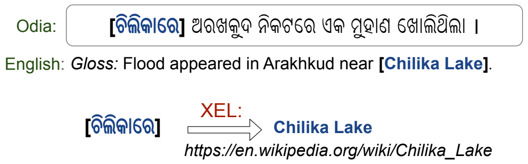

Figure 1: The EXL task: in the given sentence we link "Chilika Lake" to its corresponding English Wikipedia

While XEL techniques have been studied heavily in recent years, many challenges remain in the LRL setting. Specifically, existing candidate generation methods perform well on Wikipedia-based dataset but fail to generalize beyond Wikipedia, to news and social media text. Error analysis on existing LRL XEL systems shows that the key obstacle is candidate generation. For example, 79.3%-89.1% of XEL errors in Odia can be attributed to the limitations of candidate generation.

In this paper, we present a thorough analysis of the limitations of several leading candidate generation methods. Although these methods adopt different techniques, we find that all of them heavily rely on Wikipedia interlanguage links[2] as their cross-lingual resources. However, small SL Wikipedia size limits their performance in the LRL setting. As shown in Figure 2, while the core challenge of LRL XEL is to link LRL entities (A) to candidates in the English Wikipedia (C), interlanguage links only map a small subset of the LRL entities that appear in both LRL Wikipedia (B) and English Wikipedia. Therefore, methods that only leverage interlanguage links ($B \cap C$) as the main source of supervision cannot cover a wide range of entities.

[2] `https://en.wikipedia.org/wiki/Help:Interlanguage_links`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6418–6432,
November 16–20, 2020.

For example, the Amharic Wikipedia has 14,854 entries, but only 8,176 of them have interlanguage links to English.

Furthermore, as we show, existing candidate generation methods perform well on Wikipedia-based datasets but fail to generalize to outside-Wikipedia text such as news or social media.

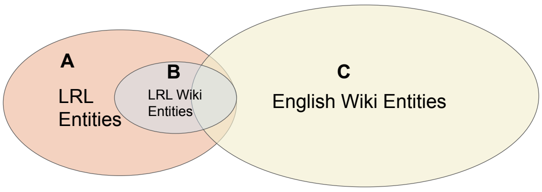

Figure 2: An illustration of Cross-lingual resources serving current XEL systems.

Our observations lead to the conclusion that the LRL setting necessitates the use of outside-Wikipedia cross-lingual resources. Specifically, we propose various ways to utilize the abundant query log from online search engines to compensate for the lack of supervision. Similar to Wikipedia, a free online encyclopedia created by Internet users, Query logs (QL) provide a free resource, collaboratively generated by a large number of users, and mildly curated. However, it is orders of magnitude larger than Wikipedia.[3] In particular, it includes all of Wikipedia cross-lingual resources as a subset since a search of an SL mention leads to the English Wikipedia entity if the corresponding Wikipedia entries are interlanguage-linked.

In this paper, the main part, Sec. 3 presents a thorough *method-wise* evaluation and analysis of leading candidate generation methods, and quantifies their limitations as a function of SL Wikipedia size and the size of the interlanguage cross-lingual resources. Based on the limitations, we analyze `QuEL_CG`, an improved candidate generation method utilizing QL in Sec. 4, showing that it exceeds the Wikipedia resource limit on LRL. To exhibit a *system-wise* XEL comparison, in Sec. 5, we suggest a simple yet efficient zero-shot XEL framework `QuEL`, that incorporates `QuEL_CG`. `QuEL` achieves an average of **25%** increase in gold candidate recall, and **13%** increase in end-to-end linking accuracy on outside-wikipedia text.

2 Related Work

2.1 Background: Wikipedia resources

Wikipedia title mappings: The mapping comes from Wikipedia interlanguage links[4] between the SL and English, and uses Wikipedia articles titles as mappings. It directly links an SL entity to an English Wikipedia entry without ambiguity.

Wikipedia anchor text mappings: A clickable text mention in Wikipedia articles is annotated with anchor text linking it to a Wikipedia entry. The following retrieving order: SL anchor text → SL Wikipedia entry → English Wikipedia entry (where the last step is done via the Wikipedia interlanguage links), allows one to build a bilingual title mapping from a SL mentions to Wikipedia English entries, resulting in a probabilistic mapping with scores calculated using total counts (Tsai and Roth, 2016).

2.2 XEL systems for Low-resource languages

We briefly survey key approaches to XEL below.

Direct Mapping Based Systems, including `xlwikifier` (Tsai and Roth, 2016) and `xelms` (Upadhyay et al., 2018a), focus on building a SL to English mapping to generate candidates. For candidate ranking, both `xlwikifier` and `xelms` combine supervision from multiple languages to learn a ranking model.

Word Translation Based Systems including Pan et al. (2017) and `ELISA` (Zhang et al., 2018), extract SL – English name translation pairs and apply an unsupervised collective inference approach to link the translated mention.

Transliteration Based Systems include Tsai and Roth (2018) and `translit` (Upadhyay et al., 2018b). `translit` uses a sequence-to-sequence model and bootstrapping to deal with limited data. It is useful when the English and SL word pairs have similar pronunciation.

Pivoting Based Systems including (Rijhwani et al., 2019; Zhou et al., 2019) and `PBEL_PLUS` (Zhou et al., 2020), remove the reliance on SL resources and use a *pivot* language for candidate generation. Specifically, they train the XEL model on a selected high-resource language, and apply it to SL mentions through language conversion.

[4] https://en.wikipedia.org/wiki/Help:Interlanguage_links

2.3 Query Logs

Query logs have long been used in many tasks such as across-domain generalization (Rüd et al., 2011) for NER, and ontological knowledge acquisition(Alfonseca et al., 2010; Pantel et al., 2012). In the English entity linking task, Shen et al. (2015) pointed out that google query logs can be an efficient way to identify candidates. Dredze et al. (2010); Monahan et al. (2011) use search result as one of their methods for candidate generation on high resource language entity linking task. While earlier work indicates that query logs provide abundant information that can be used in NLP tasks, as far as we know, it has never been used in cross-lingual tasks as we do here. And, only search information has been used, while we suggest using Maps information too.

3 Candidate Generation Analysis

In this section, we analyze four leading candidate generation methods: `p(e|m)`, `xlwikifier`, `name_trans`, `pivoting`, and `translit`(see Table 1 for the systems used by each method) and discuss their limitations.

Method	`p(e|m)`	`name_trans`	`pivoting`	`translit`
	System Usage			
`xlwikifier`	✓	-	-	-
`xelms`	✓	-	-	-
`ELISA`	-	✓	-	-
`PBEL_PLUS`	✓	-	✓	-
	Cross-lingual Resource			
Title Map	✓	✓	✓	✓
Anchor Text	✓	-	✓	-
Other Lang	-	-	✓	-

Table 1: Wikipedia cross-lingual resources and systems (introduced in Section 5) used by LRL XEL candidate generation methods.

3.1 Candidate Generation Methods

Each method listed in Table 1, is discussed below along with the level of resources it requires.

`p(e|m)` (Tsai and Roth, 2016) creates a direct probabilistic mapping table using Wikipedia title mappings and the anchor text mappings, between SL and English. E.g., if an Oromo mention "Itoophiyaatti" is the anchor text linked to an Oromo Wikipedia entity "Itoophiyaa"[5], and "Itoophiyaa" has an interlanguage link to English Wikipedia entity "Ethiopia", then "Ethiopia" will be added as a candidate for the mention "Itoophiyaatti". Thus, `p(e|m)` follows a linking flow: SL mention → SL Wikipedia entity → English Wikipedia entity.23

`name_trans` (Name Translation) as introduced in (Pan et al., 2017; Zhang et al., 2018) performs word alignment on Wikipedia title mappings, to induce a fixed word-to-word translation table between SL and English. For instance, to link the Suomi name "Pekingin tekninen instituutti" (Beijing Institute of Technology), it translates each word in the mention: ("Pekingin" – Beijing, "tekninen" – Technology, "instituutti" – Institute). At test time, after mapping each word in the given mention to English, it links the translation to English Wikipedia using an unsupervised collective inference approach.

`translit` (Upadhyay et al., 2018b) trains a seq2seq model on Wikipedia title mappings, to generate the English entity directly.

`pivoting` to a related high-resource language (HRL) (Zhou et al., 2020) attempts to generalize to unseen LRL mentions through grapheme or phoneme similarity between SL and a related HRL. Specifically, it first finds a related HRL for the SL, and learns a XEL model on the related HRL, using Wikipedia title mappings and anchor text mappings. Then it applies the model on SL mentions. If SL and related HRL share a script, showing grapheme similarity, it treats SL mentions as related HRL mentions at test time. Otherwise, if SL and related HRL have phoneme similarity it converts both SL and related HRL text into international phonetic alphabet (IPA) symbols.

3.2 Current Methods' Limitations

This section discusses four major limitations that existing methods suffer from, and quantifies these with experimental results. The results use the LORELEI dataset (Strassel and Tracey, 2016), a realistic text corpora that consist of news and social media text, all from outside-Wikipedia (see Section 5). Some tables also include a comparison with the proposed QL based candidate generation method `QuEL_CG` that we describe in Section 4. We use the definition of *gold candidate recall* in Zhou et al. (2020), which is the proportion of SL mentions that have the gold English entity in the candidate list, as the evaluation metric.

3.2.1 Shortage of Interlanguage Links

As illustrated in Figure 3 (specific numbers are in Appendix A.1) with statistics from the 2019-10-20 wikidump[6] and in Table 2 for five randomly picked

---

[5] https://om.wikipedia.org/wiki/Itoophiyaa

[6] https://dumps.wikimedia.org/

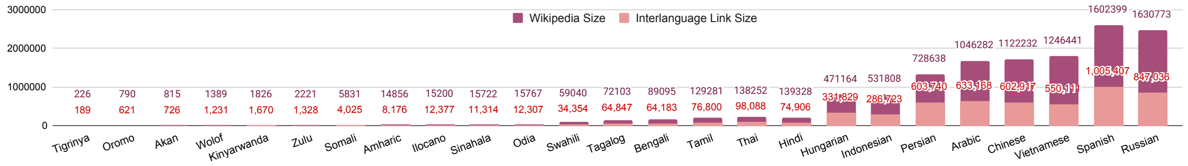

Figure 3: SL Wikipedia size (number of articles) and Interlanguage links size (between SL and English). We define low-resource languages (LRL) as Tigrinya to Odia, and high-resource ones (HRL) as Swahili to Russian.

Lang.	Oromo	Akan	Wolof	Zulu	Somali
SL-only Entity (%)	34.68	70.93	37.54	49.77	12.93

Table 2: Proportion of gold mentions in the LORELEI corpus with English Wikipedia pages but no SL ones.

Model	Hindi	Bengali	Odia	Sinahala
`translit-Wiki`	24.6	23.4	13.4	8.6

Table 3: *Gold candidate recall* of `translit`.

low-resource languages, many LRL Wikipedias only have a few interlanguage links to the English Wikipedia. Consequently, only a few Wikipedia title mappings and anchor text mappings are accessible by all four methods, as shown in Table 1.

For `p(e|m)`, the workflow is: SL mention → SL Wikipedia entity → English Wikipedia entity, and it breaks if one link is missing. For example, "Nawala" has an English Wikipedia page, but does not have a corresponding Sinhala page. Given its Sinhala mention[7], the interlink is missing and `p(e|m)` returns 0 probability for "Nawala".

For `name_trans`, its translation ability is limited by the tokens contained in the Wikipedia title mappings. For a SL mention, when none of its tokens ever appeared in the SL Wikipedia titles, it will not have any English translation, and thus generate no candidates. As for `translit` and `pivoting`, they will have fewer data pairs to train on and the model performance would suffer.

3.2.2 Small LRL Mention Coverage

In the LRL setting, few Wikipedia articles lead to fewer Wikipedia anchor text mappings, thus reducing the ability of current methods to cover many SL mentions. For instance, the LRL Oromo Wikipedia article for "Laayibeeriyaa"[8] has much fewer hyperlinks than the English Wikipedia article for "Liberia"[9], even though they are linked through an interlanguage link. Figures 3 and 4 show that *gold candidate recall* generally goes up with the increase in the Wikipedia size.

To evaluate Wikipedia coverage, we propose a global metric called *mention token coverage* that can be computed without the gold data. *Mention token coverage* is the percentage of SL mentions that have at least one token appearing in Wikipedia title mappings or in anchor text mappings. For example, when we consider Somali language, the mention "Shabeelada hoose" has a token "hoose" covered in Wikipedia titles, so it is counted in the *mention token coverage*. But"Soomaalieed" is not covered in Wikipedia titles or anchor text mappings, so it is not counted for *mention token coverage*. High *mention token coverage* values tend to guarantee better supervision when trained on Wikipedia. Indeed, in Figure 4, we can clearly see that the *mention token coverage* for LRLs is much smaller than that of high-resource languages (consult Figure 3 for the distinction between LRLs and HRLs).

We also compare the *mention token coverage* with *gold candidate recall* for each method in Figure 4. When a method has a *gold candidate recall* higher than *mention token coverage*, it means that the method is able to generalize beyond Wikipedia. In contrast, when *gold candidate recall* is lower than *mention token coverage*, it implies that the method is limited by Wikipedia resources.

To compare relation between *mention token coverage* and *gold candidate recall* more clearly, in Figure 5, we show the ratio of *gold candidate recall* over *mention token coverage*. Existing methods' ratio ranges between 0.31 to 1.27, with the average of 0.72. This suggests that existing methods are bounded by Wikipedia resources in most cases. This figure also shows the generalization ability of our QL-based candidate generation method `QuEL_CG` (introduced in Sec.4) to outside-Wikipedia mentions with an average ratio of 1.13 ranging between 0.74 and 1.92.

[8] `https://om.wikipedia.org/wiki/Laayibeeriyaa`

[9] `https://en.wikipedia.org/wiki/Liberia`

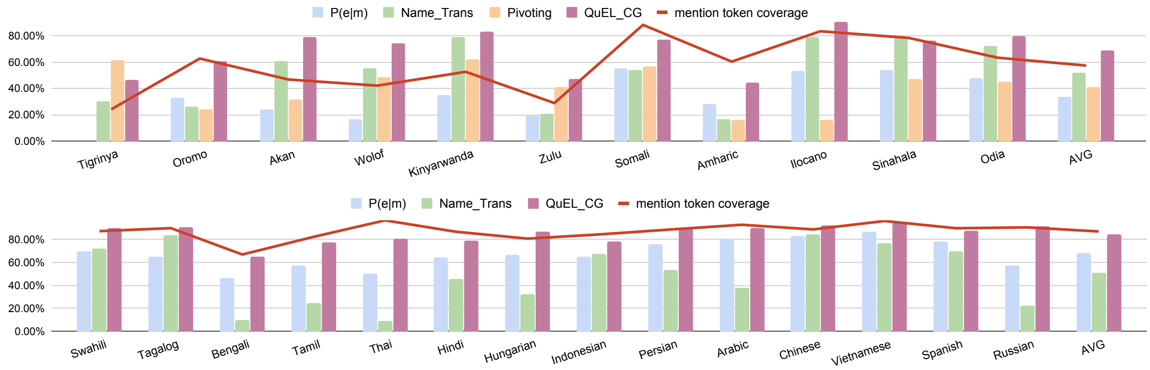

Figure 4: ***Gold candidate recall* (bars) on low-resource languages (top) and high-resource languages (bottom) correlates with *mention token coverage* (line) for existing approaches (excluding `QuEL_CG`).** *Mention token coverage* is the percentage of SL mentions that have at least one token overlapping with a SL Wikipedia title or anchor text (that correspond to it via interlanguage link). Languages appear in increasing order of Wikipedia size.

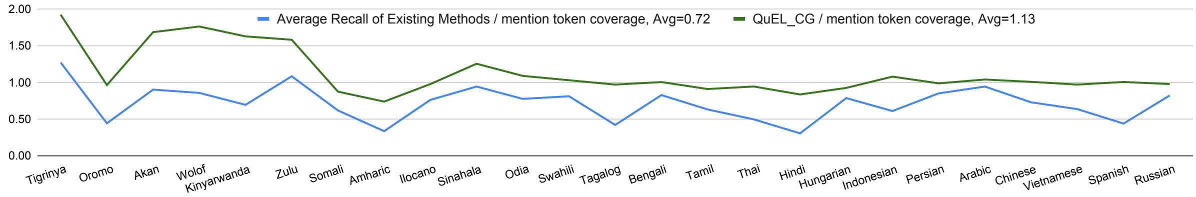

Figure 5: **Average *gold candidate recall* remains 0.5-0.8 times that of *mention token coverage* for existing approaches, but the ratio is 1.0-2.0 for `QuEL_CG`.** The lines are the ratio of *gold candidate recall* per candidate generation method divided by *mention token coverage*. Average *gold candidate recall* of existing methods: `p(e|m)`, `name_trans`, `pivoting`, is mostly limited by *mention token coverage* and cannot exceed it, with 0.72 average ratio. However, our proposed `QuEL_CG` can reach recall up to 2 times that of *mention token coverage*, with average ratio of 1.13 on all languages, tested to be statistically significant with p-value $<$ 0.01%.

3.2.3 `translit` Data Requirements

`translit` suffers from the inability to satisfy several of its data requirements. Typically, transliteration models need many training data pairs, which is hard to get using LRL Wikipedia title pairs. Also, they require SL mentions and gold English entities to have word-by-word mappings. Table 3 shows results of `translit` trained on name pairs from Wikipedia title mappings (`translit-Wiki`). We only provide results for languages for which the model has been released; this sample already shows clearly that the performance of `translit` drops significantly on LRLs.

3.2.4 `pivoting` Prerequisites

While `pivoting` does not suffer from insufficient cross-lingual resources between SL and English, it is limited by resources between related HRL and English. More importantly, it is limited the availability of related HRL that is similar enough to SL. `pivoting` learns through grapheme or phoneme similarity. However, grapheme similarity is not enough since not every LRL has a related HRL that uses the same scripts. In these cases `pivoting` uses phoneme similarity and maps strings to international phonetic alphabet (IPA) symbols. For example, (Zhou et al., 2020) uses Epitran (Mortensen et al., 2018) to convert strings to IPA symbols, but Epitran only supports 55 of the 309 Wikipedia languages, and covers only 8 out of 12 low-resource languages in the LORELEI corpus.

As in Figure 4, `pivoting` gains from the language conversion compared with `p(e|m)`, but the increase varies among languages, depending on the choice of related HRL. Most importantly, the related HRL cannot replace SL and language conversion may limit on the linking ability. For example, the language pair Oromo-Indonesian(grapheme) has same scripts but `pivoting` still suffers from low-resource on Oromo.

4 Improved Candidate Generation: `QuEL_CG`

As mentioned in Section 3, Wikipedia's cross-lingual resources are not enough for XEL to perform well in low-resource settings. We argue that outside-Wikipedia resources are essential to compensate for the lack of supervision. We suggest that search engines query logs provide an excellent resource in this situation, since it is a (very large) super-set of Wikipedia's cross-lingual data but covers even more; as pointed out in the Introduction, it is a collaboratively generated, mildly curated, resource and its effective size is a function of the number of SL native speakers using the search engine. Thus, query logs can help the candidate generation process map SL mentions to English Wikipedia candidates even when they are not covered by Wikipedia interlanguage links.

We propose an improved candidate generation method, `QuEL_CG`, that uses query log mapping files. We obtain a high-quality candidate list through directly searching SL mentions in query logs and a query-based pivoting method. While we can choose any search engines,we use here Google search[10] and Google maps[11]. `QuEL_CG` also runs in conjunction with `p(e|m)` to cover the cases where query log mapping is not robust.

4.1 Query Logs as Search Results

As the first step, we search the morphologically normalized SL mention in the Google search engine (implementation details in Appendix A.2) and retrieve a list of web-page results. We pick top k (k is usually 1 or 5) Wikipedia web-page results P_k. Note that if the searched result is SL Wikipedia article and it has an interlanguage link to English, we convert it to the corresponding English one through the link, and then mark the corresponding English entity as a candidate. When the SL mention is a geopolitical or location entity, we search its normalized mention using Google Map. Since it only returns English surface of the location instead of Wikipedia articles, we further search the resulted English surface in Google search using the same procedure described above.

4.2 Query-based Pivoting

We also conduct language-indifferent pivoting using query logs. Note that the pivoting methods described below are different from `pivoting` in Section 3.

Some LRLs have high-resource languages they are similar to (e.g. Sinhala to Hindi and Tigrinya to Amharic). In order to exploit the similarities between an LRL and HRL without having to choose one good HRL, we use query logs for pivoting. We first follow the same search steps described above to get top k Wikipedia web-pages results P_k. Finally, we continue the same process on the new pivoted mentions. A special case here is language-specific pivoting on selected language pairs. We use a simple utf-8 converter to translate SL mention into a related, but higher-resource language, such as Odia to Hindi, and then run the candidate generation process described above on the pivoted mention.

5 Experiments: System Comparison

Given the analysis of the key candidate generation process in Section 3, this section moves to study its implications on the overall performance of different LRL XEL systems. We first propose our LRL XEL framework, `QuEL`, by combining `QuEL_CG` with a zero-shot candidate ranking module. Our experimental goal is to compare all systems on both outside-Wikipedia data and Wikipedia data. We further analyze the entity distribution and entity type on the linking results. In addition, an ablation study is demonstrated in Appendix A.3.

5.1 Datasets

Dataset details are reported in Appendix A.1.

LORELEI dataset (Strassel and Tracey, 2016) is a realistic and challenging dataset that includes news and social media such as twitter. We divide its 25 languages into LRL and HRL as in Figure 3. Entities in LORELEI are of four types: geopolitical entities (GPE), locations (LOC), persons (PER) and organizations (ORG). The dataset provides a specific English KB that mentions are linked to; we processed the original dataset to link to the English Wikipedia instead. Our processed gold labels will be available along with LORELEI dataset[12]. Given a KB entity, we link it to Wikipedia if the KB provides a Wikipedia link. For a PER or ORG entity without Wikipedia link, we use its KB-provided English information, e.g. name and description, to search for Wikipedia entry, and manually check the correctness. Otherwise, we do not include this entity and remove any mentions linking to it in the EDL dataset. We process these types differently because PER and ORG entities only compose around

---

[10] https://www.google.com/

[11] https://www.google.com/maps

[12] https://catalog.ldc.upenn.edu/LDC2020T10

5% of the gold entities.

Wikipedia-based dataset collected by (Tsai and Roth, 2016) is built upon Wikipedia anchor text mappings. All languages in this dataset are high-resource ones as defined in Figure 3.

5.2 System Comparison

We compare the **supervised** SOTA systems, `xlwikifier`, `xelms`, `ELISA`, `PBEL_PLUS`, that use candidate generation methods analyzed earlier, with a new, QL-based system, that we present below. Implementation details are in Appendix A.4

5.3 A QL-based XEL: `QuEL`

Given the limitations discussed in Sec. 3 we propose a new XEL system, `QuEL`, that uses `QuEL_CG` (Sec. 4) along with the following zero-shot candidate ranking module. Given a candidate list C_m (the output of `QuEL_CG` on SL mention m), `QuEL` uses the multilingual BERT (Devlin et al., 2018) to score the candidates against m. Specifically, for each candidate $c \in C_m$ it computes a score $W(c, m)$ that measures "relatedness" between m and c. It then picks the candidate with the highest score as its output. In case of a tie, we break it by following the candidate selection order, from Google search results, to Google Map results, to `p(e|m)` candidates. We explain below the components of $W(c, m)$.

Candidate Multiplicity Weight A candidate can be suggested by multiple sources–Google search, Google Map search, query-based pivoting, or `p(e|m)`. `QuEL` prefers candidates generated by multiple sources. We define candidate c multiplicity weight as: $W_{Source}(c) = Num_{Source}(c)$, the number of sources that generate c.

Contextual Disambiguation. `QuEL` uses Multilingual BERT (M-BERT) (Devlin et al., 2018) for multilingual embeddings, to compute the similarity of the context of the mention m and the candidate's context in the English Wikipedia. We denote by $W_{context}(c, m)$ the cosine similarity between m's context embedding and c's context embedding (see details in Appendix A.5). Finally, the score for candidate c is $W(c, m) = W_{source}(c) \cdot W_{context}(c, m)$, and we select the most likely entity: $e = \arg\max_{c \in C_m} W(c, m)$ as output.

5.4 Entity Linking Results

Comprehensive evaluations of both the LORELEI and the Wikipedia based datasets are shown in Figures 6 and 7 and in Table 4. (Scores that correspond to the figures are reported in Appendix A.6.) Note that gold candidate recall on `xlwikifier` and `xelms` are identical because they use the same candidate generation module, `p(e|m)`.

`QuEL` is shown to significantly improve over existing approaches on both datasets, especially on the more difficult LORELEI dataset where it improves on almost all the languages and shows an average of **25%** increase in gold candidate recall and of **13%** in linking accuracy. On the Wikipedia-based dataset, `QuEL` shows an average increase of **4%** in gold candidate recall, while reaching the SOTA on linking accuracy. Importantly, most other systems, (`ELISA`, `xlwikifier` and `xelms`) use *supervised* ranking modules.

System	Gold Candidate Recall	Linking Accuracy
	LORELEI Dataset	
`xlwikifier`	52.54	46.58
`xelms`	52.54	48.65
`ELISA`	50.52	43.91
`PBEL_PLUS`	38.36	30.38
`QuEL`	**78.21**	**61.40**
	Wikipedia-based Dataset	
`xlwikifier`	79.40	63.51
`xelms`	79.40	**68.73**
`ELISA`	47.82	41.22
`QuEL`	**83.54**	66.16

Table 4: *Gold candidate recall* and *linking accuracy* comparison averaged over all languages.

6 Analysis

Table 4 shows huge performance gaps between the two datasets using the SOTA baseline `xelms`. The 20% percentage difference in both metrics proves that the LORELEI dataset is more difficult due to having more outside-Wikipedia mentions, and more focus on low-resource languages. One exception is `ELISA`, which has lower performance on Wikipedia-based dataset. We believe it fails to cover many Wikipedia mentions because it does not use Wikipedia anchor text mappings.

Similarly, when we consider the same language performance on the two datasets (see Figures 6 and 7), e.g., Tamil and Thai, the LORELEI dataset appears harder to deal with. However, `QuEL` achieves similar results on both datasets, and also brings the gold candidate recall for LRL much closer to that of HRL. Another important observation is that `QuEL` performs significantly better on the LORELEI dataset. It suggests that our proposed `QuEL_CG` addresses the outside-Wikipedia coverage problem well by exploiting the query logs. To understand why `QuEL` exceeds baselines largely on

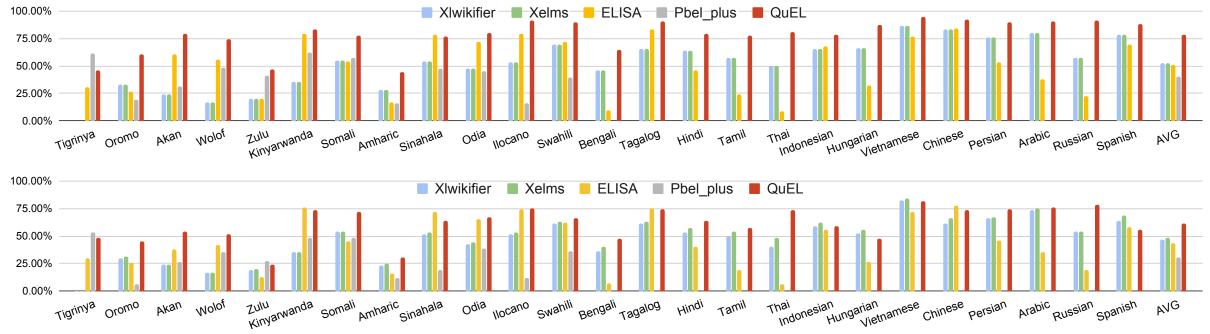

Figure 6: End-to-end XEL gold candidate recall(top) and linking accuracy(bottom) on the LORELEI dataset sorted by Wikipedia size in ascending order. Specific scores are reported in Tables 11 and 12 in Appendix A.6.

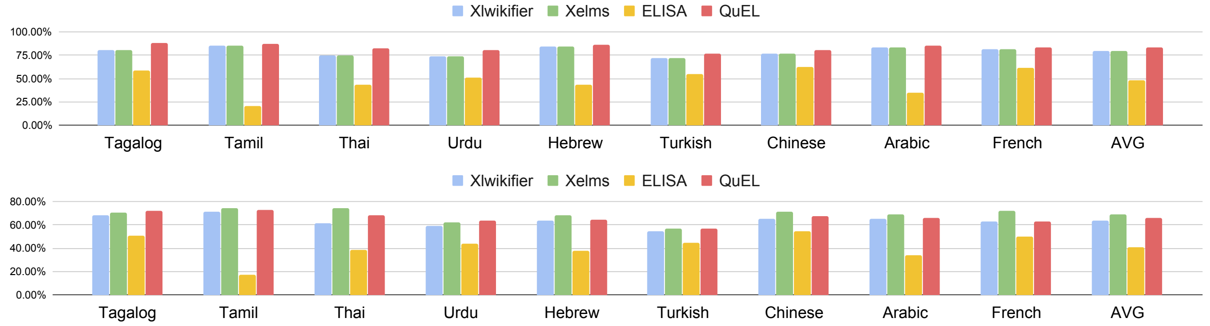

Figure 7: End-to-end XEL gold candidate recall(top) and linking accuracy(bottom) on the Wikipedia-based dataset sorted by Wikipedia size in ascending order. Specific scores are reported in Table 13 in Appendix A.6.

System	Akan	Oromo	Zulu	Wolof	Somali
			Gold Candidate Recall		
`xelms`	23.9	33.2	19.8	16.9	55.1
`ELISA`	60.7	26.2	20.4	55.5	54.3
`PBEL_PLUS`	31.7	19.1	40.8	48.5	57
`QuEL`	**79.0**	**60.6**	**47.1**	**74.4**	**77.4**
			Linking Accuracy

Lang.	**System**	**Accuracy (%)**			
		GPE	**LOC**	**PER**	**ORG**
Oromo	`xelms`	33.0	3.6	6.2	6.3
	`ELISA`	37.0	11.6	12.5	**11.9**
	`PBEL_PLUS`	53.0	40.5	6.4	0.0
	`QuEL`	**57.5**	**30.4**	**17.2**	4.2
Zulu	`xelms`	25.6	0.0	37.5	5.7
	`ELISA`	11.9	2.5	31.2	5.7
	`PBEL_PLUS`	24.6	6.2	38.1	8.7
	`QuEL`	**27.8**	**10.8**	**50.0**	**12.6**
Somali	`xelms`	55.0	28.6	21.4	42.1
	`PBEL_PLUS`	44.7	14.3	**25.6**	**75.0**
	`ELISA`	50.1	0.0	16.7	15.0
	`QuEL`	**71.7**	**57.1**	**33.3**	65.0

Table 6: *Linking accuracy* on different types of entities.

LORELEI dataset, we analyze it on entity resource and type distribution as below.

Entity Resource. Considering the insufficient Wikipedia interlanguage links for LRL in Table 2, we investigate whether `QuEL_CG` helps in this situation. In Table 5, `QuEL` shows 6.3% to 27.4% improvement in gold candidate recall, indicating that it can effectively perform XEL without the Wikipedia cross-lingual resource, leading to a significant improvement for LRL XEL.

Entity Type. Table 6 shows the evaluation on all four types of entities. We observe that `QuEL` improves more on GPE and LOC entities, than on PER and ORG entities. We believe the improvement is brought by Google Map query logs.

7 Conclusion

This work provides a thorough analysis of existing LRL XEL techniques, focusing on the step of generating English candidates for foreign language mentions. The analysis identifies the inherent lack of sufficient inter-lingual supervision signals as a key shortcoming of the current approach. This leads to proposing a rather simple method that leverages query logs, that are highly effective in addressing these challenges. Given that our experiments show a 25% increase in the candidate generation, one future research direction is to improve candidate ranking in LRL by incorporating coherence statistics and entity types. Moreover, given the effectiveness of query logs, we believe it can be applied to other cross-lingual tasks like relation extraction and Knowledge Base completion.

A.2 Implementation Details of `QuEL_CG`

To perform our improved candidate generation method `QuEL_CG`, we first conduct morphological normalization on the SL mention before querying. Then, we use the normalization output as search input. We use Google search [14] and Google Map [15]. We can also customize the search input for better results on extremely low-resource languages (Odia and Illocano) as below.

Morphological normalization. Language-specific Morphological normalization is a basic process for all candidate generation methods. An entity may have different surface forms in the document, which makes candidate generation difficult. To cope with this issue, several operations including removing, adding, or replacing suffixes and prefixes are conducted as a prior process.

Customize search input. To better retrieve Wikipedia pages as search results and ignore other web-page results, "wiki" or "[Country of SL]" can be appended to the original search input.

A.3 Ablation Study

We now quantify the effects of each component in our candidate generation method and show the results in Table 9.

Google Map. Our model is default to use the Google Map cross lingual resource. We test the effect of adding supervision from this QL.

Google top1. In everywhere that takes the Google query log (QL) results, take only the first Wikipedia page result that is in source or target language as candidate.

Google top5. Similar to Google top1, take the top 5 Wikipedia page results as candidates. We can see that Google top1 and top5's effects are language dependent.

`p(e|m)`. We test whether adding the `p(e|m)` module would help in linking performance. To better show the results, `p(e|m)` is added under the setting of using QL and Google Map KB, without adding other modules.

Pivoting. Pivoting here refers to our query-based pivoting, different from `pivoting` in Section 3. We picked two low-resource languages: Odia and Tigrinya, to explore the pivoting effect and show results in Table 10. On Odia, language-specific pivoting skill is used. Since we know in prior that Odia and Hindi are similar while the latter has much more resource, a simple utf8-converter is used to transform Odia to Hindi, and then runs the Hindi mention through our whole system. On Tigrinya, a language-indifferent pivoting skill is used. After getting QL results, besides using Google top1 or top5, we further pick Wikipedia page results that are in any other language, such as Amharic or Scots that have similar scripts, but with richer cross-lingual supervision then Tigrinya.

We further examined the effect of transliteration models using trained models (Upadhyay et al., 2018b) specifically on Sinhala and Odia, with bilingually mapped Wikipedia titles as supervision. We also used Google transliteration resource for Odia mentions. However, no increase on linking accuracy is observed, and the absolute increase in gold candidate recall is less than 0.5%. Since we only studied on Sinhala and Odia, maybe the transliteration resource is useful on other languages.

Tables 9 and 10 show that we added a lot of value beyond the use of Google search – simply using google search without adding other parts of our candidate generation methods does not have good linking results. Indeed, incorporating online search engine query logs effectively to XEL is highly non-trivial. In this context, it is important to note that all existing methods make heavy use of Wikipedia, and therefore using QL as a cross-lingual resource is as fair. Moreover, as our results show, the use of Wikipedia allows existing systems to perform well only on Wikipedia data, which is uninteresting for all practical purposes. As shown in Figure 6, Tables 11 and 12, our method works well outside Wikipedia!

	Odia (%)		**Tigrinya (%)**	
	Accuracy	**Recall**	**Accuracy**	**Recall**

Table 9: Ablation study on 6 low-resource languages that examines each candidate generation component for end-to-end linking accuracy (left) and gold candidate recall(right). Candidate number is below 5 in most languages and varies between 2-9. Our method as default includes Google Map module.

Wikipedia-based dataset provides training data, we use its provided version of candidate ranking. However, the LORELEI dataset has no training data, and thus no candidate ranking model can be trained. We just pick the first candidate as the result. For a comparison purpose, since `xelms` uses the same candidate generation module and provides better candidate ranking, `xlwikifier` is close to and mostly up-bounded by `xelms` results.

For **`xelms`**[17], we use trained ranking modules on most languages when available, and use the zero-shot version of ranking module for the rest of languages (Akan and Kinyarwanda).

For **`ELISA`**, we access the system using the API [18] directly provided by its authors, and call the GET/entity_linking/{identifier} function.

For **`PBEL_PLUS`**[19], we test this approach only on low-resource languages on the LORELEI dataset, because it generates candidates through pivoting to a related high-resource language, and it does not make sense to pivot a already high-resource language to other languages.

A.5 Implementation Details of Our System

During candidate ranking, for a mention m in a document D, we get the sentence s_m where m appears and computes its contextualized embedding $v_m = \text{M-BERT}(e, s_m)$. For each $c \in C_m$, we retrieve a list of sentences $S_c = \{s_1, s_2, ..., s_n\}$ that contains the candidate entity c in its corresponding Wikipedia page's summary. The contextualized embedding for c is denoted by v_c:

$$v_c = \frac{1}{|S_c|} \sum_{i=1}^{n} \text{M-BERT}(c, s_i)$$

Note that we picked two representative languages: Odia and Ilocano, for which we have additional LORELEI provided monolingual text, and trained the M-BERT model (Devlin et al., 2018) using their Wikipedia data along with LORELEI text. We did not use pre-trained M-BERT [20] on all languages because many low-resource languages are not supported, and for the supported ones the performance increase is much less than that of models trained with LORELEI text plus Wikipedia data. This experiment serves to show the gain one could get from additional supervision and, at the same time, highlights the results we show when M-BERT is not available, which is more realistic.

A.6 Comprehensive Evaluation

This section includes comprehensive evaluation on XEL systems.

Abstract

We present ELQ, a fast end-to-end entity linking model for questions, which uses a biencoder to jointly perform mention detection and linking in one pass. Evaluated on WebQSP and GraphQuestions with extended annotations that cover multiple entities per question, ELQ outperforms the previous state of the art by a large margin of +12.7% and +19.6% F1, respectively. With a very fast inference time (1.57 examples/s on a single CPU), ELQ can be useful for downstream question answering systems. In a proof-of-concept experiment, we demonstrate that using ELQ significantly improves the downstream QA performance of GraphRetriever (Min et al., 2019).[1]

1 Introduction

Entity linking (EL), the task of identifying entities and mapping them to the correct entries in a database, is crucial for analyzing factoid questions and for building robust question answering (QA) systems. For instance, the question "*when did shaq come to the nba?*" can be answered by examining *Shaquille O'Neal*'s Wikipedia article (Min et al., 2019), or its properties in a knowledge graph (Yih et al., 2015; Yu et al., 2017). However, real-world user questions are invariably noisy and ill-formed, lacking cues provided by casing and punctuation, which prove challenging to current end-to-end entity linking systems (Yang and Chang, 2015; Sorokin and Gurevych, 2018). While recent pre-trained models have proven highly effective for entity linking (Logeswaran et al., 2019; Wu et al., 2020), they are only designed for entity disambiguation and require mention boundaries to be given in the input. Additionally, such systems have only been evaluated on long, well-formed documents like news articles (Ji et al., 2010), but not on short, noisy text. Also, most prior works have focused mainly on improving model prediction accuracy, largely overlooking efficiency.

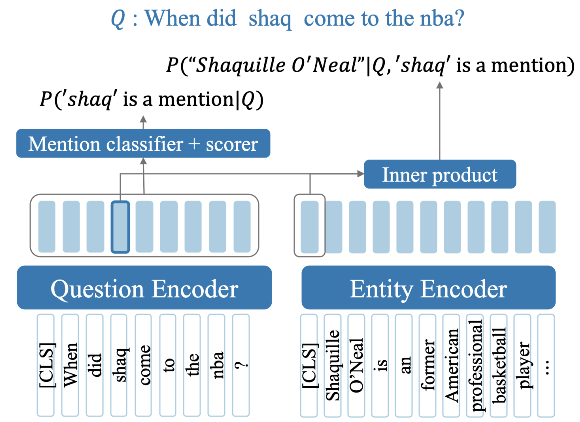

Figure 1: Overview of our end-to-end entity linking system. We separately encode the question and entity. We use the question representations to jointly detect mentions and score candidate entities through inner-product with the entity vector.

In this work, we propose ELQ, a fast and accurate entity linking system that specifically targets questions. Following the Wikification setup (Ratinov et al., 2011), ELQ aims to identify the mention boundaries of entities in a given question and their corresponding Wikipedia entity. We employ a bi-encoder based on BERT (Devlin et al., 2019) as shown in Figure 1. The entity encoder computes entity embeddings for all entities in Wikipedia, using their short descriptions. Then, the question encoder derives token-level embeddings for the input question. We detect mention boundaries using these embeddings, and disambiguate each entity mention based on an inner product between the mention embeddings (averaged embedding over mention tokens) and the entity embeddings. Our model ex-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6433–6441,
November 16–20, 2020.

tends the work of Wu et al. (2020) but with one major difference: our system does not require prespecified mention boundaries in the input, and is able to jointly perform mention detection and entity disambiguation in just one pass of BERT. Thus, at inference time, we are able to identify multiple entities in the input question efficiently.

We extend entity disambiguation annotations from Sorokin and Gurevych (2018) to create an end-to-end question entity linking benchmark. Evaluated on this benchmark, we are able to outperform previous methods in both accuracy and run-time. ELQ has much faster end-to-end inference time than any other neural baseline (by 2×), while being more accurate than all previous models we evaluate against, suggesting that it is practically useful for downstream QA systems. We verify the applicability of ELQ to practical QA models in a proof-of-concept experiment, by augmenting GraphRetriever (Min et al., 2019) to use our model, improving its downstream QA performance on three open-domain QA datasets (by up to 6%).

2 Related Work

Much prior work on entity linking has focused on long, grammatically coherent documents that contain many entities. This setting does not accurately reflect the difficulties of entity linking on questions. While there has been some previous work on entity linking for questions (Sorokin and Gurevych, 2018; Blanco et al., 2015; Chen et al., 2018; Tan et al., 2017), such works (mostly from the pre-BERT era) utilize complex models with many interworking modules. For example, Sorokin and Gurevych (2018) proposes a variable-context granularity (VCG) model to address the noise and lack of context in questions, which incorporates signals from various levels of granularity by using character-level, token-level, and knowledge-base-level modules. They also rely on external systems as a part of the modeling pipeline.

In this work, we take a much simpler approach that uses a biencoder. Biencoder models have been used in a wide range of tasks (Seo et al., 2019; Karpukhin et al., 2020; Wu et al., 2020). They enable fast inference time through maximum inner product search. Moreover, as we find, biencoders can be decomposed into reusable question and entity encoders, and we can greatly expedite training by training one component independently of the other.

3 Problem Definition & ELQ Model

We formally define our entity linking task as follows. Given a question q and a set of entities $\mathcal{E} = \{e_i\}$ from Wikipedia, each with titles $t(e_i)$ and text descriptions $d(e_i)$, our goal is to output a list of tuples, $(e, [m_{\text{s}}, m_{\text{e}}])$, whereby $e \in \mathcal{E}$ is the entity corresponding to the mention span from the m_{s}-th to m_{e}-th token in q. In practice, we take the title and first 128 tokens of the entity's Wikipedia article as its title $t(e_i)$ and description $d(e_i)$.

We propose an end-to-end entity linking system that performs both mention detection and entity disambiguation on questions in one pass of BERT.

Given an input question $q = q_1 \cdots q_n$ of length n, we first obtain question token representations based on BERT (Devlin et al., 2019):

$$[\mathbf{q}_1 \cdots \mathbf{q}_n]^\intercal = \text{BERT}([\texttt{CLS}]\, q_1 \cdots q_n [\texttt{SEP}]) \in \mathbb{R}^{n\times h},$$

where each $\mathbf{q_i}$ is a h-dimensional vector. We then obtain entity representations $\mathbf{x}_e$ for every $e_i \in \mathcal{E}$.

$$\mathbf{x}_e = \text{BERT}_{[\texttt{CLS}]}([\texttt{CLS}]t(e_i)[\texttt{ENT}]d(e_i)[\texttt{SEP}]) \in \mathbb{R}^h,$$

where $[\texttt{CLS}]$ indicates that we select the representation of the $[\texttt{CLS}]$ token. We consider candidate mentions as all spans $[i, j]$ (i-th to j-th tokens of q) in the text up to length L.

Mention Detection To compute the likelihood score of a candidate span $[i, j]$ being an entity mention, we first obtain scores for each token being the start or the end of a mention:

$$s_{\text{start}}(i) = \mathbf{w}_{\text{start}}^\intercal \mathbf{q}_i, \quad s_{\text{end}}(j) = \mathbf{w}_{\text{end}}^\intercal \mathbf{q}_j,$$

where $\mathbf{w}_{\text{start}}, \mathbf{w}_{\text{end}} \in \mathbb{R}^h$ are learnable vectors. We additionally compute scores for each token t being part of a mention:

$$s_{\text{mention}}(t) \quad = \quad \mathbf{w}_{\text{mention}}^\intercal \mathbf{q}_t,$$

where $\mathbf{w}_{\text{mention}} \in \mathbb{R}^h$ is a learnable vector. We finally compute mention probabilities as:

$$p([i, j]) = \sigma\Big(s_{\text{start}}(i) + s_{\text{end}}(j) + \sum_{t=i}^{j} s_{\text{mention}}(t)\Big).$$

Entity Disambiguation We obtain a mention representation for each mention candidate $[i, j]$ by averaging $\mathbf{q_i} \cdots \mathbf{q_j}$, and compute a similarity score

s between the mention candidate and an entity candidate $e \in \mathcal{E}$:

$$\begin{aligned}\mathbf{y}_{i,j} &= \frac{1}{(j-i+1)}\sum_{t=i}^{j}\mathbf{q}_t \in \mathbb{R}^h,\\ s(e,[i,j]) &= \mathbf{x}_e^\intercal \mathbf{y}_{i,j}.\end{aligned}$$

We then compute a likelihood distribution over all entities, conditioned on the mention $[i,j]$:

$$p(e|[i,j]) = \frac{\exp(s(e,[i,j]))}{\sum_{e' \in \mathcal{E}} \exp(s(e',[i,j]))}.$$

Training We jointly train the mention detection and entity disambiguation components by optimizing the sum of their losses. We use a binary cross-entropy loss across all mention candidates:

$$\begin{aligned}\mathcal{L}_{\text{MD}} = -\frac{1}{N} \sum_{\substack{1\le i\le j\le\\ \min(i+L-1,n)}} \Big(& y_{[i,j]} \log p([i,j]) \\ & + (1-y_{[i,j]}) \log(1-p([i,j]))\Big),\end{aligned}$$

whereby $y_{[i,j]} = 1$ if $[i,j]$ is a gold mention span, and 0 otherwise. N is the total number of candidates we consider.[2]

The entity disambiguation loss is given by

$$\mathcal{L}_{\text{ED}} = -\log p(e_g|[i,j]),$$

where e_g is the gold entity corresponding to mention $[i,j]$.

To expedite training, we use a simple transfer learning technique: we take the entity encoder trained on Wikipedia by Wu et al. (2020) and freeze its weights, training only the question encoder on QA data. In addition, we mine hard negatives. As entity encodings are fixed, a fast search of hard negatives in real time is possible.

Inference Figure 1 shows our inference process. Given an input question q, we use our mention detection model to obtain our mention set $\mathcal{M} = \{[i,j] : 1 \le i \le j \le \min(i+L-1,n), p([i,j]) > \gamma\}$, where γ is our threshold (a hyperparameter). We then compute $p(e,[i,j]) = p(e|[i,j])p([i,j])$ for each mention $[i,j] \in \mathcal{M}$, and threshold according to γ. In contrast to a two-stage pipeline which first extracts mentions, then disambiguates entities (Févry et al., 2020), a joint approach grants us the flexibility to consider multiple possible candidate mentions for entity linking. This can be crucial in questions as it can be difficult to extract mentions from short, noisy text in a single step.

4 Experiments

4.1 Data

We evaluate our approach on two QA datasets, WebQSP (Yih et al., 2016) and GraphQuestions (Su et al., 2016), with additional entity annotations provided by Sorokin and Gurevych (2018). The original datasets do not have all mention boundary labels annotated. Therefore, in order to evaluate both mention detection and entity disambiguation, we extend previous labels and create new end-to-end question entity-linking datasets, WebQSP$_{\text{EL}}$ and GraphQ$_{\text{EL}}$.[3] In line with our task definition, all entities presented in each question are labeled with $(e, [m_{\text{s}}, m_{\text{e}}])$, whereby $e \in \mathcal{E}$ is the entity corresponding to the mention span from the m_{s}-th to m_{e}-th token in q. We ask four in-house annotators to identify corresponding mention boundaries, given gold entities in the questions. We exclude examples that link to `null` or no entities, that are not in Wikipedia, or are incorrect or overly generic (e.g. linking a concept like *marry*). To check inter-annotation agreement amongst the 4 annotators, we set aside a shared set of documents (comprised of documents from both datasets) that all 4 annotators annotated. We found exact-match inter-annotator agreement to be 95% (39/41) on this shared set.

Table 1 reports the statistics of the resulting datasets, WebQSP$_{\text{EL}}$ and GraphQ$_{\text{EL}}$. Following Sorokin and Gurevych (2018), we use WebQSP$_{\text{EL}}$ for training and GraphQ$_{\text{EL}}$ for zero-shot evaluation.

Evaluation Metrics Using the rule defined by Carmel et al. (2014), a prediction is correct only

---

[2] If $n \ge L$, $N = L(L+1)/2 + (n-L)L$. Otherwise, $N = n(n+1)/2$.

Table 2: Results on WebQSP$_{\text{EL}}$ and GraphQ$_{\text{EL}}$ test data, under 3 training settings. '#Q/s' (number of questions per second) indicates inference speed on 1 CPU. Models trained in comparable settings are clustered together. Overall highest scores are **bolded**, while highest scores per setting are underlined.

[†] VCG results are different from numbers in the original paper as the evaluation sets are slightly different.

if the groundtruth entity is identified *and* the predicted mention boundaries overlap with the groundtruth boundaries. (This is sometimes known as "weak matching".) Specifically, let $\mathcal{T}$ be a set of gold entity-mention tuples and $\widehat{\mathcal{T}}$ be a set of predicted entity-mention tuples, we define precision (p), recall (r) and F1-score (F_1) as follows:

$$\begin{aligned}\mathcal{C} \;=\; & \{e \in \mathcal{E} | [m_s, m_e] \cap [\widehat{m}_s, \widehat{m}_e] \neq \varnothing, \\ & (e, [m_s, m_e]) \in \mathcal{T}, (e, [\widehat{m}_s, \widehat{m}_e]) \in \widehat{\mathcal{T}}\},\end{aligned}$$

$$p = \frac{|\mathcal{C}|}{|\widehat{\mathcal{T}}|}, \quad r = \frac{|\mathcal{C}|}{|\mathcal{T}|}, \quad F_1 = \frac{2pr}{p+r}.$$

Baselines We use the following baselines: (1) **TAGME** (Ferragina and Scaiella, 2012), a lightweight, on-the-fly entity linking system that is popular for many downstream QA tasks, being much faster than most neural models (Joshi et al., 2017; Sun et al., 2018; Min et al., 2019), (2) **VCG** (Sorokin and Gurevych, 2018), the current state-of-the-art entity linking system on WebQSP, and (3) biencoder from **BLINK** (Wu et al., 2020). As BLINK requires pre-specified mention boundaries as input, we train a separate, BERT-based span extraction model on WebQSP in order to predict mention boundaries (details in Appendix B).

4.2 Results

Table 2 show our main results. We find that BERT-based biencoder models far outperform the state-of-the-art (VCG) on both datasets, in performance and in runtime. Moreover, ELQ outperforms all other models trained in a comparable setting, and is much more efficient than every other neural baseline (VCG and BLINK). ELQ is also up to 2.3× better than TAGME — in the case of WebQSP$_{\text{EL}}$.

Performance ELQ outperforms BLINK, suggesting that it is possible to train representations from a single model to resolve both entity references as well as mention boundaries of all entities in text, without restricting the model to focusing on a single marked entity as in BLINK.

	WQ	NQ	TQA
TF-IDF†	20.8	28.7	54.0
TAGME + GRetriever†	31.8	33.5	55.0
ELQ$_{\text{Wiki}}$ + GRetriever	37.4	**37.4**	**55.4**
ELQ$_{\text{QA}}$ + GRetriever	**37.7**	37.0	54.7

Table 3: QA result (Exact Match) on the test set of WebQuestions (WQ), Natural Questions (NQ) and TriviaQA (TQA). ELQ$_{\text{Wiki}}$ represents our model trained on Wikipedia data, while ELQ$_{\text{QA}}$ represents our model trained on Wikipedia+WebQSP$_{\text{EL}}$ data.

[†] Result taken from (Min et al., 2019).

Runtime We record the inference speed on CPUs in number of questions processed per second for all models (Table 2). For BLINK, we report the combined speed of our span extraction model and the BLINK entity linker, in order to compare the *end-to-end* speeds. ELQ, which performs both detection and disambiguation in one pass of BERT, is approximately 2× faster than BLINK, which performs multiple passes, while also outperforming BLINK in F1 score. Moreover, against TAGME (Ferragina and Scaiella, 2012), ELQ is only 1.5× slower on WebQSP$_{\text{EL}}$ and 2.0× slower on GraphQ$_{\text{EL}}$, despite TAGME being a completely non-neural model (with much lower accuracy).

5 QA Experiments

To demonstrate the impact of improved entity linking on the end QA accuracy, we experiment with the task of textual open-domain question answering, using GraphRetriever (GRetriever) (Min et al., 2019). GRetriever uses entity linking to construct a graph of passages in the retrieval step and deploys

Experiment	ELQ (Wiki)	BLINK
MD + EL	87.3	82.2
MD only	94.6	92.9
EL only	90.2	86.6

Table 4: Analyzing the performance of the mention detector and entity linker respectively on WebQSP$_{\text{EL}}$ (dev). We compare our Wikipedia-trained model to BLINK. MD + EL refers to the end-to-end F1 score (the normal setup).

a reader model to answer the question. The original model uses TAGME for entity linking; we replace TAGME with ELQ and keep the other components the same, in order to isolate the impact of entity linking.[4] As an additional baseline, we also add the result of TF-IDF, implemented by Chen et al. (2017), a widely used retrieval system.

Results are shown in Table 3. Following literature in open-domain QA, we evaluate our approach on three datasets, WebQuestions (Berant et al., 2013), Natural Questions (Kwiatkowski et al., 2019) and TriviaQA (Joshi et al., 2017). In particular, WebQuestions (WQ) and Natural Questions (NQ) consist of short, noisy questions from Web queries, in line with the motivation of our work. We observe that simply replacing TAGME with ELQ significantly improves performance, including 5.9% and 3.9% absolute improvements on WQ and NQ, respectively. While ELQ trained on Wikipedia achieves good results overall, further fine-tuning on WebQSP$_{\text{EL}}$ gives extra gains on WQ. This indicates that, if entity linking annotations in the same domain are available, using them to fine-tune ELQ can bring further gains.

6 Analysis

Mention Detector vs. Entity Linker We set up experiments to disentangle the capability of ELQ's entity linker and mention detector. First, to test just the mention detector (MD only), we measure just the mention boundary overlap between predicted and groundtruth mentions, ignoring the entity label. Next, to test just the entity linker (EL only), we give the entity linking component *gold* mention boundaries, and compute the resulting F1 score. We do this for both ELQ and BLINK. For comparability, we use the version of ELQ trained on Wikipedia. Results are reported in Table 4. Surprisingly, we find that *both* components of ELQ outperform BLINK, suggesting that the two tasks might *mutually benefit* from being trained jointly.

Error Type	WebQSP$_{\text{EL}}$	GraphQ$_{\text{EL}}$
Technically Correct	49.2	23.3
Not Enough Entities	13.1	51.8
Wrong Entities	26.2	20
Insufficient Context	11.5	5

Table 5: Breakdown of frequency of each error type on each dev set (in terms of % of all errors on that dataset). We use ELQ trained on Wikipedia + WebQSP$_{\text{EL}}$ here.

Runtime To confirm that our biencoder's main bottleneck is the BERT forward pass — and thus, investing in decreasing the number of BERT forward passes is valuable — we separately time each component of ELQ during inference. We run examples from WebQSP$_{\text{EL}}$ test set one at a time through ELQ, on 1 CPU, and average runtimes across all examples. Indeed, we find that the BERT forward pass to be the slowest component of the model, taking 0.683s, over $6\times$ slower than the next slowest component of the model, inner-product search (taking 0.107s). Everything else takes a combined total of 5.08×10^{-3}s.

Qualitative We manually examine all our model's errors on the WebQSP$_{\text{EL}}$ and GraphQ$_{\text{EL}}$ dev sets. We identify four broad error categories: (1) technically correct — where our model was technically correct but limitations in evaluation falsely penalized our model (i.e., we found a more or less precise version of the same entity), (2) not enough entities — where the model did not fully identify all entities in the question, (3) wrong entities — where our model linked to the wrong entity, (4) insufficient context — where the model made reasonable mistakes due to the lack of context (that even reasonable humans would make). Error type breakdowns can be found in Table 5.

7 Conclusion

We proposed an end-to-end model for entity linking on questions that jointly performs mention detection and disambiguation with one pass through BERT. We showed that it is highly efficient, and that it outperforms previous state-of-the-art models on two benchmarks. Furthermore, when applied to a QA model, ELQ improves that model's end QA accuracy. Despite being originally designed with questions in mind, we believe ELQ could also generalize to longer, well-formed documents.

---

[4] Min et al. (2019) used two reader models, ParReader++ and GraphReader; for simplicity, we only use ParReader++

A Annotation Statistics

We show annotators a question and a gold entity in the question, and instruct them to annotate (i.e., put brackets around) the appropriate mention span.

For quality control, we created a shared annotation set by pulling a subset of examples from each dataset, and having all four annotators label that set. Inter-annotator agreement statistics on our shared set are shown in Table 6. Note that only 2 out of 41 shared examples did not have unanimous mention boundary agreement. The two conflicting examples, with the respective annotations, are shown below:

Question: ‘who are the two state senators of georgia?’
Entity: ‘United States Senate’

A1: ‘who are the two state [senators] of georgia?’
A2: ‘who are the two [state senators] of georgia?’
A3: Entity not in question

Question: ‘who was michael jackson in the wiz?’
Entity: ‘The Wiz (film)’

A1: ‘who was michael jackson in [the wiz]?’
A2: ‘who was michael jackson in the [wiz]?’

B Span-Extraction Model for Mention Boundary Detection

The BLINK Entity Linker requires mention boundaries to be marked in the input. In order to evaluate against BLINK for end-to-end Entity Linking, we train a span-extraction model to first obtain candidate mention boundaries, and subsequently use BLINK on these candidate mentions. Our span extraction model first represents every token q_i in question $q = q_1, \cdots, q_n$ of length n using a dense representation using $\mathrm{BERT}_{\mathrm{base}}$:

$$\mathbf{q_1}, \cdots, \mathbf{q_n} = \mathrm{BERT}(q_1, \cdots, q_n) \quad (1)$$

The model then computes a start span probability $p_s(q_i|q)$ and an end span probability $p_e(q_i|q)$ for every token q_i using learnable vectors $\mathbf{w_s}$ and $\mathbf{w_t}$ respectively:

$$p_s(q_i|q) = \frac{\exp(\mathbf{w_s}^\intercal \mathbf{q_i})}{\sum_j \exp(\mathbf{w_s}^\intercal \mathbf{q_j})} \quad (2)$$

$$p_e(q_i|q) = \frac{\exp(\mathbf{w_e}^\intercal \mathbf{q_i})}{\sum_j \exp(\mathbf{w_e}^\intercal \mathbf{q_j})} \quad (3)$$

The model is trained to maximize the likelihood of $p_s(q_s|q) \times p_e(q_e|q)$ for each correct mention $[q_s, q_e]$ in the training set of WebQSP, and similarly during inference, outputs the top-K scoring spans. These spans are used as mention boundary candidates, to evaluate BLINK in an end-to-end setting.

Dataset	#Examples	#Agreement
WebQSP train	9	8
WebQSP dev	6	5
WebQSP test	10	10
GraphQs train	8	8
GraphQs test	8	8

Table 6: Statistics on the shared dataset annotated by all 4 annotators. We count exact-match, unanimous agreements, i.e., both mention boundaries must exactly match, and all 4 annotators must agree.

Training method	F1
Adversarial + Pre-trained candidate encoder	87.7
Pre-trained candidate encoder	46.1
None (entirely from scratch)	17.2

Table 7: Ablations on our training scheme after 20 epochs. Both transfer learning from the pre-trained candidate encoder *and* adversarially training on hard negatives expedite convergence.

C Analysis

Training Ablations Table 7 presents the contributions of each component of our training scheme to our final result. We record model performance on $\mathrm{WebQSP}_{\mathrm{EL}}$ (valid) after 20 (of 100) epochs of training on Wikipedia, having seen just 20% of the data. We note that both our transfer learning technique and our adversarial hard-negatives training expedites convergence.

Qualitative Error Analysis We record specific examples for each of our four error categories (technically correct, not enough entities, wrong entities, and insufficient context), detailed in Section 6. Note there were 61 total mistakes for $\mathrm{WebQSP}_{\mathrm{EL}}$ dev and 158 total mistakes for $\mathrm{GraphQ}_{\mathrm{EL}}$ dev. Specific examples can be found in Table 9.

D Implementation Details and Hyperparameters

Following Wu et al. (2020), we use $\mathrm{BERT}_{\mathrm{Large}}$ (∼340M parameters) for the question and entity encoder. The span extraction model detailed in Appendix B, used for our BLINK baselines, is a $\mathrm{BERT}_{\mathrm{Base}}$ model (∼110M parameters).

We lowercase all inputs to ELQ, during both training and inference time, to make it case-insensitive. For both training and inference, the mention scorer considers all spans up to length $L = 10$.

Training During training, we use FAISS (Johnson et al., 2019) for fast inner product search when mining hard negatives. We do this in real time, *inside* the training loop. As we do not update the entity encoder, we were able to train the model with a single FAISS index, greatly increasing the training speed. For further speedup, we use a hierarchical index (`IndexHNSWFlat`), with $efConstruction = 200$ and $efSearch = 256$.

For $\mathcal{L}_{\text{ED}}$ at each iteration, computing $s(e, [i, j])$ for every $e \in \mathcal{E}$ is intractable. We thus approximate $\mathcal{L}_{\text{ED}}$ by replacing $\mathcal{E}$ with $\mathcal{E}'$ for the softmax, where $\mathcal{E}'$ is a set of hard negative entities, specifically, negative entities that have the highest 10 similarity scores with the mention representation.

For our WebQSP$_{\text{EL}}$-trained model, we train for up to 100 epochs on WebQSP$_{\text{EL}}$ data, using batch size 128 and context window size of 20 tokens. For our Wikipedia-trained model, we split the data evenly into 100 chunks and train on each (thus, making one pass through Wikipedia overall). For Wikipedia, we use batch size 32 and a context window size of 128 tokens. For Wikipedia + WebQSP$_{\text{EL}}$ model, we take our Wikipedia-trained model and further fine-tune it on WebQSP$_{\text{EL}}$ for up to 100 epochs (using the WebQSP$_{\text{EL}}$ training settings). For all three training settings, we use the AdamW optimizer with learning rate 1e-5, coupled with a linear schedule with 10% warmup. We clip gradients to max norm 1.0.

Inference During inference, we consider all mention candidates $[i, j]$ with mention score $\log p([i, j]) \geq \gamma$. If no mention candidate has mention score $\geq \gamma$, we simply take the top-50-scoring mentions. γ is a threshold we tune on each dataset's dev data.

The linker then retrieves the 10 closest entity candidates per mention boundary. We use the same hierarchical FAISS index as during training to expedite retrieval. Since the search is approximate, we expect some performance degradation. However, in practice, we found minimal performance degradation for significant speedup. On WebQSP$_{\text{EL}}$ dev set, F1 score decreased from 92.5 $\rightarrow$ 91.9, but run-time decreased from $127.0s \rightarrow 24.3s$ (for the entire dataset, with batch size 64).

As computing the softmax over all entities for $\log p(e|[i, j])$ is intractable, we simply softmax over our 10 retrieved candidates. At the end, we threshold the final joint score $\log p([i, j]) + \log p(e|[i, j])$ based on γ.

Model	WebQSP$_{\text{EL}}$	GraphQ$_{\text{EL}}$
ELQ, Wikipedia	-2.9	-3.5
ELQ, Wikipedia + WebQSP$_{\text{EL}}$	-1.5	-0.9

Table 8: Best threshold hyperparameter value γ, based on the respective development sets.

We use manual tuning and binary search to find the best-performing hyper-parameters for the threshold γ. We optimize for F1-score on the development sets of WebQSP$_{\text{EL}}$ and GraphQ$_{\text{EL}}$. Best settings are reported in Table 8.

As mention overlaps are not allowed in the questions data, we have an additional global step of removing overlapping mention boundaries — in the case of multiple entities, we greedily choose the highest-scoring entity each time, and remove all entities which overlap with it.

E Infrastructure Details

We ran all training distributed across 8 NVIDIA TESLA V100 GPUs, each with 32 GB of memory. For 80-CPU inference, we run on 2 chips of Intel(R) Xeon(R) CPU E5-2698 v4 @ 2.20GHz with 20 cores (40 threads) each. For 1-CPU inference (reported in Table 2), we run only on a single core.

Abstract

Entity representations are useful in natural language tasks involving entities. In this paper, we propose new pretrained contextualized representations of words and entities based on the bidirectional transformer (Vaswani et al., 2017). The proposed model treats words and entities in a given text as independent tokens, and outputs contextualized representations of them. Our model is trained using a new pretraining task based on the masked language model of BERT (Devlin et al., 2019). The task involves predicting randomly masked words and entities in a large entity-annotated corpus retrieved from Wikipedia. We also propose an *entity-aware* self-attention mechanism that is an extension of the self-attention mechanism of the transformer, and considers the types of tokens (words or entities) when computing attention scores. The proposed model achieves impressive empirical performance on a wide range of entity-related tasks. In particular, it obtains state-of-the-art results on five well-known datasets: Open Entity (entity typing), TACRED (relation classification), CoNLL-2003 (named entity recognition), ReCoRD (cloze-style question answering), and SQuAD 1.1 (extractive question answering). Our source code and pretrained representations are available at `https://github.com/studio-ousia/luke`.

1 Introduction

Many natural language tasks involve entities, e.g., relation classification, entity typing, named entity recognition (NER), and question answering (QA). Key to solving such entity-related tasks is a model to learn the effective representations of entities. Conventional entity representations assign each entity a fixed embedding vector that stores information regarding the entity in a knowledge base (KB) (Bordes et al., 2013; Trouillon et al., 2016; Yamada et al., 2016, 2017). Although these models capture the rich information in the KB, they require entity linking to represent entities in a text, and cannot represent entities that do not exist in the KB.

By contrast, contextualized word representations (CWRs) based on the transformer (Vaswani et al., 2017), such as BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2020), provide effective general-purpose word representations trained with unsupervised pretraining tasks based on language modeling. Many recent studies have solved entity-related tasks using the contextualized representations of entities computed based on CWRs (Zhang et al., 2019; Peters et al., 2019; Joshi et al., 2020). However, the architecture of CWRs is not well suited to representing entities for the following two reasons: (1) Because CWRs do not output the span-level representations of entities, they typically need to learn how to compute such representations based on a downstream dataset that is typically small. (2) Many entity-related tasks, e.g., relation classification and QA, involve reasoning about the relationships between entities. Although the transformer can capture the complex relationships between words by relating them to each other multiple times using the self-attention mechanism (Clark et al., 2019; Reif et al., 2019), it is difficult to perform such reasoning between entities because many entities are split into multiple tokens in the model. Furthermore, the word-based pretraining task of CWRs is not suitable for learning the representations of entities because predicting a masked word given other words in the entity, e.g., predicting *"Rings"* given *"The Lord of the [MASK]"*, is clearly easier than predicting the entire entity.

In this paper, we propose new pretrained contextualized representations of words and entities by developing **LUKE** (**L**anguage **U**nderstanding with **K**nowledge-based **E**mbeddings). LUKE is based on a transformer (Vaswani et al., 2017) trained using a large amount of entity-annotated corpus

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6442–6454,

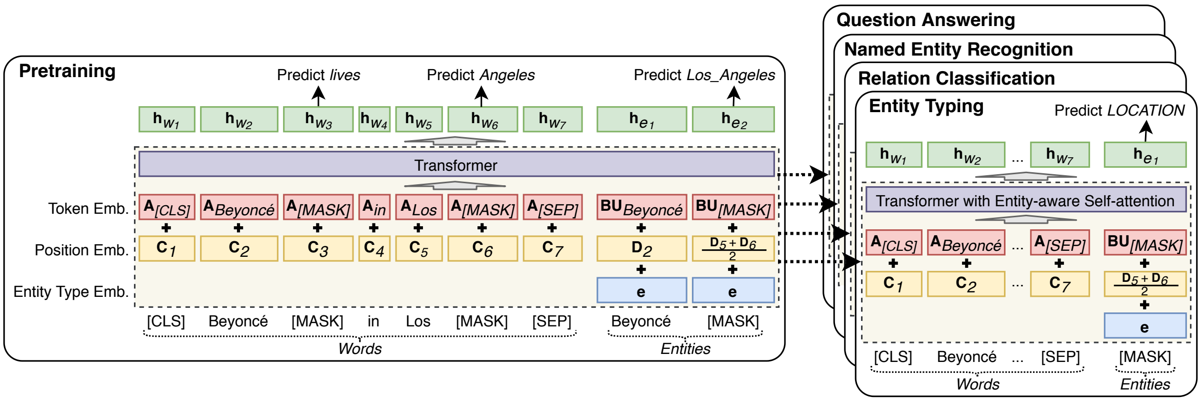

Figure 1: Architecture of LUKE using the input sentence "*Beyoncé lives in Los Angeles.*" LUKE outputs contextualized representation for each word and entity in the text. The model is trained to predict randomly masked words (e.g., *lives* and *Angeles* in the figure) and entities (e.g., *Los_Angeles* in the figure). Downstream tasks are solved using its output representations with linear classifiers.

obtained from Wikipedia. An important difference between LUKE and existing CWRs is that it treats not only words, but also entities as independent tokens, and computes intermediate and output representations for all tokens using the transformer (see Figure 1). Since entities are treated as tokens, LUKE can directly model the relationships between entities.

LUKE is trained using a new pretraining task, a straightforward extension of BERT's masked language model (MLM) (Devlin et al., 2019). The task involves randomly masking entities by replacing them with `[MASK]` entities, and trains the model by predicting the originals of these masked entities. We use RoBERTa as base pre-trained model, and conduct pretraining of the model by simultaneously optimizing the objectives of the MLM and our proposed task. When applied to downstream tasks, the resulting model can compute representations of arbitrary entities in the text using `[MASK]` entities as inputs. Furthermore, if entity annotation is available in the task, the model can compute entity representations based on the rich entity-centric information encoded in the corresponding entity embeddings.

Another key contribution of this paper is that it extends the transformer using our *entity-aware* self-attention mechanism. Unlike existing CWRs, our model needs to deal with two types of tokens, i.e., words and entities. Therefore, we assume that it is beneficial to enable the mechanism to easily determine the types of tokens. To this end, we enhance the self-attention mechanism by adopting different query mechanisms based on the attending token and the token attended to.

We validate the effectiveness of our proposed model by conducting extensive experiments on five standard entity-related tasks: entity typing, relation classification, NER, cloze-style QA, and extractive QA. Our model outperforms all baseline models, including RoBERTa, in all experiments, and obtains state-of-the-art results on five tasks: entity typing on the Open Entity dataset (Choi et al., 2018), relation classification on the TACRED dataset (Zhang et al., 2017), NER on the CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003), cloze-style QA on the ReCoRD dataset (Zhang et al., 2018a), and extractive QA on the SQuAD 1.1 dataset (Rajpurkar et al., 2016). We publicize our source code and pretrained representations at `https://github.com/studio-ousia/luke`.

The main contributions of this paper are summarized as follows:

- We propose LUKE, a new contextualized representations specifically designed to address entity-related tasks. LUKE is trained to predict randomly masked words and entities using a large amount of entity-annotated corpus obtained from Wikipedia.

- We introduce an entity-aware self-attention mechanism, an effective extension of the original mechanism of transformer. The proposed mechanism considers the type of the tokens (words or entities) when computing attention scores.

- LUKE achieves strong empirical performance and obtains state-of-the-art results on five popular datasets: Open Entity, TACRED, CoNLL-2003, ReCoRD, and SQuAD 1.1.

2 Related Work

Static Entity Representations Conventional entity representations assign a fixed embedding to each entity in the KB. They include knowledge embeddings trained on knowledge graphs (Bordes et al., 2013; Yang et al., 2015; Trouillon et al., 2016), and embeddings trained using textual contexts or descriptions of entities retrieved from a KB (Yamada et al., 2016, 2017; Cao et al., 2017; Ganea and Hofmann, 2017). Similar to our pretraining task, **NTEE** (Yamada et al., 2017) and **RELIC** (Ling et al., 2020) use an approach that trains entity embeddings by predicting entities given their textual contexts obtained from a KB. The main drawbacks of this line of work, when representing entities in text, are that (1) they need to resolve entities in the text to corresponding KB entries to represent the entities, and (2) they cannot represent entities that do not exist in the KB.

Contextualized Word Representations Many recent studies have addressed entity-related tasks based on the contextualized representations of entities in text computed using the word representations of CWRs (Zhang et al., 2019; Baldini Soares et al., 2019; Peters et al., 2019; Joshi et al., 2020; Wang et al., 2019b, 2020). Representative examples of CWRs are **ELMo** (Peters et al., 2018) and **BERT** (Devlin et al., 2019), which are based on deep bidirectional long short-term memory (LSTM) and the transformer (Vaswani et al., 2017), respectively. BERT is trained using an MLM, a pretraining task that masks random words in the text and trains the model to predict the masked words. Most recent CWRs, such as **RoBERTa** (Liu et al., 2020), **XLNet** (Yang et al., 2019), **SpanBERT** (Joshi et al., 2020), **ALBERT** (Lan et al., 2020), **BART** (Lewis et al., 2020), and **T5** (Raffel et al., 2020), are based on transformer trained using a task equivalent to or similar to the MLM. Similar to our proposed pretraining task that masks entities instead of words, several recent CWRs, e.g., SpanBERT, ALBERT, BART, and T5, have extended the MLM by randomly masking word spans instead of single words.

Furthermore, various recent studies have explored methods to enhance CWRs by injecting them with *knowledge* from external sources, such as KBs. **ERNIE** (Zhang et al., 2019) and **KnowBERT** (Peters et al., 2019) use a similar idea to enhance CWRs using static entity embeddings separately learned from a KB. **WKLM** (Xiong et al., 2020) trains the model to detect whether an entity name in text is replaced by another entity name of the same type. **KEPLER** (Wang et al., 2019b) conducts pretraining based on the MLM and a knowledge-embedding objective (Bordes et al., 2013). **K-Adapter** (Wang et al., 2020) was proposed concurrently with our work, and extends CWRs using *neural adapters* that inject factual and linguistic knowledge. This line of work is related to ours because our pretraining task also enhances the model using information in the KB.

Unlike the CWRs mentioned above, LUKE uses an improved transformer architecture with an entity-aware self-attention mechanism that is designed to effectively solve entity-related tasks. LUKE also outputs entity representations by learning how to compute them during pretraining. It achieves superior empirical results to existing CWRs and knowledge-enhanced CWRs in all of our experiments.

3 LUKE

Figure 1 shows the architecture of LUKE. The model adopts a multi-layer bidirectional transformer (Vaswani et al., 2017). It treats words and entities in the document as input tokens, and computes a representation for each token. Formally, given a sequence consisting of m words $w_1, w_2, ..., w_m$ and n entities $e_1, e_2, ..., e_n$, our model computes D-dimensional word representations $\mathbf{h}_{w_1}, \mathbf{h}_{w_2}, ..., \mathbf{h}_{w_m}$, where $\mathbf{h}_w \in \mathbb{R}^D$, and entity representations $\mathbf{h}_{e_1}, \mathbf{h}_{e_2}, ..., \mathbf{h}_{e_n}$, where $\mathbf{h}_e \in \mathbb{R}^D$. The entities can be Wikipedia entities (e.g., *Beyoncé* in Figure 1) or special entities (e.g., `[MASK]`).

3.1 Input Representation

The input representation of a token (word or entity) is computed using the following three embeddings:

- **Token embedding** represents the corresponding token. We denote the word token embedding by $\mathbf{A} \in \mathbb{R}^{V_w \times D}$, where V_w is the number of words in our vocabulary. For computational efficiency, we represent the entity token embedding by decomposing it into two small matrices, $\mathbf{B} \in \mathbb{R}^{V_e \times H}$ and $\mathbf{U} \in \mathbb{R}^{H \times D}$, where V_e is the number of entities in our vocabulary. Hence, the full matrix of the entity token embedding can be computed as $\mathbf{BU}$.

- **Position embedding** represents the position of the token in a word sequence. A word and an entity appearing at the i-th position in the sequence are represented as $\mathbf{C}_i \in \mathbb{R}^D$ and $\mathbf{D}_i \in \mathbb{R}^D$, respectively. If an entity name contains multiple words, its position embedding is computed by averaging the embeddings of the corresponding positions, as shown in Figure 1.
- **Entity type embedding** represents that the token is an entity. The embedding is a single vector denoted by $\mathbf{e} \in \mathbb{R}^D$.

The input representation of a word and that of an entity are computed by summing the token and position embeddings, and the token, position, and entity type embeddings, respectively. Following past work (Devlin et al., 2019; Liu et al., 2020), we insert special tokens `[CLS]` and `[SEP]` into the word sequence as the first and last words, respectively.

3.2 Entity-aware Self-attention

The self-attention mechanism is the foundation of the transformer (Vaswani et al., 2017), and relates tokens each other based on the attention score between each pair of tokens. Given a sequence of input vectors $\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_k$, where $\mathbf{x}_i \in \mathbb{R}^D$, each of the output vectors $\mathbf{y}_1, \mathbf{y}_2, ..., \mathbf{y}_k$, where $\mathbf{y}_i \in \mathbb{R}^L$, is computed based on the weighted sum of the transformed input vectors. Here, each input and output vector corresponds to a token (a word or an entity) in our model; therefore, $k = m + n$. The i-th output vector $\mathbf{y}_i$ is computed as:

$$\mathbf{y}_i = \sum_{j=1}^{k} \alpha_{ij} \mathbf{V}\mathbf{x}_j$$

$$e_{ij} = \frac{\mathbf{K}\mathbf{x}_j^\top \mathbf{Q}\mathbf{x}_i}{\sqrt{L}}$$

$$\alpha_{ij} = \text{softmax}(e_{ij})$$

where $\mathbf{Q} \in \mathbb{R}^{L\times D}$, $\mathbf{K} \in \mathbb{R}^{L\times D}$, and $\mathbf{V} \in \mathbb{R}^{L\times D}$ denote the query, key, and value matrices, respectively.

Because LUKE handles two types of tokens (i.e., words and entities), we assume that it is beneficial to use the information of target token types when computing the attention scores (e_{ij}). With this in mind, we enhance the mechanism by introducing an *entity-aware* query mechanism that uses a different query matrix for each possible pair of token types of $\mathbf{x}_i$ and $\mathbf{x}_j$. Formally, the attention score e_{ij} is computed as follows:

$$e_{ij} = \begin{cases} \mathbf{K}\mathbf{x}_j^\top \mathbf{Q}\mathbf{x}_i, & \text{if both } \mathbf{x}_i \text{ and } \mathbf{x}_j \text{ are words} \\ \mathbf{K}\mathbf{x}_j^\top \mathbf{Q}_{w2e}\mathbf{x}_i, & \text{if } \mathbf{x}_i \text{ is word and } \mathbf{x}_j \text{ is entity} \\ \mathbf{K}\mathbf{x}_j^\top \mathbf{Q}_{e2w}\mathbf{x}_i, & \text{if } \mathbf{x}_i \text{ is entity and } \mathbf{x}_j \text{ is word} \\ \mathbf{K}\mathbf{x}_j^\top \mathbf{Q}_{e2e}\mathbf{x}_i, & \text{if both } \mathbf{x}_i \text{ and } \mathbf{x}_j \text{ are entities} \end{cases}$$

where $\mathbf{Q}_{w2e}$, $\mathbf{Q}_{e2w}$, $\mathbf{Q}_{e2e} \in \mathbb{R}^{L\times D}$ are query matrices. Note that the computational costs of the original mechanism and our proposed mechanism are identical except the additional cost of computing gradients and updating the parameters of the additional query matrices at the training time.

3.3 Pretraining Task

To pretrain LUKE, we use the conventional MLM and a new pretraining task that is an extension of the MLM to learn entity representations. In particular, we treat hyperlinks in Wikipedia as entity annotations, and train the model using a large entity-annotated corpus retrieved from Wikipedia. We randomly mask a certain percentage of the entities by replacing them with special `[MASK]` entities[1] and then train the model to predict the masked entities. Formally, the original entity corresponding to a masked entity is predicted by applying the softmax function over all entities in our vocabulary:

$$\hat{\mathbf{y}} = \text{softmax}(\mathbf{B}\mathbf{T}\mathbf{m} + \mathbf{b}_o)$$

$$\mathbf{m} = \text{layer\_norm}\big(\text{gelu}(\mathbf{W}_h\mathbf{h}_e + \mathbf{b}_h)\big)$$

where $\mathbf{h}_e$ is the representation corresponding to the masked entity, $\mathbf{T} \in \mathbb{R}^{H\times D}$ and $\mathbf{W}_h \in \mathbb{R}^{D\times D}$ are weight matrices, $\mathbf{b}_o \in \mathbb{R}^{V_e}$ and $\mathbf{b}_h \in \mathbb{R}^D$ are bias vectors, $\text{gelu}(\cdot)$ is the gelu activation function (Hendrycks and Gimpel, 2016), and $\text{layer\_norm}(\cdot)$ is the layer normalization function (Lei Ba et al., 2016). Our final loss function is the sum of MLM loss and cross-entropy loss on predicting the masked entities, where the latter is computed identically to the former.

3.4 Modeling Details

Our model configuration follows RoBERTa$_{\text{LARGE}}$ (Liu et al., 2020), pretrained CWRs based on a bidirectional transformer and a variant of BERT (Devlin et al., 2019). In particular, our model is based on the bidirectional transformer with $D = 1024$

---

[1] Note that LUKE uses two different `[MASK]` tokens: the `[MASK]` word for MLM and the `[MASK]` entity for our proposed pretraining task.

hidden dimensions, 24 hidden layers, $L = 64$ attention head dimensions, and 16 self-attention heads. The number of dimensions of the entity token embedding is set to $H = 256$. The total number of parameters is approximately 483 M, consisting of 355 M in RoBERTa and 128 M in our entity embeddings. The input text is tokenized into words using RoBERTa's tokenizer with the vocabulary consisting of $V_w = 50K$ words. For computational efficiency, our entity vocabulary does not include all entities but only the $V_e = 500K$ entities most frequently appearing in our entity annotations. The entity vocabulary also includes two special entities, i.e., `[MASK]` and `[UNK]`.

The model is trained via iterations over Wikipedia pages in a random order for 200K steps. To reduce training time, we initialize the parameters that LUKE have in common with RoBERTa (parameters in the transformer and the embeddings for words) using RoBERTa. Following past work (Devlin et al., 2019; Liu et al., 2020), we mask 15% of all words and entities at random. If an entity does not exist in the vocabulary, we replace it with the `[UNK]` entity. We perform pretraining using the original self-attention mechanism rather than our entity-aware self-attention mechanism because we want an ablation study of our mechanism but can not afford to run pretraining twice. Query matrices of our self-attention mechanism ($\mathbf{Q}_{w2e}$, $\mathbf{Q}_{e2w}$, and $\mathbf{Q}_{e2e}$) are learned using downstream datasets. Further details of our pretraining are described in Appendix A.

4 Experiments

We conduct extensive experiments using five entity-related tasks: entity typing, relation classification, NER, cloze-style QA, and extractive QA. We use similar model architectures for all tasks based on a simple linear classifier on top of the representations of words, entities, or both. Unless otherwise specified, we create the input word sequence by inserting tokens of `[CLS]` and `[SEP]` into the original word sequence as the first and the last tokens, respectively. The input entity sequence is built using `[MASK]` entities, special entities introduced for the task, or Wikipedia entities. The token embedding of a task-specific special entity is initialized using that of the `[MASK]` entity, and the query matrices of our entity-aware self-attention mechanism ($\mathbf{Q}_{w2e}$, $\mathbf{Q}_{e2w}$, and $\mathbf{Q}_{e2e}$) are initialized using the original query matrix $\mathbf{Q}$.

Table 1: Results of entity typing on the Open Entity dataset.

Because we use RoBERTa as the base model in our pretraining, we use it as our primary baseline for all tasks. We omit a description of the baseline models in each section if they are described in Section 2. Further details of our experiments are available in Appendix B.

4.1 Entity Typing

We first conduct experiments on entity typing, which is the task of predicting the types of an entity in the given sentence. Following Zhang et al. (2019), we use the Open Entity dataset (Choi et al., 2018), and consider only nine general entity types. Following Wang et al. (2020), we report loose micro-precision, recall, and F1, and employ the micro-F1 as the primary metric.

Model We represent the target entity using the `[MASK]` entity, and enter words and the entity in each sentence into the model. We then classify the entity using a linear classifier based on the corresponding entity representation. We treat the task as multi-label classification, and train the model using binary cross-entropy loss averaged over all entity types.

Baselines **UFET** (Choi et al., 2018) is a conventional model that computes context representations using the bidirectional LSTM. We also use BERT, RoBERTa, ERNIE, KnowBERT, KEPLER, and K-Adapter as baselines.

Results Table 1 shows the experimental results. LUKE significantly outperforms our primary baseline, RoBERTa, by 2.0 F1 points, and the previous best published model, KnowBERT, by 2.1 F1 points. Furthermore, LUKE achieves a new state of the art by outperforming K-Adapter by 0.7 F1 points.

Name	Prec.	Rec.	F1

LUKE	70.4	75.1	**72.7**

Table 2: Results of relation classification on the TACRED dataset.

4.2 Relation Classification

Relation classification determines the correct relation between *head* and *tail* entities in a sentence. We conduct experiments using TACRED dataset (Zhang et al., 2017), a large-scale relation classification dataset containing 106,264 sentences with 42 relation types. Following Wang et al. (2020), we report the micro-precision, recall, and F1, and use the micro-F1 as the primary metric.

Model We introduce two special entities, `[HEAD]` and `[TAIL]`, to represent the head and the tail entities, respectively, and input words and these two entities in each sentence to the model. We then solve the task using a linear classifier based on a concatenated representation of the head and tail entities. The model is trained using cross-entropy loss.

Baselines **C-GCN** (Zhang et al., 2018b) uses graph convolutional networks over dependency tree structures to solve the task. **MTB** (Baldini Soares et al., 2019) learns relation representations based on BERT through the *matching-the-blanks* task using a large amount of entity-annotated text. We also compare LUKE with BERT, RoBERTa, SpanBERT, ERNIE, KnowBERT, KEPLER, and K-Adapter.

Results The experimental results are presented in Table 2. LUKE clearly outperforms our primary baseline, RoBERTa, by 1.4 F1 points, and the previous best published models, namely MTB and KnowBERT, by 1.2 F1 points. Furthermore, it achieves a new state of the art by outperforming K-Adapter by 0.7 F1 points.

4.3 Named Entity Recognition

We conduct experiments on the NER task using the standard CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003). Following past work, we report the span-level F1.

Name	F1
LSTM-CRF (Lample et al., 2016)	91.0
ELMo (Peters et al., 2018)	92.2
BERT (Devlin et al., 2019)	92.8
Akbik et al. (2018)	93.1
Baevski et al. (2019)	93.5
RoBERTa	92.4
LUKE	**94.3**

Table 3: Results of named entity recognition on the CoNLL-2003 dataset.

Model Following Sohrab and Miwa (2018), we solve the task by enumerating all possible spans (or n-grams) in each sentence as entity name candidates, and classifying them into the target entity types or *non-entity* type, which indicates that the span is not an entity. For each sentence in the dataset, we enter words and the `[MASK]` entities corresponding to all possible spans. The representation of each span is computed by concatenating the word representations of the first and last words in the span, and the entity representation corresponding to the span. We classify each span using a linear classifier with its representation, and train the model using cross-entropy loss. We exclude spans longer than 16 words for computational efficiency. During the inference, we first exclude all spans classified into the *non-entity* type. To avoid selecting overlapping spans, we greedily select a span from the remaining spans based on the logit of its predicted entity type in descending order if the span does not overlap with those already selected. Following Devlin et al. (2019), we include the maximal document context in the target document.

Baselines **LSTM-CRF** (Lample et al., 2016) is a model based on the bidirectional LSTM with conditional random fields (CRF). **Akbik et al. (2018)** address the task using the bidirectional LSTM with CRF enhanced with character-level contextualized representations. Similarly, **Baevski et al. (2019)** use the bidirectional LSTM with CRF enhanced with CWRs based on a bidirectional transformer. We also use ELMo, BERT, and RoBERTa as baselines. To conduct a fair comparison with RoBERTa, we report its performance using the model described above with the span representation computed by concatenating the representations of the first and last words of the span.

Results The experimental results are shown in Table 3. LUKE outperforms RoBERTa by 1.9 F1 points. Furthermore, it achieves a new state of the art on this competitive dataset by outperforming the previous state of the art reported in Baevski et al. (2019) by 0.8 F1 points.

4.4 Cloze-style Question Answering

We evaluate our model on the ReCoRD dataset (Zhang et al., 2018a), a cloze-style QA dataset consisting of over 120K examples. An interesting characteristic of this dataset is that most of its questions cannot be solved without external knowledge. The following is an example question and its answer in the dataset:

> **Question:** According to claims in the suit, "Parts of 'Stairway to Heaven,' instantly recognizable to the music fans across the world, sound almost identical to significant portions of '**X**.'"
> **Answer:** Taurus

Given a question and a passage, the task is to find the entity mentioned in the passage that fits the missing entity (denoted by **X** in the question above). In this dataset, annotations of entity spans (start and end positions) in a passage are provided, and the answer is contained in the provided entity spans one or multiple times. Following past work, we evaluate the models using exact match (EM) and token-level F1 on the development and test sets.

Model We solve this task by assigning a relevance score to each entity in the passage and selecting the entity with the highest score as the answer. Following Liu et al. (2020), given a question $q_1, q_2, ..., q_j$, and a passage $p_1, p_2, ..., p_l$, the input word sequence is constructed as: `[CLS]`$q_1, q_2, ..., q_j$`[SEP]` `[SEP]`$p_1, p_2, ..., p_l$`[SEP]`. Further, we input `[MASK]` entities corresponding to the missing entity and all entities in the passage. We compute the relevance score of each entity in the passage using a linear classifier with the concatenated representation of the missing entity and the corresponding entity. We train the model using binary cross-entropy loss averaged over all entities in the passage, and select the entity with the highest score (logit) as the answer.

Baselines **DocQA+ELMo** (Clark and Gardner, 2018) is a model based on ELMo, bidirectional attention flow (Seo et al., 2017), and self-attention mechanism. **XLNet+Verifier** (Li et al., 2019) is a model based on XLNet with rule-based answer verification, and is the winner of a recent competition based on this dataset (Ostermann et al., 2019). We also use BERT and RoBERTa as baselines.

Name	Dev EM	Dev F1	Test EM	Test F1
DocQA+ELMo (Zhang et al., 2018a)	44.1	45.4	45.4	46.7
BERT (Wang et al., 2019a)	-	-	71.3	72.0
XLNet+Verifier (Li et al., 2019)	80.6	82.1	81.5	82.7
RoBERTa (Liu et al., 2020)	89.0	89.5	-	-
RoBERTa (ensemble) (Liu et al., 2020)	-	-	90.0	90.6
LUKE	**90.8**	**91.4**	**90.6**	**91.2**

Table 4: Results of cloze-style question answering on the ReCoRD dataset. All models except RoBERTa (ensemble) are based on a single model.

Results The results are presented in Table 4. LUKE significantly outperforms RoBERTa, the best baseline, on the development set by 1.8 EM points and 1.9 F1 points. Furthermore, it achieves superior results to RoBERTa (ensemble) on the test set without ensembling the models.

4.5 Extractive Question Answering

Finally, we conduct experiments using the well-known Stanford Question Answering Dataset (SQuAD) 1.1 consisting of 100K question/answer pairs (Rajpurkar et al., 2016). Given a question and a Wikipedia passage containing the answer, the task is to predict the answer span in the passage. Following past work, we report the EM and token-level F1 on the development and test sets.

Model We construct the word sequence from the question and the passage in the same way as in the previous experiment. Unlike in the other experiments, we input Wikipedia entities into the model based on entity annotations automatically generated on the question and the passage using a mapping from entity names (e.g., "U.S.") to their referent entities (e.g., *United States*). The mapping is automatically created using the entity hyperlinks in Wikipedia as described in detail in Appendix C. We solve this task using the same model architecture as that of BERT and RoBERTa. In particular, we use two linear classifiers independently on top of the word representations to predict the span boundary of the answer (i.e., the start and end positions), and train the model using cross-entropy loss.

Baselines We compare our models with the results of recent CWRs, including BERT, RoBERTa, SpanBERT, XLNet, and ALBERT. Because the results for RoBERTa and ALBERT are reported only on the development set, we conduct a comparison

Name	Dev EM	Dev F1	Test EM	Test F1
BERT (Devlin et al., 2019)	84.2	91.1	85.1	91.8
SpanBERT (Joshi et al., 2020)	-	-	88.8	94.6
XLNet (Yang et al., 2019)	89.0	94.5	89.9	95.1
ALBERT (Lan et al., 2020)	89.3	94.8	-	-
RoBERTa (Liu et al., 2020)	88.9	94.6	-	-
LUKE	**89.8**	**95.0**	**90.2**	**95.4**

Table 5: Results of extractive question answering on the SQuAD 1.1 dataset.

Name	CoNLL-2003 (Test F1)	SQuAD (Dev EM)	SQuAD (Dev F1)
LUKE w/o entity inputs	92.9	89.2	94.8
LUKE	**94.3**	**89.8**	**95.0**

Table 6: Ablation study of our entity representations.

with these models using this set. To conduct a fair compassion with RoBERTa, we use the same model architecture and hyper-parameters as those of RoBERTa (Liu et al., 2020).

Results The experimental results are presented in Table 5. LUKE outperforms our primary baseline, RoBERTa, by 0.9 EM points and 0.4 F1 points on the development set. Furthermore, it achieves a new state of the art on this competitive dataset by outperforming XLNet by 0.3 points both in terms of EM and F1. Note that XLNet uses a more sophisticated model involving beam search than the other models considered here.

5 Analysis

In this section, we provide a detailed analysis of LUKE by reporting three additional experiments.

5.1 Effects of Entity Representations

To investigate how our entity representations influence performance on downstream tasks, we perform an ablation experiment by addressing NER on the CoNLL-2003 dataset and extractive QA on the SQuAD dataset without inputting any entities. In this setting, LUKE uses only the word sequence to compute the representation for each word. We address the tasks using the same model architectures as those for RoBERTa described in the corresponding sections. As shown in Table 6, this setting clearly degrades performance, i.e., 1.4 F1 points on the CoNLL-2003 dataset and 0.6 EM points on the SQuAD dataset, demonstrating the effectiveness of our entity representations on these two tasks.

5.2 Effects of Entity-aware Self-attention

We conduct an ablation study of our entity-aware self-attention mechanism by comparing the performance of LUKE using our mechanism with that using the original mechanism of the transformer. As shown in Table 7, our entity-aware self-attention mechanism consistently outperforms the original mechanism across all tasks. Furthermore, we observe significant improvements on two kinds of tasks, relation classification (TACRED) and QA (ReCoRD and SQuAD). Because these tasks involve reasoning based on relationships between entities, we consider that our mechanism enables the model (i.e., attention heads) to easily focus on capturing the relationships between entities.

5.3 Effects of Extra Pretraining

As mentioned in Section 3.4, LUKE is based on RoBERTa with pretraining for 200K steps using our Wikipedia corpus. Because past studies (Liu et al., 2020; Lan et al., 2020) suggest that simply increasing the number of training steps of CWRs tends to improve performance on downstream tasks, the superior experimental results of LUKE compared with those of RoBERTa may be obtained because of its greater number of pretraining steps. To investigate this, we train another model based on RoBERTa with extra pretraining based on the MLM using the Wikipedia corpus for 200K training steps. The detailed configuration used in the pretraining is available in Appendix A.

We evaluate the performance of this model on the CoNLL-2003 and SQuAD datasets using the same model architectures as those for RoBERTa described in the corresponding sections. As shown in Table 8, the model achieves similar performance to the original RoBERTa on both datasets, which indicates that the superior performance of LUKE is not owing to its longer pretraining.

6 Conclusions

In this paper, we propose LUKE, new pretrained contextualized representations of words and entities based on the transformer. LUKE outputs the contextualized representations of words and entities using an improved transformer architecture with using a novel entity-aware self-attention mechanism. The experimental results prove its effectiveness on various entity-related tasks. Future work involves applying LUKE to domain-specific tasks, such as those in biomedical and legal domains.

A Details of Pretraining

As input corpus for pretraining, we use the December 2018 version of Wikipedia, comprising approximately 3.5 billion words and 11 million entity annotations. We generate input sequences by splitting the content of each page into sequences comprising ≤ 512 words and their entity annotations (i.e., hyperlinks). We optimize the model using AdamW with learning rate warmup and linear decay of the learning rate. To stabilize training, we update only those parameters that are randomly initialized (i.e., fix the parameters that are initialized using RoBERTa) in the first 100K steps, and update all parameters in the remaining 100K steps. We run the pretraining on NVIDIA's PyTorch Docker container 19.02 hosted on a server with two Intel Xeon Platinum 8168 CPUs and 16 NVIDIA Tesla V100 GPUs. The training takes approximately 30 days. The detailed hyper-parameters are shown in Table 9.

Name	Value
Maximum word length	512
Batch size	2048
Peak learning rate	1e-5
Peak learning rate (first 100K steps)	5e-4
Learning rate decay	linear
Warmup steps	2500
Mask probability for words	15%
Mask probability for entities	15%
Dropout	0.1
Weight decay	0.01
Gradient clipping	none
Adam β_1	0.9
Adam β_2	0.999
Adam ϵ	1e-6

Table 9: Hyper-parameters used to pretrain LUKE.

Adam ϵ	1e-6

Table 10: Hyper-parameters used for the extra pretraining of RoBERTa on our Wikipedia corpus.

Table 10 shows the hyper-parameters used for the extra pretraining of RoBERTa on our Wikipedia corpus described in Section 5. As shown in the Table, we use the same hyper-parameters as the ones used to train LUKE. We train the model for 200K steps and update all parameters throughout the training.

B Details of Experiments

We conduct the experiments using NVIDIA's PyTorch Docker container 19.02 hosted on a server with two Intel Xeon E5-2698 v4 CPUs and eight V100 GPUs. For each dataset, excluding SQuAD, we conduct hyper-parameter tuning using grid search based on the performance on the development set. We evaluate performance using EM on the ReCoRD dataset, and F1 on the other datasets. Because our computational resources are limited, we use the following constrained search space:

- learning rate: 1e-5, 2e-5, 3e-5

Name	Open Entity	TACRED	CoNLL-2003	ReCoRD	SQuAD
Learning rate	1e-5	1e-5	1e-5	1e-5	15e-6
Batch size	4	32	8	32	48
Training epochs	3	5	5	2	2

Table 11: Hyper-parameters and other details of our experiments.

Name	Value
Maximum word length	512
Learning rate decay	linear
Warmup ratio	0.06
Dropout	0.1
Weight decay	0.01
Gradient clipping	none
Adam β_1	0.9
Adam β_2	0.98
Adam ϵ	1e-6

Table 12: Common hyper-parameters used in our experiments.

- batch size: 4, 8, 16, 32, 64
- number of training epochs: 2, 3, 5

We do not tune the hyper-parameters of the SQuAD dataset, and use the ones described in Liu et al. (2020). The hyper-parameters and other details, including the training time, number of GPUs used, and the best score on the development set, are shown in Table 11. For the other hyper-parameters, we simply follow Liu et al. (2020) (see Table 12). We optimize the model using AdamW with learning rate warmup and linear decay of the learning rate. We also use early stopping based on performance on the development set. The details of the datasets used in our experiments are provided below.

B.1 Open Entity

The Open Entity dataset used in Zhang et al. (2019) consists of training, development, and test sets, where each set contains 1,998 examples with labels of nine general entity types. The dataset is downloaded from the website for Zhang et al. (2019).[2] We compute the reported results using our code based on that of Zhang et al. (2019).

B.2 TACRED

The TACRED dataset contains 68,124 training examples, 22,631 development examples, and 15,509 test examples with labels of their relation types. The total number of relation types is 42. The dataset is obtained from the LDC website.[3] We compute the reported results using our code based on that of Zhang et al. (2019).

B.3 CoNLL-2003

The CoNLL-2003 dataset comprises training, development, and test sets, containing 14,987, 3,466, and 3,684 sentences, respectively. Each sentence contains annotations of four entity types, namely *person*, *location*, *organization*, and *miscellaneous*. The dataset is downloaded from the relevant website.[4] The reported results are computed using the `conlleval` script obtained from the website.

B.4 ReCoRD

The ReCoRD dataset consists of 100,730 training, 10,000 development, and 10,000 test questions created based on 80,121 unique news articles. The dataset is obtained from the relevant website.[5] We compute the performance on the development set using the official evaluation script downloaded from the website. Performance on the test set is obtained by submitting our model to the leaderboard.

B.5 SQuAD 1.1

The SQuAD 1.1 dataset contains 87,599 training, 10,570 development, and 9,533 test questions created based on 536 Wikipedia articles. The dataset is downloaded from the relevant website.[6] We compute performance on the development set using the official evaluation script downloaded from the website. Performance on the test set is obtained by submitting our model to the leaderboard.

C Adding Entity Annotations to SQuAD dataset

For each question–passage pair in the SQuAD dataset, we first create a mapping from the entity names (e.g., “U.S.”) to their referent Wikipedia entities (e.g., *United States*) using the entity hyperlinks on the source Wikipedia page of the passage. We then perform simple string matching to extract all entity names in the question and the passage, and treat all matched entity names as entity annotations for their referent entities. We ignore an entity name if the name refers to multiple entities on the page. Further, to reduce noise, we also exclude an entity name if its *link probability*, the probability that the name appears as a hyperlink in Wikipedia, is lower than 1%. We use the March 2016 version of Wikipedia to collect the entity hyperlinks and the link probabilities of the entity names.

Generating similes ~~effortlessly~~ *like a Pro*:
A Style Transfer Approach for Simile Generation

Abstract

Literary tropes, from poetry to stories, are at the crux of human imagination and communication. Figurative language, such as a simile, goes beyond plain expressions to give readers new insights and inspirations. We tackle the problem of simile generation. Generating a simile requires proper understanding for effective mapping of properties between two concepts. To this end, we first propose a method to automatically construct a parallel corpus by transforming a large number of similes collected from Reddit to their literal counterpart using structured common sense knowledge. We then fine-tune a pretrained sequence to sequence model, BART (Lewis et al., 2019), on the literal-simile pairs to generate novel similes given a literal sentence. Experiments show that our approach generates 88% novel similes that do not share properties with the training data. Human evaluation on an independent set of literal statements shows that our model generates similes better than two literary experts *37%*[1] of the times, and three baseline systems including a recent metaphor generation model *71%*[2] of the times when compared pairwise.[3] We also show how replacing literal sentences with similes from our best model in machine generated stories improves evocativeness and leads to better acceptance by human judges.

1 Introduction

Comparisons are inherent linguistic devices that express the likeness of two entities, concepts or ideas. When used in a figurative sense, these comparisons are called similes. They are a figure of speech that compare two different kind of things, usually with the intent to make the description more emphatic or vivid, being often used in literature and poetry to spark the reader's imagination (Paul et al., 1970). Take the following two examples: "The city was *like a painting*", and "If it falls into the wrong hands it would be as catastrophic *as a nuclear bomb*." In the first example, the comparison draws on the implicit "beauty" property being shared by the two very different entities, *city* and *painting*, while in the second the "catastrophic" property is shared by *falling into the wrong hands* and *nuclear bomb*.

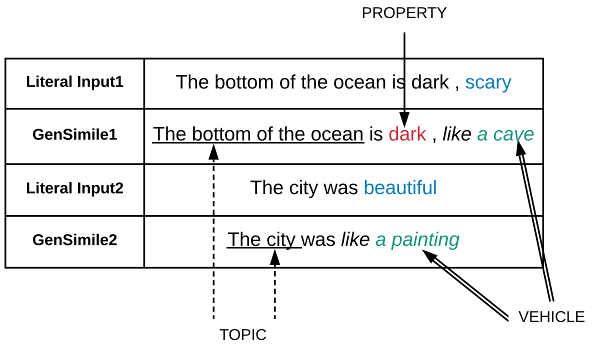

Figure 1: Examples of two generated similes GenSimile1 and GenSimile2 from their literal inputs.

While most computational work has focused on simile detection (Niculae and Danescu-Niculescu-Mizil, 2014; Mpouli, 2017; Qadir et al., 2015, 2016; Zeng et al., 2019; Liu et al., 2018), research on simile generation is under-explored. Generating similes could impact many downstream applications such as creative writing assistance, and literary or poetic content creation. To tackle the generation problem, we take advantage of the relatively simple structure of similes that consists of five elements (Hanks, 2013; Niculae and Danescu-Niculescu-Mizil, 2014): the `TOPIC` (usually a noun phrase that acts as the logical subject), the `VEHICLE` (the logical object of the comparison, usually a noun phrase), the `PROPERTY` (what

* The research was conducted when the author was at USC/ISI.

[1] We average 32.6% and 41.3% for 2 humans.

[2] We average 82% ,63% and 68% for three baselines.

[3] The simile in the title is generated by our best model. Input: Generating similes effortlessly, output: Generating similes *like a Pro*.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6455–6469,
November 16–20, 2020. ©2020 Association for Computational Linguistics

the two things being compared have in common, usually an adjective), the `EVENT` (eventuality or state, usually a verb), and the `COMPARATOR` (the trigger word or phrase that marks the presence of a comparison, usually the preposition "like" or "as...as"). All elements of a simile are explicit, with the exception of `PROPERTY`, which can be both implicit and explicit. If we take the first example above, its structure is: "[The city/`TOPIC`] [was/`EVENT`] [like/`COMPARATOR`] [a painting/`VEHICLE`]" (`PROPERTY` is implicit). Unlike metaphors, the semantic context of similes tends to be very shallow, transferring a single *property* (Hanks, 2013). Moreover, the explicit syntactic structure of similes allows, in exchange, for more lexical creativity (Niculae and Danescu-Niculescu-Mizil, 2014).

We focus on the task of generating a simile starting from a literal utterance that contains the `TOPIC`, `EVENT` and `PROPERTY`. We frame this task as a style-transfer problem (Shen et al., 2017; Fu et al., 2017; Li et al., 2018; Sudhakar et al., 2019), where the author's intent is to make the description of the `TOPIC` more emphatic by introducing a comparison with the `VEHICLE` via a shared `PROPERTY` (See Figure 1 for examples of literal descriptive sentences and the generated similes). We call our approach **SCOPE** (**St**yle transfer through **CO**mmonsense **P**rop**E**rty). There are two main challenges we need to address: 1) the lack of training data that consists of pairs of literal utterances and their equivalent simile in order to train a supervised model; 2) ensuring that the generated simile makes a meaningful comparison between the `TOPIC` and the `VEHICLE` via the shared `PROPERTY` explicitly or implicitly expressed (e.g., Figure 1 GenSimile1 and GenSimile2, respectively). To the best of our knowledge, this is the first work in attempting to generate similes. By framing the task as a style-transfer problem we make three contributions: [4]

Automatic creation of a parallel corpus of *[literal sentence, simile]* pairs. Our constructed corpus contains 87,843 such pairs. As a first step, we use distant supervision to automatically collect a set of *self-labeled similes* using the phrase *like a*. We then convert these similes to their literal versions by removing the `COMPARATOR` and replacing the `VEHICLE` with the associated `PROPERTY` by leveraging the structured common sense knowledge achieved from COMET (Bosselut et al., 2019), a language model fine-tuned on ConceptNet (Speer et al., 2017). For example, for the simile "Love is like a unicorn" our method will generate "Love is rare" (Section 2.1).

Transfer learning from a pre-trained model for generating high quality similes. Our system **SCOPE**, *fine-tunes* BART (Lewis et al., 2019) — a state of the art pre-trained denoising autoencoder built with a sequence to sequence model, on our *automatically collected parallel corpus* of *[literal sentence, simile]* pairs (Section 2.2) to generate similes. Human evaluations show that this approach generates similes that are better 37% of the time on average compared to 2 literary experts, 82% and 63% of times compared to two well-crafted baselines, and 68% of the times compared to a state of the art system for metaphor generation (Stowe et al., 2020) (Section 4).

A task-based evaluation. We show the effectiveness of the generated similes as a tool for enhancing creativity and evocativeness in machine generated stories. Evaluation via Amazon Mechanical Turk shows that stories containing similes generated by **SCOPE** is preferred by Turkers 42% of the times compared to stories without similes, which is preferred 25% of the times (Section 6).

2 SCOPE: Style Transfer through COmmonsense PropErty

Our style transfer approach for simile generation from literal descriptive sentences has two steps: 1) first convert self-labeled similes into literal sentences using structured common sense knowledge (Section 2.1); and 2) given the *[literal sentence, simile]* pairs, fine-tune a seq2seq model on these pairs to generate a simile given a literal sentence (Section 2.2). This two-step approach is shown in the upper half of Figure 2.

2.1 Automatic Parallel Corpus Creation

One of the requirements to train a supervised generative model for text style transfer is the presence of a large-scale parallel corpus. We use distant supervision to collect self-labeled similes using the phrase *like a* from Reddit (e.g., the rows labeled as Simile in Table 1). For fine-tuning, the similes form the "target" side of our parallel data. For the "source" side of our parallel data, we use commonsense knowledge to transform the similes to their

---

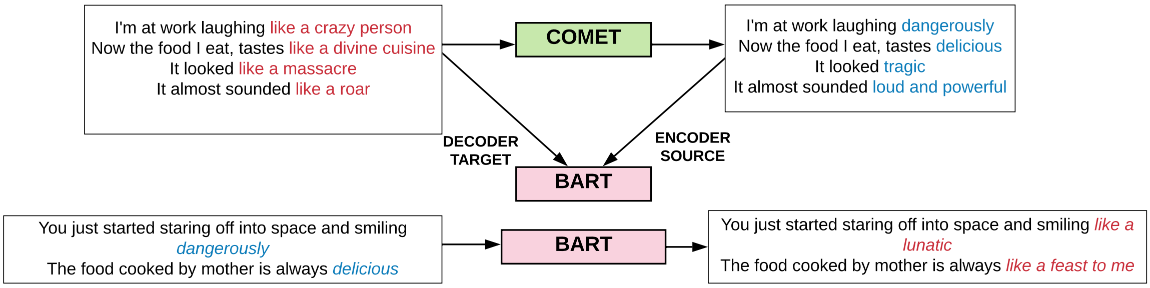

Figure 2: A schematic illustration of our system, where the top block shows our **training** process where we use COMET to transform similes to literal sentences and use them to fine-tune BART. The block below shows the **inference** step where we use fine-tuned BART to generate novel similes conditioned on a literal sentence.

literal version (e.g., the rows labeled as Best Literal in Table 1).

Simile	Love is like a *unicorn.*
Has property	very rare, rare, beautiful, beautiful and smart, color
Best Literal	Love is *rare.*
Simile	It was cool and quiet, and I stormed through like a *charging bull.*
Has property	big and strong, dangerous, big, fast, large
Best Literal	It was cool and quiet, and I stormed through *fast.*
Simile	Sir Francis's voice was calm and quiet, like a *breeze through a forest.*
Has property	very relax, soothe, cool, beautiful, relax
Best Literal	Sir Francis's voice was calm and quiet, *very relaxed.*

Table 1: Examples of self-labeled similes collected from Reddit. For each example, we show the top five commonsense properties associated with the *vehicle* obtained from COMET, and the best literal sentence constructed from these properties. The blue italic texts in the literal sentences represent the *property* inferred from the *vehicle* in the simile (denoted in black italic).

Simile Dataset Collection. One of the possible ways to collect similes would be to train a supervised model using existing data and methods for simile detection but most data sets are very small in size (in the order of a few hundreds). The only large-scale dataset is that of (Niculae and Danescu-Niculescu-Mizil, 2014), however their data is from a rather restricted domain of product reviews on Amazon, which might lack variety, diversity and creativity needed for this task. For our work, we hypothesize that similes are used frequently in creative writing or humorous content on social media (Veale, 2013). Hence, we obtain training data by scraping the subreddits WRITINGPROMPTS [5] and FUNNY [6] from social media site Reddit for comments containing the phrase *like a*. Similes can be both Open and Closed. For example the Closed Simile, *"The boy was as strong as an ox"* gives **strong** as the PROPERTY shared by the *boy* and *ox*. But most similes do not give an explicit PROPERTY such as the Open Simile (e.g., *"The boy was like an ox")* leaving the reader to infer that the boy is strong/large/fast (Qadir et al., 2016). Due to their implicit nature, generating open similes is often more challenging and hence we resort to only using *like a*[7] as a comparator instead of *as...as*. We use the API provided by pushshift.io [8] to mine comments. Through this process we collect 87,843 self-labeled human written similes, from which we use 82,697 samples for training and 5,146 for validation.

Simile to Literal Transformation via Commonsense Property. From a theoretical perspective, similes are created by making a comparison between the `TOPIC` and the `VEHICLE` through a shared `PROPERTY`. While this property is naturally known to humans through common sense and connotative knowledge, computers still struggle to perform well on such tasks when the `PROPERTY` is not expressed. Hence we use structured common sense knowledge to derive properties to transform similes to their literal versions.

To generate the common sense `PROPERTY` that is implied by the `VEHICLE` in the simile, we take advantage of the simple syntactic structure of a simile. We extract the `VEHICLE` by extract-

---

[5] https://www.reddit.com/r/WritingPrompts/

[6] https://www.reddit.com/r/funny/

[7] While there can be noisy sentences where *like a* does not introduce a simile (e.g., the TOPIC is a PP and the sentence is $<=$ 6 tokens such as *I feel like a ..*, *I would like a ..*, *I don't like a..*), these instances are rare (1.1 %), so we do not remove them. More details in Appendix A.2

[8] https://pushshift.io/

ing the phrase after *like a* and feed it as input to COMET (Bosselut et al., 2019). COMET is an adaptation framework for constructing commonsense knowledge based on pre-trained language models. Our work only leverages the **HasProperty** relation from COMET [9].

For a given simile *'Love is like a unicorn.'*, the TOPIC *Love* is compared to the VEHICLE *unicorn*. As shown in Table 1, COMET tells us the top 5 properties associated with the VEHICLE are *very rare, rare, beautiful, beautiful and smart, color*. COMET gives us the properties sorted by probability in isolation by just relying on the VEHICLE. While in most situations all of the properties are apt, we need to make the literal sentence as meaningful as possible. To do this, we append the common sense property to the portion of the simile before *'like a'*. This typically consists of the TOPIC, the EVENT, and a PROPERTY if stated explicitly. We take the top 5 properties from COMET to form 5 possible literal versions for a particular simile. To rank these literal versions and select the best one, we rely on perplexity scores obtained from a pre-trained language model GPT (Radford et al., 2018). Table 1 shows human written similes collected from Reddit, the top 5 common sense properties associated with the VEHICLE, and the literal version created by taking the best PROPERTY. To correct any grammatical errors introduced by this manipulation, we rely on a grammatical error correction model (Zhao et al., 2019).

Test Data Collection. Our task is to generate a simile given a literal input. The automatically-generated parallel data might contain stylistic biases. To truly measure the effectiveness of our approach, we need to evaluate on a dataset independent of our training and validation data. Towards this end, we again scrape WRITINGPROMPTS subreddits for sentences which are this time *literal* in nature (without any comparators *like, as*). Since literal utterances contains the description of TOPIC via a PROPERTY and usually the PROPERTY is an adjective or adverb, we restrict the last word of our literal sentences to adverbs or adjectives. We crawl 500 such sentences and randomly sample 150 literal utterance. We used two literary experts (not authors of this paper) — a student in creative writing, and a student in comparative literature who is the author of a novel — to write corresponding similes for each of these 150 inputs for evaluation and comparison.

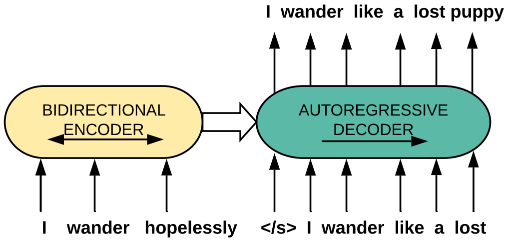

Figure 3: The backbone of SCOPE: fine-tuning BART on literal to simile pairs.

2.2 Seq2Seq Model for Simile Generation

Our goal of generating similes can be broken down into two primary tasks: 1) identifying the words in the literal sentence that should be removed or replaced and 2) generating the appropriate substitutions while being pertinent to the context. Sequence to sequence (seq2seq) neural network models (Sutskever et al., 2014) have demonstrated great success in many text generation tasks, such as machine translation, dialog system and image caption, with the requirement of a considerable amount of parallel data. Hence, we use seq2seq models for simile generation.

BART (Lewis et al., 2019) is a pre-trained model combining bidirectional and auto-regressive transformers. It is implemented as a sequence-to-sequence model with a bidirectional encoder over corrupted text and a left-to-right autoregressive decoder. In principle, the pre-training procedure has two stages: (1) text is corrupted with an arbitrary noising function, and (2) a transformer-to-transformer model is learned to reconstruct the original text. Because BART has an autoregressive decoder, it can be directly fine-tuned for most sequence generation tasks. Here, the encoder input is a sequence of words, and the decoder generates outputs autoregressively, as shown in Figure 3. BART achieves new state-of-the art results on a number of text generation tasks, making it an ideal choice for generating similes. We refer the reader to (Lewis et al., 2019) for further details.

For our task, we fine-tune BART by treating the literal input as encoder source and the simile as the the decoder target. Post fine-tuning at the inference step, we use top-k sampling strategy (Fan et al., 2018) to generate similes conditioned on a test literal input.

Implementation details. Hyper-parameters, and essential details needed for reproducing experiments are given in Appendix A.1.

3 Experimental Setup

To compare the quality of the generated similes, we benchmark our SCOPE model against human performance (i.e., the two creative writing experts HUMAN1 & HUMAN2 described in Section 2.1) and three baseline systems described below

3.1 Baseline Systems

Simile generation is a new task. The baselines outlined below have been used for other generation tasks. We adapt them to generate similes.

1. **BART**: This is the pre-trained BART model. Since BART is a pre-trained sequence to sequence model, it can still be used for conditional text generation. To this end we use the same literal sentence (For example *The city was beautiful*) as an input to the encoder and force the decoder to begin with same prefix by removing the adjective/adverb at the end and appending the comparator and the article (*The city was like a*) and generate a simile.

2. **Retrieval (RTRVL)**: We also experiment with a retrieval approach where we retrieve a `VEHICLE` from ConceptNet (Speer et al., 2017) having the highest *HasProperty* relation w.r.t our input (i.e., an adjective or adverb at the end of literal sentence)[10]. For the input *The city was beautiful* we query ConceptNet with *beautiful*, which returns *sunset* as the `VEHICLE` having the highest weight for *HasProperty beautiful*. We take this retrieved `VEHICLE` and append it to the prefix ending in *like a*. If the word is not in ConceptNet, we fall back to its synonyms obtained from WordNet (Miller, 1995).

3. **Metaphor Masking (META_M)**: The third baseline is the metaphor generation model from a literal sentence described by Stowe et al. (2020). Following their approach, we fine-tune BART where we mask the adjective or adverb in the end of the literal sentence. The input is the masked text, with the hidden adjective or adverb (*The city was <**MASK** >*), and the output is the original simile (*The city was like a painting*). Through this learning paradigm, the model learns that it needs to generate simile when it encounters the mask token. At test time, we provide the model with the literal input, mask the adjective/adverb, and the model produces an output conditioned on the adjective/adverb masking training.

	B-1	B-2	BERT-S	NOVELTY
RTRVL	0.0	0.0	0.13	92.6
BART	3.25	0.32	0.12	92.6
META_M	3.73	0.96	0.15	**93.3**
SCOPE	**8.03**	**3.59**	**0.18**	88.6

Table 2: Results using automatic metrics: BLEU-1 (B-1), BLEU-2 (B-2), BERTScores (BERT-S) and Novelty. Boldface denotes the best results.

3.2 Evaluation Criteria

Automatic evaluation. *BLEU* (Papineni et al., 2002) is one of the most widely used automatic evaluation metric for generation tasks such as Machine Translation. However, for creative text generation, it is not ideal to expect significant n-gram overlaps between the machine-generated and the gold-standard sentences. We still report the BLEU scores for generated `VEHICLE` after discarding the common prefix with the gold.

BERTScore (Zhang et al., 2019) has been used recently for evaluating text generation using contextualized embeddings and it is said to somewhat ameliorate the problems with BLEU. It computes a similarity score using contextual embeddings for each token in the candidate (here `VEHICLE` in the generated simile) with each token in the reference (`VEHICLE` in the human written simile). To compute F1-Score it uses Recall (matching each token in reference to a token in candidate) and Precision (matching each token in candidate to a token in reference). We report F1-Score of *BERTScore.*

Novelty. To measure the model's generalization capability, we also want to test how well our models can generate novel content. We capture the proportion of generated `VEHICLE` conditioned on an adverb/adjective literal `PROPERTY` that does not appears in the training set.

Human evaluation. Automated metrics are not adequate on their own for evaluating methods to generate creative text so we present a human-based evaluation as well. We evaluate on a total of 900

---

[10] ConceptNet is a weighted graph with multiple relations as can be viewed here http://conceptnet.io/. We use 'has property" for our work. There are multiple edges for objects with their properties. We choose the edge with the highest weight

System	C	R1	R2	OQ
HUMAN1	**3.61** (0.34)	**3.74** (0.43)	3.90 (0.51)	**3.54** (0.40)
HUMAN2	3.46 (0.31)	3.72 (0.43)	**3.97** (0.47)	3.44 (0.39)
RTRVL	1.90 (0.39)	1.85 (0.44)	1.73 (0.50)	1.85 (0.42)
BART	2.68 (0.39)	2.78 (0.45)	2.75 (0.51)	2.61 (0.41)
META_M	2.68 (0.42)	2.72 (0.46)	2.77 (0.47)	2.59 (0.41)
SCOPE	3.16 (0.35)	3.50 (0.43)	3.78 (0.52)	3.32 (0.43)

Table 3: Human evaluation on several criteria of similes' quality for different systems' outputs and human written similes. We show average scores on a 1-5 scale with 1 denotes the worst and 5 be the best; the corresponding inter-annotator agreement (IAA) is in the parenthesis. Boldface denotes the best results and underscore denotes the second bests.

	SCOPE/H1		SCOPE/H2		SCOPE/META_M	
	w%	l%	w%	l%	w%	l%
C	28.0	**58.6**	26.6	**57.3**	**58.6**	31.3
R1	37.3	**51.3**	33.3	**50.0**	**63.3**	18.0
R2	42.6	**45.3**	37.3	**44.6**	**69.3**	17.3
OQ	32.6	**54.6**	41.3	**50.0**	**68.6**	18.6

Table 4: Pairwise comparison between SCOPE and HUMAN1(H1), HUMAN2(H2), and META_M. Win[w]% (lose[l]%) is the percentage of SCOPE gets a higher (lower) average score compared to HUMAN1, HUMAN2 and META_M. The rest are ties.

utterances, 600 generated from 4 systems and 300 utterances generated by humans. We proposed a set of 4 criteria to evaluate the generated output: (1) **Creativity (C)** ("How creative are the utterances?"), (2) **Overall Quality (OQ)** ("How good is the simile overall? (*MTurk guidelines were to score based on how creative, well formed, meaningful and relevant it is with respect to the literal utterance*)), (3) **Relevance1 (R1)** ("How relevant is the generated `VEHICLE` in terms of portraying the `PROPERTY`?") and (4) **Relevance2 (R2)** ("How relevant is the `VEHICLE` to the `TOPIC` in the generation?"). As we evaluate on 4 separate dimensions for 900 utterances we have a total of 3600 evaluations. We hired Turkers on MTurk to rate outputs from the 4 systems and 2 humans. Each Turker was given the literal utterance as well as the 6 generated similes (randomly shuffled) Each criteria was rated on a scale from 1 (not at all) to 5 (very). Each utterance was rated by three separate Turkers. We hired 86, 48, 42, 46 Turkers for the tasks of Creativity, Overall Quality, Relevance1, Relevance2 respectively. Further details in Appendix A.4 .

4 Experimental Results

4.1 Automatic Evaluation

Table 2 shows BLEU-1, BLEU-2 and BERTScore of our system compared to the three baselines. The low scores can be attributed to the nature of creative NLG tasks. To further validate this, we also compute the BLEU-1 and BLEU-2 score between the two literary experts treating one as reference and other as candidate and get scores of 4.12 and 0.52 respectively. BERTScore is often a better metric as it utilizes contextualized embeddings. For example for a candidate [**desert**] with multi-reference as [[**sandy death trap**],[**wasteland**]] , we get a BERTscore of 0.99 while BLEU score is 0.0. Finally our best model SCOPE emerges as the winner for both BLEU and BERTScore. For novelty, SCOPE can still generate novel content 88% of the time proving it is generalizable to unseen test data. Furthermore, there are 5,558 unique `PROPERTY` in training data and 41% of `PROPERTY` in testing data does not appear in training, showing our model is generalizable to unseen `PROPERTY` as well.

4.2 Human Evaluation Scores

Table 3 presents the scores of the aforementioned human evaluation criteria for our model and the baselines on the test set. The results show that SCOPE is significantly ($p < .001$ according to approximate randomization test) better than the baselines on all four criteria. For all metrics our best system is comparable to humans. We also computed Pearson's correlation between OQ with other metrics and observed that R1 and R2 had moderate correlation of 0.54 and 0.52 with OQ, while C was fairly correlated (0.31) to OQ suggesting a relevance matters when deciding the quality of a simile.

Pairwise Comparison between systems. Table 4 shows the pairwise comparisons between SCOPE's output and human generated similes (HUMAN1 and HUMAN2), and META_M (Stowe et al., 2020), respectively. Given a pair of inputs, we decide win/lose/tie by comparing the average scores (over three Turkers) of both outputs. We see that SCOPE outperforms META_M on all the metrics. For overall quality, although it is a given that literary experts are better, our SCOPE model still has a winning rate of 32.6% and 41.3%, respectively against the two humans.

Literal	System	Simile	R1	R2	C	OQ
It was obscene, but she was drawn to it, *fascinated*	HUMAN1	It was obscene, but she was drawn to it like a *moth to a flame*	**5.0**	**4.0**	3.0	**4.7**

Table 5: Examples of generated outputs from different systems (with human written similes as references). We show average scores (over three annotators) on a 1-5 scale with 1 denotes the worst and 5 be the best. The italics texts in the literal column represent the PROPERTY while those in Simile column represents the generated VEHICLE. Boldface indicates the best results. More examples in Appendix A.3

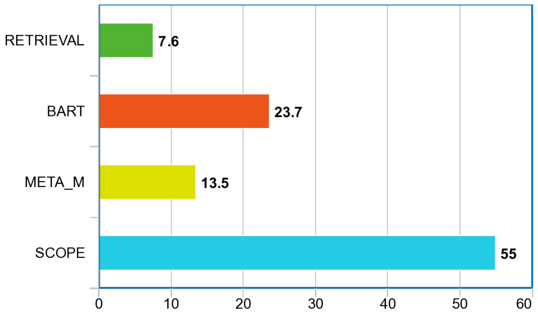

Figure 4: Barchart showing the percent of times each individual system won in terms of Overall Quality.

Storyline: sky → sunset → walk → walked → beautiful
The sky was ~~beautiful~~ [*like a blue canvas*]. Jane wanted to see the sunset. She decided to go for a walk.She walked for a long time.When she was done she saw the sunset was beautiful.
Title: car accident **Storyline**: driving → hit → hit → car → fixed
Tom was driving down the road. Suddenly he hit a tree. He swerved and hit a pole. Tom's car was ~~totaled~~ *[like a wreck]*. Luckily he was able to get it fixed

Table 6: An example of a GPT-2 generated short stories with the title **Sunset** and **Car Accident**. We replace the literal sentences with generated similes from SCOPE.

5 Qualitative Analysis

Table 9 demonstrates several generation outputs from different systems along with human judgements on individual criteria. We observe that often our model is better than at least one human on a certain criteria while outperforming the baselines by a large margin.

5.1 Role of Relevance

While conditioning on the context of literal sentences might lead to grammatically correct similes, they are often not meaningful and relevant to the `PROPERTY` in consideration. META_M generates similes by fine-tuning BART on literal sentences where the common sense `PROPERTY` is masked. The lack of relevance mapping during fine-tuning often leads to improper generations. For instance, referring to Table 9, the context of 'falling into the wrong hands' is more likely to lead to something bad and hence here 'gift' (generated by META_M) is not appropriate while 'nuclear bomb' (generated by our model) is. One explanation is that our SCOPE model uses common sense knowledge as a way of incorporating relevance.

5.2 Role of Context

The role of context is necessary for simile generation. For example given the literal input *'But times are hard, and silver bullets are* ***expensive****'* even though ConceptNet tells us **diamonds** are objects with *HasProperty* expensive, a generated simile by RTRVL model *'But times are hard, and silver bullets are like a* ***diamond****'* seems inappropriate suggesting that a context leads to better generation. Our SCOPE model generates *'But times are hard, and silver bullets are like a* ***luxury item****'*

6 Task-based Evaluation: Simile for Story Generation

Similes are often used to evoke imagery. Generating or transforming text to be evocative can be useful for computational journalism (Spangher et al.), poetry generation (Ghazvininejad et al., 2017; Van de Cruys, 2020) and story writing (Peng et al., 2018; Yao et al., 2019; Goldfarb-Tarrant et al., 2020). Table 10 shows how we can use our simile generation module as a post processing step to replace literal sentences leading to more expressive and creative stories. To further test this hypothesis we conduct an experiment further outlined below.

GPT2	GPT2+META_M	GPT2+SCOPE
23%	25%	**42%**

Table 7: Win% (in terms of average score over three annotators) of stories generated with only GPT2, GPT2 with META_M or SCOPE simile post processing. The rest are ties.

6.1 Story Generation

We use the ROCStories (Mostafazadeh et al., 2016) dataset to generate stories using the *Plan and Write* model outlined by Yao et al. (2019); Goldfarb-Tarrant et al. (2019). We introduce a two step pipeline procedure where we fine-tune a pre-trained GPT2 (Radford et al., 2018) model on titles and storyline from the training set to generate a storyline given a title (Row 1 Table 10). In parallel, we also fine-tune GPT2 on storylines and stories from the training set to generate a story given a storyline (Row 2 Table 10). At test time, we generate a storyline using an input title first and then use the generated storyline to generate a story.

6.2 Post Processing

There can be multiple sentences ending with an adjective or adverb and replacing each of them with a simile might lead to over-embellishment. Under such situations we feed only one randomly selected sentence to SCOPE and META_M module and replace the sentence in GPT2 generated story with the output from SCOPE or META_M, respectively.

6.3 Human evaluation.

We randomly select 50 titles from ROCStories data set and generate stories as described above. We postprocess it using both SCOPE and META_M separately. Thus for each title we have 3 stories 1) the original GPT2 story, 2) the GPT2 story postprocessed with SCOPE, and 3) the GPT2 story postprocessed with META_M. For each given titles, we present these 3 stories to workers in AMT and ask them to score them in a range of 1(poor) to 5 (excellent) based on creativity and evocativeness. Experimental results from Table 7 prove that effective usage of similes can improve evocativeness of machine generated stories.

7 Related Work

Simile generation is a relatively new task. Most prior work has focused on detection of similes. The closest task in NLP to simile generation is generating metaphors. However, it should be noted that the overlap between the expressive range of similes and metaphors is known to be only partial: there are similes that cannot be rephrased as metaphors, similarly the other way around (Israel et al., 2004).

7.1 Simile Detection and Analysis

Niculae and Danescu-Niculescu-Mizil (2014) proposed frameworks for annotating similes from product reviews by considering their semantic and syntactic characteristics as well as the challenges inherent to the automatic detection of similes. Qadir et al. (2015, 2016) built computational models to recognize affective polarity and implicit properties in similes. Unlike these works, we focus on generating similes by transforming a literal sentence while still being faithful to the property in context.

7.2 Metaphor Generation

Earlier works in metaphor generation (Abe et al., 2006; Terai and Nakagawa, 2010) were conducted on a lexical or phrase level, using template and heuristic-based methods. (Gero and Chilton, 2019) presented an interactive system for collaboratively writing metaphors with a computer. They use an open source knowledge graph and a modified Word Mover's Distance algorithm to find a large, ranked list of suggested metaphorical connections. Word embedding approaches (Gagliano et al., 2016) have also been used for metaphor generation. (Young, 1987) also present a relational data base method for automatic metaphor generation. However, the metaphors generated through these methods do not take semantic context into consideration and lack the flexibility and creativity necessary to instantiate similes through a natural language sentence.

Yu and Wan (2019) use neural models to generate metaphoric expressions given a literal input in an unsupervised manner. Stowe et al. (2020) develop a new framework dubbed 'metaphor masking' where they train a supervised seq2seq model with input as the masked text, where they mask or hide the metaphorical verb while preserving the original text as the output. However, both these works hinge on metaphoric verbs unlike similes where we not only need to replace the literal property with a vehicle but it also needs to be relevant to the context and the tenor. Additionally, we also use (Stowe et al., 2020) as a baseline and show that our approach leads to better similes using both quantitative and qualitative evaluation metrics.

8 Conclusion

We establish a new task for NLG: simile generation from literal sentences. We propose a novel way of creating parallel corpora and a transfer-learning approach for generating similes. Human and automatic evaluations show that our best model is successful at generating similes. Our experimental results further show that to truly be able to generate similes based on actual metaphoric or conceptual mappings, it is important to incorporate some common sense knowledge about the topics and their properties. Future directions include exploration of other knowledge bases to help the inference process and applying our simile generation approach to different creative NLG tasks such as pun (He et al., 2019), sarcasm (Chakrabarty et al., 2020), and hyperbole (Troiano et al., 2018).

A Appendix

A.1 Hyper-Parameters and Other Experimental Settings

For retrieving commonsense properties of the vehicle, we use the pre-trained COMET model [11] and retrieve top 5 candidates for each input.

1. **Number of Parameters:** For BART we use the BART large checkpoint (400M parameters) and use the implementation by FAIRSEQ (Ott et al., 2019).[12]
2. **Number of Epochs:** We fine-tune pre-trained BART for 17 epochs for SCOPE model.
3. **Training Time:** Our training time is 52 minutes.
4. **Hardware Configuration:** We use 4 RTX 2080 GPU,
5. **Training Hyper parameters:** We use the same parameters mentioned in the github repo where BART was fine-tuned for CNN-DM summarization task with the exception of MAX-TOKENS (size of each mini-batch, in terms of the number of tokens) being 1024 for us.
6. **Decoding Strategy & Hyper Parameters:** For decoding we generate similes from our models using a top-k random sampling

	#WORKERS	α
C	86	0.36
OP	48	0.41
R1	42	0.44
R2	46	0.49

Table 8: C, R1,R2 and OQ denote Creativity, Relevance of Vehicle w.r.t Property, Relevance of Tenor to Vehicle and Overall Quality. WORKERS denote number of workers employed for each task and α denotes Krippendorff's alpha (α) , reliability coefficient used for our study

scheme (Fan et al., 2018). At each timestep, the model generates the probability of each word in the vocabulary being the likely next word. We randomly sample from the k = 5 most likely candidates from this distribution. We also use a softmax temperature of 0.7.

A.2 Dataset Assumptions

Figure 5: Proprty associated with fool

While distant supervision is often used to collect a lot of data without human/ expert annotation through this process we introduce, noise in our self labeled similes. For example the sentence *I feel like a fool* is ideally not a simile.We notice 1.1% of the training data with PNP in `TOPIC` and typically $<=6$ in token count such as *I would like a , I don't like a, I feel like a, I think like a*. However our transformation method still works here. Based on Figure 5 we see the common sense properties associated for *fool* are *sneaky, stupid,funny,dangerous, bad*. Our best literal transformation for *I feel like a fool* is then *I feel stupid*. So even though there is some noise this method still benefits our training procedure

A.3 Examples

Table 9 shows generations from all 4 systems along with gold similes and how turkers scored them on a scale of 1 to 5 for C,R1,R2 and OQ.

A.4 Amazon Mechanical Turk Settings

The 2nd column Table 8 shows the number of distinct workers employed for each task. Column 3 shows inter-rater agreement between workers. Except for Creativity, for the other 3 tasks workers are moderately correlated. For creativity workers are fairly correlated.

Figure 6,7,8 and 9 show the Amazon Mechanical Turk interfaces for the tasks of *Creativity (C)* ("How creative are the utterances ?"), (2) *Relevance1 (R1)* ("How relevant is the generated `VEHICLE` in terms of portraying the `PROPERTY`?") and (3) *Relevance2 (R2)* ("How relevant is the `VEHICLE` to the `TOPIC` in the generation?") (4) *Overall Quality (OQ)* ("How good is the simile overall ?". As can be seen we provide with explicit examples and a clear description of the task to turkers. We also mention and highlight the importance of evaluating similes along with input and not in isolation.

A.5 GPT2 generated stories preprocessed with SCOPE

Table 10 shows several example stories where a literal sentence has been replaced by a simile.

Literal	System	Simile	R1	R2	C	OQ
From the day you were born, you've been *invincible*	HUMAN1	From the day you were born, you've been like a *well-seasoned superhero*	4.0	4.0	4.0	3.3

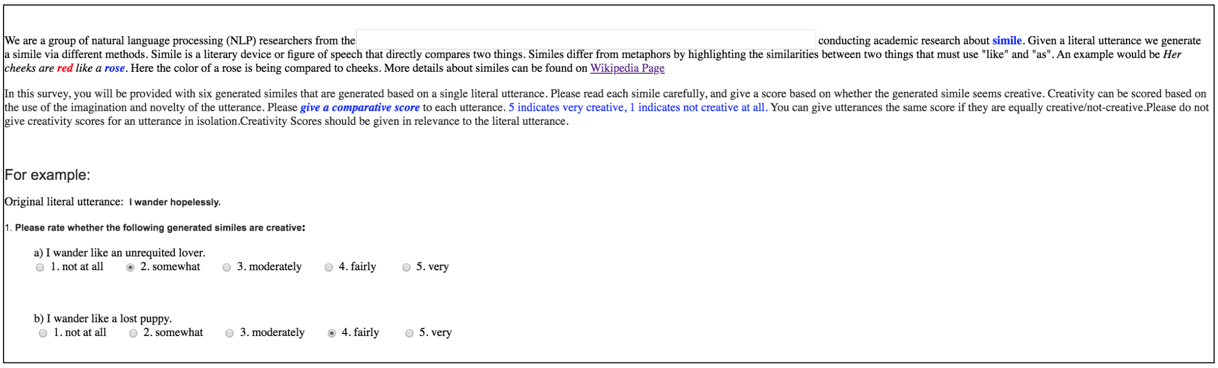
Table 9: Examples of generated outputs from different systems (with human written similes as references).We show average scores (over three annotators) on a 1-5 scale where 1 denotes the worst and 5 be the best. The italics texts in the literal column represent the PROPERTY while those in Simile column represents the generated VEHICLE. Boldface indicates the best results.



We are a group of natural language processing (NLP) researchers from the conducting academic research about **simile**. Given a literal utterance we generate a simile via different methods. Simile is a literary device or figure of speech that directly compares two things. Similes differ from metaphors by highlighting the similarities between two things that must use "like" and "as". An example would be *Her cheeks are **red** like a **rose***. Here the color of a rose is being compared to cheeks. More details about similes can be found on Wikipedia Page

In this survey, you will be provided with six generated similes that are generated based on a single literal utterance. Please read each simile carefully, and give a score based on whether the generated simile seems creative. Creativity can be scored based on the use of the imagination and novelty of the utterance. Please ***give a comparative score*** to each utterance. 5 indicates very creative, 1 indicates not creative at all. You can give utterances the same score if they are equally creative/not-creative.Please do not give creativity scores for an utterance in isolation.Creativity Scores should be given in relevance to the literal utterance.

For example:

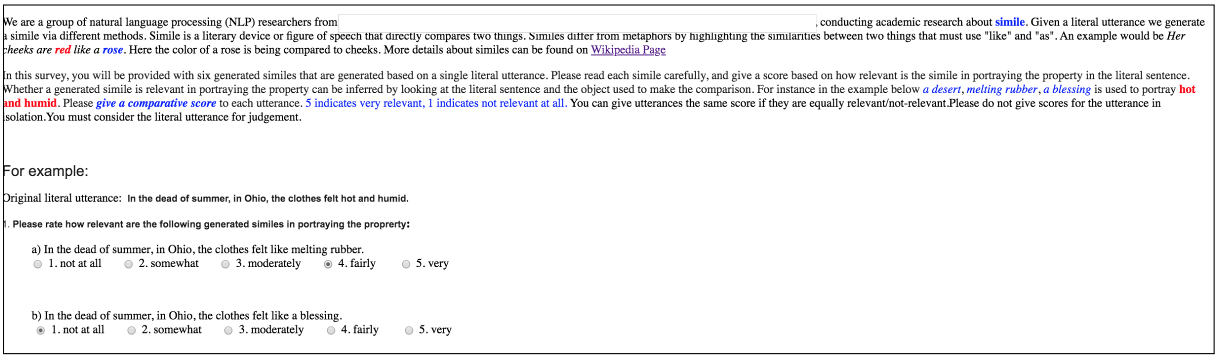
Original literal utterance: **I wander hopelessly.**

1. **Please rate whether the following generated similes are creative:**

a) I wander like an unrequited lover.
○ 1. not at all ● 2. somewhat ○ 3. moderately ○ 4. fairly ○ 5. very

b) I wander like a lost puppy.
○ 1. not at all ○ 2. somewhat ○ 3. moderately ● 4. fairly ○ 5. very

Figure 6: MTurk interface for scoring **Creativity**



We are a group of natural language processing (NLP) researchers from , conducting academic research about **simile**. Given a literal utterance we generate a simile via different methods. Simile is a literary device or figure of speech that directly compares two things. Similes differ from metaphors by highlighting the similarities between two things that must use "like" and "as". An example would be *Her cheeks are **red** like a **rose***. Here the color of a rose is being compared to cheeks. More details about similes can be found on Wikipedia Page

In this survey, you will be provided with six generated similes that are generated based on a single literal utterance. Please read each simile carefully, and give a score based on how relevant is the simile in portraying the property in the literal sentence. Whether a generated simile is relevant in portraying the property can be inferred by looking at the literal sentence and the object used to make the comparison. For instance in the example below *a desert*, *melting rubber*, *a blessing* is used to portray **hot and humid**. Please ***give a comparative score*** to each utterance. 5 indicates very relevant, 1 indicates not relevant at all. You can give utterances the same score if they are equally relevant/not-relevant.Please do not give scores for the utterance in isolation.You must consider the literal utterance for judgement.

For example:

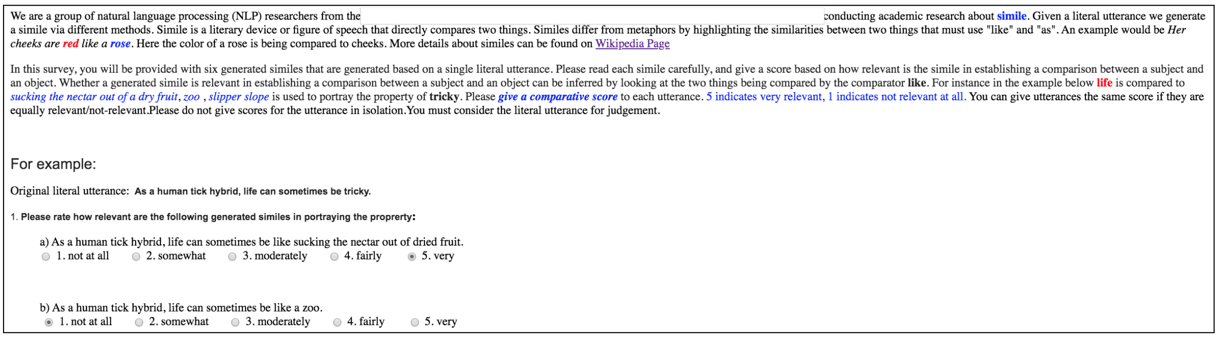
Original literal utterance: **In the dead of summer, in Ohio, the clothes felt hot and humid.**

1. **Please rate how relevant are the following generated similes in portraying the proprerty:**

a) In the dead of summer, in Ohio, the clothes felt like melting rubber.
○ 1. not at all ○ 2. somewhat ○ 3. moderately ● 4. fairly ○ 5. very

b) In the dead of summer, in Ohio, the clothes felt like a blessing.
● 1. not at all ○ 2. somewhat ○ 3. moderately ○ 4. fairly ○ 5. very

Figure 7: MTurk interface for scoring **Relevance1**



We are a group of natural language processing (NLP) researchers from the conducting academic research about **simile**. Given a literal utterance we generate a simile via different methods. Simile is a literary device or figure of speech that directly compares two things. Similes differ from metaphors by highlighting the similarities between two things that must use "like" and "as". An example would be *Her cheeks are **red** like a **rose***. Here the color of a rose is being compared to cheeks. More details about similes can be found on Wikipedia Page

In this survey, you will be provided with six generated similes that are generated based on a single literal utterance. Please read each simile carefully, and give a score based on how relevant is the simile in establishing a comparison between a subject and an object. Whether a generated simile is relevant in establishing a comparison between a subject and an object can be inferred by looking at the two things being compared by the comparator **like**. For instance in the example below **life** is compared to *sucking the nectar out of a dry fruit*, *zoo* , *slipper slope* is used to portray the property of **tricky**. Please ***give a comparative score*** to each utterance. 5 indicates very relevant, 1 indicates not relevant at all. You can give utterances the same score if they are equally relevant/not-relevant.Please do not give scores for the utterance in isolation.You must consider the literal utterance for judgement.

For example:

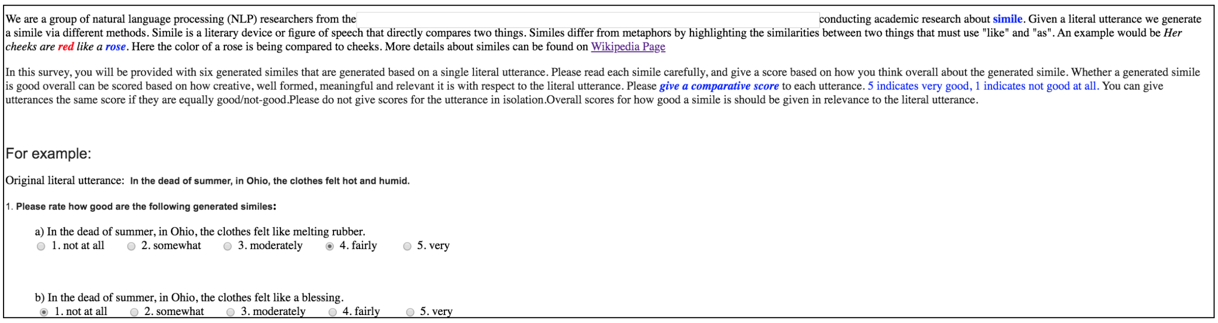
Original literal utterance: **As a human tick hybrid, life can sometimes be tricky.**

1. **Please rate how relevant are the following generated similes in portraying the proprerty:**

a) As a human tick hybrid, life can sometimes be like sucking the nectar out of dried fruit.
○ 1. not at all ○ 2. somewhat ○ 3. moderately ○ 4. fairly ● 5. very

b) As a human tick hybrid, life can sometimes be like a zoo.
● 1. not at all ○ 2. somewhat ○ 3. moderately ○ 4. fairly ○ 5. very

Figure 8: MTurk interface for scoring **Relevance2**



We are a group of natural language processing (NLP) researchers from the conducting academic research about **simile**. Given a literal utterance we generate a simile via different methods. Simile is a literary device or figure of speech that directly compares two things. Similes differ from metaphors by highlighting the similarities between two things that must use "like" and "as". An example would be *Her cheeks are **red** like a **rose***. Here the color of a rose is being compared to cheeks. More details about similes can be found on Wikipedia Page

In this survey, you will be provided with six generated similes that are generated based on a single literal utterance. Please read each simile carefully, and give a score based on how you think overall about the generated simile. Whether a generated simile is good overall can be scored based on how creative, well formed, meaningful and relevant it is with respect to the literal utterance. Please ***give a comparative score*** to each utterance. 5 indicates very good, 1 indicates not good at all. You can give utterances the same score if they are equally good/not-good.Please do not give scores for the utterance in isolation.Overall scores for how good a simile is should be given in relevance to the literal utterance.

For example:

Original literal utterance: **In the dead of summer, in Ohio, the clothes felt hot and humid.**

1. **Please rate how good are the following generated similes:**

a) In the dead of summer, in Ohio, the clothes felt like melting rubber.
○ 1. not at all ○ 2. somewhat ○ 3. moderately ● 4. fairly ○ 5. very

b) In the dead of summer, in Ohio, the clothes felt like a blessing.
● 1. not at all ○ 2. somewhat ○ 3. moderately ○ 4. fairly ○ 5. very

Figure 9: MTurk interface for scoring **Overall Quality**

Title: a gift from the mentor **Storyline**: loved → playing → promised → tried → surprised
Harry loved playing tennis. One day while playing he broke his racket. His coach had promised to buy him a new racket if he practiced. Harry tried hard to practice and was confident in his new racket. To his surprise his coach bought him a racket for his birthday and he was ~~ecstatic~~ *[like a child on Christmas day]*
Title: The pet bug **Storyline**: playing → caught → bug → hoped → release
Oliver was playing in his yard. Suddenly he spotted a bug he hadn't caught. The bug was a big beetle. He hoped it would be there ~~forever~~ *[like a shadow]*. But unfortunately it was too late to release it
Title: fishing **Storyline**: fish → lake → kids → caught → home
The kids were great at catching fish. They woke up early and packed up their tackle box and hiked to the lake. The kids set up their lures and caught as many as they could. The fish were all caught and the kids laughed ~~heartily~~ *[like a group of hyenas]*. They went home and had a great day fishing

Table 10: Example of a GPT-2 generated short story on respective title , storyline. We replace the first literal sentence with a generated simile from SCOPE.

STORIUM: A Dataset and Evaluation Platform for Machine-in-the-Loop Story Generation

Abstract

Systems for *story generation* are asked to produce plausible and enjoyable stories given an input context. This task is underspecified, as a vast number of diverse stories can originate from a single input. The large output space makes it difficult to build and evaluate story generation models, as (1) existing datasets lack rich enough contexts to meaningfully guide models, and (2) existing evaluations (both crowdsourced and automatic) are unreliable for assessing long-form creative text. To address these issues, we introduce a dataset and evaluation platform built from STORIUM, an online collaborative storytelling community. Our author-generated dataset contains 6K lengthy stories (125M tokens) with fine-grained natural language annotations (e.g., character goals and attributes) interspersed throughout each narrative, forming a robust source for guiding models. We evaluate language models fine-tuned on our dataset by integrating them onto STORIUM, where *real* authors can query a model for suggested story continuations and then edit them. Automatic metrics computed over these edits correlate well with both user ratings of generated stories and qualitative feedback from semi-structured user interviews. We release both the STORIUM dataset and evaluation platform to spur more principled research into story generation.

1 Introduction

Fiction writers express their creativity through both low-level linguistic choices and discourse-level sequencing of narrative elements (e.g., plot events and character development). Unlike more constrained text generation tasks, such as translation or summarization, fiction writing allows for almost infinite creative freedom, which budding authors often find cognitively overwhelming (Rose, 1980). Machine-in-the-loop storytelling (Clark et al., 2018), in which an author obtains automatically generated sentences or paragraphs when stuck with writer's block, lowers the barrier to entry for creative writing (Roemmele and Gordon, 2015). To spur research in this area, we partner with STORIUM,[1] an online collaborative storytelling platform, to introduce a new dataset and evaluation methodology for story generation.

The open-endedness of story writing does not just pose a barrier to humans—it also presents a challenge for building and evaluating computational models. Prior work relies on datasets that are either too artificial to generalize to long-form stories, such as the crowdsourced ROCStories (Mostafazadeh et al., 2016) corpus, or too unconstrained, as in the `r/writingprompts` dataset (Fan et al., 2018), which pairs medium-length stories with short prompts. Furthermore, lack of standardized evaluation makes measuring progress difficult: most prior work evaluates outputs using a combination of simple automatic metrics not designed for long-form creative text generation (e.g., BLEU and ROUGE against a single reference) and crowdsourced ratings (McIntyre and Lapata, 2009; Yao et al., 2019; Fan et al., 2019) that preclude evaluating long-form narratives.

We address these limitations by (1) collecting a dataset of stories (Section 2) containing fine-grained structural annotations written in natural language, and (2) providing a platform for evaluating models in a machine-in-the-loop setting by allowing real STORIUM authors to interact with the generated stories (Section 4). Our dataset contains nearly 6K longform stories (125M tokens) written by STORIUM authors, each of which is broken into discourse-level scene entries annotated with narrative elements, such as character goals or abilities. Conditioning story generation models on this infor-

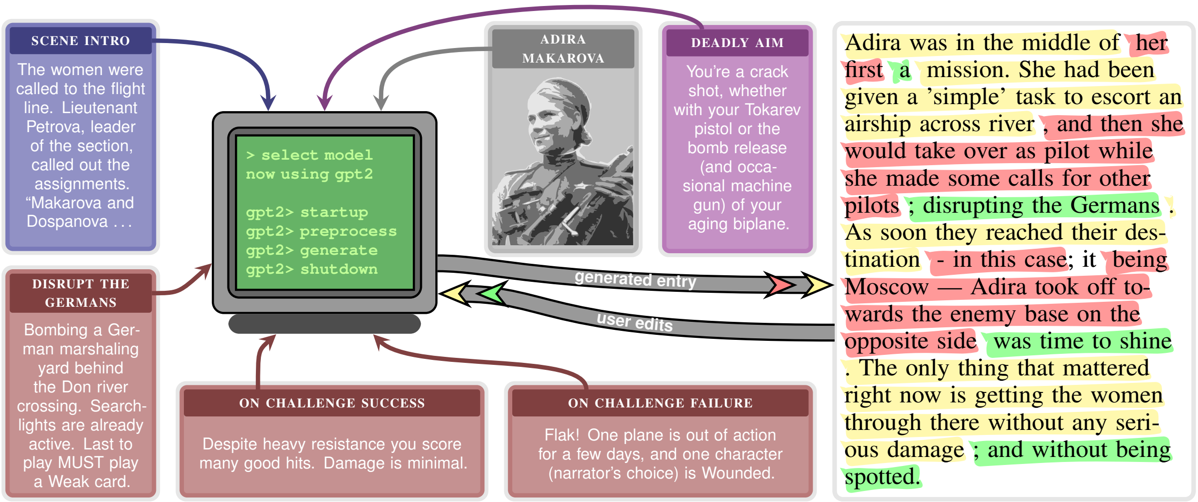
November 16–20, 2020.



The women were called to the flight line. Lieutenant Petrova, leader of the section, called out the assignments. "Makarova and Dospanova . . .

You're a crack shot, whether with your Tokarev pistol or the bomb release (and occasional machine gun) of your aging biplane.

Bombing a German marshaling yard behind the Don river crossing. Searchlights are already active. Last to play MUST play a Weak card.

```
> select model
now using gpt2

gpt2> startup
gpt2> preprocess
gpt2> generate
gpt2> shutdown
```

Despite heavy resistance you score many good hits. Damage is minimal.

Flak! One plane is out of action for a few days, and one character (narrator's choice) is Wounded.

Adira was in the middle of her first a mission. She had been given a 'simple' task to escort an airship across river , and then she would take over as pilot while she made some calls for other pilots ; disrupting the Germans . As soon they reached their destination - in this case; it being Moscow — Adira took off towards the enemy base on the opposite side was time to shine . The only thing that mattered right now is getting the women through there without any serious damage ; and without being spotted.

Figure 1: A high-level outline of our dataset and platform. In this example from a real STORIUM game, the character ADIRA MAKAROVA uses the strength card DEADLY AIM to DISRUPT THE GERMANS, a challenge card. Our model conditions on the natural language annotations in the scene intro, challenge card, strength card, and character, along with the text of the previous scene entry (not shown) to generate a suggested story continuation. Players may then edit the model output, by adding or deleting text, before publishing the entry. We collect these edits, using the matched text as the basis of our USER metric. New models can be added to the platform by simply implementing four methods: `startup`, `shutdown`, `preprocess`, and `generate`.

mation thus imposes loose constraints on what the model should produce, compared to unstructured datasets such as `r/writingprompts`, and also enables modeling of narrative planning processes.

We fine-tune large-scale pretrained language models on our dataset (Section 3) and integrate them with the STORIUM platform, where authors can query a model for the next few sentences in their story and then edit the resulting text to their liking. We devise a metric (inspired by ROUGE) on top of these edits that measures how much of the generated text is preserved in the post-edited version, and discover that this metric correlates with Likert judgments of linguistic properties such as relevance and coherence. Detailed analyses of the edits (Section 5), including semi-structured interviews with STORIUM users, suggests that generating text *relevant* to the current story context is the most important open problem in this area. We publicly release both the STORIUM dataset and user-facing evaluation platform to facilitate future research on story generation.[2]

2 STORIUM Dataset

Our STORIUM dataset derives from an online collaborative storytelling community that provides rich metadata useful for guiding computational storytelling systems. In this section, we describe how the structural elements of STORIUM stories fit together, and verify via an annotation task that this metadata indeed influences the text of the stories. Finally, we use neural topic models to highlight the thematic content and narrative sequencing of STORIUM.

2.1 STORIUM: Gamified Storytelling

The STORIUM platform enables a small group of users to collaboratively write a single story by transforming the writing process into a turn-based game. In each game, one player acts as the *narrator*, while other players take on the role of individual *characters* within the story (e.g., ADIRA MAKAROVA in Figure 1). Stories unfold through a series of high-level *scenes* that consist of multiple short *entries*, each of which is written from the perspective of a character (or the narrator). Scenes commonly revolve around *challenges* (e.g., DISRUPT THE GERMANS), that the characters tackle within the text of their entries; to help address these challenges, each character has access to a set of *cards* (e.g., DEADLY AIM, a strength card) that define various properties such as strengths, weaknesses, items, and goals. The narrator moves the story forward by introducing new challenges, locations, and characters, in the form of cards. These are either created from scratch by the narrator or se-

Dataset	**# Stories**	**# Tokens per Story**	**Prompts**	**Turns**	**Annotations**
`roleplayerguild`	1,439	3,079*	✗	✓	✗
PG-19	28,752	68,973	✗	✗	✗
ROCStories	98,156	88	✓	✗	✗
`r/writingprompts`	303,358	735	✓	✗	✗
STORIUM	5,743	19,278	✓†	✓	✓

Table 1: While STORIUM has fewer stories than other popular story datasets, each story is considerably longer and contains natural language annotations to guide story generation. *We combine character and action sets to determine average story length. †We count narrator actions introducing challenges and locations as prompts.

lected from a predefined *world* that contains a common set of story elements. Collectively, the cards played form a set of structural natural language annotations that guide the story being written.

Dataset details: We collect 5,743 publicly available stories written on STORIUM from January 2015 to August 2019. We reserve 569 stories for validation and 570 stories for test — carefully ensuring an 8:1:1 split with respect to both the number of stories and tokens. Altogether, the stories are broken down into 25,092 scenes with 448,264 individual scene entries (126,041,738 tokens), conditioned on 232,596 cards, 204,698 of which are unique.

Stories	5,743
Authors	30,119
Characters	25,955
Scenes	25,092
Scene Entries	448,264
Cards Played	232,596
Average Tokens* (per Entry)	247
Average Tokens* (per Story)	19,278
Total Tokens* (Entries & Cards)	126,041,738

Table 2: An overview of our dataset, which contains long stories, broken down into scene entries, with structural annotations in the form of cards played to guide the narrative. *We count tokens as contiguous spans of either alphanumeric or non-alphanumeric symbols.

Cards influence entry text: STORIUM does not force players to relate their written entries to selected cards or challenges, instead relying on game conventions to guide user behavior. To validate whether the structural metadata influences story text, we conduct a small-scale annotation of 235 scene entries, where we ask annotators[3] to provide binary judgments for (1) whether the card played influences the scene entry, and (2) if the scene entry addresses the current challenge. We find that 77% of scene entries reference the played cards, and 80% address the current challenge (Table A1).

Related datasets: Prior story generation papers have frequently focused on the ROCStories (Mostafazadeh et al., 2016) and `r/writingprompts` (Fan et al., 2018) datasets. While STORIUM has comparatively fewer stories than these datasets, our stories are over an order of magnitude longer (Table 1). Rather than containing a single short prompt to start the story, our stories on average contain 14 narrator prompts per story, with 41 natural language annotations which describe character goals, attributes, and key items useful for conditioning story generation models.[4] Like STORIUM, the stories in `roleplayerguild` (Louis and Sutton, 2018) are also formed from collaborative storytelling turns via a role-playing game, though this dataset lacks any prompts or annotations. Finally, datasets consisting of novels and other fiction, like PG-19 (Rae et al., 2020), provide long-form narratives without explicit structure to constrain generation.

2.2 Common Themes and Story Arcs

To provide insight into common narrative themes and substructures within our dataset, we train a neural topic model on text from entries and challenges and analyze the resulting topics and their transitions.

2.2.1 Topic model specification

Our topic model is a simplified version of the *relationship modeling network* (RMN) proposed

---

[3] The annotators were NLP graduate students.

[4] While Fan et al. (2019) extract internal structure via SRL, this is not inherent to the dataset, and can be applied to other datasets, including our own.

by Iyyer et al. (2016).[5] As in the RMN, our model relies on dictionary learning to compute topics; however, it models each entry and challenge independently, instead of considering the temporal order of scenes through recurrence. We ignore the temporal component because STORIUM contexts do not neatly fit into a chronologically-ordered timeline (e.g., entries within a single scene may not depend on each other). Building a specialized topic model for this data is beyond the scope of this work.

Concretely, given an input text (either an entry or a challenge), we first encode it by computing an average of pretrained GloVe[6] embeddings $\boldsymbol{x}$. Next, we compute the dot product between $\boldsymbol{x}$ and each row of a global *dictionary matrix* $\mathbf{R}$. Intuitively, each row of $\mathbf{R}$ is a vector representation of an individual topic. These row-wise dot products are converted to a probability distribution via a softmax function and then used to compute a weighted average $\boldsymbol{r}$ of the dictionary rows, which is then trained through a contrastive max-margin loss to reconstruct the input vector $\boldsymbol{z}$. At test time, the dictionary rows are interpreted by their nearest neighbors (using cosine distance) in the GLoVe word embedding space.[7]

Worlds	Topic words
Fantasy Classic	rotunda, courtyard, staircase, foyer
Urban Fantasy	analyze, investigate, analyse, uncover
The Mysterious Island	convoy, hiking, river, reconnaissance
Cyberpunk	synchronization, decryption, device, apparatus
Steampunk	freighter, crewmembers, cockpit, airship
The Heroes Return	thine, fealty, uphold, valor
Medical Drama	tumor, ligament, laceration, mortem
Los Chicos Malos	sublight, biosphere, aetheric, gravitational
The University	explanation, undergrad, spelling, reasoning
The 33	melodramatic, reenactment, film, thriller
Scrapjack	brake, soldering, heater, corrosion

Table 3: Topics with the highest relative importance for a sample of STORIUM worlds, which illustrate the diversity of the dataset.

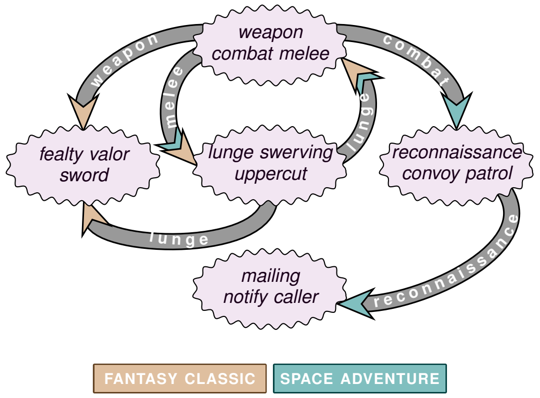

Figure 2: Example story arcs derived from the adjacency matrix of topic transitions over the text of entries (e.g., in FANTASY CLASSIC stories, the *weapon, combat, melee* topic is often followed by a transition, as denoted by **weapon**, to the *fealty, valor, sword* topic).

2.2.2 Examining topics and their transitions

To explore the content of the STORIUM dataset, we train our model with 50 topics (i.e., $\mathbf{R}$ has 50 rows) on the union of entry and challenge text. Table 3 shows the most distinguishing topic (ranked by relative importance) for a sample of different STORIUM worlds. These topics illustrate the diversity of our dataset: topics range from science fiction (*Cyberpunk*, *Steampunk*) to detective fiction (*Urban Fantasy*) and stories set in hospitals (*Medical Drama*) and schools (*The University*).

Following the methodology of Antoniak et al. (2019), we also examine common local topic transitions between entries written by the *same* character across different scenes in a story. We compute the transition probability from topic A to topic B by counting how many times A and B are the most probable topics for two consecutive entries, respectively, and normalizing by the total number of occurrences of topic A. Figure 2 shows a topic transition diagram originating from a weapons-related topic. In the *Space Adventure* world, stories progress into vehicle and technology-related topics, while in *Fantasy Classic*, they tend to transition to topics about valor instead. That said, both of these worlds are not completely different, as they share a transition topic associated with physical action.

3 Generating Scene Entries

We focus our modeling efforts on generating scene *entries*, which are the smallest units of each story, because we want to evaluate the generated text on

---

[5] Preliminary experiments with LDA (Blei et al., 2003) yielded less coherent topics, which is consistent with evaluations in Iyyer et al. (2016).

[6] glove.840B.300d

[7] We encourage interested readers to see Iyyer et al. (2016) for more details. The only difference between our setup and theirs is that we directly use $\boldsymbol{x}$ to compute the row weights without any feed-forward or recurrent layers in between.

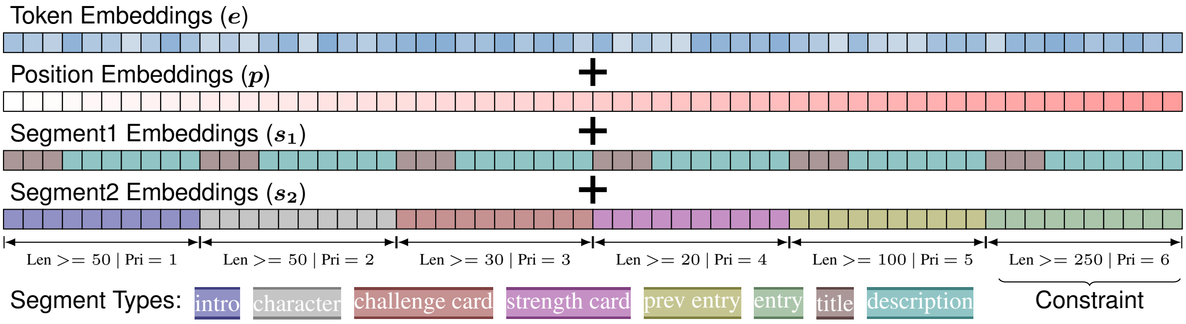

Figure 3: An illustration of our segment embeddings and packing strategy. In addition to token and position embeddings, common to all Transformer models, we employ compositional segment embeddings for conditioning on story metadata (e.g., DEADLY AIM is the title of a strength card). Each metadata segment has linear constraints with associated priorities (e.g., Len >= 30 | Pri = 3) for optimally packing tokens within the available space.

the STORIUM platform within a machine-in-the-loop framework.[8] Our method relies on fine-tuning a pretrained language model (GPT-2) on the STORIUM dataset using segment embeddings to differentiate each type of context. While GPT-2 has successfully been used as a state-of-the-art model for story generation (Mao et al., 2019; Guan et al., 2020), one crucial challenge is the length of the contexts: each entry in a story can condition on any narrative element that comes before it (e.g., previous entries, scenes, challenges). Thus, the number of context tokens quickly grows larger than what is feasible to fit in GPU memory. Another challenge lies in how to properly tune hyperparameters in a machine-in-the-loop setting, as it is infeasible to obtain human judgments for a huge number of configurations. The rest of this section fully specifies our model, a token-packing strategy to optimize use of the input context, and preliminary user-facing experiments that helped us decide on our final model hyperparameters.

3.1 Model Specification

We fine-tune the GPT-2 medium-sized (355M parameters) language model (Radford et al., 2019) for story generation, as it has been shown to generate coherent long-form prose. Before fine-tuning, we need to account for the complexity of STORIUM contexts: each scene consists of multiple entries, each of which may reference a different number of semi-structured cards (e.g., both the DEADLY AIM strength card and the ADIRA MAKAROVA character in Figure 1 contain a title and description). To handle the compositional and semi-structured nature of the scenes and cards, we allow each input token to condition on an arbitrary number of *segment embeddings* (Wolf et al., 2019) (Figure 3). Concretely, we augment the token vocabulary V of GPT-2 with a segment vocabulary S for delineating each segment. The final embedding vector $\boldsymbol{e}_i$ at position i is computed by summing the token embedding $\boldsymbol{v}_i$ with the positional embedding $\boldsymbol{p}_i$ and the corresponding set of n segment embeddings $\{\boldsymbol{s}_{i_1}, \ldots, \boldsymbol{s}_{i_n}\}$:

$$e_i = p_i + v_i + \sum_{m=1}^{n} s_{i_m} \tag{1}$$

During training, a single input instance to our models contains the text of the current entry, its associated challenge, card metadata, as well as the current character's biography and the scene's introductory text (Figure 1). Our final model also includes the text of the immediately preceding story entry,[9] which improves human and automatic evaluation scores (Table 4). At test time, we provide only the story context and autoregressively sample a scene entry.

3.1.1 Context packing

The average story in our dataset has over 19K tokens broken up into 78 scene entries, which is much longer than GPT-2's maximum sequence length of 1024 tokens. We thus face the challenge of how best to optimize our usage of the limited input space, which is made more difficult by the many different types of input context (e.g., entries, characters, challenges) within STORIUM. Naïvely reserving a fixed number of tokens per context type

---

[8] Our dataset also enables modeling high-level decisions made by the narrator, such as challenge sequencing; we leave this for future work.

[9] If the preceding entry is not written by the current character, we also include the current character's last entry.

wastes significant space, as the number and length of metadata instances varies considerably per entry. For example, some scene entries do not make use of cards (Table 2), while others reference multiple cards.

Our solution applies the Cassowary algorithm (Badros et al., 2001), well-known for arranging UI elements in Apple's iOS, to pack the input tokens more efficiently. Cassowary allows for efficiently solving linear equality and inequality constraints incrementally, using a dual simplex based method. We define a set of linear constraints on the size of each metadata segment (e.g., include at least 250 tokens from an entry when possible), and Cassowary's solver produces an optimal arrangement of context tokens with respect to these constraints (Figure 3). Compared to naïvely packing tokens into fixed length segments, Cassowary allows us to vary the minimum and maximum bounds on segments, as well as collapse missing segments. This flexibility results in increased human and automatic evaluation scores (Table 4).

3.2 Hyperparameter Selection

Before launching our full machine-in-the-loop evaluation, we conduct preliminary experiments on the STORIUM platform to validate our design choices. Since we want *real* users on STORIUM to enjoy interacting with the generated text, we want to avoid alienating them with poorly performing models. We measure the impact of (1) including history information from the immediately preceding entry in the story, and (2) using Cassowary to densely pack the context. In total, we fine-tune four models on the Cartesian product of these complementary modeling ideas, keeping all other hyperparameters constant, and deploy these models to STORIUM.

The results (Table 4) highlight the importance of both modeling choices: after including more story history and applying the Cassowary solver, validation perplexity decreases while STORIUM user ratings of fluency, coherence, relevance, and likability all increase. This motivates us to use only the best-performing model for the full-scale evaluation. Additionally, user feedback from these experiments suggested that we generate *shorter* entries, as longer ones frequently devolved into unrelated and incoherent sentences. Thus, for our final experiments detailed in the next section, we also truncate model outputs to a maximum of four sentences.

Cas	His	F	C	L	R	Ppl	Jdg
		3.4	2.9	3.8	2.3	25.1	90
	✓	3.1	2.7	3.9	2.3	22.4	77
✓		3.6	2.8	3.6	2.4	22.9	62
✓	✓	**3.7**	**3.2**	**4.1**	**2.7**	**21.0**	85

Table 4: Exploratory experiments indicate optimally packing tokens using Cassowary (Cas), and including more history (His) is key to achieving low perplexity (Ppl), along with high fluency (F), coherence (C), likability (L), and relevance (R) based on a number of user judgments (Jdg).

4 A Machine-in-the-Loop Evaluation Platform

The inadequacies of existing human and automatic evaluation methods are a major roadblock for story generation research. Automatic evaluations correlate weakly with human judgments (Sagarkar et al., 2018), and these judgments are obtained from crowd workers who are not invested in the narratives they are assessing. These concerns are magnified with STORIUM, as the story contexts are far too long for crowd workers to reliably evaluate (Section 5). In this section, we propose an improved evaluation methodology by directly integrating our models onto the STORIUM platform. This allows story *authors* to query a machine (Clark et al., 2018) for suggestions during the process of writing their own stories. We develop a new evaluation metric, User Story Edit Ratings (USER), computed on top of the *edits* that STORIUM users make to generated entries. Finally, we provide experimental results that compare two configurations of our best model from Section 3.2.

4.1 Evaluation Lifecycle

To evaluate generated stories, we develop a dedicated web service for serving model outputs to the STORIUM platform. STORIUM users simply press a button on the user interface to obtain a generated scene entry conditioned on the story context. Users can then add new text while deleting any of the generated text that they wish (Figure 1). When users publish their edited entry, they are also asked to evaluate the generated text on a 5-point Likert scale[10] with respect to *relevance* (fit with the current story), *fluency* (judgment of grammaticality), *coherence* (logical ordering of sentences), and *likability* (subjective assessment of enjoyability). This process allows experts (STORIUM authors)

---

[10] They also provide optional freeform comments on generated text; we leave analysis of the comments to future work.

to evaluate generated stories, which is a substantial improvement over prior evaluation efforts. We make our evaluation platform publicly accessible for researchers to develop and integrate their own models. Our framework makes adding a new model using any Python-based deep learning framework very easy, requiring implementation of only four methods: `startup`, `shutdown`, `preprocess`, and `generate`.

4.2 A Metric Over User Edits

Intuitively, the amount of generated text that a user preserves in their final published entry clearly indicates the usefulness of the generated text. We quantify this by developing User Story Edit Ratings (USER), inspired by the longest common subsequence (LCS) variant of ROUGE (Lin, 2004), applied to user edits. Given a generated entry X and the final published entry Y, we compute $\text{USER}(X, Y) = \frac{|\text{MATCH}(X,Y)|}{|X|}$, where $\text{MATCH}(X, Y)$ considers *contiguous substrings* with at least one non-stopword as matches (see Figure 1 for an example and Appendix C for a more thorough treatment). We do not use ROUGE-L because vanilla LCS typically favors subsequences of unigram matches (often stopwords) over longer contiguous n-gram matches. In our STORIUM setting, users preserving n-grams or full sentences is a clear indication that the generated text was useful.

5 Analysis

Compared to existing work on story generation, the main novelty of our STORIUM evaluation platform is that it enables authors to interact directly with model-generated text through their edits. In this section, we conduct experiments on our platform and analyze the edits by examining the correlation of USER to Likert scores. We explore linguistic properties of text that users preserve and also conduct a crowdsourced evaluation on Amazon Mechanical Turk that demonstrates its unsuitability for this task. Finally, we qualitatively describe feedback obtained from interviews with ten STORIUM users who engaged with our models, which provides a roadmap for future work.

Top-k vs. nucleus sampling: Using our platform (Section 4), we evaluate our best model (Table 4) with two different decoding strategies: (1) top-k sampling (Fan et al., 2018) with $k = 40$, and (2) nucleus sampling (Holtzman et al., 2020) with $p = 0.9$.[11] The sampling parameters, such as the k in top-k sampling, can significantly affect output quality of story generation models (See et al., 2019), so we choose values that worked well in prior work (Qin et al., 2019).[12]

		Lik	Flu	Coh	USER	Rating
Rel	top-k	0.51	0.28	0.55	0.51	**2.55**
	nucleus	0.53	0.40	0.57	0.39	2.47
Lik	top-k	—	0.28	0.35	0.34	**3.32**
	nucleus	—	0.38	0.55	0.35	3.21
Flu	top-k	—	—	0.54	$0.13^{\dagger}$	**3.96**
	nucleus	—	—	0.61	0.23	3.76
Coh	top-k	—	—	—	0.25	**3.41**
	nucleus	—	—	—	0.36	2.96
USER	top-k	—	—	—	—	**15.63**
	nucleus	—	—	—	—	9.86

Table 5: Despite its low rating, relevance is clearly important as indicated by the moderately strong Pearson's r correlations (first four columns) with USER and the remaining human judgments. All correlations are significant ($p < 0.01$), except those indicated by † ($p > 0.05$).

Interestingly, while Holtzman et al. (2020) show that nucleus sampling improves over top-k sampling on measures like repetition, STORIUM users clearly prefer the top-k variant across all categories (last column of Table 5). We collect roughly 200 feedback ratings and 175 edits for each model over a span of three months beginning in late February 2020. We discover that both configurations score best on *fluency* and worst on *relevance*. This is unsurprising as (1) GPT-2 is known to produce fluent text and (2) the complex and lengthy STORIUM data is a challenge for limited-context models. Finally, USER scores are generally low (15.6 for top-k vs. 9.9 for nucleus sampling), indicating that users delete most of the current model's generated text. This result demonstrates that story generation models still have a long way to go.[13]

USER correlates with human judgments: A natural question is whether our USER metric correlates with judgments of fluency, coherence, relevance, and likability. Table 5 shows that for the top-k configuration, relevance has a significantly higher correlation (Pearson's r) with USER than the other properties. In other words, users are most

---

[11] We use a temperature of 0.9, a repetition penalty (Keskar et al., 2019) of 1.2, and an analogous length penalty that dynamically penalizes producing the end of sequence token inversely proportionally to a desired length l_d.

[12] It is possible that a better set of sampling hyperparameters exists, which we leave to future work.

[13] See the supplementary HTML for an export of all results (including generated text and edits) used for this paper.

	Top-k		Nucleus	
First Run	Rating	κ	Rating	κ
Fluency	**3.59**	0.17	3.47	0.11
Coherence	**3.50**	0.10	3.44	0.20
Likability	**3.27**	0.07	3.22	0.11
Relevance	**3.32**	0.09	3.27	0.13

	Top-k		Nucleus	
Second Run	Rating	κ	Rating	κ
Fluency	**4.01**	0.46	3.77	0.33
Coherence	**3.63**	0.27	3.38	0.23
Likability	**3.28**	0.12	3.06	0.16

Table 6: Despite our best efforts, our first crowd sourced judgments show low agreement (κ) on open-ended story generation. Our second run, which removes context, thus excluding relevance judgments, greatly increases agreement for fluency and coherence.

likely to preserve generated text when it is relevant to the overall story. Fluency correlates only weakly with USER, which makes sense as most generated entries are fluent due to GPT-2's pretraining. Finally, nucleus sampling exhibits lower correlation for relevance, but higher correlation for the other three properties, possibly due to its lower average scores for these properties (see Appendix C for a comparison of USER to ROUGE-based metrics).[13]

Linguistic properties of preserved text: Knowing that users delete most of the generated text, we instead explore the linguistic commonalities of the preserved text. We run spaCy part-of-speech tagging and named entity recognition (Honnibal and Montani, 2017) over the edited entries. Strikingly, 29.5% of generated proper nouns are preserved in the edited text, compared to only 13.5% for all other POS tags. A major confound is that our model could unfairly receive credit for simply copying character names from the input context, as users are likely to write about these characters anyway. To measure the extent of this effect, we match all generated named entities that users preserve to predefined character lists from each story, and discover that 63% of generated entities already exist within the story context. The remaining 37% of entities are often completely new character names. User interviews also suggest that this ability to generate new names is a useful feature.

Crowdsourced evaluation is unreliable: Thus far, we have argued for our evaluation platform by claiming that crowdsourced methods are unsuitable for evaluating stories with complex and lengthy contexts. Here, we measure fluency, coherence, relevance, and likability of our generated entries with a crowdsourced Amazon Mechanical Turk task, to see if the results correspond to STORIUM user ratings. Designing this crowdsourced task is difficult, as we cannot show crowd workers the entire story context due to its length; we thus decide to show the same inputs that the model receives (Section 3). We collect ratings of 100 examples per model, with three judgments per example.[14]

Table 6 (top) shows that workers have very low agreement (Fleiss' κ) for all properties, including even fluency. An analysis of the median task completion time[15] reveals most workers did not actually read the context. We run a second experiment, showing only the generated text (no context), and remove the relevance rating. Table 6 (bottom) shows this improves agreement (Table 6), and that the average fluency scores align closely with those from STORIUM users. Overall, our struggle to obtain quality judgments from Mechanical Turk further validates our platform: STORIUM provides free expert judgments from people invested in storytelling.

Feedback from user interviews: To better understand the strengths and weaknesses of our current model, we conduct semi-structured interviews with ten STORIUM users. Most were surprised with the overall fluency of our models. This partly explains the low correlation of fluency with USER. Relevance was mentioned by 9 out of 10 users as the number one area of improvement for our model, confirming our experimental results (Table 5). Four users called out the model's tendency to fabricate facts and introduce new characters. Despite these concerns, three users explicitly stated the model inspired them to write or found portions of the generated text useful, though mostly as a source for character and place names (supporting the linguistic analysis in Section 5). Finally, some users considered the system a curiosity and decided to write stories using only generated text (without edits).[16]

---

[14] We limit annotations to crowd workers living in the US and the UK, with over 1000 completed annotations and a 99% approval. We pay \$0.50 per annotation, by assuming 2 minutes per annotation, for an effective hourly rate of \$15.

[15] Mechanical Turk automatically reports a *WorkTimeInSeconds* field for each annotation, which is ten minutes on average for our task — more than enough time to read and assess the generated entry and associated context. Sadly, this interval is misleading. Analyzing the median time between submits, we see workers accept multiple concurrent tasks, wait a few minutes, then submit each annotation in quick succession, thus inflating the *WorkTimeInSeconds* interval.

[16] These AI-guided narratives are prevalent enough that we manually exclude these games from our experiments as they

6 Related Work

Our work builds on prior research in computational modeling for story generation. Early narrative prose generation systems (Meehan, 1977; Callaway and Lester, 2001; Riedl and Young, 2004) relied on graph-based planning formalisms and custom rules to structure their narratives, while story graphs have been used for interactive storytelling (Riedl and Bulitko, 2013). More recent work uses deep learning to generate stories by training neural models with limited context (Peng et al., 2018; Fan et al., 2018; Goldfarb-Tarrant et al., 2019) and structured knowledge, either external (Mao et al., 2019; Guan et al., 2020; Goldfarb-Tarrant et al., 2020) or derived (Yao et al., 2019; Fan et al., 2019). Compared to the datasets studied in those works, our STORIUM dataset contains much longer stories with built-in structural annotations written in natural language in the form of cards (Table 2).

Our work connects more closely to existing machine-in-the-loop storytelling work (Roemmele and Gordon, 2015; Samuel et al., 2016; Clark et al., 2018), in which systems work in concert with users to collaboratively author a narrative. Much like the Creative Help platform of Roemmele and Gordon (2015), we provide writing assistance by interactively generating continuations of STORIUM stories. We improve over Roemmele and Gordon (2015) by evaluating a trained model (instead of a retrieval-based approach) with a large user population.

Finally, our STORIUM evaluation takes a different approach to prior research that measures the quality of generated stories. Sagarkar et al. (2018) train an automatic scorer on human annotations of overall story quality, relevance, and interestingness based on evaluation criteria from (McIntyre and Lapata, 2009). See et al. (2019) consider a number of *diversity* related measures for automated evaluation of story generation systems by focusing on the GPT-2 small model, noting that *quality* assessments are still best measured through human evaluation.

Limitations

Evaluating on the STORIUM platform enables researchers to receive high-quality judgements on the outputs of their story generation models. These judgements are made possible by the significant time and effort spent by real authors on crafting their narratives, as their incentives are substantially different than those of crowdsourced workers. The amount of author effort involved in evaluation, when combined with the relatively small size of the STORIUM community, can cause evaluation to take a considerable amount of time (i.e., to collect hundreds of judgements) as evidenced in our analysis (Section 5). Thus, our platform is not currently suitable for "instant" evaluation of generated stories. Furthermore, as the evaluation platform is specifically deployed on STORIUM, it cannot be trivially used to evaluate models trained on other story generation datasets, as users of the website are mainly invested in writing narratives that follow the STORIUM format.

7 Conclusion

We introduce the STORIUM dataset and evaluation platform for machine-in-the-loop story generation, built from an online collaborative storytelling community. STORIUM contains 6K long stories annotated with structural metadata useful for conditioning language models. Importantly, *real* STORIUM *authors* evaluate model outputs by adding and removing text to create their own stories. We devise a metric on top of their edits that correlates strongly with judgments of the *relevance* of the generated text, which user interviews suggest is the most important area for improvement moving forward. Our dataset and evaluation platform will be made publicly available to spur progress into story generation.

Appendix

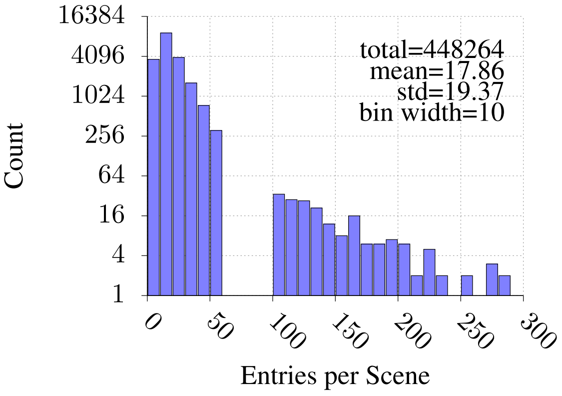
A Additional Dataset Statistics

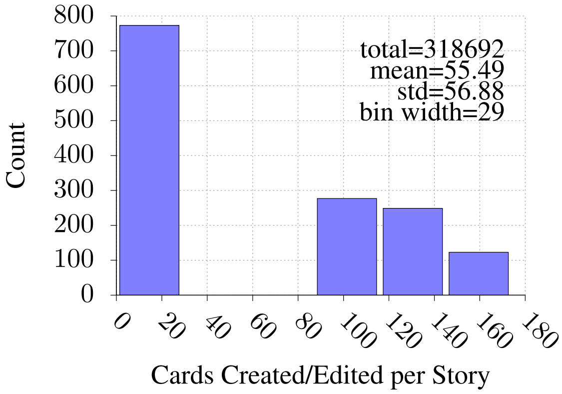
As our dataset derives from a collaborative storytelling game that is highly compositional by nature, it is difficult to concisely capture the full scope of the data within the main body. Here we highlight the full results of our small scale annotation that indicates cards influence the scene entry text.

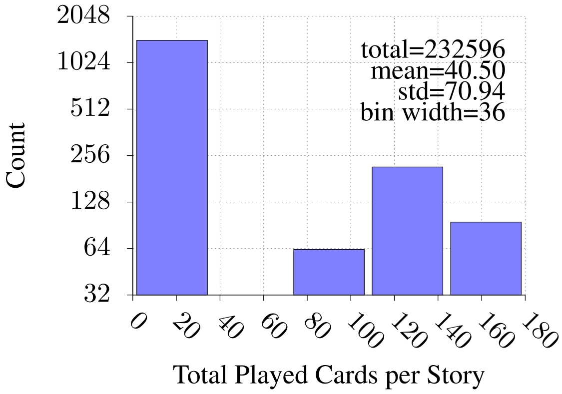
Total Annotations	248
Valid Entries†	235
Card Influences Entry	182
Entry Addresses Challenge	189
Card Influence ∩ Challenge Addressed	151

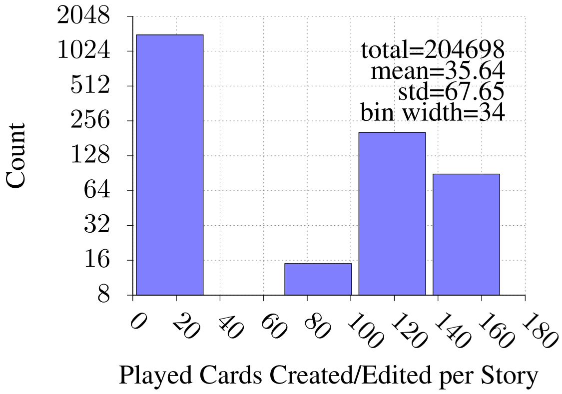
Table A1: We ask annotators to determine how frequently cards influence an entry, and if the entry addresses the challenge. †Annotators were asked to flag stories not written in English or otherwise could not be understood.

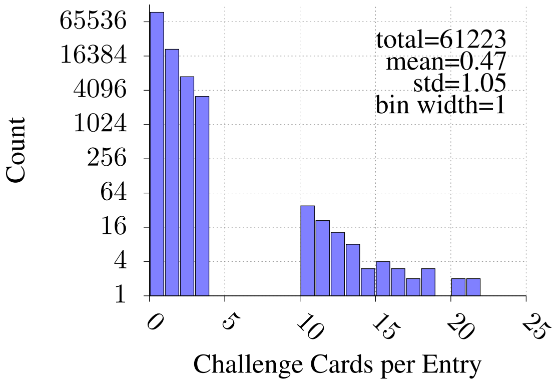
Additionally, there are many small details which are important distinctions in the game, but may not require separate modeling for generating a scene entry. For example, there is a distinction between regular cards, which have a fixed title and description provided by the narrator; versus wild cards, which allow individual characters to write their own title and description. For the sake of completeness, we provide Table A2 to help further explore the depths of this unique dataset. The following histograms[1] further break down the data in Table A2, clearly demonstrating the long tail distributions indicative of user generated stories:











---

B Web Service

Our web service is modular and allows easily adding new models. It consists of a frontend service, which acts as a mediator between STORIUM and each backend service responsible for serving model outputs. The frontend stores data in a PostgreSQL database and provides a dashboard for viewing realtime ratings and evaluation metrics. It also displays user comments, scene entry diffs based on user edits, and Pearson's r correlations among metrics and user ratings — all sortable per model. A new model can be served by simply implementing four methods (`startup`, `shutdown`, `preprocess`, and `generate`). The backend automatically installs all Python requirements for serving a model and is agnostic to the underlying tensor library used. Additionally, we follow the latest best practices, including the use of Docker containers and the Asynchronous Server Gateway Interface (ASGI)[2],the latest Python web standard, which allows for asynchronous programming using `asyncio`.[3] We host the web service using an on-premise server with four 2080Ti GPUs.

C User Story Edit Ratings

Recently, the discriminative power of BLEU has been called into question when evaluating state-of-the-art machine translation systems, leading researchers to investigate alternative evaluation metrics (Freitag et al., 2020; Sellam et al., 2020). Similarly, we question the use of ROUGE metrics for automatic evaluation of open-ended story generation. Using our evaluation platform, we show that USER improves upon ROUGE in the story generation domain.

	Likability		Fluency		Coherence		ROUGE-L		ROUGE-W		USER	
	top-k	nuc	top-k	nuc	top-k	nuc	top-k	nuc	top-k	nuc	top-k	nuc
Relevance	0.51	0.53	0.28	0.40	0.55	0.57	0.52	0.38	0.50	0.36	0.51	0.39
Likability	—		0.28	0.38	0.35	0.55	0.29	0.34	0.28	0.31	0.34	0.35
Fluency	—		—		0.54	0.61	$0.11^\dagger$	0.23	$0.10^\dagger$	0.22	$0.13^\dagger$	0.23
Coherence	—		—		—		0.27	0.38	0.24	0.34	0.25	0.36
ROUGE-L	—		—		—		—		0.98	0.98	0.95	0.93
ROUGE-W	—		—		—		—		—		0.97	0.94

Table A3: USER correlates well with both ROUGE-L and ROUGE-W when removing stopwords.

When evaluating story continuations, we cannot compare against an *a priori* gold standard. Rather, we consider the final published story a user generates to be the gold standard, and thus evaluate models by how much text the user retains. Using ROUGE-L *precision*, which simply computes the ratio of the longest common subsequence (LCS) with the number of tokens in the generated text, we can measure this quantity.

As highlighted by Lin (2004), ROUGE-L contains a subtle mismatch with expectations, as the LCS does not consider *locality* of matches — assigning equal weight to subsequences of the same length even when the distance between matched words differs. Given a reference sequence X, the following two candidate sequences Y_1 and Y_2 produce the same ROUGE-L score (an underscore indicates a subsequence match):

$$X : [\underline{A}\ \underline{B}\ \underline{C}\ \underline{D}\ E\ F\ G]$$
$$Y_1 : [\underline{A}\ \underline{B}\ \underline{C}\ \underline{D}\ H\ I\ K]$$
$$Y_2 : [\underline{A}\ H\ \underline{B}\ K\ \underline{C}\ I\ \underline{D}]$$

ROUGE-W tries to address this shortcoming by introducing a weighting which favors subsequences with less separation. Sadly, for long texts, both ROUGE-L and ROUGE-W often favors long *subsequences* of stopwords over *contiguous substrings*, a sign that a user clearly used part of the output unchanged. While acceptable for short summaries, this is much less appropriate for long-form open-ended text generation. Removing stopwords helps alleviate the mismatch, so we do so in our comparison to ROUGE (Table A4), though the fundamental issue still remains. This mismatch calls into question the ability of ROUGE-L and ROUGE-W to distinguish among models with strong story generation capability.

	Top-k		Nucleus	
	Score	Count	Score	Count
ROUGE-L	**28.61**	174	20.66	178
ROUGE-W	**20.73**	174	13.80	178
USER	**15.63**	174	9.86	178

Table A4: USER produces lower scores on average than ROUGE-L or ROUGE-W.

Our new metric, User Story Edit Ratings (USER), is based on a diff-like approach. We begin by applying the same text preprocessing as ROUGE. Afterwhich, we find the longest contiguous substring, then use it as a pivot to divide the remaining string into two halves (excluding the pivot), and recursively repeat the process in each half.[4] We then only consider substrings with at least one non-stopword as matches (careful scrutiny of Figure 1 reveals an unmatched stopword *it*). Subsequently, we compute precision, recall, and F1 identically to ROUGE.

Table A3 shows USER correlates with user judgments approximately similarly to ROUGE metrics, while correlating strongly with both metrics. Additionally, USER produces lower scores on average compared to ROUGE (Table A4). Taken in combination, these insights indicate USER is better capable of discerning differences among the strong story generation models of the future, as it provides more stark evaluations while still correlating well with human judgments.

Substance over Style:
Document-Level Targeted Content Transfer

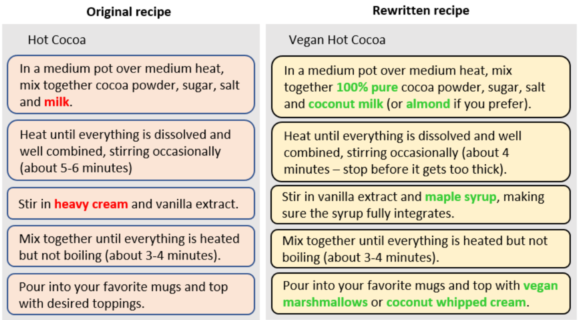
Abstract

Existing language models excel at writing from scratch, but many real-world scenarios require rewriting an existing document to fit a set of constraints. Although sentence-level rewriting has been fairly well-studied, little work has addressed the challenge of rewriting an entire document coherently. In this work, we introduce the task of document-level targeted content transfer and address it in the recipe domain, with a recipe as the document and a dietary restriction (such as *vegan* or *dairy-free*) as the targeted constraint. We propose a novel model for this task based on the generative pre-trained language model (GPT-2) and train on a large number of roughly-aligned recipe pairs.[1] Both automatic and human evaluations show that our model out-performs existing methods by generating coherent and diverse rewrites that obey the constraint while remaining close to the original document. Finally, we analyze our model's rewrites to assess progress toward the goal of making language generation more attuned to constraints that are substantive rather than stylistic.

1 Introduction

We often think that writing starts from a blank page, but in practice, writing often involves adapting an existing document to fit a new context. This might involve rewriting documentation written for a Mac so that it will apply to a PC, rewriting a lesson plan for a different grade level, or rewriting a product description to appeal to customers in multiple regions. Automating such rewriting is valuable but challenging, since it requires learning to make coordinated changes spanning an entire document while adhering to constraints that apply not to the style but to the substance of the document.



Original recipe	Rewritten recipe
Hot Cocoa	Vegan Hot Cocoa
In a medium pot over medium heat, mix together cocoa powder, sugar, salt and **milk**.	In a medium pot over medium heat, mix together **100% pure** cocoa powder, sugar, salt and **coconut milk** (or **almond** if you prefer).
Heat until everything is dissolved and well combined, stirring occasionally (about 5-6 minutes)	Heat until everything is dissolved and well combined, stirring occasionally (about 4 minutes – stop before it gets too thick).
Stir in **heavy cream** and vanilla extract.	Stir in vanilla extract and **maple syrup**, making sure the syrup fully integrates.
Mix together until everything is heated but not boiling (about 3-4 minutes).	Mix together until everything is heated but not boiling (about 3-4 minutes).
Pour into your favorite mugs and top with desired toppings.	Pour into your favorite mugs and top with **vegan marshmallows** or **coconut whipped cream**.

Figure 1: Document-level targeted content transfer in the recipe domain: given a hot cocoa recipe and the user constraint *vegan*, the task is to rewrite the recipe into a vegan hot cocoa recipe.

We introduce the novel task of **document-level targeted content transfer**, defined as rewriting a document to obey a user-provided constraint resulting in some systematic alteration of the document's content. Success at this task involves both transfer and controlled generation at the document level. Prior work on controlled generation guides the output of a model using attribute classifiers (Dathathri et al., 2020) or control codes (Keskar et al., 2019), but we find that these models do not perform well on our transfer task (§4.1.2). In contrast, models built for the transfer task are generally trained at the sentence level (Hu et al., 2017b,a; Li et al., 2018; Rao and Tetreault, 2018; Syed et al., 2019).

Document-level transfer has typically found success by rewriting each sentence independently (Maruf et al., 2019). However, many real-world rewriting scenarios require interdependent changes across multiple sentences. A clear example is cooking, where rewriting a hot cocoa recipe to make it *vegan* requires more than just substituting "coconut milk" for "milk" in a single step—it may also require changing the cooking times and techniques, adjusting ingredient amounts, or replacing other ingredients like toppings or spices (Figure 1). Such

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6485–6504,
November 16–20, 2020.

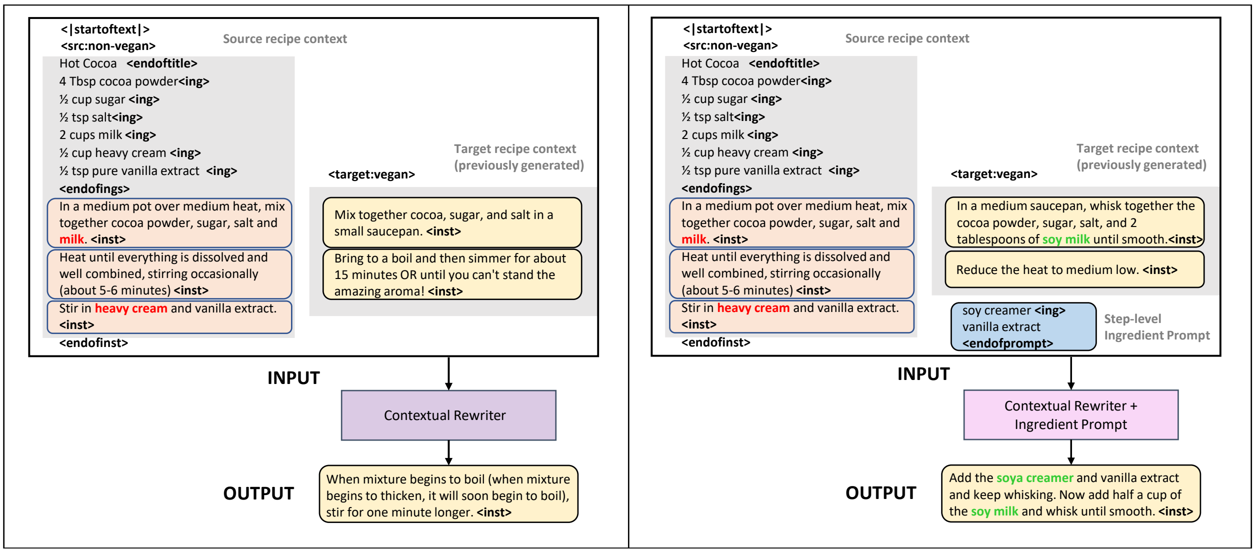

Figure 2: Rewrites of the source n^{th} step obtained by the two variants of our proposed model (at test time): (left) Contextual Rewriter, which uses the source context until the n^{th} step and the target context until the $(n-1)^{th}$ step to generate the target n^{th} step; and (right) Contextual Rewriter + Ingredient Prompt, which uses the same context as the previous variant with the addition of a step-level ingredient prompt.

a rewriting task is substantive rather than stylistic because it changes the content of the recipe, while a stylistic transfer on recipes might instead focus on rewriting a recipe for a different audience, reading level, or writing style such that the content remains the same and only the expression of the recipe changes.

In this work, we address the task of document-level targeted content transfer in the recipe domain, where the document is a recipe and the target constraint is a dietary restriction such as *vegan*. Given a recipe (source) and a dietary constraint, the task is to rewrite it into a new recipe (target) that obeys the constraint. Training a fully-supervised model for this task requires a large number of (recipe, rewritten recipe) pairs, which are difficult to obtain at scale. We therefore leverage an alignment algorithm (Lin et al., 2020) to construct our *noisy* training data pairs where the source is a recipe that violates a dietary constraint and the target is another recipe for the same dish that obeys the constraint but may not be similar to the source (§2).

We propose a novel model for this task which learns to rewrite a source document one step at a time using document-level context. We start with the recently successful generative pre-trained (GPT-2) language model (Radford et al., 2019) and fine-tune it on text that combines {document-level context, source step, constraint, target step} using appropriate separators. We investigate two variants of our model in the recipe domain:

Contextual Rewriter (§3.1) where the context includes the source recipe (including title, list of ingredients, and steps), any previously rewritten steps, and the targeted constraint (Figure 2 left);

Contextual Rewriter + Ingredient Prompt (§3.2) where, in addition to the context discussed above, we predict a set of step-level ingredients to prompt our rewriter model (Figure 2 right).

We compare our proposed models to sentence-level transfer baselines that rewrite each recipe step independently, and to document-level controllable baselines that ignore the source recipe and only control for the dietary constraint (§4.1). We use automatic metrics and human judgments to evaluate the rewritten recipes, measuring their overall quality, their fluency, their dietary constraint accuracy, and their ability to produce diverse outputs without straying too far from the source recipe (§4.2). Comprehensive experiments demonstrate that our proposed model outperforms baselines by simultaneously accomplishing both transfer and control, but still lacks the substantive knowledge humans rely on to perform well at this task (§4.5). Finally, we conduct an in-depth analysis of various model rewrites and the strengths and weaknesses of the models (§5).

2 Dataset Creation

The recipe domain, constrained by dietary restrictions, is particularly well-suited to our task since recipes are commonly rewritten according to dietary constraints in real-world scenarios[2], and this process often requires multiple related changes across the recipe. To construct our dataset, we use three steps: collect recipes spanning a range of dietary constraints (§2.1), tag recipes with dietary constraints using a rule-based method (§2.2), and align recipes into pairs with similar content but opposite dietary tags (§2.3).

Although our model relies on large amounts of parallel data, we obtain this parallel data automatically by running an unsupervised alignment algorithm (Lin et al., 2020) on non-parallel data. Large collections of non-parallel data are readily available on the web for many other domains, such as lesson plans for different grade levels or technical documentation for different operating systems. With the methods outlined in this section, non-parallel data can be aligned and transformed into a parallel dataset for transfer tasks in other domains.

2.1 Collect Recipes

We collect English recipes from online recipe websites.[3] We remove recipes that lack a title or a list of ingredients, or that have less than two steps. The resulting dataset contains 1,254,931 recipes, with a median of 9 ingredients and 9 steps.

2.2 Tag Recipes with Dietary Constraints

We consider seven dietary constraints: dairy-free, nut-free, egg-free, vegan, vegetarian, alcohol-free, and fish-free.[4] For each dietary constraint, we obtain a list of ingredients that violate it using food lists from Wikipedia.[5] We then compare each recipe's ingredients against that list, and tag it *valid* if there are no violating ingredients, or *invalid* if a violating ingredient is in the recipe.

Dietary Constraint	Recipe Pairs Train	Dev	Test	Step Pairs Train
Diary-Free	194,309	10,607	9,190	2,552,492
Nut-Free	161,596	8,722	8,989	2,060,228
Egg-Free	124,207	5,786	5,662	1,794,047
Vegan	110,718	5,708	4,859	1,765,865
Vegetarian	59,847	2,765	2,629	682,845
Alcohol-Free	52,157	2,348	2,136	570,627
Fish-Free	34,786	1,546	1,278	383,162

Table 1: Number of recipe pairs and step pairs for each dietary restriction in our data.

2.3 Create Recipe and Step Pairs

Our goal is to find recipe pairs for the same dish where one obeys a dietary constraint and the other violates it. Lin et al. (2020) propose a method for automatically aligning two recipes of the same dish. We use their method to first group recipes into dishes, and then find aligned pairs of recipes within a dish where one is valid and the other is invalid. Table 1 shows the number of recipe pairs in our dataset for each dietary constraint. It should be noted that these pairs are *noisy* for our rewrite task since the pairs were not created by rewriting.

The alignment algorithm also gives an alignment score at the step level. We threshold on this score to keep only the highest-quality step pairs. Further, in cases where a single source step is aligned to more than one target step with a high score, we combine the target steps together into one, enabling our rewrite model to learn to rewrite one step into multiple steps whenever appropriate. Table 1 (rightmost column) shows the total number of high quality step-level pairs for each dietary constraint that we use to train our rewrite model.

3 Model Description

We propose two model variants for document-level targeted content transfer in the recipe domain. Given a recipe and a dietary constraint, the goal is to rewrite the recipe one step at a time to fit the dietary constraint.

3.1 Contextual Rewriter

We start with a pre-trained GPT-2 model which is trained on text from 45 million websites with a language modeling objective to predict the next word given previous words.[6] We fine-tune this model

---

[2] In a survey of 250 randomly selected user comments from recipe websites, we found that one third discussed modifying the recipe, often to accommodate dietary restrictions. In addition, U.S. public school cafeterias are required by law to accommodate food allergies and other dietary needs (USDA, 2017). Such rewriting that is currently done manually could benefit from our proposed automated approach.

[3] Websites include Food.com, AllRecipes.com, FoodNetwork.com, and 8 other websites, as well as four existing recipe datasets. Appendix contains full list and associated statistics.

[4] Each of these constraints is commonly mentioned in recipe titles, and is one of the most common diets (USDA, 2020) or dietary restrictions (FDA, 2020).

[5] E.g. for the dairy-free constraint, we used `https://en.wikipedia.org/wiki/Dairy_product`.

[6] This and any future discussion of a pre-trained GPT-2 model refers to the GPT-2 medium model available at `https:`

using the same language modeling objective on the train split of step-level recipe pairs (Table 1). The left column of Table 2 shows how we format our pairwise data for fine-tuning. Given an aligned pair of a source step (n) and a target step (n'), we prepend the source step n with the source recipe's title, ingredients, and steps from 1 to $(n-1)$; we also prepend the target step n' with target steps from 1 to $(n'-1)$. We use separators to demarcate each piece of contextual information. Further, to allow the GPT-2 model to understand the dietary constraint, we prepend the entire source-level context with a special tag <src:non-constraint> (e.g. non-vegan) and prepend the entire target-level context with a special tag <tgt:constraint> (e.g. vegan).

Note that during fine-tuning we use only those steps of a recipe that have been aligned into a pair with a high alignment score (§2.3). However, at test time, we rewrite all steps in the source recipe using the fine-tuned model. Also, during fine-tuning, we use the teacher forcing strategy: while rewriting source step n, the target recipe context corresponds to the true target steps 1 to $(n'-1)$, whereas during test time, the target recipe context corresponds the previously generated steps 1 to $(n-1)$.[7]

3.2 Contextual Rewriter + Ingredient Prompt

We observe that the rewriter described above often uses ingredients and techniques that diverge from the source recipe. For example, on the left side of Figure 2, the rewritten output diverges from the source recipe when it ignores the ingredients of *"heavy cream and vanilla extract"* in the source step rather than suggesting an appropriate vegan alternative. We hypothesize that if the model had the capacity to accept step-level ingredients (in the form of a prompt) as an additional input while rewriting each step, then it could learn to follow the source recipe more closely. This strategy has proven effective in other domains, including automatic storytelling, where prompting a model with a rough "storyline" helps models stay on-topic (Yao et al., 2018).

We therefore propose a variant of the previous model that uses step-level ingredients as a prompt in addition to document-level context. We again start with a pre-trained GPT-2 model and fine-tune it on the train split of step-level recipe pairs (Table 1) using a different data format (see the right column of Table 2). As in the previous model, we use the source recipe data until step n and the target recipe steps until $(n'-1)$. But before including the target step n', we prompt with the ingredients in n' separated by an <ing> separator, and end with an <endofprompt> special token. This enables our model to learn to use the ingredient prompt while generating the rewrite.

< |startoftext| >	< |startoftext| >
<src:non-constraint>	<src:non-constraint>
src_title <endoftitle>	src_title <endoftitle>
src_ingredient 1 <ing>	src_ingredient 1 <ing>
...	...
src_ingredient K	src_ingredient K
<endofings>	<endofings>
src_step 1 <inst>	src_step 1 <inst>
...	...
src_step n	src_step n
<endofinst>	<endofinst>
<tgt:constraint>	<tgt:constraint>
tgt_step 1 <inst>	tgt_step 1 <inst>
...	...
tgt_step n'	tgt_step $(n'-1)$
<endofinst>	<endofinst>
< |endoftext| >	tgt_step n' ingredient 1 <ing>
	...
	tgt_step n' ingredient K'_n
	<endofprompt>
	tgt_step n'
	< |endoftext| >

Table 2: Data format for fine-tuning a GPT-2 model to rewrite source recipe step n into target recipe step n' (where n' is aligned to n) using our Contextual Rewriter (left) and our Contextual Rewriter + Ingredient Prompt (right).

We investigate two methods for generating the step-level ingredient prompt. During fine-tuning, we use the rule-based method. At test time, we generate results using both methods.

Rule-based ingredient prompt: Given a source recipe step, we first identify all ingredients mentioned in the step.[8] We then use a rule-based method to substitute any ingredients that violate the dietary constraint with alternatives from a food substitution guide (Steen and Newman, 2010). While there is work on automatically substituting recipe ingredients with similar ones (Teng et al., 2012; Boscarino et al., 2014; Yamanishi et al., 2015), to our knowledge no work makes recipe substitutions in accordance with dietary constraints.

`//github.com/huggingface/transformers`.

[7] For decoding, we use top-k sampling ($k = 40$). Appendix contains implementation details for all models.

[8] For each ingredient in the recipe's ingredient list, we find the longest n-gram match between ingredient and step, ignoring common recipe stopwords such as "tablespoons" and descriptors like "chopped."

GPT-2 ingredient prompt: We use a GPT-2 model to predict the step-level ingredients to use as prompts. We first collect a dataset of recipe steps from ~1.2 million recipes (from §2.1). We extract the ingredients from each recipe step using the rule-based method above. We then construct texts by combining {recipe title, full list of ingredients, steps 1 to $n-1$, ingredients in step n} and fine-tune another GPT-2 model on this text.[9]

4 Experimental Results

We aim to answer the following research questions:

1. Do generation-based rewriters outperform simpler non-learning baselines (§4.1.1)?
2. Do our proposed rewriters do a better job of staying close to the source recipe while obeying the constraint compared to controllable generation models (§4.1.2) that obey the constraint but ignore the source recipe?
3. Do our proposed document-level rewriters outperform sentence-level rewriters (§4.1.3)?
4. Does using ingredients as a prompt help our proposed rewriter stay close to the source recipe while obeying the dietary constraint?
5. Finally, how do models compare to human performance on the rewrite task (§4.5)?

4.1 Baselines and Model Ablations

4.1.1 Non-learning Baselines

Rule-Based: We use the rule-based method discussed in §3.2 to rewrite each step independently. This baseline only substitutes ingredients and does not change the cooking times or techniques that may be required for the substitutions to fit.

Retrieval: We imitate a simple approach to the recipe rewrite task: searching the web for a version of the dish that obeys the given dietary constraint. Given a source recipe, we determine the dish to which this recipe belongs and retrieve a recipe for the same dish that fits the dietary constraint from the combined pool of train, dev, and test recipes.

4.1.2 Document-level Controllable Baselines

We build the following baseline models by providing the title and ingredient list of the target recipe (which obeys the dietary constraint) as the prompt to generate the first target recipe step. For generating each of the subsequent n^{th} steps, we append the previously generated steps 1 to $(n-1)$ to the prompt. We stop when the model has generated as many steps as there are in the source recipe.

PPLM: Plug-and-Play Language Model (Dathathri et al., 2020) combines a pre-trained language model with a classifier to guide the generation toward a user-specified attribute. We build a PPLM model for our task using a GPT-2 model fine-tuned on ~1.2 million recipes (§2.1) as the pre-trained language model and using separate bag-of-words classifiers for each of our dietary constraints.[10]

CTRL: The conditional transformer language model (Keskar et al., 2019) uses a 'control' code to govern the style and content of the generated text. For our task, we use the "Links" control code to specify the recipe domain.[11]

4.1.3 Sentence-level Transfer Baselines

We build additional baseline models for rewriting each step independent of context and train them on our recipe step pairs (Table 1).

Seq2Seq Copy: We use a sequence-to-sequence model that is enriched with a copy mechanism (Jhamtani et al., 2017). We train separate models for each of our dietary constraints.

Transformer We train a transformer (Vaswani et al., 2017) model with byte-pair encoding.[12]

4.1.4 Model Ablations

No-Source Rewriter: We fine-tune a pre-trained GPT-2 model on ~1.2 million recipes (from §2.1) with a simple language modeling objective. This ablation does not make use of the source recipe, but rather uses only the title and the ingredient list of the aligned target recipe as the prompt, generating the target recipe sequentially.

End-to-End Rewriter: This model variant is trained end-to-end to rewrite the entire source recipe at once rather than one step at a time. As a prompt, it takes a dietary constraint, a source recipe (title, ingredients and steps), and the title and ingredients of the target recipe. We start with a GPT-2 pre-trained model and fine-tune it on the train split of our recipe pair data (Table 1) for our task.

---

[9] Data format used for fine-tuning is included in appendix.

[10] See appendix for PPLM implementation details.

[11] See appendix for CTRL implementation details.

[12] We use the implementation at `https://github.com/gooppe/transformer-summarization`.

	Fluency	Dietary Constraint	Closeness to Source	Diversity
Model	Perplexity ↓	% Adherence ↑	ROUGE ↑	Trigram ↑
Non-learning Baselines				
Rule-Based	10.24	96.1	*98.76*	0.550
Retrieval	**9.01**	93.4	28.40	0.344
Document-level Controllable Baselines				
PPLM	9.28	94.9	20.48	0.577
CTRL	13.47	94.3	24.69	0.418
Sentence-level Transfer Baselines				
Seq2seq Copy	15.60	99.0	25.98	0.145
Transformer	9.88	93.5	30.67	0.360

No-Source Rewriter	N/A	96.4	20.35	0.548
End-to-End Rewriter	9.51	97.0	25.60	0.488
No-Context Rewriter	10.79	**99.9**	31.81	0.615
Contextual Rewriter	11.61	**99.6**	31.16	0.634
+ GPT-2 Ingredient Prompt	13.86	**99.6**	28.93	0.590
+ Rule Ingredient Prompt	12.54	**99.5**	**34.06**	**0.674**

Table 3: Automatic metric results on model rewrites of 1000 randomly sampled recipes from the test set. The difference between bold and non-bold numbers is statistically significant with $p < 0.001$. We do not compare to *Rule-Based* under closeness to source since it copies steps from the source, leading to an artificially high score.

No-Context Rewriter: This variant does not make use of the document-level context, but rather learns to rewrite using only (source step, target step) pairs.

Contextual Rewriter: This variant makes use of document-level context, but does not use a step-level ingredient prompt.

Contextual Rewriter + GPT-2 Prompt: At test time, in addition to document-level context, this variant uses the GPT-2 step-level ingredient prediction model (§3.2) to generate an ingredient prompt.

Contextual Rewriter + Rule Prompt: This variant uses the rule-based method (§3.2) to generate an ingredient prompt.

4.2 Evaluation Metrics

4.2.1 Automatic Metrics

We evaluate model rewrites on 1000 recipes each from the test and dev sets on these criteria:

Fluency: We measure the perplexity of the model-generated recipes using a GPT-2 language model fine-tuned on recipe data for fair comparison.[13]

Dietary constraint accuracy: We report the percentage of ingredients in the rewritten recipes that obey the dietary constraint.[14]

Closeness to source:[15] We report ROUGE-L (Lin and Hovy, 2002) recall score between the source recipe and the rewritten recipe.

Diversity: Since generation models can produce results that are bland and repetitive, we measure the diversity of the generated recipes in terms of the proportion of unique trigrams (Li et al., 2015).

4.2.2 Human Judgments

We conduct human-based evaluation using a crowdsourcing platform[16] on rewrites from the best-performing models based on automatic metrics. We randomly sample 150 recipes from our test set with equal proportions of each dietary constraint.

Individual: We ask 5 judges to rate each rewritten recipe on a scale of 1 to 5 on these criteria:

a. Ingredient usage: *"Does this recipe use appropriate ingredients for the type of dish it is making?"*

b. Closeness to source: *"How close is this recipe to the source while fitting the dietary constraint?"* While some difference from the source is necessary for the rewriting task, this metric evaluates whether the recipe has strayed so far from the source that it may no longer be considered a rewriting of the source recipe.

---

[13] We do not report perplexity for the No-Source Rewriter since we use that model to calculate perplexity.

[14] To identify all ingredients in a recipe, we match against a list of foods from `https://foodb.ca/`.

[15] Note that we do not measure closeness to target since we do not have gold target rewritten recipes.

[16] We use `https://www.mturk.com/`. Details on selection, questions, design, and payment in appendix.

c. Dietary constraint: *“Does this recipe fit the specified dietary constraint?”*

d. Overall quality: *“Is this a good recipe for someone who follows this dietary constraint?”* We expect this metric to indirectly reflect qualities for which there are no well-accepted automatic metrics, such as coherence and the appropriateness of the ingredient prompts.

Comparative: We also collect human judgments on head-to-head comparisons between models by displaying two rewrites of the same source recipe side by side: one from our best-performing model (Contextual Rewriter + Rule Prompt) and the other from one of the Rule-Based, Retrieval, End-to-End Rewriter, or Contextual Rewriter models. We ask them to choose which of the two rewrites is better overall. Each pairwise comparison is rated by five judges.

4.3 Automatic Metric Results

While each model has its strengths, our proposed models provide the best balance of both transfer and control. Table 3 shows the results on model rewrites of 1000 randomly sampled recipes from the test set.[17] The retrieval baseline produces the most fluent rewrites, which is expected given that its outputs consist of human-written recipes. However, its scores for closeness to source and adherence to the dietary constraint are considerably lower. Document-level controllable baselines produce more diverse outputs than sentence-level transfer baselines, but sentence-level transfer baselines stay closer to the source recipe. In particular, Seq2seq Copy achieves a high dietary constraint accuracy, but we noticed that this model generates bland and repetitive outputs (as reflected in its diversity score). Each of these models has a shortcoming in a key component of the rewrite task.

Under our model ablations, we find that the No-Source Rewriter earns the lowest score for closeness to source, which is predictable given that it does not see the source recipe. By introducing source context, the End-to-End Rewriter does slightly better, producing fluent rewrites but still lacking diversity and dietary constraint accuracy. By rewriting each step independent of context, the No-Context Rewriter achieves a very high dietary constraint accuracy, but does not stay as close to the source as variants that use context. The model that introduces a GPT-2 predicted ingredient prompt obeys the dietary constraint well, but is not able to maintain diversity while staying close to the source, suggesting that there is room for improvement in how we build our ingredient prediction model. Finally, the rewriter that uses context and a rule-based ingredient prompt performs best across dietary constraint accuracy, closeness to source, and diversity while remaining reasonably fluent.

Model	Ingredient Usage	Dietary Const.	Close to Source	Overall Quality
Rule-Based	4.64	4.70	*4.58*	4.47
Retrieval	4.48	4.40	3.29	3.91
End-to-End	4.64	4.72	3.73	4.52
Contextual	**4.71**	**4.74**	3.84	**4.60**
+ Rule Prompt	4.67	**4.75**	**4.06**	4.57

Table 4: Human judgments on a scale of 1 to 5 on model rewrites of 150 recipes from test set.

4.4 Human Judgment Results

Table 4 shows the results of human judgments on 150 recipe rewrites from the test set.[18] We find that all models except the retrieval baseline achieve similarly high scores. The Contextual Rewriter + Rule Prompt, the best-performing variant of our model according to automatic metrics, performs well in closeness to source and diversity, reaffirming our previous findings.[19] Interestingly, the Contextual Rewriter without an ingredient prompt performs better at ingredient usage and receives the highest overall score. Upon further investigation, we find that the rule-based method we used to generate the ingredient prompt sometimes suggests awkward ingredient substitutions such as *“goat soymilk”*, which leads to a lower ingredient usage score.

Figure 3 shows the results of model comparisons.[20] We find that humans prefer our best model considerably over the retrieval baseline, but the Rule-Based method and the End-to-End Rewriter come close to our best model. The Contextual Rewriter performs similarly to our best model.

4.5 Comparison to Human Rewrite

We ask three experienced cooks who are current or former vegetarians to rewrite 30 randomly sampled non-vegetarian recipes from our test set into vegetarian recipes. We find that the human rewrites

---

[17] Results on 1000 recipes from the dev set are reported in the appendix. They follow the same pattern as the test set.

[18] Inter-annotator agreement (Krippendorff’s alpha) is 0.12.

[19] As with automatic metrics, we do not compare to Rule-Based in closeness to source since it copies from the source.

[20] Inter-annotator agreement (Krippendorff’s alpha) is 0.14.

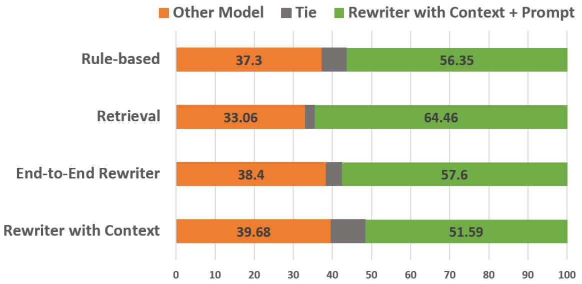

Figure 3: Results of a pairwise comparison between rewrites of our best model and other models on 150 recipes from the test set as judged by human evaluators.

significantly exceed our best model's performance in all four automatic metrics: fluency (perplexity: 13.91 vs. 20.8), adherence to the dietary constraint (99.7% vs. 96.3%), closeness to the source (ROUGE: 77.08 vs. 35.44), and diversity (0.908 vs. 0.836). These findings suggest that there is room for further improvement on this task.

5 Analysis

Simple substitution is not adequate for the task of document-level targeted content transfer. In a recipe that contains a single violating ingredient *"meat"*, the rule-based method makes the minimal edit of substituting *"imitation meat"*, but ignores the other parts of the recipe that must change as a result. Although on automatic metrics our model does only marginally better, qualitatively we found many cases where the rule-based method fails: it always suggests the same substitutions independent of the type of recipe leading to awkward food combinations, it misses a long tail of uncommon ingredients, and it does not make contextual changes to ingredient amounts, cooking times, or techniques. These flaws lead to the rule-based method performing worse than our model according to human judges (Table 4 and Figure 3).

As Figure 4 shows, the Contextual Rewriter + Rule Prompt is capable of more extensive changes based on document-level context. Human evaluators preferred our model's output, which changes multiple ingredients, adds additional techniques, and increases the cooking time. In general, while many of the baseline models tend to produce generic outputs such as *"Preheat the oven"*, our model produces much more diverse recipes and ingredient substitutions.

The larger the number of invalid ingredients for a dietary constraint, the more difficult it was for our model to follow that constraint. Vegan, the most restrictive constraint we studied, had the lowest dietary adherence accuracy across all models (93.6%). The alcohol-free constraint, which is dominated by one common ingredient (wine), had the highest accuracy (99.5%) despite the models seeing fewer training examples for that constraint.[21]

The Contextual Rewriter + Rule Prompt falls short in its understanding of the physical entities involved in cooking. Some of the steps it generates are not physically possible, such as *"Dip the cheese into the bread"*. The model can also suggest unrealistic or illogical cooking times (e.g. *"Bake for 10-10 minutes"*), or change oven temperature mid-recipe. While these results are uncommon, they highlight that the model has not learned the physical rules governing the use of ingredients and cooking techniques.

6 Related Work

Text attribute transfer: Most work in text attribute transfer has been at the sentence level, including sentiment (Hu et al., 2017b), formality (Rao and Tetreault, 2018), tense (Hu et al., 2017a), and authorship (Syed et al., 2019). While the text attribute transfer approach works well at the sentence level, our work tests a model's ability to make changes across multiple sentences that result in a coherent document. Further, our method allows for more drastic alterations to the source text than edit-based methods (Li et al., 2018) since we do not restrict the words that the model can alter.

Document-level controlled generation: The difficulty of text attribute transfer is amplified when the task expands to the document level. While controlled generation models such as Grover (Zellers et al., 2019), PPLM (Dathathri et al., 2020), and CTRL (Keskar et al., 2019) have been successful at the document level, they do not make use of context beyond an initial prompt. For many NLP tasks, contextual information from surrounding sentences can improve the quality of a generated sentence. We have seen this for coreference resolution (Joshi et al., 2019), relation extraction (Tang et al., 2020), and machine translation (Werlen et al., 2018; Macé and Servan, 2019). In this work, we show the effectiveness of including document-level context when rewriting recipes to fit a dietary constraint.

---

[21] Appendix shows a breakdown of each model's accuracy by dietary restriction.

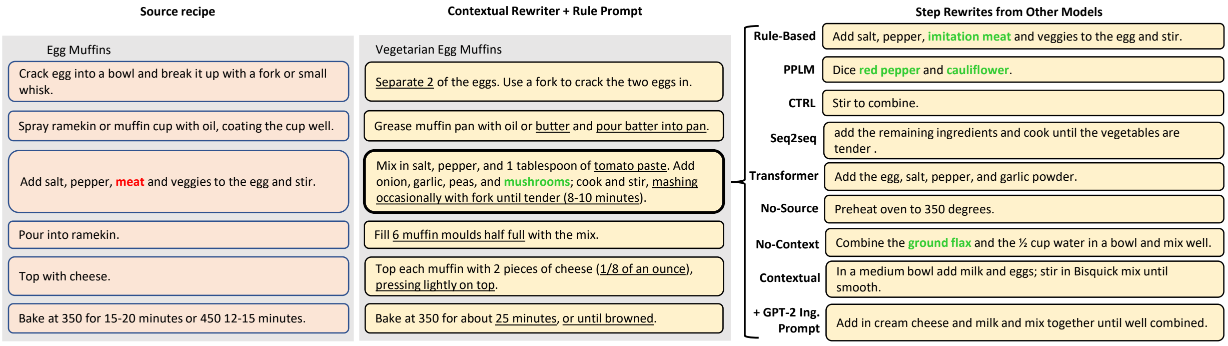

Figure 4: A recipe rewritten by the Contextual Rewriter + Rule Prompt, with outputs for a single step from other models for comparison. Our model replaces the violating ingredient (in **red**) with a substitution (in **green**), as well as modifying or adding new ingredients and techniques in every step (underlined).

Recipe generation: Recipe generation has been a research focus for decades, using methods ranging from rule-based planning systems (Hammond, 1986) to more recent neural network models that use targeted information such as entity types (Parvez et al., 2018), cooking actions (Bosselut et al., 2017), ingredients (Kiddon et al., 2016), or order information (Bosselut et al., 2018) to guide the generations. Building on the insight that knowledge about ingredients improves recipe generation, our work uses ingredient prompts to guide the generation of each recipe step. While there has been extensive work on recipe generation, few studies focus on controlled recipe generation. Majumder et al. (2019) recently introduced the task of personalized recipe generation, producing customized recipes based on user preferences. To our knowledge, our work is the first to generate recipes that conform to a given dietary constraint.

7 Conclusion

We introduce the novel task of document-level targeted content transfer and address it in the recipe domain, where our documents are recipes and our targeted constraints are dietary restrictions. We propose a novel model for rewriting a source recipe one step at time by making use of document-level context. Further, we find that conditioning the model with step-level constraints allows the rewritten recipes to stay closer to the source recipe while successfully obeying the dietary restriction. We show that our proposed rewriter is able to outperform several existing techniques, as judged both by automatic metrics and human evaluators.

Although we focus on the recipe domain, our method naturally generalizes to other domains where procedural tasks can be substantively rewritten. For example, one could rewrite technical documentation by constraining on the target operating system, rewrite lesson plans by constraining on the target grade level, or rewrite furniture assembly instructions by constraining on the tools used.

More broadly, this approach makes it possible to customize existing content to better fit a user's physical reality, whether that entails accommodating their dietary needs, updating their schedule based on the weather forecast, or providing information on a dashboard based on what's in their field of view. As language generation becomes more grounded in signals outside of language, work in the area of substantive transfer becomes increasingly relevant.

Acknowledgments

This work would not have been possible without the support of Microsoft Research's AI Residency program, particularly Becky Tucker and the 2019-20 cohort of residents who maintained a tight-knit research community despite our physical distance. We would also like to thank Sam Leiboff, Zach Price, and Matt Runchey for their feedback on the recipe content transfer task that informed our modeling approach. Finally, we are grateful to our anonymous reviewers for their thoughtful comments and suggestions.

A Dataset Creation

We collect recipes from recipe websites and existing recipe datasets listed in Table 5.

Recipe Website	Number of Recipes
AllRecipes.com	58,535
BBCGoodFood.com	9,171
Chowhound.com	3,890
CommonCrawl	424,621
Epicurious.com (Epicurious)	20,110
Food52.com	20,595
Food.com	268,914
FoodNetwork.com	47,187
Instructables.com	11,190
MasterCook (Loginetics)	72,141
MealMaster (Loginetics)	312,344
ShowMeTheYummy.com	555
SimplyRecipes.com	2,372
SmittenKitchen.com	986
WikiHow.com	2,320

Table 5: Online recipe data sources and amounts.

While some websites use tags to indicate that a recipe obeys a dietary constraint, not all do, and the tags are often noisy or missing. We therefore choose not to rely on recipe websites for these tags, and instead we use a rule-based method to tag recipes in our dataset as either *valid* or *invalid* in relation to a dietary constraint. While the method improves our model's performance, we observe several shortcomings. Despite constructing a large set of rules, we still miss words that are uncommon or that did not appear in the train set. Also, since we search for invalid ingredients using the recipe's list of ingredients, we miss ingredients that have been omitted from the ingredient list, as well as ingredients that are not mentioned explicitly by name (e.g. *"fillet"* as in *"catfish fillet"* will not be flagged as an invalid ingredient for a fish-free recipe) or ingredients that are referred to by a brand name or slang term that is not part of our rule set.

While we tried to catch as many of these cases as possible, there are many ambiguous words that the method will incorrectly classify such as *"beefsteak tomato"* appearing to contain meat (*"steak"*), *"oyster crackers"* appearing to contain fish (*"oyster"*), or a variety of *"egg replacer"* brand-name products appearing to contain egg.

The method is also unable to recognize negation (e.g. *"This recipe is not vegan!"*), or distinguish when a food is marked as optional or as an alternative (e.g. *"Flax is a good substitute for eggs"*). Both of these situations would cause a recipe to be marked with the wrong tag.

After assigning tags, we align similar recipes to form pairs of recipes for the same dish. Table 6 shows an example alignment between two recipes for Hot Cocoa with the alignment scores for each step. Recipes were divided into 80% train, 10% dev, and 10% test sets before aligning them into pairs, resulting in slightly uneven sizes for each set.

B GPT-2 Model Details

For each GPT-2 model, we use the 355 million parameter pre-trained GPT-2 medium model. We fine-tune using batch sizes ranging from 2-16 distributed across 64 NVIDIA Tesla V100 GPUs. We use a block size of 1024 for the end-to-end rewriter, and smaller block sizes for models that generate one step at a time of 128 for models without context and 256 for models with context. We train

ID	Source Recipe Steps	ID	Target Recipe Steps	Score
0	In a medium pot over medium heat, mix together cocoa powder, sugar, salt and milk.	0	Heat milk to your desired temperature.	10.0
		1	While milk is being heated, mix hot cocoa mix, creamer, and cinnamon sugar in bowl.	99.7
1	Heat until everything is dissolved and well combined, stirring occasionally (about 5-6 minutes).	2	Add small squirt or about 1/4 teaspoon of chocolate syrup to dry mix.	1.0
2	Stir in heavy cream and vanilla extract.	3	Add same amount of syrup again, or enough so that dry mix becomes lumps.	37.0
3	Mix together until everything is heated but not boiling (about 3-4 minutes).	4	Add confectioner's sugar and cocoa powder to mix (doesn't have to be as lumpy anymore).	1.1
4	Pour into your favorite mugs and top with desired toppings.	5	Pour mix into mug and pour milk on top.	99.9
		6	Add whipped cream and extra chocolate syrup.	87.4

Table 6: Step-level alignment scores between two Hot Cocoa recipes from the dataset.

each model for 2 epochs on datasets of aligned recipe steps ranging from 1.4 million to 10 million instances. The No-Context Rewriter was the fastest model to train, at 26 hours per epoch, and the slowest were the End-to-End Rewriter and the Contextual Rewriter + Rule Prompt at 318 hours per epoch.

We experimented with several hyperparameters for generation, including top-k sampling, nucleus sampling, and temperature (Table 7) using manually-chosen values. Since most variants performed well in adherence to the dietary constraint, we chose the best-performing variant in perplexity and diversity for our experiments.

We observe that our models can generate diverse rewrites from the same prompt, each with a different degree of fluency and adherence to the dietary constraint. We therefore create a set of rules to select the best generation out of 10 using a set of criteria including use of invalid ingredients, non-dictionary words, and incorrect punctuation. The criteria for selecting from multiple generations include:

- The step does not contain any violating ingredients
- The length is less than 100 characters
- The step does not contain special characters including '%', '*', or '$'.
- The first character is capitalized
- The last character is punctuation
- All words appear in an English dictionary (Merejkowsky, 2020)

C Data Format for Document-Level Controllable Baselines

PPLM We use the official codebase for PPLM: `https://github.com/uber-research/PPLM`. To build our PPLM model on our datasets, we use a pre-trained GPT-2 model on ~1.2 million recipes as the pre-trained language model. We build separate bag-of-words classifiers for each of our seven dietary constraints. We construct the bag-of-words for each dietary constraint by selecting words that appear at least 5 times in recipes fitting the constraint and do not appear in recipes that violate the constraint. At test time, we format the data with the same separators for title, ingredients, and steps used to fine-tune the GPT-2 model on recipe data.

CTRL For our task, we use the "Links" control code to specify the recipe domain. We include the desired dietary restriction in the prompt in addition to the target recipe context and separate them by newlines as they would appear in a web link. We also append the appropriate step number (e.g. "1.") to the prompt before generating each step.

D Data Format for Model Ablations

We format our recipe data differently for each model ablation described in the main paper. Table 8 shows the data format we use to fine-tune the GPT-2 model that predicts the ingredients in the next step. Table 9 shows the data format we use to fine-tune the End-to-End Rewriter. Table 10 shows the data format we use to fine-tune the No-Context Rewriter. Finally, Table 11 shows the data format we use to fine-tune the Contextual Rewriter.

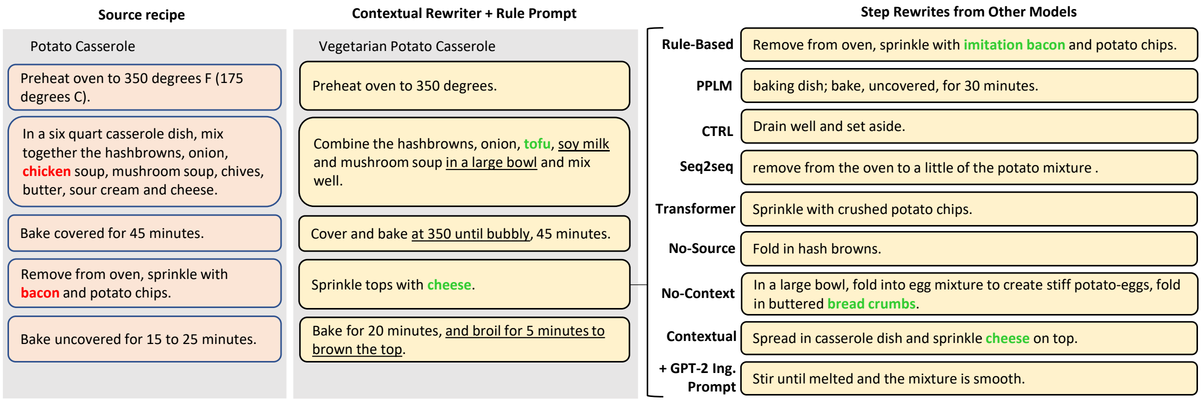
E Example Outputs

Figure 5 shows a source recipe alongside the recipe generated by the Contextual Rewriter + Rule Prompt, as well the generated fourth recipe step from each other model for comparison.

We provide additional step-level examples for each model in Table 12, and examples of an entire recipe rewrite for each model in Table 13. We also

	Perplexity	% Adherence	Trigram Diversity
Contextual Rewriter + Rule Prompt			
top k = 40, nucleus = 1, temperature = 1	**12.54**	99.5	**0.709**
top k = 40, nucleus = 0.8, temperature = 1	12.57	95.1	0.472
top k = 40, nucleus = 0.9, temperature = 1	12.82	94.8	0.498
top k = 40, nucleus = 1, temperature = 0.9	14.13	94.0	0.526
top k = 0, nucleus = 1, temperature = 1	17.02	99.3	0.551
top k = 10, nucleus = 1, temperature = 1	13.98	99.3	0.492
top k = 20, nucleus = 1, temperature = 1	14.85	**99.6**	0.511

Table 7: Results on the dev set for various generation hyperparameters, including top-k sampling, nucleus sampling, and temperature.



Potato Casserole

Preheat oven to 350 degrees F (175 degrees C).

In a six quart casserole dish, mix together the hashbrowns, onion, chicken soup, mushroom soup, chives, butter, sour cream and cheese.

Bake covered for 45 minutes.

Remove from oven, sprinkle with bacon and potato chips.

Bake uncovered for 15 to 25 minutes.

Vegetarian Potato Casserole

Preheat oven to 350 degrees.

Combine the hashbrowns, onion, tofu, soy milk and mushroom soup in a large bowl and mix well.

Cover and bake at 350 until bubbly, 45 minutes.

Sprinkle tops with cheese.

Bake for 20 minutes, and broil for 5 minutes to brown the top.

Rule-Based	Remove from oven, sprinkle with imitation bacon and potato chips.
PPLM	baking dish; bake, uncovered, for 30 minutes.
CTRL	Drain well and set aside.
Seq2seq	remove from the oven to a little of the potato mixture .
Transformer	Sprinkle with crushed potato chips.
No-Source	Fold in hash browns.
No-Context	In a large bowl, fold into egg mixture to create stiff potato-eggs, fold in buttered bread crumbs.
Contextual	Spread in casserole dish and sprinkle cheese on top.
+ GPT-2 Ing. Prompt	Stir until melted and the mixture is smooth.

Figure 5: A recipe rewritten by the Contextual Rewriter + Rule Prompt, with outputs for a single step from other models for comparison. Our model replaces the violating ingredient (in **red**) with a substitution (in **green**), as well as modifying or adding new ingredients and techniques in every step (underlined).

Table 11: Data format used to fine-tune the Contextual Rewriter.

show several examples of the ingredient prompts and resulting generations for our two prompt-based models, Contextual Rewriter + GPT-2 Prompt and Contextual Rewriter + Rule Prompt (Table 14).

F Additional Results

We provide the automatic metric results for 1000 recipes randomly sampled from the dev set in Table 15. We also provide a detailed breakdown of each model's accuracy across the seven dietary constraints in Table 16. Finally, we show a comparison of the results for human-written recipe rewrites against our best model, the Contextual Rewriter + Rule Prompt, on a subset of 30 vegetarian recipes from the test set (Table 17).

G Human Evaluation

For human evaluation, we limited our annotators to workers who met the following criteria:

- HIT Approval Rate (%) for all Requesters' HITs greater than 90
- Location is one of AU, CA, NZ, GB, US
- Number of HITs Approved greater than 500
- Masters has been granted (user was identified by the platform as a high-performing annotator)

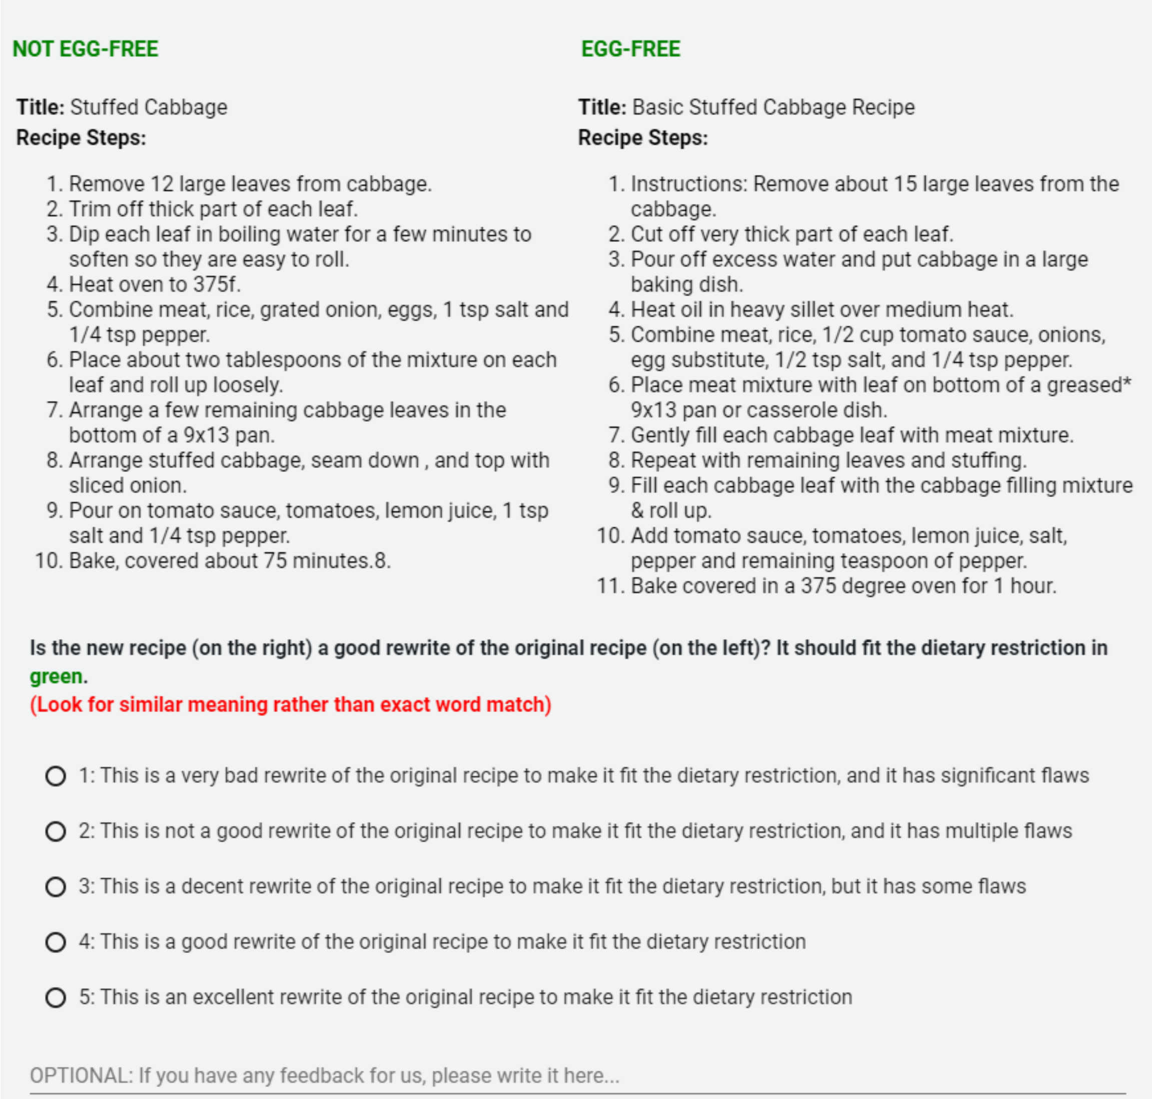
We obtained 5 evaluations per recipe for each of the questions listed in Figure 6 (paying $0.30 per response), Figure 7 ($0.25), and Figure 8 ($0.50). For the head-to-head model comparison, if fewer than 3 of the 5 evaluations agreed, we considered it a tie between the models. We did not have our human annotators evaluate the fish-free dietary constraint since the most common violating ingredient, Worcestershire sauce, is not commonly known to contain fish, which caused our annotators confusion in an initial test run.

Model	**Ultimate Green Beans (Vegetarian)**
Original Recipe Step	Cook the bacon in a large, deep skillet over medium-high heat until crisp, about 10 minutes.
Rule-Based	Cook the imitation bacon in a large, deep skillet over medium-high heat until crisp, about 10 minutes.
PPLM	Saute mushrooms in butter until lightly browned.
CTRL	Place the mushrooms, butter, and sugar in a large pot.
Seq2seq Copy	heat oil in a large pot over medium heat .
Transformer	In a large skillet, heat the oil.
No-Source Rewriter	Saute mushrooms in butter until soft; set aside.
No-Context Rewriter	WEST FRONT STREET, ST. LOUIS.
Contextual Rewriter	Saute the diced onion in the olive oil over medium heat until golden around the edges.
Contextual Rewriter + GPT-2 Prompt	Chop a bunch of mushrooms, and slice a small onion.
Contextual Rewriter + Rule Prompt	In large skillet, over medium heat, saute mushrooms in butter 5 minutes.
Human Rewrite	Peel and sautee garlic and olive oil in large, deep skillet over high heat until slightly scorched skin, about 3 minutes.
	Vegetable Stock (Dairy-Free)
Original Recipe Step	Melt butter in 8-quart pan over medium heat.
Rule-Based	Melt nondairy butter in 8-quart pan over medium heat.
PPLM	Strain through a fine sieve.
CTRL	Add the carrots, celery stalks, green onions, garlic cloves and 1 cup of water.
Seq2seq Copy	heat oil in a large saucepan over medium heat .
Transformer	In a large saucepan, combine the stock, water, and seasonings.
No-Source Rewriter	Clean and half the vegetables
No-Context Rewriter	Heat the olive oil in a large pot over medium heat.
Contextual Rewriter	Heat the oil in a large 4-quart stockpot over medium heat.
Contextual Rewriter + GPT-2 Prompt	Step 4 Then add the trimmings from the carcass and 1 onion and a turnip, and the carrots and celery, and cook until the vegetables are soft, around 4 to 5 hours on a medium heat.
Contextual Rewriter + Rule Prompt	Feel free to play with this amounts; for a cheesy flavour, you can add vegan cheese or sprinkle nutritional yeast on top.
	Low Cholesterol Muffins (Egg-Free)
Original Recipe Step	In another bowl, beat the egg white and mix together with a fork rapidly for 30 seconds.
Rule-Based	In another bowl, beat the egg white substitute and mix together with a fork rapidly for 30 seconds.
PPLM	Bake in a preheated oven at 375F for 15
CTRL	Bake for 20-25 minutes till golden brown.
Seq2seq Copy	in a large bowl , combine the flour , sugar , baking powder , and salt .
Transformer	Bake at 350 degrees for 30 minutes.
No-Source Rewriter	Bring to boil water/juice.
No-Context Rewriter	Mix together dry ingredients.
Contextual Rewriter	In a small bowl, beat egg replacer with water until fluffy.
Contextual Rewriter + GPT-2 Prompt	Combine 1T globs of the mix onto greased cookie sheets.
Contextual Rewriter + Rule Prompt	Then add egg or egg replacer.
	N'Awlins Stuffed Bell Peppers (Fish-Free)
Original Recipe Step	Add shrimp, and cook for 2 minutes.
Rule-Based	Add tofu, and cook for 2 minutes.
PPLM	Makes 8 to 10 servings.
CTRL	To serve, place on serving platter and top each portion with another layer of vegetables.
Seq2seq Copy	add the shrimp and cook for 5 minutes .
Transformer	Add the rice and cook, stirring occasionally, until the rice is tender
No-Source Rewriter	Heat the oven to 350F.
No-Context Rewriter	Simmer covered until the peppers are tender.
Contextual Rewriter	Add in the minced garlic and red pepper flakes.
Contextual Rewriter + GPT-2 Prompt	Add rice and simmer just until the liquid has been absorbed.
Contextual Rewriter + Rule Prompt	Add the tofu and cook for 8 minutes.

Table 12: Example step outputs for different dietary constraints. Ingredients that violate the dietary constraint and their substitutions are colored.

Model	**Caramel Popcorn (Dairy-Free)**
Original Recipe	Melt butter, corn syrup, and brown sugar together. Add sweetened condensed milk slowly. Cook to soft ball stage. Pour over popcorn and mix.
Rule-Based	Melt nondairy butter, corn syrup, and brown sugar together. Add sweetened condensed soymilk slowly. Cook to soft ball stage. Pour over popcorn and mix.
Retrieval	In a large saucepan combine brown sugar, corn syrup, and baking soda. Stir to combine and bring to a soft boil. Add vinegar and boil again. Remove from heat and add vanilla. Place popcorn in a large baking pan. Pour sauce over popcorn and coat evenly. Cover with plastic wrap to keep fresh. Fill brown bags with a scoop of caramel popcorn for take home treats!
PPLM	Combine sugar, margarine, syrup and salt in a heavy pan. Stir over low heat until mixture is melted and boiling. Boil for 5 minutes, stirring occasionally. Remove from heat.
CTRL	Preheat oven to 350 degrees F. In a large bowl, combine the cornstarch, coconut oil, and salt. Add the peanuts, sugar, salt, vanilla, and baking soda. Stir until well combined.
Seq2seq Copy	in a large bowl , combine the sugar , brown sugar , and vanilla . add the egg and vanilla extract . cook on low for about 5 minutes . pour into a large bowl and set aside .
Transformer	In a large saucepan, combine brown sugar, corn syrup, and margarine In a large saucepan, combine the brown sugar, corn syrup, and Place popcorn in a large, buttered baking pan. Pour over popcorn and toss to coat.
End-to-End Rewriter	Pop popcorn. Remove any un-popped kernels. Put popcorn in a large bowl. Put the nuts on top. In a saucepan, melt margarine, brown sugar, corn syrup and salt. Bring to a boil, stirring constantly. Boil without stirring for 5 minutes. Remove from heat and add vanilla and soda. Pour syrup over popcorn and mix well. Bake in a preheated 200 degree oven for 1 hour, stirring every 15 minutes.
No-Context Rewriter	Combine margarine, Kahlua, brown sugar, corn syrup and salt in a large, nonstick saucepan. Heat margarine, brown sugar and corn syrup. Boil for 5 minutes over medium heat without stirring. Stir; bake 5 minutes more. Stir; bake 5 minutes longer. Pour caramel over popcorn and stir well. Spread evenly onto cookie sheet 4 Bake 45 to 55 minutes or until golden brown. Cool completely, about 15 minutes.
Contextual Rewriter	In a saucepan, mix brown sugar, margarine, corn syrup & salt. Add 2 cups maple syrup, salt, and ground cinnamon to a large saucepan. Cook until the mixture reaches soft ball stage (236 degrees F). Pour the caramel over the popcorn and stir until all of the popcorn is coated.
Contextual Rewriter + GPT-2 Prompt	In a large pot, place your popped corn and cover it in the popped corn. Bring to a boil, stirring, then reduce the heat and simmer, stirring once or twice, for 20 minutes or until thick. Continue cooking for 5 minutes while gently stirring once in awhile to stop the edge of the pot from burning. Slowly pour in the corn syrup, and continue mixing until you can form a ball of dough. Roll out dough balls on a board lightly dusted with cornstarch to 1/4 to 1/2-inch thick.
Contextual Rewriter + Rule Prompt	Add nondairy butter, corn syrup and brown sugar to a medium saucepan over medium high heat. Combine the soymilk and dry ingredients in a medium bowl, then whisk in the wet. Cook over low heat, stirring constantly, about 10 minutes or until thickened; stir twice during cooking. Dump in the popcorn. Stir the mixture to coat it all with corn and pop it in the oven.

Table 13: Examples of document-level recipe rewrite outputs for Caramel Popcorn when the dietary constraint is dairy-free. Ingredients that violate the dietary constraint and their substitutions are colored.



NOT EGG-FREE

Title: Stuffed Cabbage
Recipe Steps:

1. Remove 12 large leaves from cabbage.
2. Trim off thick part of each leaf.
3. Dip each leaf in boiling water for a few minutes to soften so they are easy to roll.
4. Heat oven to 375f.
5. Combine meat, rice, grated onion, eggs, 1 tsp salt and 1/4 tsp pepper.
6. Place about two tablespoons of the mixture on each leaf and roll up loosely.
7. Arrange a few remaining cabbage leaves in the bottom of a 9x13 pan.
8. Arrange stuffed cabbage, seam down , and top with sliced onion.
9. Pour on tomato sauce, tomatoes, lemon juice, 1 tsp salt and 1/4 tsp pepper.
10. Bake, covered about 75 minutes.8.

EGG-FREE

Title: Basic Stuffed Cabbage Recipe
Recipe Steps:

1. Instructions: Remove about 15 large leaves from the cabbage.
2. Cut off very thick part of each leaf.
3. Pour off excess water and put cabbage in a large baking dish.
4. Heat oil in heavy sillet over medium heat.
5. Combine meat, rice, 1/2 cup tomato sauce, onions, egg substitute, 1/2 tsp salt, and 1/4 tsp pepper.
6. Place meat mixture with leaf on bottom of a greased* 9x13 pan or casserole dish.
7. Gently fill each cabbage leaf with meat mixture.
8. Repeat with remaining leaves and stuffing.
9. Fill each cabbage leaf with the cabbage filling mixture & roll up.
10. Add tomato sauce, tomatoes, lemon juice, salt, pepper and remaining teaspoon of pepper.
11. Bake covered in a 375 degree oven for 1 hour.

Is the new recipe (on the right) a good rewrite of the original recipe (on the left)? It should fit the dietary restriction in green.
(Look for similar meaning rather than exact word match)

○ 1: This is a very bad rewrite of the original recipe to make it fit the dietary restriction, and it has significant flaws

○ 2: This is not a good rewrite of the original recipe to make it fit the dietary restriction, and it has multiple flaws

○ 3: This is a decent rewrite of the original recipe to make it fit the dietary restriction, but it has some flaws

○ 4: This is a good rewrite of the original recipe to make it fit the dietary restriction

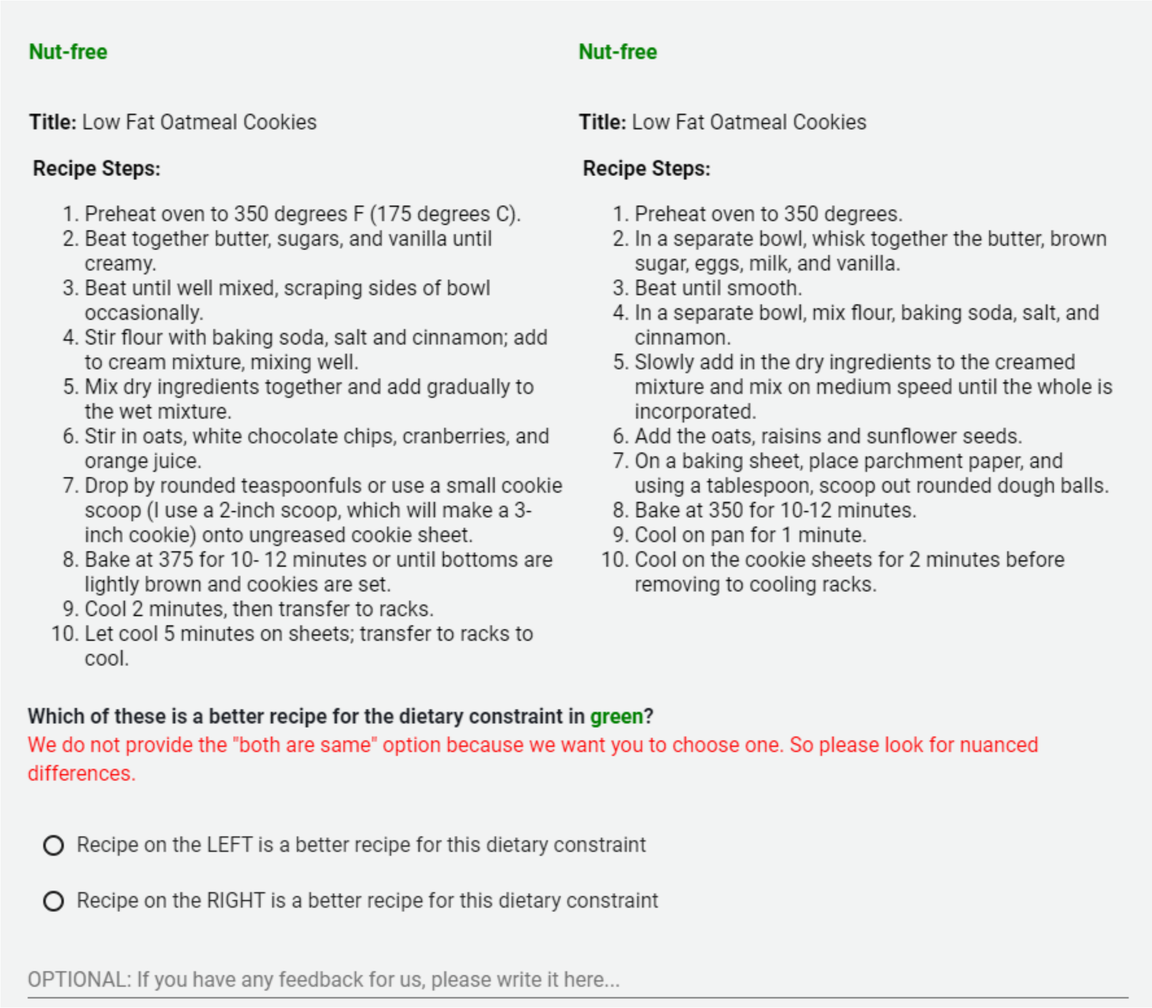
○ 5: This is an excellent rewrite of the original recipe to make it fit the dietary restriction

OPTIONAL: If you have any feedback for us, please write it here...

Figure 6: An example of a question used for human evaluation of the recipe rewrite task on Amazon Mechanical Turk.

Source Recipe Step	Model	Ingredient Prompt	Generated Recipe Step
a slice is delicious to eat on its own or with coconut butter, cashew butter, almond butter, or grass fed butter spread on top!	Contextual Rewriter + GPT-2 Prompt	banana, brown sugar, cinnamon, nutmeg, clove	In a large bowl, stir together banana, brown sugar, egg, butter and nutmeg.
	Contextual Rewriter + Rule Prompt	coconut, sunflower seed butter	Coat with your favorite healthy mix of seeds butter a few drops of liquid stevia or sweetener of choice sprinkled on top (optional).
Serve with milk or with a lump of butter melting into the nice warm pudding.	Contextual Rewriter + GPT-2 Prompt	spray oil, vanilla, chocolate bread pudding	Spray with cooking spray and add the chocolate bread pudding.
	Contextual Rewriter + Rule Prompt	soymilk, nondairy butter, pudding	Top pudding with dollops of vegan butter and a sprinkle of cinnamon.
Stir in beer.	Contextual Rewriter + GPT-2 Prompt	coconut, paprika	Heat up about 2 to 3 inches of coconut oil in a cast iron skillet.
	Contextual Rewriter + Rule Prompt	non-alcoholic beer	Slowly pour in 3/4 cup non-alcoholic beer, whisking briskly to blend.

Table 14: Examples to show the effect of the predicted and rule-based ingredient prompts on the generated steps.



Nut-free

Title: Low Fat Oatmeal Cookies

Recipe Steps:

1. Preheat oven to 350 degrees F (175 degrees C).
2. Beat together butter, sugars, and vanilla until creamy.
3. Beat until well mixed, scraping sides of bowl occasionally.
4. Stir flour with baking soda, salt and cinnamon; add to cream mixture, mixing well.
5. Mix dry ingredients together and add gradually to the wet mixture.
6. Stir in oats, white chocolate chips, cranberries, and orange juice.
7. Drop by rounded teaspoonfuls or use a small cookie scoop (I use a 2-inch scoop, which will make a 3-inch cookie) onto ungreased cookie sheet.
8. Bake at 375 for 10- 12 minutes or until bottoms are lightly brown and cookies are set.
9. Cool 2 minutes, then transfer to racks.
10. Let cool 5 minutes on sheets; transfer to racks to cool.

Nut-free

Title: Low Fat Oatmeal Cookies

Recipe Steps:

1. Preheat oven to 350 degrees.
2. In a separate bowl, whisk together the butter, brown sugar, eggs, milk, and vanilla.
3. Beat until smooth.
4. In a separate bowl, mix flour, baking soda, salt, and cinnamon.
5. Slowly add in the dry ingredients to the creamed mixture and mix on medium speed until the whole is incorporated.
6. Add the oats, raisins and sunflower seeds.
7. On a baking sheet, place parchment paper, and using a tablespoon, scoop out rounded dough balls.
8. Bake at 350 for 10-12 minutes.
9. Cool on pan for 1 minute.
10. Cool on the cookie sheets for 2 minutes before removing to cooling racks.

Which of these is a better recipe for the dietary constraint in green?

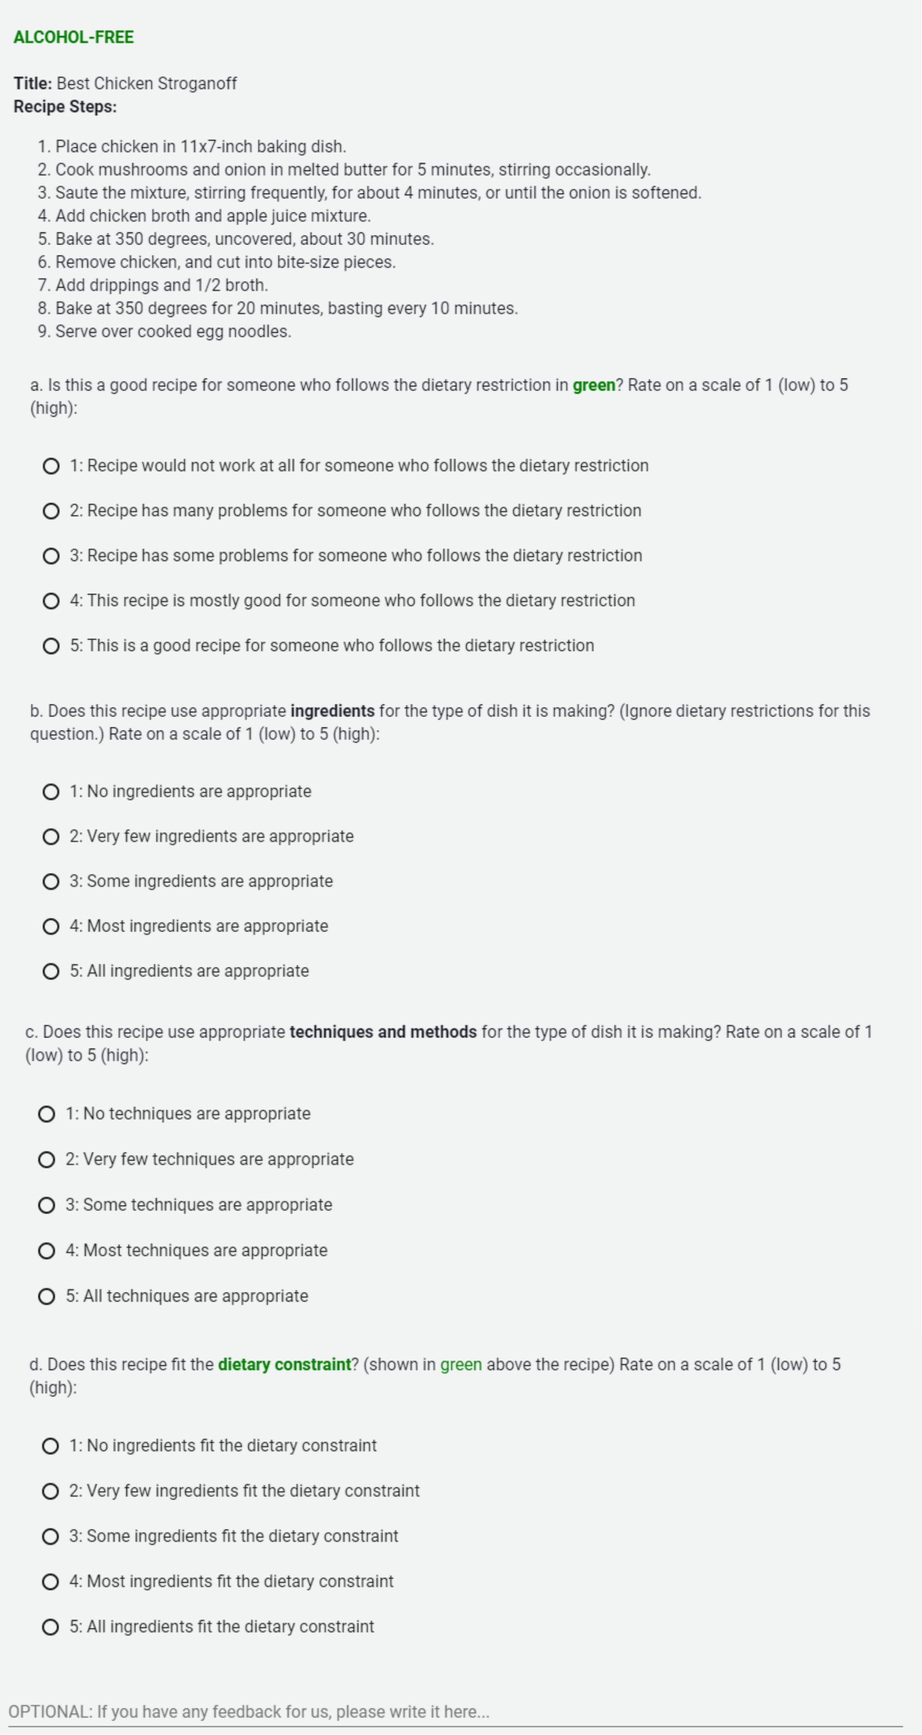
We do not provide the "both are same" option because we want you to choose one. So please look for nuanced differences.

○ Recipe on the LEFT is a better recipe for this dietary constraint

○ Recipe on the RIGHT is a better recipe for this dietary constraint

OPTIONAL: If you have any feedback for us, please write it here...

Figure 7: An example of a question used for human evaluation of the recipe rewrite task on Amazon Mechanical Turk.



ALCOHOL-FREE

Title: Best Chicken Stroganoff
Recipe Steps:

1. Place chicken in 11x7-inch baking dish.
2. Cook mushrooms and onion in melted butter for 5 minutes, stirring occasionally.
3. Saute the mixture, stirring frequently, for about 4 minutes, or until the onion is softened.
4. Add chicken broth and apple juice mixture.
5. Bake at 350 degrees, uncovered, about 30 minutes.
6. Remove chicken, and cut into bite-size pieces.
7. Add drippings and 1/2 broth.
8. Bake at 350 degrees for 20 minutes, basting every 10 minutes.
9. Serve over cooked egg noodles.

a. Is this a good recipe for someone who follows the dietary restriction in **green**? Rate on a scale of 1 (low) to 5 (high):

○ 1: Recipe would not work at all for someone who follows the dietary restriction

○ 2: Recipe has many problems for someone who follows the dietary restriction

○ 3: Recipe has some problems for someone who follows the dietary restriction

○ 4: This recipe is mostly good for someone who follows the dietary restriction

○ 5: This is a good recipe for someone who follows the dietary restriction

b. Does this recipe use appropriate **ingredients** for the type of dish it is making? (Ignore dietary restrictions for this question.) Rate on a scale of 1 (low) to 5 (high):

○ 1: No ingredients are appropriate

○ 2: Very few ingredients are appropriate

○ 3: Some ingredients are appropriate

○ 4: Most ingredients are appropriate

○ 5: All ingredients are appropriate

c. Does this recipe use appropriate **techniques and methods** for the type of dish it is making? Rate on a scale of 1 (low) to 5 (high):

○ 1: No techniques are appropriate

○ 2: Very few techniques are appropriate

Abstract

Virtual assistants such as Google Assistant, Amazon Alexa, and Apple Siri enable users to interact with a large number of services and APIs on the web using natural language. In this work, we investigate two methods for Natural Language Generation (NLG) using a single domain-independent model across a large number of APIs. First, we propose a schema-guided approach which conditions the generation on a schema describing the API in natural language. Our second method investigates the use of a small number of templates, growing linearly in number of slots, to convey the semantics of the API. To generate utterances for an arbitrary slot combination, a few simple templates are first concatenated to give a semantically correct, but possibly incoherent and ungrammatical utterance. A pre-trained language model is subsequently employed to rewrite it into coherent, natural sounding text. Through automatic metrics and human evaluation, we show that our method improves over strong baselines, is robust to out-of-domain inputs and shows improved sample efficiency. [1]

1 Introduction

Virtual assistants have become popular in recent years and task-completion is one of their most important aspects. These assistants help users in accomplishing tasks such as finding restaurants, buying sports tickets, finding the weather etc., by providing a natural language interface to many services or APIs available on the web. Most systems include a natural language understanding and dialogue state tracking module for semantic parsing of the dialogue history. This is followed by a policy module which interacts with the APIs, whenever required, and generates the actions to be taken by the system to continue the dialog. In the end, the Natural Language Generation (NLG) module converts these actions into an utterance, which is surfaced to the user. Being the user-facing interface of the dialogue system, NLG is one of the most important components impacting user experience.

Traditional NLG systems heavily utilize a set of templates to produce system utterances. Although the use of templates gives good control over the outputs generated by the system, defining templates becomes increasingly tedious as more APIs are added. Supporting multi-domain conversations spanning multiple APIs quickly grows out of hand, requiring expert linguists and rigorous testing to ensure the grammatical correctness and appropriateness of generated utterances. Consequently, data-driven generative approaches have gained prominence. Such systems require much less effort and can generate utterances containing novel patterns. Meanwhile, with the rapid proliferation of personal assistants, supporting large number of APIs across multiple domains has become increasingly important, resulting in research on supporting new APIs with few labelled examples (few-shot learning). To this end, generative models pre-trained on large amounts of unannotated text have been increasingly successful.

In this work, we address the challenges of joint modeling across a large number of domains, and data efficient generalization to new domains and APIs for NLG. Our contributions are the following:

1. We propose two methods for zero-shot and few-shot NLG. Our first method, the Schema-Guided NLG, represents slots using their natural language descriptions. Our second method - Template Guided Text Generation (T2G2) employs a simple template-based representation of system actions and formulates NLG as an utterance rewriting task (Figure 1).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6505–6520,
November 16–20, 2020.

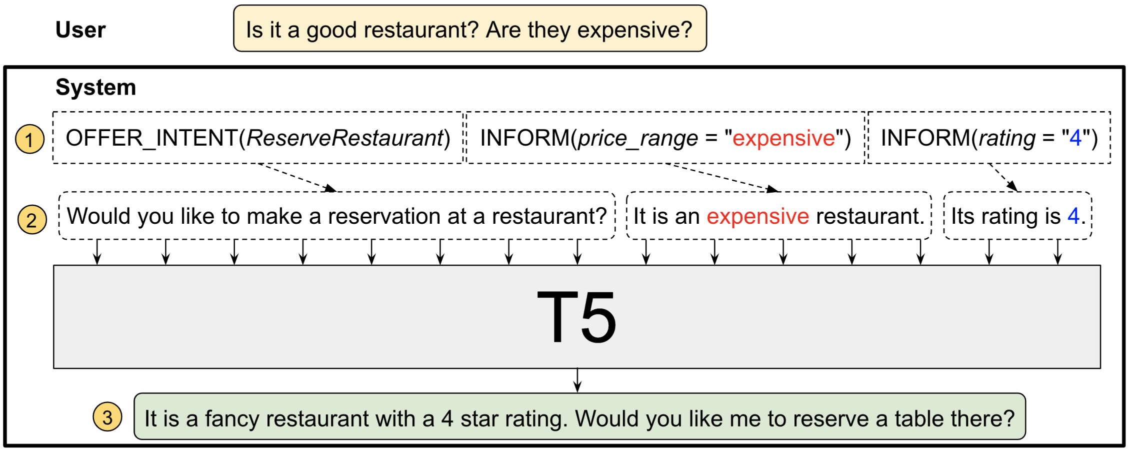

Figure 1: Overall architecture of our proposed template guided approach. 1. The policy module outputs a set of actions in response to the user utterance. 2. Simple templates convert each action into a natural language utterance. 3. Template-generated utterances are concatenated and fed to a T5 encoder-decoder model(Raffel et al., 2020). The model rewrites it to a conversational response surfaced to the user.

2. We present the first NLG results on the Schema-Guided dialogue dataset (Rastogi et al., 2019), which exceeds all other datasets in scale, providing a total of 45 APIs over 20 domains. While the current state-of-the-art pre-training based methods struggle to generalize to unseen (zero-shot) APIs, our proposed methods are robust to out-of-domain inputs and display improved sample efficiency.

3. We conduct an extensive set of experiments to investigate the role of dialogue history context, cross-domain transfer learning and few-shot learning. We share our findings to guide the design choices in future research.

2 Related Work

Natural language generation from structured input (NLG) has been an active area of research, facilitated by creation of datasets like WikiBio (Lebret et al., 2016), E2E challenge (Novikova et al., 2017), WebNLG (Gardent et al., 2017) and MultiWOZ (Budzianowski et al., 2018). Neural sequence models have been extensively used in a variety of configurations for NLG in dialogue systems. Wen et al. (2017) proposed a two-step approach: first generating a delexicalized utterance with placeholders for slots and then post-processing it to replace placeholders with values from API results, whereas Nayak et al. (2017) highlighted the importance of conditioning responses on slot values.

Sequence to sequence architectures directly converting a sequential representation of system actions to a system response are also very common (Wen et al., 2015; Du sek and Jurcicek, 2016b; Zhu et al., 2019; Chen et al., 2019). Domain-adaptation and transfer learning in low resource settings has also been an extensively studied problem (Tran and Le Nguyen, 2018; Chen et al., 2020; Peng et al., 2020; Mi et al., 2019), with recently released datasets like SGD (Rastogi et al., 2019) and FewShotWOZ (Peng et al., 2020) providing a good benchmark. Meanwhile, language models pre-trained on large amount of unannotated text corpus have achieved state-of-the-art performance across several natural language processing tasks (Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019; Radford et al., 2019; Keskar et al., 2019), including natural language generation (Peng et al., 2020; Kale and Roy, 2020).

Our template based approach bears similarities to sentence fusion (Barzilay and McKeown, 2005), and prototype based text editing (Hossain et al., 2020; Cao et al., 2018; Guu et al., 2018; Wu et al., 2019). However, none of these works tackle text generation from structured data.

3 Model

For a given system dialogue turn, let $\mathcal{A} = \{d_i(s_i = v_i)\}_{i=1}^{A}$ be the set of actions which are produced by the system, where A is the total number of actions for this turn. Each action consists of a single dialogue act d_i representing the semantics of the action, along with optional slot and value parameters - s_i and v_i respectively. For example, *inform*, *req_more* and *request* are some of the dialogue acts

Approach	Representation of System Actions
Naive	inform (restaurant = Opa!) inform (cuisine = greek)
Schema Guided	inform (name of restaurant = Opa!) inform (type of food served = greek)
Template Guided	How about the restaurant Opa!. The restaurant serves greek food.
Ground Truth	Opa! is a nice greek restaurant. How does it sound?

Figure 2: An example showing the representation of system actions utilized by the three schemes. The template representation is generated by concatenating sentences obtained from two templates, which are "*inform(restaurant = $x) → How about the restaurant $x.*" and "*inform(cuisine = $x) → The restaurant serves $x food.*".

defined in the SGD dataset (Rastogi et al., 2019), which are used for informing the value of a slot to the user, asking if the user needs some other help, and requesting the value of a slot from the user respectively. Some acts like *inform* require both the slot and value parameters, whereas acts like *request* require the slot parameter only and acts like *req_more* require none. Some datasets allow multiple slot-value arguments for a single act, but such actions can generally be converted to the above representation by decomposing them into multiple actions with the same act, each containing exactly one slot-value pair.

The goal of NLG is to translate $\mathcal{A}$ to a natural language response with the same semantic content. To this end, we first convert the set $\mathcal{A}$ into a sequence. Then, we finetune a Text-to-Text Transfer Transformer (T5) (Raffel et al., 2020) model, which is a pre-trained sequence to sequence transformer, to generate the natural language response using this sequence as input. Now, we present three different methods for converting $\mathcal{A}$ into a sequence, the last two being our contributions. They are also summarized in Figure 2.

3.1 Naive Representation

This approach uses the most basic representation of actions, similar to that used in many prior works (Novikova et al., 2017; Zhu et al., 2019; Peng et al., 2020). Canonical representations of each action - $a_i, a_i(s_i)$ or $a_i(s_i = v_i)$, depending on the parameters present in the action, are concatenated together to obtain a sequence representation of $\mathcal{A}$. Although this representation is simple to obtain and gives state of the art results for several data-to-text benchmarks (Kale and Rastogi, 2020), it suffers from two drawbacks -

(i) **Semantics -** This representation doesn't convey much information about the semantics of a slot. Consequently, the model may need a larger number of training examples to identify the semantics of a slot from its usage in the system utterances in the training data.

(ii) **Representation Bias -** This representation is very different from what the encoder has seen during pre-training phase, which is natural language text. As a result, the representations learnt during pre-training may not transfer well. Peng et al. (2020) mitigate this by conducting additional pre-training using large scale annotated dialogue datasets. While this method is effective, a large in-domain corpus may not always be available.

3.2 Schema Guided Representation

Recent work on low-resource natural language understanding tasks have used natural language descriptions of slots. These descriptions are easy to obtain, directly encode the semantics of the slot and have been shown to help when in-domain training data is sparse. While description based representations have become popular for tasks like spoken language understanding (Bapna et al., 2017) and dialogue state tracking (Rastogi et al., 2019), they have not yet been applied to the language generation task. We propose an extension of the Naive representation by replacing the slot names with their natural language descriptions. The action representations, as illustrated in Figure 2, are $a_i, a_i(desc(s_i))$ and $a_i(desc(s_i) = v_i)$, where $desc(s)$ represents a natural language description of slot s. This solves the first drawback of the Naive representation mentioned above.

3.3 Template Guided Representation

We solve the representation bias problem by converting the set of actions output by the system into a natural language utterance. We employ a technique similar to that used in Rastogi et al. (2019), where simple utterances are generated using a minimal set of manually defined templates. Specifically, as shown in Figure 3, we define one template for each

Action	Template
notify_success	Your ride is booked and the cab is on its way.
goodbye	Have a safe ride!
request(dest)	Where are you riding to?
request(shared)	Are you comfortable sharing the ride?
confirm(dest=$x*)*	You are going to $x.
inform(fare=$x*)*	Your ride costs $x dollars.
inform(seats=$x*)*	The cab is for $x riders.

Figure 3: Example templates for a ride-sharing API. Parameterized templates are defined for actions which contain a slot value.

Statistic	E2E	MWoz	SGD
Domains	1	7	20
Unseen domains	0	0	4
System acts	1	7	10
Slots	8	23	184
Unseen slots	0	0	41
Train size	33k	57k	160k
Dev size	4.3k	7.3k	24k
Test size	4.7k	7.3k	42k

Table 1: Comparison of NLG datasets. MWoz is short for MultiWOZ. Train/Dev/Test sizes represent the number of system turns. Unseen domains refers the test set.

system action. The representation of $\mathcal{A}$ is obtained by concatenating the corresponding templatized representation of each action in $\mathcal{A}$. See Figure 2 for a complete example.

Note that, our focus here is not to generate conversational and grammatically correct utterances, but to have a simple representation of the actions, which can be rewritten by the model into a natural and fluent response. Hence, we do not need to cover all edge cases typically required in template based methods - handling of plurals, subject-verb agreement, morphological inflection etc. - and only need to define a small number of templates. For most APIs, this amounts to around 15-30 templates, which can easily be written by the API developer. The actual number varies depending on the number of slots and intents supported by the API [2]. Some special slots like date, time and price are formatted using special rules, which can be reused across APIs. For instance, we convert the date “2019-03-06” to “6th March”, the time “18:40” to “6:40 pm”, and price “60” to “$60”. We call this step *value paraphrasing*. Since this method relies on a combination of templates and transfer learning from language models, we name it **Template Guided Text Generation (T2G2)**.

4 Experimental Setup

We conduct a series of experiments to compare the three system action representations presented above. We also evaluate NLG in few-shot settings and investigate a few other aspects of the SGD dataset. In each of the experiments reported in this paper, we start with a pre-trained T5-small model[3]. It has 6 layers each in the encoder and decoder, with a total of around 60 million parameters. The model is then fine-tuned on the corresponding dataset using a constant learning rate of 0.001 and batch size of 256 for 5000 steps. The checkpoint yielding the highest BLEU score on the development set is picked for reporting test set results. During inference, we use beam search with a width of 4 and length penalty $\alpha = 0.6$.

5 Action Representations

We compare the different methods of action representation on MultiWOZ 2.1 (Budzianowski et al., 2018), the cleaned version of the E2E restaurant corpus (Novikova et al., 2017; Du sek et al., 2019) and the Schema-Guided Dialogue (SGD) (Rastogi et al., 2019) dataset. The SGD dataset features a larger number of domains and slots, and the presence of multiple APIs per domain (Figure 4) makes it representative of practical scale-related challenges faced by today’s virtual assistants. Furthermore, as opposed to the other two datasets, its evaluation sets contain many domains, and consequently slots, which are not present in the training set. Even for domains shared between the training and evaluation sets, the evaluation sets contain additional slots in some cases. This focus on zero-shot generalization to new domains and APIs makes SGD more challenging than existing NLG benchmarks. Table 1 compares these datasets.

5.1 Automatic Evaluation

Following prior work (Wen et al., 2015), we use BLEU (Papineni et al., 2002) and Slot Error Rate

Table 2: Performance of models on MultiWOZ.

(SER) (Dušek and Jurcicek, 2019) as automatic metrics. SER represents the fraction of generated texts where at least one slot was not correctly copied from the structured data. Since this metric relies on string matching, we cannot use it to evaluate binary slots like *has_live_music*. Its exact match nature also prevents it from identifying paraphrases of slot values, e.g. *expensive* and *costly*. For E2E we use additional metrics used in prior work for this benchmark - NIST (Doddington, 2002), ROUGE-L (Lin, 2004), METEOR (Lavie and Agarwal, 2007), CIDEr (Vedantam et al., 2015), and BLEU.

MultiWOZ and E2E Table 2 lists results on the MultiWOZ and Table 3 on E2E. We train separate models for each dataset. On both datasets, T2G2 and Schema are comparable to the state-of-the-art Naive approach. We note that the SER score on MultiWOZ is slightly worse in comparison with SC-GPT. SC-GPT generates 5 predictions for each input and then ranks them based on the SER score itself. On the other hand, we generate a single output, on which SER is evaluated. Overall, the results indicate that with enough annotated data, the Naive approach is enough to attain good performance. Both datasets are large and feature limited variety (MultiWOZ has 57K utterances spread over just 5 domains, while E2E has 33k utterances spread over just 8 slots). Zero-shot and few-shot settings offer a greater and more realistic challenge, and we explore these settings next. The SGD dataset, which spans 20 domains, enables us to study these settings.

Model	BLEU	N	M	R	C
SC-LSTM	23.7	4.0	32.9	39.3	0.4

Table 4: BLEU and SER metrics on SGD dataset. *Copy* refers to a trivial baseline comprising of the template based input representation and has 0 SER by definition.

Adaptation to New Domains The ideal NLG model should be able to handle domains it was not exposed to during training. The SGD dataset, which features unseen domains in the evaluation sets, lets us us assess the zero-shot capability of NLG systems. We report results in Table 4 on two test sets - the *seen* set consists of domains that were seen during training, while the *unseen* set consists of brand new domains aka the zero-shot setting. Firstly, all models exhibit low SER scores in both seen and unseen domains, with the template approach being the lowest. This suggests that pre-trained language models are adept at copying and this skill also generalizes to out-of-domain examples.

The Schema-Guided representation performs at par with Naive representation on seen domains. At the same time, the slot descriptions do improve performance on the unseen domains (+0.9 BLEU), albeit to a limited degree. More effective ways of incorporating descriptions is a promising area for future work. For the seen domains, T2G2 outperforms Naive by 1.7 BLEU. The results on the

Model	Input or Generated sequence
Actions	Flights offer(airlines=American Airlines, outbound_departure_time=2:40 pm, is_nonstop=True, price=$78)
Template	Would you like to fly with American Airlines? The onward flight takes off at 2:40 pm. It is a direct flight. The ticket costs $78.
Reference	Do you wish to fly on American Airlines? The onward direct flight leaves at 2:40 pm, and the ticket price is $78. The ticket costs $78
Naive	There is an American Airlines flight that leaves at 2:40 pm and is not stop. The ticket costs $78.
Schema	There is an American Airlines flight that leaves at 2:40 pm and is not stop. The total cost is $78.
T2G2	How about an American Airlines flight that leaves at 2:40 pm? It's a direct flight and costs $78.
Actions	RentalCars confirm(has_insurance=True, car_type=hatchback)
Template	Please confirm the following details: It is a Hatchback car. It comes with insurance.
Reference	Please confirm: You want me to book a Hatchback car with insurance.
Naive	Please confirm: You want me to reserve a Hatchback car with a reassurance.
Schema	Please confirm: You want to rent a Hatchback.
T2G2	Okay, please confirm that you'd like to have a Hatchback car with an insurance.
Actions	Media inform(starring=Andrea Martin)
Template	Antonio Bustorff acted in it.
Reference	The actor is Antonio Bustorff.
Naive	The movie is directed by Antonio Bustorff.
Schema	The movie is directed by Antonio Bustorff.
T2G2	Antonio Bustorff acted in the movie.

Figure 5: A few examples of utterances generated from different models, along with the system actions, their template based representation (as shown in Figure 1) and the reference output. The errors are underlined.

unseen domains are more striking with an improvement of 7.3 points. This confirms the hypothesis that our simple template based input scheme offers superior generalization capabilities with a low overhead. The template model learns to "fuse" sentences and is able to successfully extend this skill to unseen domains.

5.2 Qualitative Analysis

In Figure 5 we list a few examples of model predictions. The first example illustrates a case where the model has to deal with a seen domain *Flights* but an unseen slot *is_nonstop*. Such a case would be common when new functionality needs to be added to an existing domain. Both Naive and Schema are unable to verbalize the slot correctly. While the template input contains all the information, it sounds very robotic. T2G2, on the other hand, takes the 4 template sentences as input and rewrites them into a fully accurate but much more natural sounding response.

The next example is from *RentalCars*, and features an unseen slot *has_insurance*. Schema fails to mention this slot. Naive attempts to verbalize it, but uses the wrong word (*reassurance*). T2G2, however, is able to paraphrase the template input into grammatical text without dropping any information.

The final example features an unseen slot *starring* from the *Movies* domain. Naive and Schema treat Antonio Bustroff as a director, since the slot *directed_by* appears during training. However, T2G2 simply relies on the template input and copies the phrase *acted in*. We refer the reader to Appendix F for more qualitative examples.

5.3 Human Evaluation

We conduct a human evaluation study via crowd sourcing [4]. Each human rater is shown the responses generated by different models and the ground truth response in a random order. Following (Peng et al., 2020), they are asked to rate each response on a scale of 1 (bad) to 3 (good) along two axes - *informativeness* and *naturalness*. Informativeness quantifies whether the response contains all the information contained in the dialogue acts, whereas naturalness evaluates whether the response sounds coherent, grammatical and natural. Each example is rated by 3 different workers. The final metric is an average of all the ratings.

A total of 500 randomly chosen examples are rated - 250 each from seen and unseen domains - across the 3 models discussed above and the ground truth response (*human*). With 3 ratings per example, this leads to a total of 6,000 ratings. Results are shown in Table 5.

Naturalness On the overall test set, all models outperform the human authored ground truth. This showcases the strength of pre-trained language models in generating natural sounding utterances, echoing findings from prior works. (Radford et al.,

Unseen	2.36	2.49^{1}	$\mathbf{2.55}^{1,2}$	2.51^{1}
Seen	2.57	$\mathbf{2.59}^{4}$	2.56	2.54
Overall	2.46	2.54^{1}	$\mathbf{2.56}^{1}$	2.53^{1}

Table 5: Human evaluation results comparing different models and the ground truth. The superscripts 1 to 4 indicate that the model is significantly better than Naive, Schema, T2G2 and ground truth respectively, as determined by a one-tailed paired t-test with $p < 0.05$.

2019; Peng et al., 2020).

Informativeness Simply generating a fluent response is not enough. Its paramount for the responses to be factually grounded in the structured data, so that the wrong information is not conveyed to the user. For informativeness, we notice that all models perform well on the seen domains. However, on unseen domains, the Naive approach fares poorly. Schema outperforms Naive by a large margin on unseen domains. T2G2 further improves upon Schema. These results suggest Schema and T2G2 offer promising avenues to improve the zero-shot generalization capability of NLG systems. Moreover, both Naive and Schema see large drops on unseen domains, while T2G2 performs equally well on both seen and unseen domains.

Recall that Naive representation demonstrated strong scores on the SER metric for unseen domains. However, the low human scores on informativeness suggest that getting perfect scores on metrics like SER may not be a reliable way to judge factual accuracy. As models become stronger, better evaluation metrics need to be developed to accurately measure the improvements.

6 Few-Shot NLG

Virtual assistants need to support a constantly increasing number of domains and APIs. In order to keep labelled data costs under control, improving few-shot learning methods is important. In this section, we study the trade-off between the number of annotated training examples and performance of NLG.

6.1 Dataset

K	Dialogues	Examples
5	70	558
10	140	1,075
20	280	2,140
40	560	4,312
80	1,120	8,624
All	16,141	164,978

Table 6: Data statistics of FewShotSGD training splits.

Prior work (Mi et al., 2019; Tran and Le Nguyen, 2018; Wen et al., 2016) has studied few-shot learning and domain adaptation in a simulated setting by creating small subsets. However, lack of knowledge of the exact data splits makes it difficult to make comparisons to other methods. To remedy this, we create a new canonical split of the SGD dataset as described below.

- We make K-shot subsets for varying values of K $[5, 10, 20, 40, 80]$. In this setting each of the 14 domains from the training set have K dialogs.
- For all the few-shot splits we make sure that they contain examples for every dialogue act and slot type present in the full training set. For every domain, we make sure that each dialog act (inform, request etc.) and slot (name, time, price etc.) is represented at least once. However, all combinations of dialog acts and slots may not exist.
- The dev and test sets are left untouched.

This benchmark is referred to as FewShotSGD and we make the exact splits publicly available. The exact number of examples in each split is given in Table 6.

6.2 Results

In few shot experiments, we examine the performance of different models as a function of the amount of labelled data. The training setup remains the same, as described in section 4. Results are reported in Figure 6, where we can clearly see the performance improving as more training data becomes available. In all the K-shot settings, T2G2 gives consistent improvements of 4-5 BLEU while reducing the SER by a large margin. Even in the extreme 5-shot setting, the SER is just 3.6%.

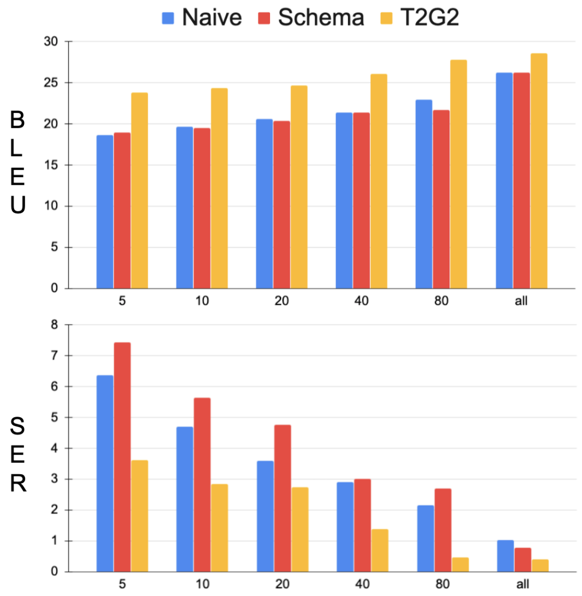

Figure 6: Performance in few-shot settings. The x-axis indicates the number of dialogues per domain in the training set. For exact scores, please refer to Appendix A.

Remarkably, T2G2 in the 80-shot setting outperforms the Naive model trained on the *entire* dataset, which is 20x larger. In the 5-shot setting, T2G2 performs on par with 80-shot Naive. We take this as evidence that our template guided input representation can lead to significant reduction in labelled data requirements.

7 Other Experiments

In this section, we conduct experiments to explore a few other aspects of our setup on the SGD dataset. For these experiments we use the Naive representation, since it is more widely adopted in prior work. We hope that these experiments will guide design choices in the future NLG models.

7.1 Joint Modeling

Joint modeling, instead of domain specific models, could be beneficial in low resource settings if there is some similarity between the underlying structure. Furthermore, having a single model for all domains also reduces the maintenance workload and is resource efficient. For NLG systems, it could also help in maintaining consistent styles across domains and APIs.

Domain	**Separate**		**Joint**	
	BLEU	**SER**	**BLEU**	**SER**
Homes	22.9	1.6	26.3	0.2
Buses	18.6	4.0	23.4	0.0
Media	28.9	8.4	29.9	4.6
RideShare	20.3	2.1	26.0	0.0
Movies	21.4	23.0	29.3	4.9
Flights	19.7	1.0	20.5	0.0
Music	25.3	0.6	28.5	0.0
Services	25.3	0.6	29.2	0.0
RentalCars	17.6	9.2	22.1	2.0
Restaurants	25.8	4.0	27.5	0.1
Events	30.7	0.5	31.9	0.0
Hotels	26.6	1.6	29.7	0.2
Average	23.6	4.7	**27.0**	**1.0**

Table 7: Joint vs domain-specific (separate) NLG.

k	0	1	3	5	7
BLEU	26.2	29.0	31.5	32.4	32.6
SER	1.0	1.0	0.8	0.9	0.7

Table 8: Changing the size of the context. k represents the number of previous utterances used.

Because of these merits, we investigate the effect of joint modeling on SGD dataset. We focus on the 12 domains that are present in all 3 splits - train, dev and test. We train a single model on all these domains and compare it with individual models trained for each domain separately. As shown in Table 7, joint modeling leads to a win-win situation by improving BLEU by 3.4 points and reducing SER from 4.7% to just 1%, while requiring fewer parameters and resources. For further analysis of transfer learning across domains, we refer the reader to Appendix C.

7.2 Role of Context

Dialogue acts represent the semantic content of the system response, but they don't contain any information about the lexical and syntactic content. The previous utterances in the dialogue history or context are important for generating good responses because they can help model conversational phenomena such as co-reference, elision, entrainment (lexical and syntactic alignment of responses) and avoid repetition (Du sek and Jurcicek, 2016a). Context also helps add variations to the responses generated across different conversations for the same system actions.

Table 8 shows the performance of NLG as more utterances from the dialogue context are given as input. In these experiments, we concatenate the last k utterances to the system action representation obtained from the Naive method. The model benefits from the additional context, showing an improvement of upto 6 BLEU. Just a single context utterance - the previous user utterance - results in an improvement of nearly 3 BLEU.

The evaluation for $k >= 2$ is not completely realistic, because we used the ground truth system utterances in the context during evaluation as opposed to the utterances generated by the NLG model itself. Regardless, the improvements clearly point to effectiveness of the added context at the cost of more resources. We hope these results inspire more work in this exciting direction.

8 Conclusion and Future Work

In this work, we proposed schema guided and template guided input representation schemes for task oriented response generation. Coupled with pre-trained language models, the template guided approach enables zero-shot generalization to new domains with little effort. Moreover, we show that it can lead to drastic reduction in annotation costs. We also present the first set of results on the multi-domain SGD dataset, which we hope will pave the way for further research in few-shot, zero-shot and multi-domain language generation.

While in this paper we use standard pre-trained models, designing pre-training tasks tailored to *sentence fusion* is an interesting line of future work. We also hope to apply T2G2 to languages other than English. Obtaining annotated data in non-English languages is an even bigger challenge, making the sample efficiency of our template rewriting approach especially suited to this setting. Another interesting line of future work is to investigate the use of T2G2 for generating user utterances, which could be useful for dialogue data augmentation and user simulation. This requires adding the ability to generate utterances with stylistic variations to capture different user personalities while maintaining consistency in style and vocabulary over a single dialogue.

A Additional Experiment Details

All models are trained on a 4x4 TPU slice, each taking 1-3 hours to finish training for 5000 steps. We provide development set BLEU scores in Tables 9 and 10. These scores are computed on the entire development set which includes both seen and unseen domains. In Table 11, we list the exact performance numbers for the few-shot NLG experiments.

B Automatic Metrics

Prior work has used different metrics for different benchmarks. Moreover, for the same metric (e.g. BLEU), different implementations are used. For fair comparison, for each dataset, we report the results using the implementation used in prior work. For E2E, we use the implementation from the e2e-metrics [5] suite. For computing BLEU on MultiWOZ, we use code made available in the SC-GPT codebase [6]. For model development i.e checking the best checkpoint based on the validation set, we rely on *sacrebleu* [7] across all experiments, since it has become the standard implementation in machine translation literature. We urge the NLG community to also converge upon a single implementation of BLEU. Taking inspiration from MT, the BLEU scores on experiments involving the SGD dataset are computed using *sacrebleu*.

model	BLEU
Naive	28.8
SG	29.9
T2G2	30.3

Table 9: Development set performance on the SGD dataset.

K	Naive	Schema	T2G2
5	19.8	20.0	22.0
10	21.3	22.0	24.0
20	23.4	22.4	24.5
40	23.1	25.3	25.6
80	26.1	24.9	27.8
All	28.8	29.9	27.5

Table 10: Development set BLEU scores in few-shot settings. K-shot denotes K dialogs for an API in the training set.

C Transfer Learning Across Domains

To measure the amount of transfer learning from one domain to another, we evaluate each domain specific model trained in Section 7.1 on all the domains and observe domain specific metrics. Results can be found in Table 12 and 13.

D Templates

In Tables 14, 15 and 16, we provide templates used for a few different APIs. The full set of templates is available with the code. Note that the linguistic quality of the templates does not need to be very

high, as long as the semantics of the dialog act are captured. This makes it easy for the API developers themselves to quickly create the simple templates.

E Human Evaluation Tasks

Figures 7 and 8 show examples of rater tasks for naturalness and informativeness respectively.

F Example Outputs

Sample utterances generated using the different models for various domains are shown in the examples below. The system actions, its template based representation used by the T2G2 model as input, and the reference response are also provided. The predictions are from models trained on the full SGD dataset and without any dialogue history context. The unseen domains have been marked with an asterisk.

	T2G2	Please confirm: Booking 4 tickets for Acting For Teens on March 11th in New York.
Events	*Actions*	confirm(event_name=Mxmtoon) confirm(number_of_tickets=2) confirm(date=March 10th) confirm(city=New York)
	Template	Please confirm the following details: Booking tickets for Mxmtoon. You have 2 tickets in your reservation. The date of it is March 10th. The event is taking place in New York.
	Reference	Can you please confirm that you want to buy 2 tickets for the Mxmtoon event which happens on March 10th in New York?
	Naive	Please confirm: 2 tickets for Mxmtoon on March 10th in New York.
	SlotDesc	Please confirm: 2 tickets to Mxmtoon on March 10th in New York.
	T2G2	Please confirm: 2 tickets for Mxmtoon on March 10th in New York.
Alarm*	*Actions*	offer(alarm_time=4 pm) offer(alarm_name=Event)
	Template	There is an alarm for 4 pm with name Event.
	Reference	A 4 pm alarm with name Event.
	Naive	There is an event at 4 pm.
	SlotDesc	There is an event at 4 pm.
	T2G2	There is an alarm for 4 pm with event name.
Alarm*	*Actions*	offer(alarm_time=10:30 am) offer(alarm_name=commute) inform_count(count=1)
	Template	You have 1 alarms currently set. There is an alarm for 10:30 am with name Commute.
	Reference	You have 1 alarm at 10:30 am. with name commute
	Naive	I found 1 suitable for you. It's at 10:30 am and it's a commute.
	SlotDesc	I found 1 alarm at 10:30 am. It's a commute.
	T2G2	You have 1 alarm for 10:30 am with the name Commute.
Weather	*Actions*	inform(humidity=30)
	Template	The humidity is around 30 percent.
	Reference	The humidity is about 30 percent.
	Naive	It's 30 minutes.
	SlotDesc	The humidity is 30.
	T2G2	The humidity is around 30 percent.
Weather	*Actions*	inform(humidity=75) inform(wind=4)
	Template	The humidity is around 75 percent. The average wind speed should be 4 miles per hour.
	Reference	The humidity for today is around 75 percent. The average wind is 4 miles an hour.
	Naive	It's a 7 star, and it's a 4 star.
	SlotDesc	The humidity is 75 and the wind speed is 4 miles per hour.
	T2G2	The average wind speed should be 4 miles per hour and the humidity is around 75 percent.
Messaging*	*Actions*	notify_success
	Template	You've successfully shared the location.
	Reference	The location was successfully shared.
	Naive	Your reservation has been made.
	SlotDesc	Your contact has been confirmed.
	T2G2	Your location has been shared.
Messaging*	*Actions*	confirm(location=2190 Bancroft Way) confirm(contact_name=Peter)
	Template	Please confirm the following details: You're sharing the location 2190 Bancroft Way with Peter.
	Reference	So share the location 2190 Bancroft Way with Peter?
	Naive	Please confirm the following details: You are scheduling a visit to Peter at 2190 Bancroft Way.
	SlotDesc	Please confirm the following details: You would like to contact Peter at 2190 Bancroft Way.
	T2G2	Please confirm the following details: You're sharing the location 2190 Bancroft Way with Peter.
Trains*	*Actions*	offer(journey_start_time=7:10 am) offer(total=$91)
	Template	What about the train departing at 7:10 am? It costs $91 in total.
	Reference	There is a train leaving at 7:10 am and costs $91.
	Naive	There is a bus that departs at 7:10 am and costs $91.
	SlotDesc	There is a 7:10 am train that costs $91.
	T2G2	How about the 7:10 am train? It costs $91 in total.
Travel	*Actions*	offer(attraction_name=BODY WORLDS London) offer(category=Museum)
	Template	You should check out BODY WORLDS London. This is a Museum.
	Reference	I suggest a museum called BODY WORLDS London.
	Naive	BODY WORLDS London is a Museum.
	SlotDesc	BODY WORLDS London is a museum.
	T2G2	BODY WORLDS London is a museum.

Abstract

Posing reading comprehension as a generation problem provides a great deal of flexibility, allowing for open-ended questions with few restrictions on possible answers. However, progress is impeded by existing generation metrics, which rely on token overlap and are agnostic to the nuances of reading comprehension. To address this, we introduce a benchmark for training and evaluating generative reading comprehension metrics: ***MO****deling* ***C****orrectness with* ***H****uman* ***A****nnotations*. MOCHA contains 40K human judgement scores on model outputs from 6 diverse question answering datasets and an additional set of minimal pairs for evaluation. Using MOCHA, we train a *__L__earned __E__valuation metric for __R__eading __C__omprehension*, LERC, to mimic human judgement scores. LERC outperforms baseline metrics by 10 to 36 absolute Pearson points on held-out annotations. When we evaluate robustness on minimal pairs, LERC achieves 80% accuracy, outperforming baselines by 14 to 26 absolute percentage points while leaving significant room for improvement. MOCHA presents a challenging problem for developing accurate and robust generative reading comprehension metrics.[1]

1 Introduction

Reading comprehension (RC) has seen significant progress in the last few years, with a number of question answering (QA) datasets being created (Rajpurkar et al., 2016; Lai et al., 2017; Talmor et al., 2018). However, a majority of datasets are presented using a span-selection or multiple-choice (MC) format. Both formats are easy to evaluate, but in return, have restrictions placed on the questions that can be asked or the answers that can be returned. Furthermore, both formats hinge on distractor spans/choices for learning to be effective. Ensuring high quality distractors is a challenging task in and of itself, which can lead to models that exploit spurious correlations (Jia and Liang, 2017; Min et al., 2019; Geva et al., 2019). Posing RC as a generation task addresses the aforementioned issues. Generative RC does not require distractors, circumventing biases that could be introduced by them, and allows arbitrary questions and answers.

Passage: . . . Behind one door is a lady whom the king has deemed an appropriate match for the accused; behind the other is a fierce, hungry tiger. Both doors are **heavily soundproofed to prevent the accused from hearing what is behind each one**. . .

Question: What feature do the doors have?
Reference: soundproofed
Candidate: They are **heavily soundproofed to prevent the accused from hearing what's behind each one**.

Human Judgement: 5 out of 5
LERC: 4.98 out of 5

BLEU-1: 0.07
ROUGE-L: 0.15
METEOR: 0.17

Figure 1: Generative reading comprehension example. Properly scoring the candidate requires access to the passage. Current metrics, such as BLEU, ROUGE and METEOR, are agnostic to the end-task while LERC is trained with the passage and question as input. As a result, LERC assigns a score that better reflects human judgement.

Unfortunately, existing metrics for evaluating text generation come with significant shortcomings. Many metrics score n-gram overlap, and it is well established that using token overlap as a measure of similarity has drawbacks (Chen et al., 2019; Edunov et al., 2019; Wang et al., 2020). Cur-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6521–6532,
November 16–20, 2020.

rent metrics also only consider the reference and are agnostic to the end-task being evaluated. Fig. 1 demonstrates that this is problematic for generative RC because scoring a candidate may require a metric to also consider the passage and the question. Without cheap and reliable evaluation, progress in generative reading comprehension has been extremely slow.

To address the need for better evaluation metrics tailored to reading comprehension, we present a dataset called MOCHA, aimed at developing *learned* metrics that **MO**del the **C**orrectness of candidates using **H**uman **A**nnotation scores. MOCHA contains human judgement scores on 40K candidates, an order of magnitude larger than prior work (Chen et al., 2019). The candidates come from six diverse QA datasets which test a wide range of RC phenomena such as commonsense reasoning and understanding narrative over movie scripts. After collecting all annotations, we follow work on creating more robust evaluation sets (Kaushik et al., 2020; Gardner et al., 2020) and augment the test set of MOCHA by manually writing a small set of minimal pairs (Table 3). The set of minimal pairs serve as a harder evaluation set for probing metric robustness.

Using MOCHA, we train a **L**earned **M**etric for **R**eading **C**omprehension which we abbreviate as LERC. We compare LERC against two sets of baselines: (1) existing metrics such as METEOR (Banerjee and Lavie, 2005) and BERTScore (Zhang et al., 2019); and (2) a sentence similarity model trained on STS-B (Cer et al., 2017). To ensure fair comparison, we evaluate LERC in an out-of-dataset setting: LERC is trained on all datasets *except* the one it is being evaluated on. On the test set, LERC outperforms baselines by as much as 36 Pearson correlation points and on the minimal pairs set, by as much as 26 accuracy points. Error analysis and minimal pair results indicate that there is substantial room to improve the robustness of LERC and its sensitivity to different linguistic phenomena. We hope that MOCHA and LERC enables a continual cycle of generative RC model and dataset developments that will enable easier collection of more diverse and useful candidates, allowing better learned metrics to be trained.

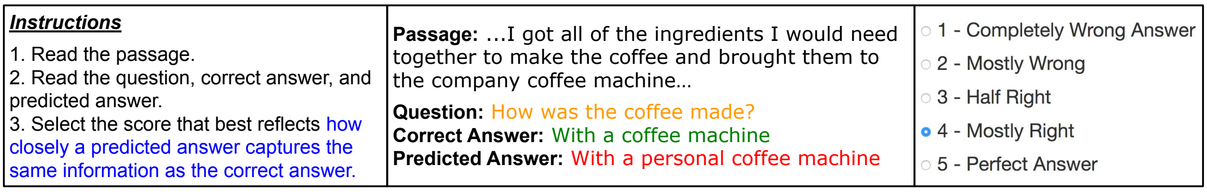
Instance	Score
Passage: With the aid of his daughter, Abigail, Barabas recovers his former assets. Barabas then uses his daughter's beauty to embitter Lodowick and Mathias against each other. **Q:** Why did Lodowick and Mathias fight? **Ref:** Over the affection of Abigail **Cand:** They fight over Barabas's daughter.	5
Passage: Miss Moppet ties a duster about her head and sits before the fire. The mouse thinks she looks very ill and comes down the bell-pull. **Q:** What does the mouse think when she sees the duster on Miss Moppet's head? **Ref:** that Miss Moppet is ill **Cand:** Miss Moppet thinks it is ill and is trying to sniff him.	2
Passage: Robin took a very long time to clean the windows of her house. **Q:** How would you describe Robin? **Ref:** a neat freak **Cand:** a clean person	5
Passage: The strangest thing that has happened was when they were singing the Chinese National Anthem she was standing in front of the TV swaying and singing. **Q:** What is probably true about this story? **Ref:** They are watching the Olympics **Cand:** The Olympics are watching	2

Table 1: Example instances with human judgement scores from MOCHA highlighting the diverse phenomenon that an evaluation metric needs to handle. These phenomenon include resolving coreference, dealing with factual correctness, understanding paraphrases, and understanding semantic roles.

2 A Description of MOCHA

Reading comprehension is the task of probing how well systems can understand passages of text. Framing reading comprehension as a generation problem provides a great deal of flexibility, but introduces the challenging problem of evaluation. These challenges are further amplified when applied to generative reading comprehension, where the introduction of a passage and a question can add to the complexity of evaluation (Table 1). To handle this challenge, we propose to *train* a generative reading comprehension metric. This first requires a large set of human judgement scores to be gathered.

In this section, we present MOCHA, a dataset that pairs reading comprehension instances, which consists of a passage, question, and reference, with candidates and human judgement scores. We describe the process of gathering candidates, collect-



Instructions

1. Read the passage.
2. Read the question, correct answer, and predicted answer.
3. Select the score that best reflects how closely a predicted answer captures the same information as the correct answer.

Passage: ...I got all of the ingredients I would need together to make the coffee and brought them to the company coffee machine...

Question: How was the coffee made?
Correct Answer: With a coffee machine
Predicted Answer: With a personal coffee machine

○ 1 - Completely Wrong Answer
○ 2 - Mostly Wrong
○ 3 - Half Right
● 4 - Mostly Right
○ 5 - Perfect Answer

Figure 2: A compressed version of the Mechanical Turk interface for evaluating answer correctness. Workers were asked to score (1 to 5) how similar a candidate is to a reference **using** the passage and the question.

ing human judgement scores, and creating minimal pairs for evaluation.

2.1 Datasets

Candidates in MOCHA come from 6 constituent QA datasets that are diverse in their domains and answer types. This ensures that training and evaluation with MOCHA does not overfit to the characteristics of any constituent dataset.

NarrativeQA (Kociský et al., 2017) tests reasoning about events, entities, and their relations on movie scripts and book summaries.

MCScript (Ostermann et al., 2018) tests reasoning on stories written for a child-level reader.

CosmosQA (Huang et al., 2019) tests commonsense reasoning on blogs describing everyday events.

SocialIQA (Sap et al., 2019) tests social reasoning with passages constructed from a knowledge base.

DROP (Dua et al., 2019) tests predicate argument structure and numerical reasoning on Wikipedia articles concerning American football games, census results, and history.

Quoref (Dasigi et al., 2019) tests coreferential reasoning on Wikipedia articles.

NarrativeQA was created as a generative RC dataset. CosmosQA, MCScript, and SocialIQA were created as MC datasets which we re-purpose as generative datasets by using the correct choice as the reference. Our motivation for doing this is that the number of generative QA datasets is quite small, which we attribute to the quality of evaluation metrics.

The main focus of this work is in developing and evaluating metrics for generative RC. However, we wanted to see whether a learned metric could do well on span-selection datasets. We collected candidates on two span-based datasets, DROP and Quoref, to test this.

2.2 Collecting Candidates

Candidates on all four generative datasets are generated using backtranslation (Sennrich et al., 2016) and using a fine-tuned GPT-2 model (Radford et al., 2019). We also generate candidates for NarrativeQA and MCScript using a trained MHPG model (Bauer et al., 2018). We tried using MHPG for CosmosQA and SocialIQA but candidates were of poor quality. Unique to NarrativeQA, each question has two references. We treat the second reference as a candidate to be annotated if it has low n-gram overlap with the first reference. We use a span-selection BERT-based model to generate candidates for Quoref and NAQANET (Dua et al., 2019) and NABERT[2] models for DROP.

Models are trained on the training sets of each constituent dataset and candidates are produced on instances from the validation set (and test set if available). We filtered out candidates that exactly matched the reference. We also filtered out instances in DROP where the reference and the candidate are both numbers.[3]

In total, MOCHA contains 40K candidates, large enough for training a learned metric as well as for evaluating current and future metrics.

2.3 Annotation Procedure

Annotations are collected with Mechanical Turk using the interface in Fig. 2. Workers are asked to score candidate answers on an ordinal scale from 1 to 5. We start by collecting a single annotation per candidate. Following this, candidates are split into training, validation, and test sets such that all candidates from a passage are contained within a dataset split. For instances in our validation and

---

[2] https://github.com/raylin1000/drop-bert

[3] From our inspection, if the reference and candidate are both numbers that are not equal, the candidate is always wrong.

Dataset	Avg Pass. Len	Avg Ques. Len	Avg Ref. Len	Avg Cand. Len	# Passages			# Ques./Ref. Pairs			# Candidates		
					Train	Dev	Test	Train	Dev	Test	Train	Dev	Test
NarrativeQA	333.0	9.6	5.8	5.9	85	11	18	2249	277	500	7471	890	1707
MCScript	197.1	7.8	4.3	4.1	462	61	93	2940	390	583	7210	978	1409
CosmosQA	72.8	10.8	7.5	8.8	1064	142	212	1139	156	226	5033	683	1017

Total					4950	662	989	11043	1436	2217	31069	4009	6321

Table 2: Statistics for the human judgements per constituent dataset in MOCHA.

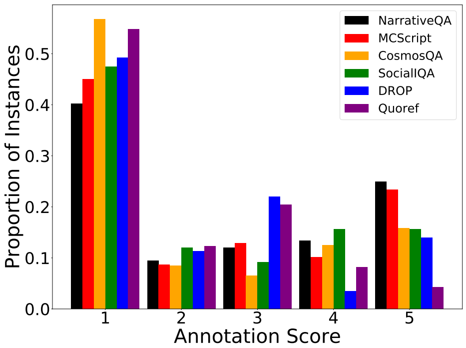

Figure 3: Human judgement score distribution on the training set of MOCHA, divided into the 6 constituent datasets. The distribution of scores is right-skewed because we did not annotate candidates that exactly matched a reference.

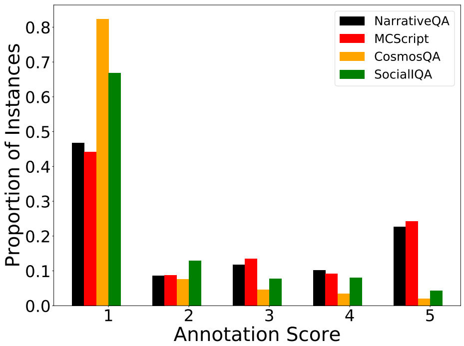

Figure 4: Score distribution on candidates from GPT-2. GPT-2 produces a *very* skewed score distribution for CosmosQA and SocialIQA, highlighting the difficulty of generative RC on commonsense questions.

test sets, we collect one additional human judgement score per candidate for span-based datasets, and two additional human judgement scores per candidate for generative datasets. Multiple annotations for a given candidate are averaged to form a gold annotation. More details such as payout and qualification testing are provided in Appendix D.

We calculated inter-annotator agreement using Krippendorff's Alpha-Reliability (Krippendorff, 2011) on the validation set of all 6 constituent datasets. We choose this metric because it applies to our setting, where there are multiple annotators per instance, and the annotators vary between instances. Agreement on our 6 datasets range from 0.71 to 0.92 (average = 0.82), indicating strong agreement.

2.4 Statistics for MOCHA

Statistics of instances and dataset splits in MOCHA are provided in Table 2. The number of unique passages varies considerably across datasets. NarrativeQA, which has the longest passages, has few unique passages, while SocialIQA has a unique passage for each question/reference pair. The number of candidates also varies across datasets. The most pronounced outlier is DROP, where we collected a tenth of the candidates compared to the other datasets. This is because we filtered out instances when both the candidate and reference were numbers, leaving much fewer candidates to annotate. The number of candidates outnumbers the question/reference pairs because for each pair, we generated multiple candidates using different generation sources (e.g. backtranslation, different model outputs).

Fig. 3 provides the annotation score distribution on the training set of MOCHA. Score distributions are right-skewed because we did not collect annotations when the reference exactly matched the candidate. The right-skew is most pronounced for Quoref because the number of ways a candidate can get a perfect score while not matching the reference is limited in a span extraction format.

2.5 Limitations and Robust Evaluation with Minimal Pairs

Candidates in MOCHA come from existing models, so that a metric learned on this data will be most applicable to current research. However, as

Phenomenon	Original Instance	Minimal Pairs
Coreference	**Passage:** Norman is the supposed son of Frenchman de Vac . . . As de Vac dies, he reveals Norman is Richard, the king's son and Edward's brother, who he kidnapped. **Q:** Who is the Frenchman de Vac? **Ref:** a fencing master who kidnapped Norman	**Cand. 1:** a fencing master who kidnapped Richard **(5)** **Cand. 2:** a fencing master who kidnapped Edward **(3)**
Hyponymy	**Passage:** With the electric rifle, Tom and friends bring down elephants, rhinoceroses, and buffalo. **Q:** What does Tom bring down with his rifle? **Ref:** Rhinoceroses, buffalo, and elephants.	**Cand. 1:** Animals **(4)** **Cand. 2:** Humans **(1)**
Negation	**Passage:** skylar told quinn's friend about a secret that quinn wanted to keep hidden. **Q:** What will Quinn want to do next? **Ref:** be angry	**Cand. 1:** Quinn will be mad at Skylar **(5)** **Cand. 2:** Quinn will not be mad at Skylar **(1)**
Semantic Role	**Passage:** Taylor gave a raise and promotion to Kendall. **Q:** How would you describe Taylor? **Ref:** As someone who appreciates what Kendall does	**Cand. 1:** Taylor appreciates Kendall **(5)** **Cand. 2:** Kendall appreciates Taylor **(1)**
Syntax	**Passage:** Taylor looked around in Robin's cupboards and peeked inside Robin's drawers and medicine cabinet. **Q:** How would you describe Taylor? **Ref:** intrusive	**Cand. 1:** I would describe Taylor as intrusive **(5)** **Cand. 2:** Would I describe Taylor as intrusive **(3)**
Word Sense	**Passage:** Taylor got married but kept her last name. **Q:** How would you describe Taylor? **Ref:** independent	**Cand. 1:** individualistic **(5)** **Cand. 2:** nonpartisan **(1)**
Other	**Passage:** The Princess stuffs her ears with cotton and begins her journey. **Q:** What does the Princess put in her ears? **Ref:** She puts cotton in her ears.	**Cand. 1:** Her ears have cotton **(4)** **Cand. 2:** Her ears are cotton **(2)**

Table 3: Minimal pairs categorized by the linguistic phenomena. Given a passage, question, and reference, we create two new candidates, $\mathbf{c_1}$ and $\mathbf{c_2}$, with associated human judgement scores $\mathbf{s_1}$ and $\mathbf{s_2}$. In total, we wrote 200 minimal pairs (50 for each generative QA dataset).

research in generative reading comprehension models is presently limited, the strength of these models can be low. Fig. 4 shows that generative QA models struggle to produce quality answers when asked about commonsense scenarios. The majority of 5's in CosmosQA and SocialIQA are produced via backtranslation, while GPT-2 struggles to produce "correct" candidates. This raises an issue with the evaluation; a metric can look strong when evaluated on current model outputs, but may in-fact struggle in the future when QA systems produce better answers. Thus, using only these candidates for evaluation could lead to overconfidence in a learned metric's capabilities.

We take inspiration from from recent work creating more robust evaluations (Kaushik et al., 2020; Gardner et al., 2020) and augment the test set of MOCHA with a small number of minimal pairs created by the authors. Given a passage, question, and reference from the test set, we manually create two new candidates, $\mathbf{c_1}$ and $\mathbf{c_2}$, which form a minimal pair. Accompanying $\mathbf{c_1}$ and $\mathbf{c_2}$ are human judgement scores, $\mathbf{s_1}$ and $\mathbf{s_2}$, collected using the same interface in Fig. 2. The minimal pair is created so that $\mathbf{c_1}$ has a higher score (i.e. is a better answer) than $\mathbf{c_2}$. Each minimal pair is designed to capture a particular linguistic phenomenon (see Table 3). Using this set of minimal pairs, we can study how often a metric prefers the better candidate. We create 200 minimal pairs (50 for each generative QA dataset), which we use for evaluation *separately* from the original test set.

3 A Learned Metric

We provide details on LERC, our learned metric. LERC is initialized using BERT-base (Devlin et al., 2019) We define as input a tuple consisting of a passage, $\mathbf{p}$, a question, $\mathbf{q}$, a reference answer, $\mathbf{a}$, and a candidate answer, $\hat{\mathbf{a}}$. The input to BERT is

Metric	NarrativeQA		MCScript		CosmosQA		SocialIQA		DROP		Quoref		Avg. *r*

Table 4: Pearson correlation to human judgement scores on the validation and test sets of MOCHA. LERC results are from a model trained in an out-of-dataset fashion, averaged across three runs.

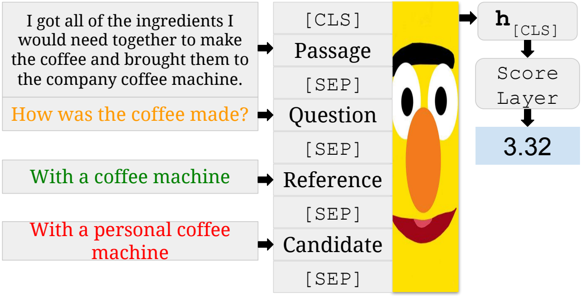

Figure 5: LERC is a BERT model that has been fine-tuned on human judgment scores. LERC takes as input a passage, question, reference, and candidate, and returns a score rating the "correctness" of the candidate.

structured as:

$$[\text{CLS}]\ \mathbf{p}\ [\text{SEP}]\ \mathbf{q}\ [\text{SEP}]\ \mathbf{a}\ [\text{SEP}]\ \hat{\mathbf{a}}\ [\text{SEP}]$$

BERT returns a hidden state for each input token. We use the first hidden state $\mathbf{h}_{[CLS]}$, as the pooled representation of the input.

3.1 Fine-Tuning with Human Judgements

Our goal is to train BERT to mimic the human judgements given a set of input tuples, $\{(\mathbf{p}, \mathbf{q}, \mathbf{a}, \hat{\mathbf{a}})\}_{i=1}^{n}$, and a set of human judgment scores, $\{y\}_{i=1}^{n}$, We apply a regression layer on top of our pooled representation (Fig. 5) and train with a MSE loss.

$$\hat{y}_i = \mathbf{W}\,\mathbf{h}_{i\,[CLS]}$$
$$\text{loss}_i = (y_i - \hat{y}_i)^2$$

3.2 Pre-Training the Learned Metric

Learning the interactions between the input components can be difficult with only human judgement fine-tuning. To overcome this, we *pre-train* on four multiple-choice QA datasets: BoolQ (Clark et al., 2019a), MCTest (Richardson et al., 2013), RACE (Lai et al., 2017), and MultiRC (Khashabi et al., 2018). We use the same input structure as fine-tuning, but the reference and candidate are replaced by two answer choices, $\mathbf{a_1}$ and $\mathbf{a_2}$:

$$[\text{CLS}]\ \mathbf{p}\ [\text{SEP}]\ \mathbf{q}\ [\text{SEP}]\ \mathbf{a_1}\ [\text{SEP}]\ \mathbf{a_2}\ [\text{SEP}]$$

We pre-train BERT via 3-way classification to predict whether: $\mathbf{a_1}$ is the correct answer, $\mathbf{a_2}$ is the correct answer, or $\mathbf{a_1}$ and $\mathbf{a_2}$ are both correct. MultiRC has multiple correct answers per question and we create additional instances where both $\mathbf{a_1}$ and $\mathbf{a_2}$ are correct by duplicating the correct answer for all three datasets.

4 Experiments

Training LERC: We use the PyTorch (Paszke et al., 2019), HuggingFace Transformers (Wolf et al., 2019), and AllenNLP (Gardner et al., 2017) libraries to implement LERC. We pre-train LERC before fine-tuning on MOCHA. We evaluate LERC in two settings, an out-of-dataset (OOD) setting and an all-datasets (AD) setting. In the OOD setting, we train and tune LERC on all datasets in MOCHA *except* the dataset we are evaluating on. This reflects the use case where we want to apply LERC to evaluate a new dataset where we do not have human judgement scores. In the AD setting, we train on all datasets in MOCHA and evaluate on all datasets. All results reported for LERC are the average of three runs using the best set of hyperparameters found on the validation set of MOCHA.

Baselines: We compare LERC against BLEU-1 (Papineni et al., 2001), ROUGE-L (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and BERTScore (Zhang et al., 2019). We also compare LERC against a BERT-base model fine-tuned on the sentence similarity task, STS-B (Cer et al., 2017). Results for BERT STS-B are the average of three runs using the best set of hyperparameters found on the

validation set of STS-B. All baselines are agnostic to the passage and the question.

4.1 Correlation Results

We evaluate the baselines and OOD LERC in Table 4 using Pearson correlation. LERC outperforms the baseline metrics despite being trained in a out-of-dataset situation. METEOR does surprisingly well despite relying on *n*-gram overlap to do evaluation. Interestingly, the sentence similarity model does better than the baseline metrics while falling behind LERC.

We also study whether having human judgements for a particular dataset helps. We present results in Table 5 on the validation set of MOCHA when LERC is trained in an AD setting. Having human judgements for the target dataset is always helpful.

4.2 Error Analysis of LERC

We gather the 10 validation instances per generative dataset (40 instances total) with the highest absolute difference between the human judgement score and LERC score. We categorize the errors made by LERC in Table 7. A large source of error is the inability to leverage the passage correctly as well as handling large lexical gaps between references and correctly paraphrased candidates. The "Other" category includes understanding semantic roles and misspellings of the reference.

Error Source	Example
Passage Use *(22.5%)*	**Passage:** Edward takes charge and the children develop and expand the farmstead, aided by the entrepreneurial spirit of the younger brother Humphrey. They are assisted by a gypsy boy, Pablo, who they rescue from a pitfall trap. **Q:** Who do the children rescue from a trap? **Ref:** Pablo **Cand:** A gypsy kid **Human Score:** 4.6 **LERC:** 1.0
Same Meaning *(35%)*	**Passage:** The story centres on the relationship between Mrs Kitty Warren and her daughter, Vivie. Mrs. Warren, a former prostitute. **Q:** What did Mrs. Warren previously do for work? **Ref:** Prostitution **Cand:** She was an escort. **Human Score:** 4.6 **LERC:** 1.06
Opposite Meaning *(15%)*	**Passage:** Sasha hated her neighbours dog as it barked all day and night so after going to the shop and buying poisonous slug pellets, Sasha gave the dog some pills. **Q:** How would you describe Sasha? **Ref:** mean **Cand:** kind **Human Score:** 1 **LERC:** 4.32
Other *(27.5%)*	**Passage:** The train was slow and ambling, so much so that we were 2 hours late when we arrived in Montreal, missing our connection. **Q:** What might be true if the freight trains didn't cause a delay ? **Ref:** They wouldn't have missed their connection **Cand:** they couldn't help noticing their connection **Human Score:** 1 **LERC:** 4.2

Table 7: Error analysis of LERC. We take the 10 validation instances per *generative* dataset (40 total) with the largest difference between the score assigned by LERC and the score assigned by humans. We then group the highest error instances by the sources of the error.

4.3 Ablation Results

We study five ablations of OOD LERC with results in Table 6. All ablations do not involve any pre-training. When looking at ablations of LERC, several interesting phenomena emerge.

Pre-training is important with such a complex input structure. Removing pre-training while still

Metric	**NarrativeQA**	**MCScript**	**CosmosQA**	**SocialIQA**	**Avg.**
BLEU-1	53	54	52	55	53.5
ROUGE-L	53	57	53	53	61.2

BERTScore	70	58	**74**	62	66
BERT STS-B	70.6	70	59.3	66.6	66.6
LERC	**80**	**87.3**	72.6	**81.3**	**80.3**

Table 8: Results of LERC (OOD setting) and baselines evaluated on minimal pairs. Numbers are accuracy values: given a minimal pair of candidates, what percent of the time does a metric prefer the better candidate.

using the passage and question as input hurts performance. Ablations of LERC that do not use the passage but still have the reference and candidate as input only fall slightly behind the complete metric. One explanation is that current generative QA models may not generate many candidates that would require the metric to use the passage. Therefore, even the complete version of LERC may have learned to ignore the passage. We explore this in the following section when conducting an error analysis of LERC.

As sanity checks for dataset biases, we also evaluate impoverished ablations that should not perform well: when the model has access only to the reference or to the candidate. These ablations correlate quite poorly with human judgments. The correlation is slightly positive for both, however, perhaps measuring the grammaticality of a candidate, or the difficulty of matching long references.

4.4 Minimal Pair Results

We now present results on the set of minimal pairs. We use these minimal pairs to evaluate preference: given a minimal pair of candidates ($\mathbf{c_1}, \mathbf{c_2}$), what percentage of the time does a metric prefer the better candidate? For cases where a metric assigns the same score to both candidates, we give a half-point.

Results are reported in terms of accuracy in Table 8. N-gram based metrics are close to random, which aligns with intuition because minimal pairs were created such that both candidates have a similar token overlap with the reference. The sentence similarity model does much better, likely because it generalizes beyond token overlap. Finally, LERC (OOD setting) does the best, suggesting that while there is still room for improvement, the phenomena targeted by the minimal pairs is captured when evaluated using preference.

Difference Source	**Examples**
BLEU under-scores paraphrases *(92.5%)*	**Passage:** Tracy took Jesse's students to the park. Jesse had an emergency and asked her to. **Q:** How would Jesse feel afterwards? **Ref:** grateful **Cand:** thankful **LERC:** 5.0 **BLEU-1:** 0 **Human Score:** 5
LERC overly sensitive *(7.5%)*	**Passage:** By 17, Norman is the best swordsman in all of England; by the age of 18, he has a large bounty on his head, and by the age of 19, he leads the largest band of thieves in all of England. **Q:** What age was Norman when there was a bounty on his head? **Ref:** 18 **Cand:** 19 **LERC:** 5.0 **BLEU-1:** 0 **Human Score:** 1

Table 9: Analysis of LERC vs BLEU-1. We take the 10 validation instances per *generative* dataset (40 total) with the largest difference between the score assigned by LERC and the score assigned by BLEU-1. We then group these instances by the source of the difference.

4.5 LERC vs BLEU

To understand the differences in behavior between LERC and the popular BLEU metric, we collect the 10 validation instances per generative dataset with the highest absolute difference between the BLEU-1 and LERC score. We categorize the source of the differences in Table 9. In about 90% of the cases, the gap is due to BLEU scoring candidates too low (e.g. not capturing paraphrases). In the remaining cases, the gap is due to LERC over-scoring the candidate, usually due to the reference and candidate being similar (e.g. both are numbers).

5 Related Work

There has been a long history of developing evaluation metrics, which have generally fallen into one of three categories. The first consists of metrics that use some variant of *n*-gram matching (Papineni et al., 2001; Lin, 2004; Banerjee and Lavie, 2005). They are easy to implement, but lack flexibility by focusing only on token overlap. The second cateogry of metrics eschew some of the aforementioned issues by calculating a *softer* similarity score using *embeddings* of tokens (Clark et al., 2019b; Zhang et al., 2019). However, it is unclear how to tailor them to question answering, where the passage and question should be assimilated. The final category consists of metrics learned end-to-end from human judgements (Cui et al., 2018; Sellam et al., 2020). These metrics are flexible in that they can be tuned to the specific evaluation setting but depend on a large corpus of human judgement scores to train on. We hope that the release of MOCHA pushes the development of QA metrics that fall into this category.

MOCHA is directly inspired by the annual WMT Metrics Shared Task (Machácek and Bojar, 2014; Stanojević et al., 2015; Bojar et al., 2016, 2017; Ma et al., 2018, 2019). Participants submit automatic translations and human judgement scores are collected for the submitted translations. The annotations collected as part of the WMT Metrics Shared Task have made it easy to evaluate and create new translation metrics (Popovic, 2015; Ma et al., 2017; Shimanaka et al., 2018). In a similar vein, SummEval is a recently released dataset that evaluates a number of evaluation metrics for summarization (Fabbri et al., 2020).

6 Conclusion

We present MOCHA, a dataset of human judgement scores for training and evaluating generative reading comprehension metrics. Using MOCHA, we train a learned metric, LERC, that outperforms all existing metrics and is much more robust when evaluated on a set of minimal pairs.

While we have demonstrated that LERC is a better metric for evaluating generative reading comprehension than any existing metric, considerable work remains. Error analysis reveals that there exist gaps in LERC's ability to handle certain phenomena, such as correctly leveraging the passage. Future work involves collecting data to addresses weaknesses of LERC. We also anticipate a continual cycle of generative RC model and dataset developments that will enable easier collection of more diverse and useful candidates. This in turn will allow better learned metrics, which can be used to evaluate ever more complex models.

Acknowledgements

We would like to thank AI2 for the funding to collect MOCHA. We would also like to thank members of AI2 and UCI NLP for looking over early drafts of the paper. This paper is based upon work sponsored by the DARPA MCS program under Contract No. N660011924033 with the United States Office Of Naval Research.

Appendix

A Details on Training LERC

Training of LERC is broken into pre-training on multiple-choice QA datasets followed by fine-tuning on human judgement scores.

During pre-training, we used batch size of 32 and train for 4 epochs. We tune the learning rate ({1e-5, 2e-5, 3e-5}) over held out questions using a single runs' loss. We use accuracy as the criteria to pick the best pre-trained model.

We then take the best pre-trained model and fine-tune on human judgement scores in MOCHA. We again fix the batch size at 32 and train for 3 epochs, tuning the learning rate ({1e-5, 2e-5, 3e-5}) over the validation set of MOCHA using the average of three runs. We use Pearson correlation to pick the best fine-tuned model. When LERC is trained in an OOD setting, we do not tune on the held-out dataset.

B Details on Baselines

We use implementations of BLEU, METEOR, and ROUGE using Microsoft MS COCO evaluation scripts [4]. We removed question marks, periods, and exclamation marks from references and candidates when evaluating with BLEU, METEOR, and ROUGE.

The hash-code for BERTScore is `roberta-large_L17_no-idf_version=0.3.6(hug_trans=3.0.2)`.

We fine-tune BERT-base on STS-B as another baseline. We use a batch size of 32 and train for 4 epochs. We tune the learning rate ({1e-5, 2e-5, 3e-5}) over the validation set of STS-B using the average of three runs.

C Computational Resources

All experiments on conducted on a NVIDIA Titan RTX with 24 GB of RAM. Pre-training of LERC takes about 3.5 hours while fine-tuning (one run) takes roughly 20 minutes.

D Details on Mechanical Turk

Collecting MOCHA involves three stages: a qualification testing stage, a trial stage, and the full dataset collection stage.

During qualification testing, workers are given 10 candidates to label, and they must score 80% to pass the test. After qualification testing, we run a small trial. During this trial, we release 200 candidates and gather 5 human judgements per candidate to get a sense of annotation agreement and to see if our instructions and examples need to be revised. Finally, during the full dataset collection process we solicit human judgements on all candidates. Here, each HIT is an aggregate of 10 candidates that all share the same passage to amortize the cost of reading the passage and workers are paid 40 cents per HIT.[5] During dataset collection, we randomly sample annotations to check for quality and remove workers that consistently do a poor job.

Workers are paid for working on any of the three stages. The total cost of collecting MOCHA is about $6,000.

E Correlation Results based on Generation Source

We supplement Table 4 by calculating correlation results per generation source for the generative datasets in Table 10. We find that LERC handles candidates from different generation sources with roughly the same performance.

Plan ahead: Self-Supervised Text Planning for Paragraph Completion Task

Abstract

Despite the recent success of contextualized language models on various NLP tasks, language model itself cannot capture textual coherence of a long, multi-sentence document (e.g., a paragraph). Humans often make structural decisions on what and how to say about before making utterances. Guiding surface realization with such high-level decisions and structuring text in a coherent way is essentially called a planning process. Where can the model learn such high-level coherence? A paragraph itself contains various forms of inductive coherence signals called self-supervision in this work, such as sentence orders, topical keywords, rhetorical structures, and so on. Motivated by that, this work proposes a new paragraph completion task PARCOM; predicting masked sentences in a paragraph. However, the task suffers from predicting and selecting appropriate topical content with respect to the given context. To address that, we propose a self-supervised text planner SSPlanner that predicts what to say first (content prediction), then guides the pretrained language model (surface realization) using the predicted content. SSPlanner outperforms the baseline generation models on the paragraph completion task in both automatic and human evaluation. We also find that a combination of noun and verb types of keywords is the most effective for content selection. As more number of content keywords are provided, overall generation quality also increases.

1 Introduction

One may think textual coherence can be achieved from a gigantic language model trained on massive data. This might be true in simple cases, such as generating short replies (Kannan et al., 2016), but not in a long, multi-sentence generation. This is mainly because per-word predictions from the autoregressive models can not capture the long-term flow of text, while humans often make structural decisions on what and how to say about before they speak (Byrne, 1979; McKeown, 1985; Hovy, 1990; Swan, 2002; Kang, 2020). Guiding the surface-level realization with such high-level decisions and coherently structuring output text is called a *planning* process.

Where can the model learn such high-level decisions related to long-term coherence? A written paragraph itself can be a pot of golden resources, containing various forms of inductive coherence signals. Different types of coherence signals in a paragraph have been studied and used in many different ways: a sequence of words or sentences (Devlin et al., 2019; Radford et al., 2019), a discourse structure of a text (Appelt, 1982; Hovy, 1991; Kang et al., 2019), an order of sentences (Chambers and Jurafsky, 2008; Barzilay and Lapata, 2008), topic introduction, co-reference, a sequence of events (Tomkins, 1978; Schank and Abelson, 2013), and more. In this work, we primarily focus on the effect of topical content in text planning.

Despite the recent advances of contextualized language models (Devlin et al., 2019; Radford et al., 2019), the lack of appropriate tasks makes it difficult to evaluate generation models' long-term coherence. Prior tasks fall into classification or ranking problems, such as narrative close task (Chambers and Jurafsky, 2008; Mostafazadeh et al., 2016), sentence ordering (Barzilay and Lapata, 2008), and next sentence prediction (Devlin et al., 2019). Some recent works focused on designing generation tasks: story generation (Fan et al., 2019), text infilling (Huang et al., 2019; Fedus et al., 2018; Hua and Wang, 2019), or paragraph bridging (Kang et al., 2019). However, most of them suffer from predicting appropriate topical content given limited context, due to the limited usage of self-supervision

November 16–20, 2020.

signals from the paragraph.

This work proposes a new open-ended paragraph completion task; PARCOM; predicting the masked sentences in a paragraph. Unlike the prior works, our task uses two effective ways of self-supervision learnt from a written paragraph itself: (1) we augment more training instances via permutation masking and (2) resolve the context sparsity problem by providing a set of ground-truth content keywords and predicting them directly from context at testing time.

For the task, we propose a self-supervised text planner (SSPlanner) that explicitly predicts content keywords (content prediction) from context and guides the pretrained language model (surface-realization) using the predicted content. The distribution of predicted keywords is then combined with the distribution of words in the language model using copy mechanism (See et al., 2017). The predicted content keywords are an approximation of topical intents by the generator, providing a hint to guide the surface realizer to bridge the coherency gap between the given context and text to generate. Overall, SSPlanner combines two advantages; micro-level language fluency from the pre-trained language model (bottom-up) and macro-level content choice controlled by the macro-level planning (top-down). Our experiment shows that SSPlanner achieves significant improvements over the baselines in both automatic and human evaluation.

2 Related Work

We first categorize a wide range of long-term coherent generation tasks (Table 1), based on their inclusion relationship (**C**-**T**) between the given context (**C**) and target to predict (**T**).

C-T	Tasks	Content Selection	Content Planning	Content Ordering	Surface Realization
⊂	Data-to-text	×	×	✓	✓
⊃	Summarization	✓	×	△	✓
≈	Paraphrasing	△	×	×	✓
⊥⊥	StoryGen, Text Infilling, Bridging, PARCOM (ours)	✓	✓	✓	✓

Table 1: Comparison of generation tasks by different inclusion relationships between **C**ontext and **T**arget.

C ⊂ **T**: Data-to-text produces text from structured data (e.g., table). Moryossef et al. (2019); Puduppully et al. (2019); Shen et al. (2019); Miculicich et al. (2019) combine content planning with surface realization. However, since content is explicitly provided as a data form, the planner mostly orders and structures, not prediction.

C ⊃ **T**: In abstractive summarization, all context information is entirely given in the source document, as a superset of target summaries to predict. Thus, generation only pays attention to abstracting the context into a shorter form instead of content prediction or ordering.

C ≈ **T**: Paraphrasing is transforming surface patterns of text while preserving its semantics. Fu et al. (2019) used variational autoencoders for surface realization with a latent bag of words model for differentiable content planning, where content to generate itself is given in context, not requiring any content planning.

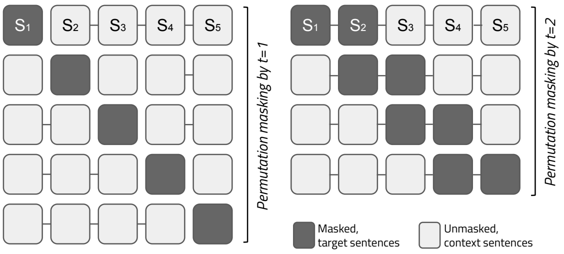
C ⊥⊥ **T**: Story generation (Fan et al., 2019), text infilling (Fedus et al., 2018; Huang et al., 2019), paragraph bridging (Kang et al., 2019), and our proposed PARCOM are very challenging tasks where context and target have no overlap (open-ended), but they should be coherently connected. Table 2 categorize various generation models applied on the open-ended tasks (C⊥⊥T), based on its self-supervision types:

Models (⊥⊥)	Bidirect. Flow	Permutation Masking	Content Guidance	Content Prediction
Keskar et al. (2019)	✓	✓	✓	×
Fan et al. (2019)	×	×	✓	×
Huang et al. (2019)	✓	✓	×	×
Hua and Wang (2019)	×	×	✓	×
Kang et al. (2019)	✓	×	×	×
SSPlanner (ours)	✓	✓	✓	✓

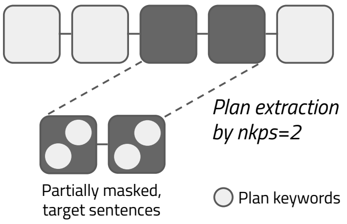
Table 2: Comparison of generation models in C⊥⊥T tasks by different self-supervision types.

Keskar et al. (2019) conditioned language models with topical words to control the target text. Fan et al. (2019) developed a surface realizer on anonymized entities using semantic role labeling. Hua and Wang (2019) used pre-extracted topics to guide a generator to produce stylized argumentation text. However, they are given the topical content as input (content guidance), while our SSPlanner directly predicts plan words from context (content prediction).

Fedus et al. (2018); Huang et al. (2019) developed various methods for text infilling task. Very similar to our task, Kang et al. (2019) developed language models informed by discourse relations on the bridging task; given the first and last sentences, predicting the intermediate sentences (bidirectional flow). However, they did not explicitly predict content words given context nor use them as a self-supervision signal in training. Unlike random masking in Keskar et al. (2019); Huang et al. (2019), we propose a better data augmentation training method via permutation masking.



(a) Sentence masking via permutation: t=1 (left) or t=2 (right): One paragraph has a total of 5+4=9 training instances.



(b) Plan extraction on target sentence. The maximum number of keywords per sentence (*nkps*=2) is given.

Figure 1: Paragraph completion (ParCom) task: (a) predicting the masked, target sentences given the unmasked, context sentences and (b) each masked, target sentence is given a small number of keywords extracted from the original target sentence.

3 ParCom: Paragraph Completion Task from Self-Supervision Signals

Our task is motivated by the recently proposed task; paragraph bridging (Kang et al., 2019), predicting intermediate sentences of a paragraph, given the first and the last sentences. To prevent generation becoming too divergent from the context in story or prompt generation (Fan et al., 2019), the bridging task restricts generation to end with the last sentence given, provided as an ending goal for generation.

However, in the bridging task, the objective is to generate text by coherently linking the two extreme sentences, making the task itself too challenging even for human[1]. For instance, the first and last sentences are too sparse to generate multiple (from 2 to 5) target sentences, increasing divergence of generation exponentially. Also, data usage in (Kang et al., 2019) is very inefficient; training a single instance per paragraph.

To address those issues, we propose a new paragraph completion task ParCom by maximizing self-supervision presented in a paragraph itself (Figure 1). We describe two types of self-supervisions: (1) masking a fixed-length of consecutive sentences in any position over a paragraph to maximize usage of a paragraph and (2) extracting partial keywords of the masked text as plan keywords to resolve the content sparsity problem. Mainly, we learn the patterns between the context and the plan keywords in training and at testing time predict the plan keywords, and guide the surface generator (§4).

3.1 Data Augmentation via Permutation Masking

Our work is motivated by word masking, in training contextualized language models (Devlin et al., 2019), but extending it to *sentence-level* for learning longer coherence.

Let t be the number of targets, masked sentences to predict and c be the number of unmasked, context sentences given, where l=t+c is the total length of a paragraph. For instance, in Figure 1, we have a l=5 length paragraph. We restrict the number of context sentences to be larger than the number of target sentences ($c > t$), to avoid context become too sparse. Also, we produce a total of 5+4=9 training instances, making use of data more efficient.

3.2 Denser Context by Plan Extraction

We provide extra partial information as a set of keywords to guide the surface generator. This is motivated by data-to-text tasks, but our plans are topical content instead of structured data.

We then question what types of plan keywords are the most effective for completing the paragraph. We extract keywords using various keyword extraction systems:

- `Off-the-shelf` systems extract keywords for each sentence using the three off-the-shelf systems: YAKE (Campos et al., 2020) using statistical features (e.g., TF, IDF), RAKE (Rose et al., 2010) using graph-based features (e.g., word degree), and PositionRank (Florescu and Caragea, 2017) using position-based PageRank. Then we choose duplicate keywords by majority voting.
- `Syntactic` features (e.g., part-of-speech tags, named entities (Fan et al., 2019), events

---

[1] METEOR score from human generation on the task is only about 4.5 (Kang et al., 2019)

(Tomkins, 1978)) are often regarded as the most salient topical content in generation. Using off-the-shelf Part-of-speech (PoS) tagger[2], we extract three types of syntactic features: *nouns*, *verbs*, and *nouns+verbs*.

- `Attention` weights are used to capture context-aware keywords. We use the pre-trained BERT (Devlin et al., 2019) to encode context and target text, then average the attention weights of context words with respect to each target word. We only use the first head's attentions, then average them over all 12 layers[3]. We finally choose words with the maximum weight except for the special tokens (e.g., [CLS]) and punctuation marks.

We set the maximum number of keywords per sentence (*nkps*) to 5. Some extractors output an empty keyword list, so the number of keywords across the systems is different. Our keywords are always uni-grams. In case they are not uni-grams, we split them by whitespaces and use individual unigrams as unique keywords. If the target text has multiple sentences, we combine all keywords from the sentences and randomly shuffle them. The plan keywords extracted are only provided while training our plan predictor, but not at test time. At testing time, we explicitly predict the keywords given context.

4 Self-supervised Text Planning (SSPlanner)

SSPlanner has various self-supervision modules that learn coherence signals from a paragraph itself: **surface realizer** (language model) by learning from a sequence of words, **next sentence predictor** by learning from a sequence of two consecutive sentences, **sentence position embeddings** by learning from an order of context sentences, **plan predictor** by learning from the relationship between the given context and important keywords used in the generation of the target text, and **content guidance** by learning from whether the predicted plan keywords are used or not in the target (See Figure 2).

Our planner is motivated by the two-stage generation framework (Moryossef et al., 2019; Miculicich et al., 2019; Fu et al., 2019; Hua and Wang, 2019). While in prior works, the content is explicitly given from the dataset or task itself, our plan predictor in SSPlanner predicts the plan keywords only from the given context, by learning the topical relationship between context and content in target from training data.

Given l length of a paragraph $s_1..s_l$ where each sentence s consists of a n number of words $s = w_1..w_n$, ParCom splits it into the context sentences $\texttt{x}{=}s_1..s_{j-1}, s_{j+t}..s_n$ and t target sentences to predict $\texttt{y}{=}s_j..s_{j+t-1}$. For each target sentence, p number of plan keywords $k_{j,1}..k_{j,p}$ for arbitrary target sentence s_j are given only at training time. The plan keywords are chosen from the entire vocabulary $\mathbb{V}^W$ and later combined with word distribution from the language model. We describe each self-supervision module in SSPlanner as follows:

Surface realization with pre-trained language models. We use two different types of transformer-based language models: BERT (Devlin et al., 2019) and GPT2 (Radford et al., 2019). While GPT2 is trained on bidirectionally tied language modeling, BERT is trained on masked language modeling. For BERT, we use the sequential sampling method (Wang and Cho, 2019). Using them, we encode context $\texttt{x}$ and output the hidden representation $h_{j,i} = \texttt{f}(h_{j-1,i}, \texttt{x}_{k<(j,i)})$ for j^{th} word in i^{th} sentence, where $\texttt{f} \in \{\text{BERT, GPT2}\}$ is the transformer language model. We then output the sentence vector h_i by averaging all word vectors in a sentence.

Sentence position embedding. We concatenate the encoded sentence representation with its sentence position embedding. By adding the sentence position embeddings into context encoding, the model is aware of where the context sentence came from (e.g., from the first or last). Compared to the simple concatenation of them (Kang et al., 2019), our sentence position embedding helps better learn the bi-directional coherence. The context vector's final representation is then $h^c = \frac{1}{n}\sum_i h_i; \texttt{pos}_i^c$ where n is the number of sentences in a text and $\texttt{pos}_i^c$ is the position embedding of i^{th} sentence in the context paragraph.

Plan prediction. This work assumes that high-level plan words consist of bag-of-words (Fu et al., 2019), so that the model directly predicts the plan keywords from the vocabulary used in surface realization. We calculate the plan probabilities over the entire vocabularies $\mathbb{V}$ given the context vector h^c and choose the p number of keywords with maximum probability estimates over vocabulary: $\hat{p}_{k\in\mathbb{V}} = \texttt{softmax}(h^c W^{cv} \mathbb{V})$ where $\mathbb{V}$ is the vocabu-

---

[2] `https://spacy.io/`

[3] Vig (2019) observed that which layers or heads are important for syntactic and semantic tasks.

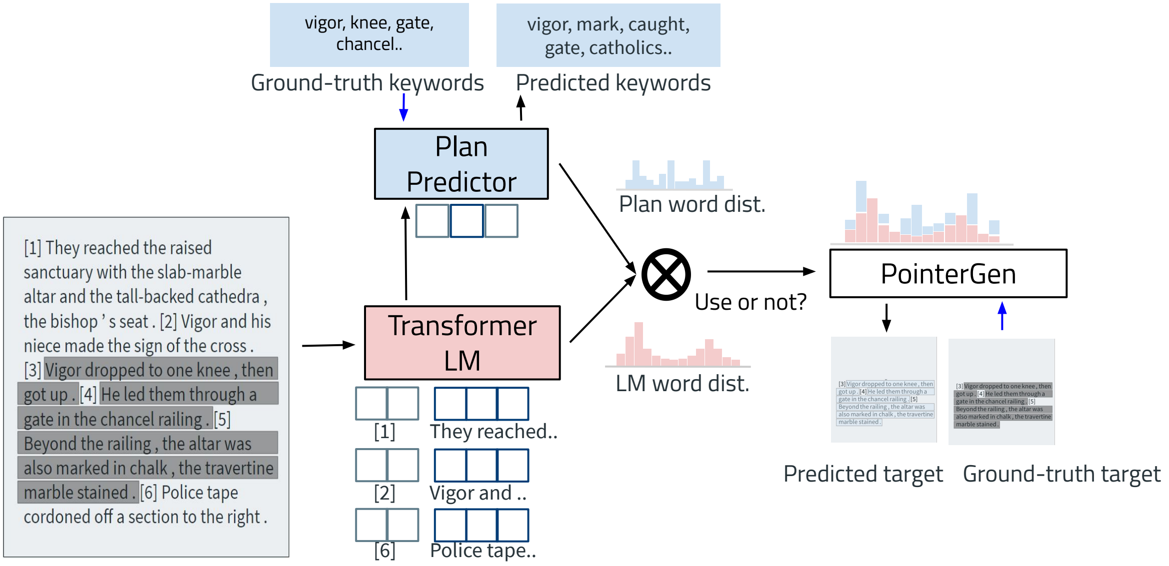


Figure 2: SSPlanner: first predicts high-level plan keywords (Plan Predictor) then guides the surface generation (Transformer LM) using the predicted plan keywords. The ground-truth plan keywords and target sentences (blue arrows) are only given in training time, whereas not in testing time. The predicted and ground-truth target can be seen in Table 7. Best viewed in color.

lary from the training data and W^{cv} is the trainable model parameter. We do not control any explicit cut-off in the $p_{k\in\mathbb{V}}$ in order to make the distribution differentiable. The objective is then:

$$\mathbb{L}_{\texttt{plan}} = -\sum_{k\in\mathbb{V}} \log p^*_k \log \hat{p}_k \tag{1}$$

where the loss is calculated by cross-entropy, $\hat{p}$ is the estimated probability distribution over vocabulary and $p*$ is the true one-hot distribution over plan keywords extracted from the extraction algorithms (i.e., [0,1..0,1] over $\mathbb{V}$).

Next sentence prediction. Motivated by Devlin et al. (2019), we also add an auxiliary task of predicting whether the target sentence is related to context or not. For negative samples, ParCom assigns 50% of random target sentences. We optimize $\hat{p}_{next} = softmax(W^c h^c)$ where W^c is the trainable parameter for the binary classification. Next sentence prediction's objective is then:

$$\mathbb{L}_{\texttt{next}} = -\sum_{j} p^*_{next} \log \hat{p}_{next} \tag{2}$$

where the loss is calculated by binary cross-entropy, p^*_{next} is the true label for next sentences and $\hat{p}_{next}$ is the predicted label.

Content guidance. We combine two distributions between plan predictions and language modeling through copy mechanism following the pointer-generator (See et al., 2017). For j^{th} sentence, we learn the probability of choosing the plan keyword or the word from language modeling based on context vectors, plan keyword distributions, and sentence position embedding of target sentences: $\mathsf{P}_{plan}(v_k) = \sigma(\mathsf{W}^{ck}[h^c;\hat{p}_k;\texttt{pos}^t_j])$, where σ is a sigmoid function, W^{ck} is the trainable parameter, and $\mathsf{v} \in [0,1]$ is a probability of whether choosing the plan keyword or not.

We then decode each target sentence using the same language model decoder: $s_j = \mathsf{g}(s_{j-1}, \hat{y}_{j-1})$, where $\mathsf{g} \in \{$BERT, GPT2$\}$ is the language model decoder and s is its output hidden state. We can obtain the attention over plan keywords k:

$$\alpha_k^{plan} = \texttt{softmax}(\hat{p}_k \mathsf{W}^{kj}[s_j;\texttt{pos}^t_j]) \tag{3}$$

where W^{kj} is the trainable parameter. Lastly, we combine the distribution of plan probabilities P_{plan} and word probabilities in decoding P_{lm}.

$$P(y) = \mathsf{P}_{plan}\sum_{k}(\alpha_k^{plan}) + (1-\mathsf{P}_{plan})P_{lm}(y) \tag{4}$$

The objective of the pointer-generator is then:

$$\mathbb{L}_{\texttt{gen}} = -\sum_{i\in\texttt{t}, j=1..n} P(\hat{y}_{i,j}) \log P(y^*_{i,j}) \tag{5}$$

Final objective. The final objective of our training is to minimize the three objectives; plan prediction, next sentence prediction, and pointer generation, together:

$$\mathbb{L}_{SPP} = \lambda_{plan}\mathbb{L}_{\texttt{plan}} + \lambda_{next}\mathbb{L}_{\texttt{next}} + \mathbb{L}_{\texttt{gen}} \tag{6}$$

where the weighting terms; λ_{plan} and λ_{next}, are obtained through the cross-validation.

5 Experiment

We answer three questions in our experiments: Q1. Does SSPlanner help produce a more coherent generation in ParCom? If so, which of the self-supervision modules are the most helpful? Q2. What types of plan keywords (e.g., noun, verb, attention) are most effective in terms of generation quality? How many keywords given are the most helpful? Q3. Is ParCom a valid generation task to measure text coherence?

Dataset	Domain	#Sent.	#Para.	Length	#Inst.	#Keyw.
`Fantasy`	book	1.6M	352K	4.7	21M	3.2-19M
`Romance`	book	5.3M	1.1M	4.6	67M	27-62M
`WikiText`	wiki	510K	3.3M	6.5	82M	14M-78M
`CNNDM`	news	12M	311K	39.3	246M	63-315M

Table 3: Data statistics: domain of text, the number of sentences, the number of paragraphs, the averaged length (number of sentences) of paragraph, the number of training instances permuted from the paragraphs, and minimum to maximum number of keywords extracted.

Paragraph datasets. Table 3 shows the paragraph datasets collected for our experiment. We collect paragraphs from various domains: the two most frequent sub-genres extracted from BookCorpus (Zhu et al., 2015) dataset; `Fantasy` and `SciFi`, Wikipedia text from `wikiText`-103 (Merity et al., 2016), and news articles from CNN/DailyMail (`CNNDM`) dataset (See et al., 2017). `CNNDM` and `WikiText` contain factual knowledge about events or things, whereas `Fantasy` and `Romance` are more narrative.

For a fair comparison, we restrict the number of sentences in a paragraph from 4 to 7, the same as the setup in Kang et al. (2019). Since `CNNDM` has no specific line breakers in the document, each document is regarded as a single paragraph (39.3 lengths on average). Each dataset is randomly split by 0.9/0.05/0.05 for the train, valid, and test set, respectively.

Models. As baselines, we compare non-pretrained sequence-to-sequence models: **BiLSTM** (Hochreiter and Schmidhuber, 1997) and hierarchical seq2seq **HRED** (Serban et al., 2017; Sordoni et al., 2015) by encoding the concatenation of context sentences and then decoding the target sentences. We also compare two strong paragraph generation models: **FlowNet**$_{disc}$ using discourse relations and **FlowNet**$_{latent}$ using latent delta relations (Kang et al., 2019), following the same setups (e.g., discourse parser, hyper-parameters) of the original paper.

Also, we use the pre-trained language model baselines fine-tuned on our paragraph datasets: the fine-trained bert-base-uncased (**BERT**$_{finetune}$) and gpt2-base (**GPT2**$_{finetune}$) models (Wolf et al., 2019). For BERT, we use the sequential sampling method (Wang and Cho, 2019) with Nucleus sampling strategies for producing more diverse text (Holtzman et al., 2019).

Our proposed method **SSPlanner** is trained using either bert-base-uncased or gpt2-base. As an upper-bound of our method, we predict masked, target text using the ground-truth plan keywords $\hat{p}$.

We find the best hyper-parameters on the validation set using a grid search on the learning rate, the number of training epochs, sampling parameters, and so on. We follow the default parameters used in the HuggingFace's transformer models (Wolf et al., 2019). For a pointer-generator, we follow the default parameters in (See et al., 2017). The maximum number of plan keywords per sentence is 3. For more details, see the Appendix.

Metrics. We evaluate our models using both automatic metrics and human evaluation: For automatic metrics, we use two hard metrics: BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005), as well as an embedding similarity metric to capture the semantic similarity: Vector Extrema (VE) (Liu et al., 2016).

For human evaluation, we measure fluency, coherence with respect to context, and overall quality with 1-5 Likert scale. We randomly select 100 samples from the test set in each `Romance`, `WikiText`, and `CNNDM` (total 300 paragraphs). Each sample is annotated by three crowd-workers then averaged. We also measure how human performs on the task by asking workers to predict the masked text in these 300 paragraphs.

5.1 Automatic and Human Evaluation

Table 4 and 5 show automatic and human evaluation result on ParCom task. The fine-tuned models ({BERT,GPT2}$_{finetune}$)[4] and FlowNet models show significant improvements over the seq2seq

---

[4] In our experiment, no fine-tuned models (original pre-trained models) show very poor performance on our task.

baselines (BiLSTM and HRED) by large margins (∼1.5 METEOR), showing the importance of fine-tuning on target text and modeling inter-sentential relation, respectively.

In all datasets, SSPlanner shows significant improvements in both hard and soft metrics. This indicates that explicitly predicting content words before surface realization helps generate more coherence text on target-oriented generation in PARCOM. SSPlanner with GPT2 outperforms SSPlanner with BERT, because such autoregressive models like GPT2 are more appropriate for our task, whereas BERT is not. Finally, the performance of SSPlanner with the ground-truth keywords ($\hat{p}$) achieves the dramatic gain, which can be seen as an upper bound of our planning framework. Among domains, `Fantasy` and `Romance` seem to be better predicted compared to `WikiText` and `CNNDM` that require additional factual knowledge as well as narrative coherence.

Using the best model; **SSPlanner** (GPT2), we conduct a human evaluation on various system outputs and human-generated text (Table 5). The fine-tuned GPT2 model shows high fluency as itself but very low coherence with context, because PARCOM requires not only fluent and natural text but also context-aware text. SSPlanner achieves much higher coherence and overall quality than the baselines, but still is far behind the upper-bound model (SSPlanner with $\hat{p}$) and human generation.

5.2 Performance of Self-supervision Modules

We measure performance (i.e., accuracy) of each self-supervision module in SSPlanner: next sentence prediction (NSP) and plan prediction (PP) on the test samples (Table 6). SSPlanner achieves very high accuracy in NSP. In PP, SSPlanner correctly predicts almost half of the keywords from the total vocabulary size, indicating that the plan prediction module in SSPlanner can capture a certain level of coherence between the given context and target text to predict, although it is not perfect.

5.3 Comparison of Self-supervision Modules and Keyword Types in Training

Table 8 shows ablation on self-supervision modules. All scores are macro-averaged on three datasets: `Romance`, `WikiText`, and `CNNDM`. Each module helps improve the overall performance (METEOR): plan prediction (+2.1 M), sentiment positional embedding (+1.4 M), and next sentence prediction (+0.4 M),

Among the different types of keywords used in training (Table 9), the combination of nouns and verbs and the keywords extracted from the off-the-

Task: given context sentences ⓪, ①, ⑤, predict target sentences ②, ③, ④

⓪ ”They reached the raised sanctuary with the slab-marble altar and the tall-backed cathedra , the bishop ’ s seat .” ① ”Vigor and his niece made the sign of the cross .” ② ”Vigor dropped to one knee , then got up .” ③ ”He led them through a gate in the chancel railing .” ④ ”Beyond the railing , the altar was also marked in chalk , the travertine marble stained .” ⑤ ”Police tape cordoned off a section to the right .”

Plan keywords extracted from target sentences using different systems:

`Off-the-shelf`	② (vigor, dropped, one), ③ (chancel, railing, led), ④ (travertine, marble, stained)
`Syntactic` (noun)	② (vigor, knee), ③ (gate, chancel), ④ (railing, altar, chalk)
`Syntactic` (verb)	② (dropped, got), ③ (led, railing), ④ (marked, stained)
`Syntactic` (nounverb)	② (vigor, dropped, knee), ③ (led, gate, chancel), ④ (railing, altar, marked)
`Attention`	② (vigor, dropped, got), ③ (led, gate, railing), ④ (altar, chalk, travertine)

	SSPlanner	**Human writer**
Human eval.	F : 4.3, C: 3.9, Q: 3.8	F : 4.8, C: 4.9, Q: 4.8
Predicted plan keywords	② (vigor, mark, caught), ③ (gate, catholics, police), ④ (altar, mark, bishop)	② (vigor, show, sanctuary), ③ (altar, blood, trace), ④ (kill, sacrifice, recently)
Predicted target sentences	② “vigor continuously walked down the road .” ③ “he opened the gate which has a sign of catholics .” ④ “both bishop and vigor met a police officer .”	② “Then vigor showed around the sanctuary to them.” ③ “In there, they found a trace of the blood on the altar.” ④ “They thought that recently the sacrifice was killed in here.”

Table 7: Example paragraph with the plan keywords extracted from different algorithms and output predictions by SSPlanner and human writer. **F** is fluency, **C** is coherence with context, and **Q** is overall quality.

Models	**M**	**VE**
SSPlanner	7.9	66.6
- Sentence Position (SP)	-1.4	-8.1
- Plan Prediction (PP)	-2.1	-13.2
- Next Sentence Prediction (NSP)	-0.5	-3.6

Table 8: Ablation on self-supervision modules.

Models	**M**	**VE**
\w Random	6.1	54.0
\w Syntac(Verb)	7.6	63.7
\w Syntac(Noun)	7.5	62.2
\w Syntac(N+V)	**8.0**	**66.3**
\w Off-the-shelf	7.8	66.8
\w Attention	7.6	63.6

Table 9: Comparison of plan keyword types at training (right). All scores are macro-averaged on three datasets: `Romance`, `WikiText`, and `CNNDM`.

shelf algorithm outperform the other types. We conjecture that since a sentence consists of both entities (i.e., nouns) and events (i.e., verbs) according to the script theory (Schank and Abelson, 2013), the combination of them provides the largest amount of information to complete the sentence. Attention-based keywords are not that helpful because the averaged attention weights themselves may not be a good indicator for topical coherence.

5.4 Comparison of Keyword Types and Ratios in Testing

In Figure 3, at test time, the predicted keywords from SSPlanner (red) shows dramatic improvements in both METEOR and VE against the random keywords (blue), but far behind the ground-truth keywords (yellow). As more predicted keywords are used at testing time, the generation quality increases. We include the full table of our ablation tests over the three datasets in the Appendix.

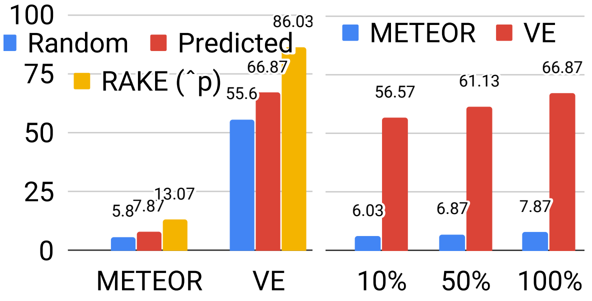

Figure 3: Comparison of plan keyword types (left) and plan keyword ratios used (right) in testing. Best viewed in color.

Table 7 shows an example paragraph with

ground-truth keywords extracted from different algorithms in ParCom and predicted target sentences with plan keywords by SSPlanner and a human writer. In the prediction by SSPlanner, half of the predicted keywords are used in the generation, making the story more coherent to the first two sentences and the last ending sentence. In the entire test set, we observe that about 43% of predicted keywords are actually used in generation.

6 Conclusion

A written paragraph itself contains various inductive coherence signals to be learned through *self-supervision*. Motivated by this, we propose a paragraph completion task for measuring textual coherence from a long document using different types of self-supervision signals. To solve the task, we propose a text planner SSPlanner that explicitly predicts topical content keywords, and then guides the surface generator using the predicted plan keywords. SSPlanner consists of different kinds of self-supervision modules: sentence positions, a sequence of words or sentences, and the topical relationship between context and target. Our self-supervised planning, in addition to other types of planning (e.g., discourse, goals, coreference, tenses) can be an important step toward modeling a long-term coherence in text generation.

Our results suggest several promising directions: Although our ablation tests show the effect of each self-supervision module, types of plan keywords, and the amount of keywords with respect to generation quality, there are more spaces to explore in self-supervised text planning. For example, one can study the generation quality with respect to the position of the target sentences (beginning, middle, end), the comparison of plan keywords predicted by human and system, the effect of data augmentation by their positions (e.g., masking the only middle), the generation quality with respect to the ratio between masked and unmasked sentences, and more.

Second, we can extend the set of plan keywords to be more structured like a discourse tree. For instance, one can write a simple structure like "(CAUSALITY (ELABORATE (Buy, Coffee)) (Pay, Tip, 12 dollars))" then the system can generate a long, coherent text reflected by the structure. Predicting such structural plans from context and imposing them into the generator would be a potential direction for future work.

Last, text planning is a cognitive function commonly used in human language generation. To generate more human-like utterances, different planning stages should be simultaneously combined together (Kang, 2020), such as abstractive planning, strategic planning, coherence planning, and diversity planning. Combining the heterogeneous planning systems will be a crucial step towards developing a human-like language generation.

Abstract

Inquisitive probing questions come naturally to humans in a variety of settings, but is a challenging task for automatic systems. One natural type of question to ask tries to fill a gap in knowledge during text comprehension, like reading a news article: we might ask about background information, deeper reasons behind things occurring, or more. Despite recent progress with data-driven approaches, generating such questions is beyond the range of models trained on existing datasets.

We introduce INQUISITIVE, a dataset of ∼19K questions that are elicited while a person is reading through a document. Compared to existing datasets, INQUISITIVE questions target more towards high-level (semantic and discourse) comprehension of text. We show that readers engage in a series of pragmatic strategies to seek information. Finally, we evaluate question generation models based on GPT-2 (Radford et al., 2019) and show that our model is able to generate reasonable questions although the task is challenging, and highlight the importance of context to generate INQUISITIVE questions.

1 Introduction

The ability to generate meaningful, inquisitive questions is natural to humans. Studies among children (Jirout, 2011) showed that questions serving to better *understand* natural language text are an organic reflection of curiosity, which "arise from the perception of a gap in knowledge or understanding" (Loewenstein, 1994). Because of its prominence in human cognition and behavior, being able to formulate the right question is highly sought after in intelligent systems, to reflect the ability to understand language, to gather new information, and to engage with users (Vanderwende, 2007, 2008; Piwek and Boyer, 2012; Rus et al., 2010; Huang et al., 2017). A recent line of work on data-driven question generation techniques (Zhou et al., 2017; Yuan et al., 2017; Song et al., 2018; Zhao et al., 2018) focuses on generating questions for datasets like SQuAD (Rajpurkar et al., 2016, 2018). However, factoid questions generated with an answer in mind after the user has read the full text look very different from more natural questions users might have (Kwiatkowski et al., 2019). This has led to work on "answer-agnostic" question generation (Du et al., 2017; Subramanian et al., 2018; Scialom and Staiano, 2019), but the sources of data still emphasize simple factoid questions. Other prior work used question generation to acquire domain-specific knowledge (Yang et al., 2018) and seek clarification in conversation (Rao and Daumé III, 2018, 2019; Braslavski et al., 2017). However, data-driven generation of questions that reflect text understanding in a more general setting is challenging because of the lack of appropriate training data.

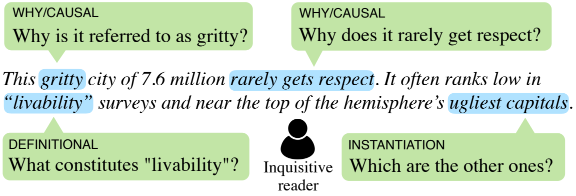

Figure 1: Example questions in INQUISITIVE reflecting a range of information-seeking strategies.

We introduce INQUISITIVE, a new, large-scale dataset of questions that target high level processing of document content: we capture questions elicited from readers *as they naturally read* through a document sentence by sentence. Because these questions are generated while the readers are processing the information, the questions directly communicate gaps between the reader's and writer's knowledge about the events described in the text, and are not necessarily answered in the document it-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6544–6555,
November 16–20, 2020.

self. This type of question reflects a real-world scenario: if one has questions during reading, some of them are answered by the text later on, the rest are not, but any of them would help further the reader's understanding at the particular point when they asked it. This resource is a first step towards understanding the generation of such curiosity-driven questions by humans, and demonstrates how to communicate in a natural, inquisitive way by learning to rely on context.

Specifically, we crowdsource ∼19K questions across 1,500 documents[1], each question accompanied by the specific span of the text the question is about, illustrated in Figure 1. The questions are verified to ensure that they are grammatically correct, semantically plausible and meaningful, and not already answered in previous context. We show that the questions capture a variety of phenomena related to high-level semantic and discourse processes, e.g., making causal inferences upon seeing an event or a description, being curious about more detailed information, seeking clarification, interpreting the scale of a gradable adjective (Hatzivassiloglou and Wiebe, 2000), seeking information of an underspecified event (where key participants are missing), and seeking background knowledge. Our analyses reveal that the questions have a very different distribution from those in existing factoid and conversational question answering datasets (Rajpurkar et al., 2016; Trischler et al., 2017; Choi et al., 2018), thus enabling research into generating natural, inquisitive questions.

We further present question generation models on this data using GPT-2 (Radford et al., 2019), a state-of-the-art pre-trained language model often used in natural language generation tasks. Human evaluation reveals that our best model is able to generate high-quality questions, though still falls short of human-generated questions in terms of semantic validity, and the questions it generates are more often already answered. Additionally, our experiments explore the importance of model access to already-established common ground (article context), as well as annotations of which part of the text to ask about. Finally, transfer learning results from SQuAD 2.0 (Rajpurkar et al., 2018) show that generating inquisitive questions is a distinct task from question generation using factoid question answering datasets.

The capability for question generation models to simulate human-like curiosity and cognitive processing opens up a new realm of applications. One example for this sort of question generation is guided text writing for either machines or humans: we could use these questions to identify important points of information that are not mentioned yet and should be included. In text simplification and summarization, these questions could be used to prioritize what information to keep. The spans and the questions could also help probing the specific and vague parts of the text, which can be useful in conversational AI. Because of the high level nature of our questions, this resource can also be useful for building education applications targeting reading comprehension.

2 Related Work

Among question generation settings, ours is most related to answer-agnostic, or answer-unaware question generation: generating a question from text without specifying the location of the answer (Du et al., 2017). Recent work (Du and Cardie, 2017; Subramanian et al., 2018; Wang et al., 2019; Nakanishi et al., 2019) trains models that can extract phrases or sentences that are question-worthy, and uses this information to generate better questions. Scialom and Staiano (2019) paired the question with other sentences in the article that do not contain the answers to construct curiosity-driven questions. However, these approaches are trained by re-purposing question-answering datasets that are factual (Rajpurkar et al., 2016) or conversational (Choi et al., 2018; Reddy et al., 2019). In contrast, we present a new dataset targeting questions that reflect the semantic and discourse processes during text comprehension.

Several other question answering datasets contain questions that are more information-seeking in nature. Some of them are collected from questions that users type in search engines (Yang et al., 2015; Bajaj et al., 2016; Dunn et al., 2017; Kwiatkowski et al., 2019). Others are collected given a small amount of information on a topic sentence (Trischler et al., 2017; Clark et al., 2020) or in the context of a conversation (Choi et al., 2018; Reddy et al., 2019; Qi et al., 2020). Our data is collected from news articles and our questions are precisely anchored to spans in the article, making our questions less open-ended than those in past datasets. While Li et al. (2016b) also collected a

---

[1] Data available at `https://github.com/wjko2/INQUISITIVE`

small number of reader questions from news articles, their goal was to study underspecified phrases in sentences when considered out-of-context. Contemporaneously, Westera et al. (2020) presented a dataset of 2.4K naturally elicited questions on TED talks, with the goal to study linguistic theories of discourse.

Previous work generating clarification questions (Rao and Daumé III, 2018, 2019; Braslavski et al., 2017) uses questions crawled on forums and product reviews. The answers to the questions were used in the models to improve the utility of the generated question. In our data, clarification is only one of the pragmatic goals. In addition, we focus on news articles which contains more narrative discourse and temporal progression.

3 INQUISITIVE: A corpus of questions

This section presents INQUISITIVE, a corpus of ∼19K questions for high level text understanding from news sources (Section 3.1), which we crowdsource with a specific design to elicit questions as one reads (Section 3.2). We then discuss a second validation step for each question we collected as quality control for the data (Section 3.3).

3.1 Text sources

In this work we focus on news articles as our source of documents. News articles consist of rich (yet consistent) linguistic structure around a targeted series of events, and are written to engage the readers, hence they are natural test beds for eliciting inquisitive questions that reflect high level processes.

We use 1500 news articles, 500 each from three sources: the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993), Associated Press articles from the TIPSTER corpus (Harman and Liberman, 1993), and Newsela (Xu et al., 2015), a commonly used source in text simplification (we use the most advanced reading level only). We select articles that are not opinion pieces and contain more than 8 sentences to make sure that they are indeed news stories and that would involve sufficiently complex scenarios.

3.2 Question collection

To capture questions that occur as one reads, we design a crowdsourcing task in which the annotators ask questions about what they are reading currently and without access to any upcoming context.

The annotators start from the beginning of an article, and are shown one sentence at a time in article order. After reading each sentence, they ask questions about the sentence, grounded in a particular text span within the sentence (via highlighting) that they would like elaboration or explanation of. We specifically asked for questions that would enhance their understanding of the overall story of the news article. An annotator can ask 0 to 3 questions per sentence, and the next sentence is only revealed when the annotator declares that no more question needs to be asked. The annotation instructions and interface is shown in Figures 4 and 5 in the Appendix.

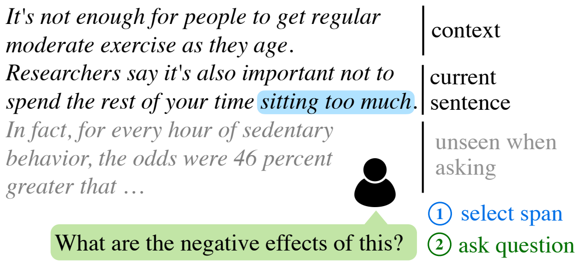

Figure 2: Workers highlight spans and ask questions they are curious about the span as they read through the article.

In this manner, we elicit questions from annotators for the first 5 sentences from each article. We restrict the annotation to these sentences as they reflect a reader's cognitive process of context establishment from the very beginning, and that lead sentences are known to be the most critical for news articles (Errico et al., 1997). For each sentence, we asked 5 distinct annotators from Amazon Mechanical Turk to ask questions. For quality control, we restrict to workers who are located in English speaking countries, and who have completed at least 100 tasks with an approval rating above 0.98.

3.3 Question validation

To ensure that our final corpus contain high quality questions, we design a second crowdsourcing task for the validation of these questions, inspired by prior work that also validated crowdsourced questions manually (FitzGerald et al., 2018). At a high level, we want to ensure that the questions are grammatically correct and semantically plausible, related to the highlighted span, and not already answered in the sentence or any previous sentence in the article.

Specifically, for each question gathered in Sec-

	Average length	std.dev
Question	7.1	3.4
Highlighted span	3.2	2.3

Table 1: Average length and standard deviation of the questions asked by workers and the chosen span

tion 3.2, we show the validation annotators the first few sentences of the article up to the sentence where the question is asked, so that the validation annotators have access to the same context as those who asked the questions. We also show the highlighted span for that question. The workers are instructed to answer the following yes/no questions: (1) Is it a valid question? An invalid question is incomplete, incomprehensible, not even a question at all, or completely unrelated to the article. (2) Is this question related to the highlighted span? (3) Is the question already answered in prior context?

Each question is answered by 3 workers from Mechanical Turk. If more than half of the workers judge the question to be either invalid, unrelated to the span, or already answered, the question is deemed low-quality and excluded. About 5% of the collected questions are low-quality questions; this low rate is consistent with our inspection. Additionally, we manually annotated 100 of the questions removed and we agreed with 92 of them.

Table 1 shows the average and standard deviation of the number of tokens for all validated questions, and those of tokens in the highlighted spans.

3.4 Corpus setup

For experimentation, in order to ensure model generalizability, we split by articles instead of by sentences: we set aside 50 articles from each news source for validation, which contains 1991 questions, and 50 articles each as the test set, which contains 1894 questions. The remaining articles, with 15931 questions in total, are used as the training set.[2]

4 Data analysis

In this section, we present a deep dive into INQUISITIVE, showing that the questions are much higher level than existing datasets (Section 4.1), and have rich pragmatic functions (Section 4.2). We also investigate the highlighted span associated with each question (Section 4.3), and the relative salience of questions to the article (Section 4.4).

4.1 Question types and diversity

We first investigate the types of questions in the corpus, in comparison to existing question-answering datasets that are also often used in answer-agnostic question generation, in particular, SQuAD 2.0 (Rajpurkar et al., 2018) and QuAC (Choi et al., 2018). We additionally compare with NewsQA (Trischler et al., 2017) which also uses news articles.

Question types To get a basic sense of question types, Table 2 shows the most frequent bigrams that start a question. For comparison, we also show the data for SQuAD, QuAC, or NewsQA. It is notable that INQUISITIVE contains a much higher percentage of high level questions — those signaled by the interrogatives "why" and "how" — than either QuAC, SQuAD and NewsQA; these three datasets are characterized by substantially more "what" questions.

Lexical diversity We also check whether two annotators ask the same questions if they highlighted the same span. We estimate this by calculating the average percentages of shared unigram, bigram, and trigrams among the all pairs of questions when the highlighted span exactly match another. In the 919 pairs, the percentages of shared ngrams are 33.8 % for unigrams, 15.4 % for bigrams, and 8.5% for trigrams. This shows that even if the annotated spans are exactly the same, annotators often ask different questions. For example, with the context below (the highlighted span in italic), the annotators asked very different questions:

> It was the type of weather that would have scrubbed a space shuttle launch. The rain was *relentless*. [**Q1**: Why was the rain relentless?] [**Q2**: How heavy is considered relentless?]

Additionally, we found that the percentage of words appearing in the highlighted span that also appeared in the corresponding question is only 22%, showing that the annotators are not simply copying from the span they had highlighted into the question.

To estimate the overall lexical diversity of the collected questions, we report the distinct bigram metric (Li et al., 2016a) that is often used to evaluate lexical diversity of dialog generation systems. This metric calculates the number of distinct bigrams divided by the total number of words in the all questions. The metric of our dataset is 0.41; this is much higher than QuAC (0.26), NewsQA (0.29), and slightly higher than SQuAD 2.0 (0.39),[3]

---

[2] The numbers before filtering are: 2153, 1968, 16816.

[3] We use a subset of the same size as our data, taken from

Table 2: Most frequent leading bigrams in different datasets

possibly because SQuAD contains highly specific questions with many named entities.

4.2 What information are readers asking for?

To gain insights into the pragmatic functions of the questions, we manually analyze a sample of 120 questions from 37 sentences. Of those questions, 113 of them are judged as high-quality using the validation process described in Section 3.3. We now describe a wide range of pragmatic phenomena that signal semantic and discourse understanding of the document. With each category, we also show examples where the highlighted span corresponding to the question are displayed in *italic*. Due to space constraints, we show only the minimal required context to make sense of the questions in the examples.

Why questions Causal questions — those signaled by the interrogative "why" as well as its paraphrases such as "what is the reason that" — account for 38.7% of the questions we inspected. Such why-questions tend to associate very often with an adjective or adverb in the sentence:

> Predicting the financial results of computer firms has been a *tough job lately*. [**Q:** Is there a particular cause for this?]

Verbs also trigger why-questions, indicating that readers are making causal inferences around events:

> The stock market's *dizzying gyrations* during the past few days have made a lot of individual investors wish they could buy some sort of insurance. [**Q:** Why is it gyrating?]

Elaboration questions In 21.6% of the questions, readers seek more detailed descriptions of concepts in the text ranging from entities and events to adjectives. These questions are very often "how" questions, although they can take different forms, especially if the question is about an entity:

> The solution, at least for some investors, may be a *hedging technique* that's well known to players in the stock-options market . [**Q:** What is the technique?]
>
> Undeterred by such words of caution, corporate America is flocking to Moscow, lured by a huge untapped market and Mikhail Gorbachev's *attempt to overhaul the Soviet economy.* [**Q:** How is he overhauling the economy?]

The second example above shows a elaboration question for a verb phrase; in this case, the patient and the agent are both specified for the verb phrase. In addition, we found that some elaboration questions about events are about missing arguments, especially at the beginning of articles when not enough context has established, e.g.,

> It was the kind of *snubbing* rarely seen within the Congress, let alone within the same party. [**Q:** Who got snubbed?]

Definition questions A notable 12.6% of the questions are readers asking for the meaning of a technical or domain-specific terminology; for example:

> He said Drexel — the *leading underwriter* of high-risk junk bonds — could no longer afford to sell any junk offerings. [**Q:** What is a leading underwriter?]

In some cases, a simple dictionary or Wikipedia lookup will not suffice, as the definition sought can be highly contextualized:

> Mrs. Coleman, 73, who declined to be interviewed, is the Maidenform *strategist.* [**Q:** What is the role of a strategist?]

Here the role of a strategist depends on the company that employed her.

---

the beginning of each dataset, since the metric is sensitive to the amount of data.

Background information questions We found that 10% of the questions aim at learning more about the larger picture of the story context, e.g., when the author draws comparisons with the past:

> Seldom have *House hearings caused so much apprehension* in the Senate. [**Q:** When have house hearings caused apprehension?]

Other times, answering those questions will provide topical background knowledge needed to better understand the article:

> The stock market's dizzying gyrations during the past few days have made a lot of individual investors wish they could buy some sort of *insurance*. [**Q:** How would that insurance work?]

Instantiation questions In 8.1% of the questions, the readers ask for a specific example or instance when a set of entities is mentioned; i.e., answering these questions will lead to entity instantiations in the text (McKinlay and Markert, 2011):

> The solution, at least for *some investors*, may be a hedging technique that's well known to players in the stock-options market. [**Q:** Which ones?]

This indicates that the reader sometimes would like concrete and specific information.

Forward looking questions Some questions (4.5%) reflect that the readers are wondering "what happened next", i.e., these questions can bear a reader's inference on future events:

> Ralph Brown was 31,000 feet over Minnesota when both jets on his Falcon 20 flamed out. At 18,000 feet, he says, he and his co-pilot "were looking for an *interstate* or a cornfield" to land. [**Q:** Would they crash into cars?]

Others We have noticed several other types of questions, including asking about the specific timeframe of the article (since readers were only shown the body of the text). Some readers also asked rhetorical questions, e.g., expressing surprise by asking *Are they really?* to an event.

Finally, we observed that a small percentage of the questions are subjective, in the sense that they reflect the reader's view of the world based on larger themes they question, e.g., *Why is doing business in another country instead of America such a sought-after goal?*.

4.3 What do readers ask about?

In addition to understanding what type of information is sought after, we also investigate whether there are regularities in what the questions are about. This is reflected in the highlighted spans accompanied with each question.

Constituent	%	Constituent	%
NP	22.5	VBN	2.8
NN	13.5	VBD	2.7
JJ	9.6	ADJP	2.5
VP	4.9	VB	2.2
NNS	4.3	S	2.0
NNP	3.9	VBG	1.9
NML	2.8	PP	1.4

Table 3: Top constituents in highlighted spans.

Table 3 shows the most frequent syntactic constituents that are highlighted.[4] Readers tend to select short phrases (the average number of tokens in the spans is 3.2) or individual words; while noun phrases are most frequently selected, a variety of constituents are also major players.

We found that the probability that two highlighted spans overlap is fairly high: 0.6. However, F1-measure across all spans pairs is only 0.25. The percentages of highlighted tokens chosen by 2, 3, 4, or all 5 annotators are: 0.8, 0.17, 0.03, and 0.006. Upon manual inspection, we confirm the numerical findings that there is a high variance in the location of highlights, even though the question quality is high. Secondly, while there are spans that overlap, often a question's "aboutness" can have many equally valid spans, especially within the same phrase or clause. This is exacerbated by the short average length of the highlights.

4.4 Question salience

The analysis in Section 4.2 implied that the information readers sought after differs in terms of their relative salience with respect to the article: some information (e.g., background knowledge) can be important but typically isn't stated in the article, while others (e.g., causal inference or elaboration) are more likely to be addressed by the article itself. To characterize this type of salience in our data, we ask workers to judge if the answer to each question *should* be in the remainder of the article, using a scale from 1 to 5. Each validated question is annotated by 3 workers. The average salience rating is 3.18, with a standard deviation of 0.94, showing that the questions are reasonably salient. The distribution of salience ratings is shown in Table 4.

5 Question generation from known spans

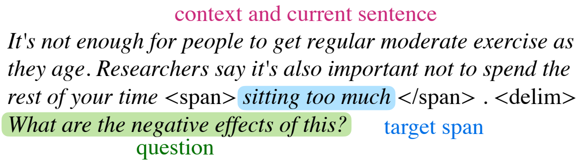
We use INQUISITIVE to train question generation models and evaluate the models' ability to generate questions *with access to* the gold-standard spans

---

[4] Parsed by Stanford CoreNLP (Manning et al., 2014).

Range	%	Range	%
$[1,2)$	6.9	$[3,4)$	41.6
$[2,3)$	22.5	$[4,5]$	29.1

Table 4: Distribution of question salience ratings.



It's not enough for people to get regular moderate exercise as they age. Researchers say it's also important not to spend the rest of your time *sitting too much* . <delim> *What are the negative effects of this?*

Figure 3: We concatenate the context, sentence and questions and learn a language model on them using GPT-2.

highlighted by annotators, while also contrasting this task with question generation from SQuAD 2.0 data. In Section 6, we present experiments that simulate the practical scenario where the highlighted spans are not available.

5.1 Models

Our question generation model is based on GPT-2 (Radford et al., 2019), a large-scale pre-trained language model, which we fine-tune on our data. Each training example consists of two parts, illustrated in Figure 3. The first part is the article context, from the beginning to the sentence where the question is asked. Two special tokens are placed in line to indicate the start and end positions of the highlighted span. The second part is the question. The two parts are concatenated and separated by a delimiter. The model is trained the same way as the GPT-2 language modeling task, with the loss only accumulated for the tokens in the question. During testing, we feed in the article context and the delimiter, and let the model continue to generate the question. We call this model, which uses the span and all prior context, **Inquirer**.

To analyze the contribution of prior context that serve as common ground when humans generated the questions, we train two additional variants of the model: (1) A **span+sentence** model, in which the conditioning context only contains the single sentence where the question is asked. (2) A **span-only** model, in which the conditioning context only contains the highlighted span inside the sentence where the question is asked.

SQuAD pre-training. To investigate whether models could leverage additional supervision from SQuAD, we experiment on our Inquirer model that is first fine-tuned on SQuAD 2.0. We treat the SQuAD answer spans as the highlighted spans. Note that in SQuAD, the span is where the answer to the generated question should be; in our task, the span is what the question should be *about*. This parallel format allows us to show the pragmatic distinction of INQUISITIVE question generation and SQuAD-based question generation. Nevertheless, such pre-training could in principle help our model learn a language model over questions, albeit ones with a different distribution than our target data (Table 2).

Model parameters. We use the GPT2-medium model for all question generation models. The batch size is 2 and we fine-tune for 7 epochs. For SQuAD pre-training, the batch size is 1 and we fine-tune for 1 epoch. We use the Adam (Kingma and Ba, 2015) optimizer with $(\beta_1, \beta_2) = (0.9, 0.999)$ and a learning rate of 5e-5. The parameters are tuned by manually inspecting generated questions in the validation set.

5.2 Human evaluation

We mainly perform human evaluation on the generated questions by collecting the same validity judgments from Mechanical Turk as described in Section 3.3.

The results are shown in Table 6. We can see that *Inquirer* generates a valid question 75.8% of the time, the question is related to the span 88.7% of the time, and the question is already answered 9.6% of the time. This shows that *Inquirer* is able to learn to generate reasonable questions. Compared to crowdsourcing workers, *Inquirer* questions are as related to the given span and more salient, though the questions are more often invalid or already answered.

With SQuAD pre-training, human evaluation results did not improve, showing that the structure of questions learned from SQuAD is not enough to offset the difference between the two tasks.

The results also show that removing context makes the questions less valid and related to the span. The weakest model is the span-only one, where no context is given but the span. This finding illustrates the importance of building up common ground for the question generation model, illustrated in an example output below:

> **Context:** Health officials said Friday they are investigating why a fungicide that should have been cleaned off was found on apples imported from the United States . In a random sampling of apples

Model	Train-2	Train-3	Train-4	Article-1	Article-2	Article-3	Span
Ours	0.627	0.352	0.135	0.397	0.147	0.0877	0.278
Ours + SQuAD pretraining	0.603	0.340	0.145	0.404	0.155	0.0931	0.284
Human	0.520	0.229	0.069	0.341	0.115	0.064	0.219

Table 5: n-gram overlap between the generated question and either the training set, the conditioned span, and the source article. We see that the model generates novel questions without substantial copying from any of these sources, approaching the novelty rates in human questions.

> purchased at shops in the Tokyo area , two apples imported from Washington State were found to have trace amounts of the fungicide , health officials said . " This is not a safety issue by any means , " said U . S . embassy spokesman Bill Morgan . " It ' s a technical one . This fungicide is also commonly used by farmers in Japan . " Several stores in Tokyo that stocked apples packed by Apple King , a packer in Yakimo , Washington state , were voluntarily recalling the apples Friday because of possible health hazards , a city official said .
> **Sentence:** But a spokesman for Japan ' s largest supermarket chain , Daiei Inc . , said the company has *no plans to remove U . S . apples from its shelves* .
> **Inquirer:** If this is the case, why have no plans to remove them from their shelves?
> **Span+sentence**: Why would the supermarket chain remove U.S. apples from its shelves?

5.3 Automatic evaluation

We also use several metrics that capture the generation behavior of the models. These include: (1) Measuring the extent of copying. **Train-n**: percentage of n-grams in the generated questions that also appeared in some question in the training set. This metric could show if the model is synthesizing new questions or simply copying questions from the training set. **Article-n**: percentage of n-grams in the generated questions that also appeared in either the sentence where the question is asked, or any prior sentence in the same article. This metric estimates the extent to which the system is copying the article. (2) **Span**: percentage of words appeared in the annotated span that also appeared in the generated question. This is an rough estimation of how the question is related to the span. Table 5 shows that *Inquirer*-generated questions are not simply copied from the training data or the article, though the n-gram scores are comparatively much higher than questions asked by human.

6 Question generation from scratch

In this section, we assume that spans are not given, and discuss two approaches to generating questions from scratch: a pipeline approach with span prediction, and a question generation model without access to any span information.

6.1 Models

Pipeline. The pipeline approach consists of 2 stages: span prediction and question generation using Inquirer. To predict the span, we use a model similar to the BERT model for the question answering task (Devlin et al., 2019) on SQuAD 1.1 (Rajpurkar et al., 2016). We replace the concatenation passage and question with a concatenation of the target sentence and the previous sentences in the document. Now, the span to ask a question about is treated analogously to the answer span in SQuAD: we find its position in the "passage" which is now the target sentence.[5]

Sentence+Context. We also experiment with a *Sentence+Context* model, where the model has no knowledge of any span information in both training and testing; it is trained based purely on (context, sentence) pairs from our dataset. This baseline evaluates the usefulness of predicting the span as an intermediate task.

6.2 Results

Question evaluation Human evaluation results for *Inquirer-pipeline* and *Sentence+Context* are shown in Table 6. *Inquirer-pipeline* is able to produce questions with a validity performance only slightly below *Inquirer*. However, without access to gold spans, more questions are already answered, and are unrelated to the predicted spans. Yet predicting the spans is clearly useful: compared with *Sentence+Context*, which does not use the spans at all, *Inquirer-pipeline* generates more valid questions. While more of these are already answered in the text, we argue that it is more important to ensure that the questions make sense in the first place, illustrated in this example below:

---

[5] We use the pretrained bert-large-uncased-whole-word-masking model, and fine-tune it for 4 epochs. The learning rate is 3e-5, batch size 3, maximum sequence length 384. We use the Adam optimizer with $(\beta_1, \beta_2) = (0.9, 0.999)$. The parameters are tuned by manually inspecting generated questions in the validation set.

Context: Bank of New England Corp . , seeking to streamline its business after a year of weak earnings and mounting loan problems , said it will sell some operations and lay off 4 % of its work force . The bank holding company also reported that third - quarter profit dropped 41 % , to $ 42 . 7 million , or 61 cents a share , from the year - earlier $ 72 . 3 million , or $ 1 . 04 a share .
Sentence: Among its restructuring measures , the company said it plans to sell 53 of its 453 branch offices and to lay off 800 employees .
Inquire Pipeline: What other measures did the company have?
Sentence+context: What are those?

Span evaluation Finally, we present the results for the intermediate task of span prediction. Note however that since we already observed that spans can be highly subjective (c.f. Section 4.3), these results should be interpreted relatively.

We use two metrics: (1) *Exact match*: the percentage of predictions that exactly match one of the gold spans in a sentence. (2) *Precision*: the portion of tokens in the predicted span that is also in a gold span. Since there are usually multiple spans annotated in a sentence, we report the micro-average across all spans. We do not report recall or F1, since considering recall would lead to a misleading metric that prefers long span predictions. In particular, the "best" length that optimizes F1 is about 20 tokens, while the average length of gold spans is 3.2 tokens.

Table 7 shows the results of span prediction. Our span prediction model is compared with 3 scenarios. The Random model picks a span at a random position with a fixed length that is tuned on the validation set. The human-single scores are the average scores between two spans that are highlighted by different annotators. The human-aggregate baseline compares the annotation of one worker against the aggregation of the annotations of the other 4 workers. These results show that the task is highly subjective, yet our model appears to agree with humans at least as well as other humans do.

7 Conclusion

We present INQUISITIVE, a large dataset of questions that reflect semantic and discourse processes during text comprehension. We show that people use rich language and adopt a range of pragmatic strategies to generate such questions. We then present question generation models trained on this data, demonstrating several aspects that generating INQUISITIVE questions is a feasible yet challenging task.

Model	Valid	Related	Answered	Salience
Conditioning on gold span				
Span	0.592	0.746	0.082	3.12
Span+Sentence	0.719	0.867	0.086	3.64
Inquirer	0.758	0.887	0.096	3.65
Inquirer+SQuAD	0.742	0.854	0.075	3.59
From scratch				
Sentence+Context	0.711	-	0.115	3.01
Inquirer Pipeline	0.748	0.777	0.178	3.00
Human	0.958	0.866	0.047	3.18

Table 6: Human evaluation results for generated questions. Conditioning on the immediate sentence (+Sentence) and further context (+Context) help generate better questions, but SQuAD pre-training does not.

Model	Exact	Precision
Ours	0.121	0.309
Random	0.002	0.118
Human-single	0.075	0.265
Human-aggregate	0.115	0.391

Table 7: Results for predicting the span. Note that human agreement is low, so our automatic method is on par with held-out human comparisons.

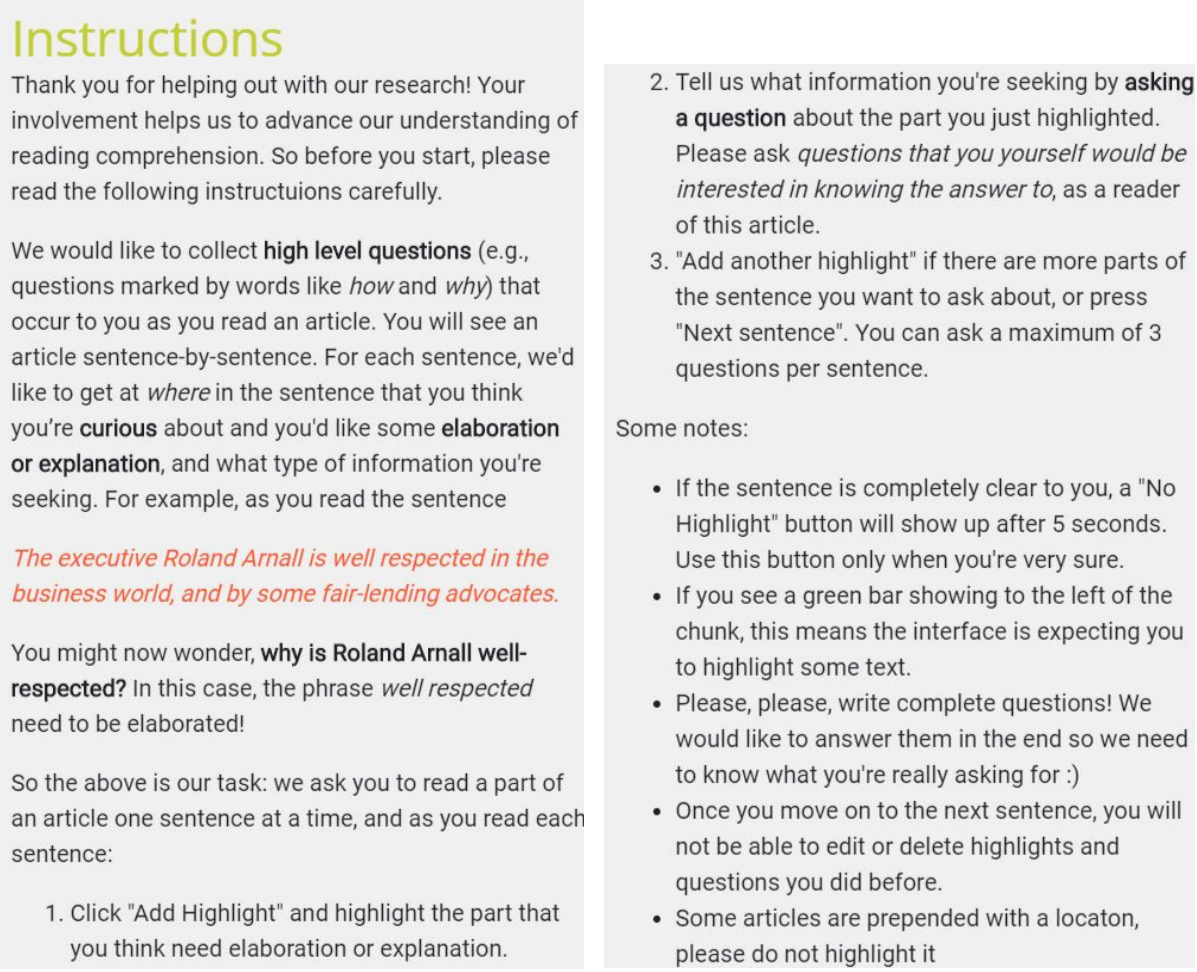
A Crowdsourcing Instructions



Instructions

Thank you for helping out with our research! Your involvement helps us to advance our understanding of reading comprehension. So before you start, please read the following instructuions carefully.

We would like to collect **high level questions** (e.g., questions marked by words like *how* and *why*) that occur to you as you read an article. You will see an article sentence-by-sentence. For each sentence, we'd like to get at *where* in the sentence that you think you're **curious** about and you'd like some **elaboration or explanation**, and what type of information you're seeking. For example, as you read the sentence

The executive Roland Arnall is well respected in the business world, and by some fair-lending advocates.

You might now wonder, **why is Roland Arnall well-respected?** In this case, the phrase *well respected* need to be elaborated!

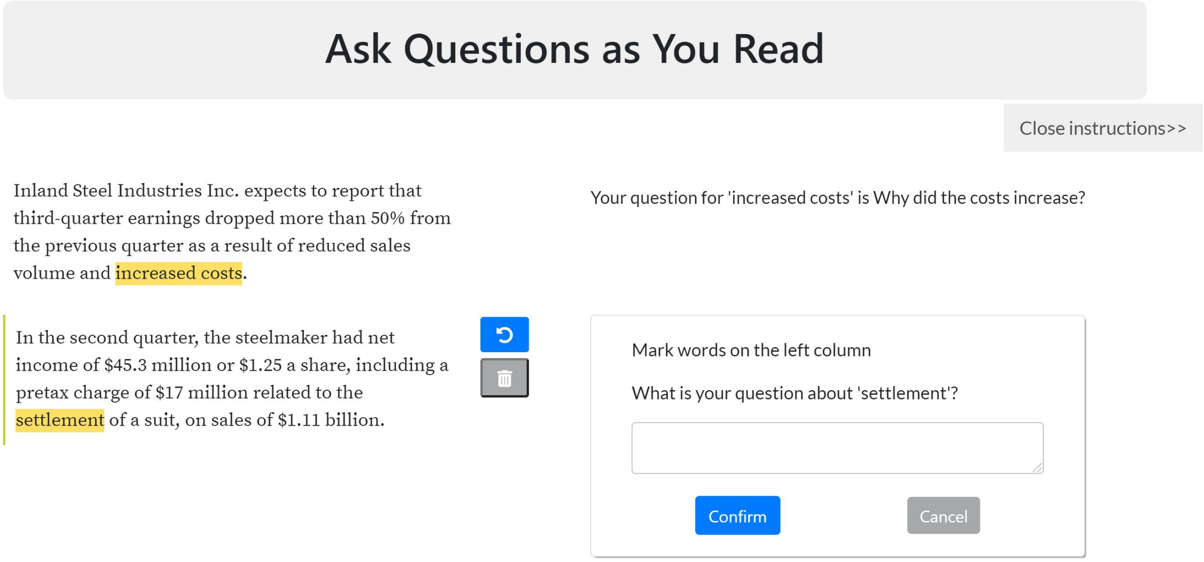
So the above is our task: we ask you to read a part of an article one sentence at a time, and as you read each sentence:

1. Click "Add Highlight" and highlight the part that you think need elaboration or explanation.
2. Tell us what information you're seeking by **asking a question** about the part you just highlighted. Please ask *questions that you yourself would be interested in knowing the answer to*, as a reader of this article.
3. "Add another highlight" if there are more parts of the sentence you want to ask about, or press "Next sentence". You can ask a maximum of 3 questions per sentence.

Some notes:

- If the sentence is completely clear to you, a "No Highlight" button will show up after 5 seconds. Use this button only when you're very sure.
- If you see a green bar showing to the left of the chunk, this means the interface is expecting you to highlight some text.
- Please, please, write complete questions! We would like to answer them in the end so we need to know what you're really asking for :)
- Once you move on to the next sentence, you will not be able to edit or delete highlights and questions you did before.
- Some articles are prepended with a locaton, please do not highlight it

Figure 4: Instructions for question collection.



Ask Questions as You Read

Inland Steel Industries Inc. expects to report that third-quarter earnings dropped more than 50% from the previous quarter as a result of reduced sales volume and increased costs.

Your question for 'increased costs' is Why did the costs increase?

In the second quarter, the steelmaker had net income of $45.3 million or $1.25 a share, including a pretax charge of $17 million related to the settlement of a suit, on sales of $1.11 billion.

Mark words on the left column

What is your question about 'settlement'?

Figure 5: Turk interface for collecting questions.

Towards Persona-Based Empathetic Conversational Models

Abstract

Empathetic conversational models have been shown to improve user satisfaction and task outcomes in numerous domains. In Psychology, persona has been shown to be highly correlated to personality, which in turn influences empathy. In addition, our empirical analysis also suggests that persona plays an important role in empathetic conversations. To this end, we propose a new task towards persona-based empathetic conversations and present the first empirical study on the impact of persona on empathetic responding. Specifically, we first present a novel large-scale multi-domain dataset for persona-based empathetic conversations. We then propose CoBERT, an efficient BERT-based response selection model that obtains the state-of-the-art performance on our dataset. Finally, we conduct extensive experiments to investigate the impact of persona on empathetic responding. Notably, our results show that persona improves empathetic responding more when CoBERT is trained on empathetic conversations than non-empathetic ones, establishing an empirical link between persona and empathy in human conversations.

1 Introduction

Empathy, specifically affective empathy, refers to the capacity to respond with an appropriate emotion to another's mental states (Rogers et al., 2007). In NLP, empathetic conversational models have been shown to improve user satisfaction and task outcomes in numerous domains (Klein, 1998; Liu and Picard, 2005; Wright and McCarthy, 2008; Fitzpatrick et al., 2017; Zhou et al., 2018a). For example, empathetic agents received more positive user ratings, including greater likeability and trustworthiness than controls (Brave et al., 2005).

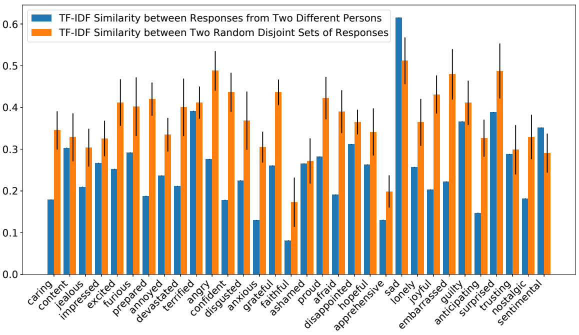

Figure 1: TF-IDF similarity between two sets of empathetic responses (Rashkin et al., 2019) for each emotion (best viewed in color). For most emotions (28 out of 32), the similarity between responses from two different speakers (blue) is substantially smaller than the similarity between two random disjoint sets of responses (orange, averaged over five runs).

In recent years, neural network based conversational models (Vinyals and Le, 2015; Lowe et al., 2015) are becoming dominant. Zhou et al. (2018a) designed XiaoIce, a popular AI companion with an emotional connection to satisfy the human need for communication, affection, and social belonging. Recently, Rashkin et al. (2019) presented a new dataset and benchmark towards empathetic conversations and found that both Transformer-based generative models (Vaswani et al., 2017) and BERT-based retrieval models (Devlin et al., 2019) relying on this dataset exhibit stronger empathy.

However, most existing studies, e.g., (Rashkin et al., 2019), do not consider persona when producing empathetic responses[1]. In Psychology, persona refers to the social face an individual presents to the world (Jung, 2016). Persona has been shown to be highly correlated with personality (Leary and Allen, 2011), which in turn influences empathy (Richendoller and Weaver III, 1994; Costa et al., 2014). In addition, our empirical analysis of empathetic con-

---

[1] One exception is XiaoIce (Zhou et al., 2018a), however, her persona is not configurable and thus difficult to satisfy various human needs.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6556–6566,
November 16–20, 2020.

versations in (Rashkin et al., 2019) also shows that for most emotions, the empathetic responses from two different persons[2] have more differences than that between two disjoint sets of random responses, as shown in Figure 1. Both the theories in Psychology and the evidence from our empirical analysis suggest that persona plays an important role in empathetic conversations, which, to the best of our knowledge, has not been investigated before[3].

To this end, we propose a new task towards persona-based empathetic conversations and present the first empirical study on the impact of persona on empathetic responding. Our study would be beneficial to researchers in Dialogue Systems and Psycholinguistics. However, one major challenge of this study is the lack of relevant datasets, i.e., existing datasets only focus on either persona or empathy but not both (see Table 4 for details). In this paper, we present a novel large-scale multi-turn **P**ersona-based **E**mpathetic **C**onversation (**PEC**) dataset in two domains with contrasting sentiments, obtained from the social media Reddit, to facilitate our study.

We then propose CoBERT, an efficient BERT-based response selection model using multi-hop co-attention to learn higher-level interactive matching. CoBERT outperforms several competitive baselines on PEC, including Poly-encoder (Humeau et al., 2020), the state-of-the-art BERT-based response selection model, by large margins. We conduct additional comparisons with several BERT-adapted models and extensive ablation studies to evaluate CoBERT more comprehensively.

Finally, based on PEC and CoBERT, we investigate the impact of persona on empathetic responding. In addition, we analyze how limited persona data improves model performance, and how our model generalizes to new personas.

In summary, our contributions are as follows:

- We propose a new task and a novel large-scale multi-domain dataset, PEC, towards persona-based empathetic conversations. Our data and code are available here[4].

- We propose CoBERT, a BERT-based response selection model that obtains the state-of-the-art performance on PEC. Extensive experimental evaluations show that CoBERT is both effective and efficient.

- We present the first empirical study on the impact of persona on empathetic responding. The results show that persona improves empathetic responding *more* when CoBERT is trained on empathetic conversations than non-empathetic ones, establishing an empirical link between persona and empathy in human conversations.

2 Related Work

Empathetic Conversational Models Despite the growing number of studies in neural conversational models, less attention has been paid to make conversations empathetic until recently (Siddique et al., 2017; Morris et al., 2018; Shi and Yu, 2018; Lin et al., 2019b; Shin et al., 2019; Rashkin et al., 2019; Li et al., 2019; Lin et al., 2019a; Zandie and Mahoor, 2020), possibly due to the lack of empathetic conversation datasets. Rashkin et al. (2019) proposed EMPATHETICDIALOGUES (**ED**), the first empathetic conversation dataset comprising 25K conversations in 32 emotions. Conversational models trained on the role of the listener in the dataset exhibited stronger empathy than models trained on non-empathetic datasets. We compare ED and PEC in the last paragraph of Section 3.

Persona-Based Conversational Models In recent years, personalized conversational models are emerging (Li et al., 2016; Zhang et al., 2018a; Wolf et al., 2019; Chan et al., 2019; Madotto et al., 2019; Zheng et al., 2019). Li et al. (2016) proposed persona embeddings in a response generation model and achieved improved generation quality and persona consistency. Zhang et al. (2018a) proposed PERSONA-CHAT (**PC**), a crowd-sourced conversation dataset with persona information, to improve model engagingness and consistency. Mazare et al. (2018) further presented a much larger persona-based conversation dataset collected from Reddit (**PCR**) and showed that persona consistently improves model performance even when a large number of conversations is available for training. We compare PC, PCR, and PEC in the last paragraph of Section 3. Recently, Gu et al. (2019) proposed DIM, a personalized response selection model with interactive matching and hierarchical aggregation, and achieved state-of-the-art performance on PC.

Retrieval-based Conversational Models Recent neural retrieval-based conversational models gener-

---

[2] Each response in (Rashkin et al., 2019) has a speaker id but no persona.

[3] A very recent work (Roller et al., 2020) incorporates persona and empathy by fine-tuning on corresponding datasets, however, it does not investigate the impact of persona on empathetic responding.

Empathy	0.73	0.61	0.25

Table 2: Sentiment and empathy of PEC and the control group based on human ratings. Sentiment ranges from -1 (negative) to 1 (positive). Empathy ranges from 0 (non-empathetic) to 1 (empathetic). Ratings are aggregated by majority voting (averaging shows similar results). The inter-annotator agreement, measured by Fleiss' kappa (Fleiss, 1971), for sentiment and empathy are 0.725 and 0.617, respectively. Both agreement statistics indicate "substantial agreement".

ally have three modules: encoding, matching and aggregation (Lowe et al., 2015; Zhou et al., 2016; Wu et al., 2017; Zhou et al., 2018b; Zhang et al., 2018b; Chen and Wang, 2019; Feng et al., 2019; Yuan et al., 2019). The encoding module encodes text into vector representations using encoders such as LSTM, Transformer, or BERT. The matching module measures context-response associations using various attention mechanisms at different granularities. The aggregation module summarizes the matching information along the sequence dimension to obtain the final representation. A recent work Humeau et al. (2020) proposed Poly-encoder, an efficient BERT-based response selection model that obtained the state-of-the-art performance on multiple conversation datasets.

3 The PEC Dataset

In this section, we introduce the collection procedure and statistics of our proposed persona-based empathetic conversation (PEC) dataset.

Data Source We collect empathetic conversations from two subreddits *happy*[5] and *offmychest*[6] on Reddit, a discussion forum where users can discuss any topics on their corresponding subforums/subreddits. The *happy* subreddit is where users share and support warm and happy stories and thoughts. The *offmychest* subreddit is where users share and support deeply emotional things that users cannot tell people they know. We choose these two subreddits as our data source because their posts have contrasting sentiments and their comments are significantly more empathetic than casual conversations, i.e., the control group, as shown in Table 2.

Conversation Collection Discussions on Reddit are organized in threads where each thread has one post and many direct and indirect comments. Each thread forms a tree where the post is the root node and all comment nodes reply to their parent comment nodes or directly to the root node. Therefore, given a thread with n nodes, we can extract $n-1$ conversations where each conversation starts from the root node and ends at the $n-1$ non-root nodes. We randomly split conversations by threads according to the ratio of 8:1:1 for training, validation, and test sets, respectively.

Persona Collection Following (Mazare et al., 2018), for each user in the conversations, we collect persona sentences from all posts and comments the user wrote on Reddit. The posts and comments are split into sentences, and each sentence must satisfy the following rules to be selected as a persona sentence: 1) between 4 and 20 words; 2) the first word is "i"; 3) at least one verb; 4) at least one noun or adjective; and 5) at least one content word. Our rules are stricter than that from (Mazare et al., 2018), allowing us to extract less noisy persona sentences. For each user, we extract up to 100 persona sentences.

Note that we choose our approach to persona collection because 1) the well-established work (Mazare et al., 2018) successfully trained personalized agents using this approach; 2) this approach is significantly more scalable and cost-effective than crowd-sourcing; and 3) we are concerned that using crowd-sourcing, i.e., assigning artificial personas to crowd-workers and asking them to chat empathetically based on the assigned personas, would introduce worker-related noises such that models may merely learn superficial empathetic responding patterns that crowd-workers deem suitable given the assigned personas.

Data Processing We keep a maximum of 6 most recent turns for each conversation. We filter con-

Conversation	Celebrating 43 years of marriage with the love of my life.	Worried. Am I becoming depressed again? Please don't leave me. Is everything okay? You don't seem yourself.
	She looks very young for someone who has been married 43 years. That must surely put her in the 63-73yr age range?!	I'm living these exact words.
	I just turned 61, thanks!	I hope everything works out for you. I'm trying not to fall apart.
	I hope I look that young when I'm 61! You guys are too cute, congratulations :)	Me too. If you ever want someone to talk to my messages are open to you.
Persona	I took an 800 mg Ibuprofen and it hasn't done anything to ease the pain.	I think I remember the last time I ever played barbies with my litter sister.
	I like actively healthy.	I have become so attached to my plants and I really don't want it to die.
	I want a fruit punch!	I'm just obsessed with animals.

Table 3: Two example conversations with personas from PEC. The persona sentences correspond to the last speakers in the conversations.

Dataset	Source	Persona	Empathy	Size	Public
ED	CS	✗	✓	78K	✓
PC	CS	✓	✗	151K	✓
PCR	Reddit	✓	✗	700M	✗
PEC (ours)	Reddit	✓	✓	355K	✓

Table 4: Comparisons between PEC and related datasets. ED denotes EMPATHETICDIALOGUES (Rashkin et al., 2019). PC denotes PERSONA-CHAT (Zhang et al., 2018a). PCR denotes the persona-based conversations from Reddit (Mazare et al., 2018). CS denotes crowd-sourced. The size denotes the number of expanded conversations.

versations to ensure that 1) each post is between 2 and 90 words; 2) each comment is between 2 and 30 words[7]; 3) all speakers have at least one persona sentence; and 4) the last speaker is different from the first speaker in each conversation. The last requirement is to maximally ensure that the last utterance is the empathetic response instead of a reply of the poster. In addition, persona sentences appearing in the conversation responses are removed to avoid data leakage. Finally, we lowercase all data and remove special symbols, URLs, and image captions from each sentence. The statistics of PEC are presented in Table 1. Two examples of PEC are shown in Table 3.

Note that it may not be easy to see explicit links in Table 3, but that's exactly what we are studying for, i.e., to uncover the implicit (and possibly unexpected) links between persona and empathy using real user data. For example, the utterance "I hope I look that young" may implicitly link to the persona "I like actively healthy" in Table 3.

Data Annotations We manually annotate 100 randomly sampled conversations from each domain to estimate their sentiment and empathy. To avoid annotation bias, we add a control group comprising 100 randomly sampled casual conversations from the *CasualConversation*[8] subreddit, where users can casually chat about any topics. Finally, we mix and shuffle these 300 conversations and present them to three annotators. The annotation results are presented in Table 2. The posts in the happy and offmychest domains are mostly positive and negative, respectively. Both domains are significantly more empathetic than the control group ($p < 0.001$, one-tailed t-test).

Conversation Analysis We conduct conversation analysis for PEC, similar to our analysis for ED (Rashkin et al., 2019) in Figure 1. Specifically, the TF-IDF similarities between responses from two different persons are 0.25 and 0.17 for happy and offmychest, respectively, whereas the TF-IDF similarities between two disjoint sets of random responses are 0.38 (± 0.05) and 0.31 (± 0.05) for happy and offmychest over 5 runs, respectively. The results show that empathetic responses between different persons are more different than that between random empathetic responses in PEC, suggesting that different speakers in PEC have different "styles" for empathetic responding.

Comparisons with Related Datasets Table 4 presents the comparisons between PEC and related datasets. PEC has the unique advantage of being both persona-based and empathetic. In addition, PEC is collected from social media, resulting in a much more diverse set of speakers and language patterns than ED (Rashkin et al., 2019) and PC (Zhang et al., 2018a), which are collected from only hundreds of crowd-sourced workers. Finally,

---

[7] Posts are usually longer than comments. 87% posts and 82% comments on *happy* are less than 90 and 30 words, respectively. 24% posts and 59% comments on *offmychest* are less than 90 and 30 words, respectively.

[8] https://www.reddit.com/r/CasualConversation/

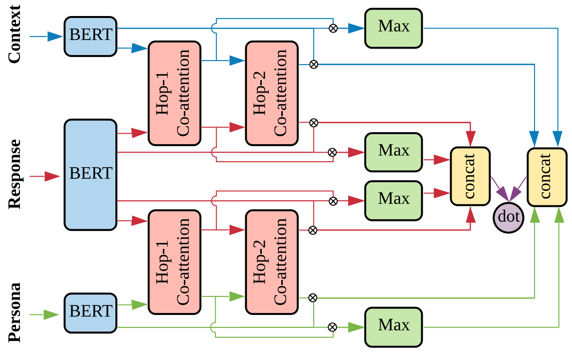

Figure 2: Our CoBERT architecture.

PEC is over 2x larger than the other two public datasets, allowing the exploration of larger neural models in future research.

4 Our CoBERT Model

In this section, we briefly introduce the task of response selection and present our proposed CoBERT model, as shown in Figure 2.

4.1 Task Definition

We denote a training conversation dataset $\mathcal{D}$ as a list of N conversations in the format of (X, P, y), where $X = \{X_1, X_2, ..., X_{n_X}\}$ denotes the n_X context utterances, $P = \{P_1, P_2, ..., P_{n_P}\}$ denotes the n_P persona sentences of the respondent, and y denotes the response to X. The task of response selection can be formulated as learning a function $f(X, P, y)$ that assigns the highest score to the true candidate y and lower scores to negative candidates given X and P. During inference, the trained model selects the response candidate with the highest score from a list of candidates.

4.2 BERT Representation

We use BERT (Devlin et al., 2019) as our sentence encoders. Similar to the Bi-encoder (Humeau et al., 2020), we concatenate context utterances as a single context sentence before passing it into BERT. Since there is no ordering among persona sentences, we concatenate randomly ordered persona sentences[9]. After passing the context, persona and response to BERT encoders, we obtain their vector representations $\mathbf{X} \in \mathbb{R}^{m \times d}$, $\mathbf{P} \in \mathbb{R}^{q \times d}$ and $\mathbf{Y} \in \mathbb{R}^{n \times d}$ from the last layer, respectively, where d denotes the embedding size of BERT, and m, q and n denote the sequence lengths of context, persona and response, respectively. Note that different segment ids are used to differentiate speaker and respondent utterances in the context.

4.3 Hop-1 Co-attention

Given $\mathbf{X}$ and $\mathbf{Y}$, we learn the first-order matching information using co-attention (Lu et al., 2016). Specifically, we first compute the word-word affinity matrix $\mathbf{A_{XY}} \in \mathbb{R}^{m \times n}$:

$$\mathbf{A_{XY}} = \mathbf{X}\mathbf{Y}^T. \tag{1}$$

Then the context-to-response attention $\mathbf{A_{X2Y}} \in \mathbb{R}^{m \times n}$ and the response-to-context attention $\mathbf{A_{Y2X}} \in \mathbb{R}^{n \times m}$ can be computed as follows:

$$\mathbf{A_{X2Y}} = \mathit{softmax}(\mathbf{A_{XY}}), \tag{2}$$

$$\mathbf{A_{Y2X}} = \mathit{softmax}(\mathbf{A}_{\mathbf{XY}}^T), \tag{3}$$

where *softmax* denotes the softmax function along the second dimension. Finally, we obtain the attended context representation $\mathbf{X}' = \mathbf{A_{X2Y}}\mathbf{Y} \in \mathbb{R}^{m \times d}$ and response representation $\mathbf{Y}'_{\mathbf{X}} = \mathbf{A_{Y2X}}\mathbf{X} \in \mathbb{R}^{n \times d}$.

To aggregate the first-order matching information and extract discriminative features, we apply max-pooling to $\mathbf{X}'$ and $\mathbf{Y}'_{\mathbf{X}}$ along the sequence dimension and obtain $\mathbf{X}'_{max} \in \mathbb{R}^d$ and $\mathbf{Y}'_{\mathbf{X},max} \in \mathbb{R}^d$.

4.4 Hop-2 Co-attention

We propose a hop-2 co-attention to learn second-order interactive matching. Different from the attention-over-attention for reading comprehension (Cui et al., 2017), our method learns bidirectional matching for response selection. Specifically, we apply attention over the attention matrices:

$$\mathbf{A_X}' = \mathit{mean}(\mathbf{A_{X2Y}})\mathbf{A_{Y2X}}, \tag{4}$$

$$\mathbf{A_Y}' = \mathit{mean}(\mathbf{A_{Y2X}})\mathbf{A_{X2Y}}, \tag{5}$$

where $\mathbf{A_X}' \in \mathbb{R}^{1 \times m}$ and $\mathbf{A_Y}' \in \mathbb{R}^{1 \times n}$ denote the second-order attention over $\mathbf{X}$ and $\mathbf{Y}$, respectively, and *mean* denotes mean pooling along the first dimension. Then we obtain the attended context representation $\mathbf{X}'' = \mathbf{A_X}'\mathbf{X} \in \mathbb{R}^d$ and response representation $\mathbf{Y}''_{\mathbf{X}} = \mathbf{A_Y}'\mathbf{Y} \in \mathbb{R}^d$.

We apply the same procedure to match $\mathbf{P}$ and $\mathbf{Y}$, and obtain the first-order matching information $\mathbf{P}'_{max} \in \mathbb{R}^d$ and $\mathbf{Y}'_{\mathbf{P},max} \in \mathbb{R}^d$, and the second-order matching information $\mathbf{P}'' \in \mathbb{R}^d$ and $\mathbf{Y}''_{\mathbf{P}} \in \mathbb{R}^d$.

---

[9] Reusing the same positional information for all persona sentences (Wolf et al., 2019) to model position invariance produces worse performance in our preliminary experiments.

Intuitively, our hop-1 co-attention learns attended representations for $\mathbf{X}$ and $\mathbf{Y}$, and our hop-2 co-attention learns "truly" attended representations for $\mathbf{X}$ and $\mathbf{Y}$ where the weights are computed from attentions over attentions.

4.5 Loss

We obtain the final persona-aware context representation $\mathbf{X}_f = [\mathbf{X}'_{max}; \mathbf{X}''; \mathbf{P}'_{max}; \mathbf{P}''] \in \mathbb{R}^{4d}$ and the final response representation $\mathbf{Y}_f = [\mathbf{Y}'_{\mathbf{X},max}; \mathbf{Y}''_{\mathbf{X}}; \mathbf{Y}'_{\mathbf{P},max}; \mathbf{Y}''_{\mathbf{P}}] \in \mathbb{R}^{4d}$, where $[;]$ denotes concatenation. Then we use dot product to compute the final matching score:

$$f(X, P, y) = dot(\mathbf{X}_f, \mathbf{Y}_f). \tag{6}$$

We optimize our model by minimizing the cross-entropy loss for selecting the true candidate from a list of candidates. Formally, the loss Φ is computed as follows:

$$\Phi = \sum_{(X,P,y)\sim\mathcal{D}} -\frac{e^{f(X,P,y)}}{\sum_{\hat{y}\sim\mathcal{N}(X)\cup\{y\}} e^{f(X,P,\hat{y})}}, \tag{7}$$

where $\mathcal{N}(X)$ denotes a set of randomly sampled negative candidates for the context X.

5 Experiments

In this section we present the datasets, baselines, experimental settings, model comparisons and ablation studies.

5.1 Datasets and Baselines

We evaluate models on PEC and its two subdomains, i.e., happy and offmychest. The training, validation and test splits of PEC are combined from the corresponding splits from happy and offmychest. The dataset statistics are shown in Table 1.

We compare CoBERT with several competitive baselines. Note that the BoW, HLSTM (Lowe et al., 2015) and Bi-encoder (Humeau et al., 2020) baselines share the same Tri-encoder architecture, where the final matching score is the dot product between the average of context and persona representations and the response representation.

BoW: The context, persona and response encoders compute the averaged word embedding.

HLSTM (Lowe et al., 2015): The context encoder has an utterance-level BiLSTM and a context-level BiLSTM. All encoders share the same utterance-level BiLSTM.

DIM (Gu et al., 2019): A state-of-the-art non-pretraiend model for persona-based response selection. DIM adopts finer-grained matching and hierarchical aggregation to learn rich matching representation.

Bi-encoder (Humeau et al., 2020): A state-of-the-art BERT-based model for empathetic response selection (Rashkin et al., 2019).

Poly-encoder (Humeau et al., 2020): A state-of-the-art BERT-based model for response selection. Poly-encoder learns latent attention codes for finer-grained matching. Note that we do not consider Cross-encoder (Humeau et al., 2020) as an appropriate baseline because it performs two orders of magnitude slower than Poly-encoder in inference, rendering it intractable for real-time applications.

5.2 Experimental Settings

Model Settings We use fastText (Paszke et al., 2019) embeddings of size 300 to initialize BoW and HLSTM. We follow the released code[10] to implement DIM. For all BERT-based models, we use the base version of BERT and share parameters across all three encoders[11]. We use 128 context codes for Poly-encoder[12]. We optimize all BERT-based models using Adam (Kingma and Ba, 2014) with batch size of 64 and learning rate of 0.00002. The positive to negative candidates ratio during training is set to 1:15. We use a maximum of $n_X = 6$ contextual utterances and a maximum of $n_P = 10$ persona sentences for each conversation. We conduct all experiments on NVIDIA V100 32GB GPUs in mixed precision.

Evaluation Metrics Following (Zhou et al., 2018b; Gu et al., 2019; Humeau et al., 2020), we evaluate models using Recall@k where each test example has C possible candidates to select from, abbreviated to R@k, as well as mean reciprocal rank (MRR). In our experiments, we set $C = 100$ and $k = 1, 10, 50$. The candidate set for each test example includes the true response and other $C - 1$ randomly sampled responses from the test set.

5.3 Comparison with Baselines

We report the test results of response selection in Table 5. Among the non-pretrained models, DIM

---

[10] https://github.com/JasonForJoy/DIM

[11] A shared BERT encoder obtained better performance than separate encoders in our preliminary experiments.

[12] More context codes result in memory error in our experiments. According to (Humeau et al., 2020), more context codes only lead to marginally better results.

	happy				**offmychest**				**PEC (happy + offmychest)**			
Models	R@1	R@10	R@50	MRR	R@1	R@10	R@50	MRR	R@1	R@10	R@50	MRR
BoW	10.2	45.6	85.2	21.8	13.9	51.6	87.1	26.2	15.4	52.9	86.7	27.4
HLSTM	15.7	53.6	91.6	28.1	17.6	55.7	91.8	30.2	22.2	63.0	94.8	35.2
DIM	31.3	67.0	95.5	43.0	40.6	72.6	96.4	51.2	39.3	74.6	97.3	50.5
Bi-encoder	32.4	71.3	96.5	45.1	42.4	78.4	97.6	54.5	42.3	79.2	98.1	54.4
Poly-encoder	33.7	72.1	96.7	46.4	43.4	79.3	97.7	55.3	43.0	79.8	98.2	55.2
CoBERT (ours)	**36.2**	**73.0**	**96.9**	**48.4**	**47.0**	**79.7**	**97.8**	**58.0**	**45.1**	**80.5**	**98.3**	**56.7**

Table 5: Test performance (in %) of CoBERT and all baselines. Values in bold denote best results.

Test Train	happy	offmychest	PEC
happy	36.2	41.2	40.5
offmychest	28.8	47.0	38.4
PEC	37.0	47.5	45.1

Table 6: Transfer test of CoBERT in R@1 (in %).

outperforms BoW and HLSTM by large margins on all datasets, demonstrating the importance of finer-grained matching and hierarchical aggregation for response selection. The simple Bi-encoder performs noticeably better than DIM, suggesting that sentence representation is another critical factor in response selection and that BERT can provide much richer representation than the BiLSTM used in DIM. Poly-encoder performs best among all baselines because it leverages the strengths of both BERT and attention-based finer-grained matching.

Our CoBERT consistently outperforms all baselines on all datasets with large margins, including the state-of-the-art Poly-encoder. The performance gain is primarily attributed to our multi-hop co-attention, which learns higher-order bidirectional word-word matching between context and response, whereas Poly-encoder only learns the first-order unidirectional attention from response to context using latent attention codes. Efficiency-wise, CoBERT has slightly longer inference time (1.50x) but requires much less memory usage (0.62x) than Poly-encoder, as shown in Table 7.

We further investigate the transfer performance of CoBERT in Table 6. In general, in-domain test results are better than out-of-domain test results. The transfer performance from happy to offmychest (41.2%) and vice versa (28.8%) are comparable to the in-domain performance of DIM (40.6% on offmychest and 31.3% on happy), suggesting that our CoBERT can generalize well across empathetic conversations in contrasting sentiments.

Model	R@1	MRR	InfTime	RAM
Baselines				
DIM	40.3	51.6	10.36x	**0.79x**
Bi-encoder	42.6	55.2	1.00x	1.00x

+ mean	46.1	57.8	2.71x	1.15x

Table 7: Validation performance (in %), inference time (InfTime) and memory usage (RAM) for baselines, BERT-adapted models and ablation studies on PEC. InfTime and RAM are relative to the Bi-encoder.

5.4 Comparison with BERT-adapted Models

To perform a more comprehensive evaluation of CoBERT, we further compare CoBERT with several competitive BERT-adapted models where the sentence encoders are replaced by BERT. We report the results in the middle section of Table 7.

BERT + MemNet (Zhang et al., 2018a): MemNet incorporates persona into context using a Memory Network (Sukhbaatar et al., 2015) with residual connections. The BERT+MemNet model performs slightly worse than Bi-encoder and much worse than our CoBERT, although it achieves slightly faster inference than Bi-encoder.

BERT+DAM (Zhou et al., 2018b): DAM aggregates multi-granularity matching using convolutional layers. The BERT+DAM model performs significantly better than Bi-encoder in R@1, demonstrating the usefulness of learning n-gram matching over the word-word matching matrices. Nevertheless, CoBERT performs noticeably better and has faster inference (7.13x) than BERT+DAM.

BERT+DIM (Gu et al., 2019): The BERT+DIM model combines the benefits from both the strong sentence representation of BERT and the rich finer-

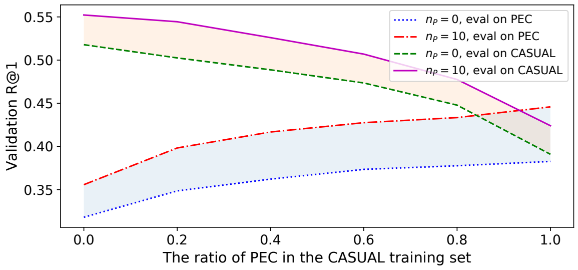

Figure 3: Validation R@1 (in %) against different ratios of PEC in the CASUAL training set.

grained matching of DIM. However, BERT+DIM performs slightly worse than CoBERT, suggesting that the more complex matching and aggregation methods in DIM do not lead to performance improvement over our multi-hop co-attention. In addition, our CoBERT is substantially faster (9.18x) than BERT+DIM in inference, thus more practical in real-world applications.

5.5 Ablation Study

We conduct ablation studies for CoBERT, as reported in the bottom section of Table 7.

Removing either hop-1 or hop-2 co-attention results in noticeably worse performance, albeit slightly faster inference. Removing hop-1 leads to larger performance drop than removing hop-2, suggesting that the first-order matching information seems more important than the second-order matching information for response selection. An additional hop-3 co-attention results in slightly worse performance, suggesting that our two-hop co-attention is the sweet spot for model complexity.

Replacing the max pooling in the hop-1 co-attention by mean pooling leads to much worse performance. In addition, concatenating the results from both max and mean pooling slightly degrades performance, as well as inference speed, suggesting that max pooling may be essential for extracting discriminative matching information.

6 Discussion

6.1 Empathetic vs. Non-empathetic

We investigate whether persona improves empathetic responding more when CoBERT is trained on empathetic conversations than non-empathetic ones. First, we introduce a non-empathetic conversation dataset as the control group, denoted as CASUAL, which is the same as the control group in Section 3 but much larger in size. The CASUAL dataset is collected and processed in the same way as PEC but has significantly lower empathy than PEC (see Table 2). The sizes of training, validation, and testing splits of CASUAL are 150K, 20K, and 20K, respectively. Then, we replace a random subset of training examples from CASUAL by the same number of random training examples from PEC. We then compare the persona improvement, i.e., R@1 ($n_P = 10$) − R@1 ($n_P = 0$), on the PEC validation set and the CASUAL validation set for different replacement ratios.

The results are illustrated in Figure 3. It is unsurprising that for both cases, i.e., $n_P = 0$ and $n_P = 10$, the validation R@1 on PEC increases, and the validation R@1 on CASUAL decreases as the ratio of PEC in the training dataset increases. We also observe that persona consistently improves performance on both validation sets for all ratios.

By investigating the widths of the two shaded regions in Figure 3, we find that the persona improvement on casual responding remains almost constant as more CASUAL training examples are used (3.31% when trained on all 150K PEC conversations vs. 3.44% when trained on all 150K CASUAL conversations). However, the persona improvement on empathetic responding consistently increases as more PEC training examples are used (3.77% when trained on all 150K CASUAL conversations versus 6.32% when trained on all 150K PEC conversations), showing that persona improves empathetic responding significantly more when CoBERT is trained on empathetic conversations than non-empathetic ones ($p < 0.001$, one-tailed t-test).

This result reveals an empirical link between persona and empathy in human conversations and may suggest that persona has a greater impact on empathetic conversations than non-empathetic ones. The result also shows that CoBERT can learn this link during training and use it to perform better empathetic responding during testing. One possible psychological root of this link is that persona is highly correlated to personality (Leary and Allen, 2011), which in turn influences empathy and empathetic responding (Costa et al., 2014). A more detailed analysis of this empirical link is left for future work.

6.2 Number of Persona Sentences

We analyze the persona improvement with respect to different numbers of persona sentences n_P, as

n_P	0	1	2	5	10	20
R@1	40.4	42.0	42.8	45.1	46.2	**47.1**
InfTime	**1.00x**	1.34x	1.38x	1.55x	1.90x	2.96x
RAM	**1.00x**	1.05x	1.06x	1.19x	1.51x	2.29x

Table 8: Validation R@1 (in %), inference time (InfTime) and memory usage (RAM) on PEC against different number of persona sentences n_P.

n_P	seen (57.9%)	unseen (42.1%)	all (100%)
0	40.3	38.5	39.6
10	46.5	43.2	45.1

Table 9: Test R@1 (in %) on PEC against examples with seen or unseen personas. n_P denotes the number of persona sentences.

Context: I'm on a diet and lost ten pounds this month!	
Persona	**Model Response**
I am a college graduate.	Congrats! I'm trying to lose weight as well.
I work in a gym.	Good job! Doing some exercises will help you stay fit!
I am a doctor.	Congrats! Don't forget to take adequate nutrition though.

Table 10: Case study.

shown in Table 8[13]. It is clear that model performance, inference time, and memory usage all increase when more persona sentences are incorporated. Note that memory usage grows quadratically with n_P due to the self-attention operations in BERT. We chose $n_P = 10$ in our experiments because it achieves competitive performance at a reasonable cost of efficiency.

6.3 Performance on New Personas

We analyze the CoBERT performance on examples with new personas. In PEC test set, 42.1% examples are from new speakers. The performance of CoBERT on test examples with seen and unseen (new) speakers is shown in Table 9. The results show that 1) CoBERT performs reasonably well on examples with unseen personas, suggesting that CoBERT can generalize well to unseen personas and retrieve the right response for new speakers accurately; 2) CoBERT performs worse on examples with unseen personas than seen personas; 3) leveraging personas during model training and testing improves CoBERT on examples with either seen or unseen personas; and 4) the persona improvement is more noticeable for examples with seen personas than unseen personas.

6.4 Case Study

We conduct a case study on how persona affects empathetic responding, as shown in Table 10. The model responses are selected by CoBERT from 1K candidates. It is clear that given the same context, different personas lead to different persona-based empathetic responses. For example, when the persona is "I am a doctor.", the model response expresses both praises and caring about the speaker's health.

7 Conclusion

We present a new task and a large-scale multi-domain dataset, PEC, towards persona-based empathetic conversations. We then propose CoBERT, an effective and efficient model that obtains substantially better performance than competitive baselines on PEC, including the state-of-the-art Poly-encoder and several BERT-adapted models. CoBERT is free from hyper-parameter tuning and universally applicable to the task of response selection in any domain. Finally, we present the first empirical study on the impact of persona on empathetic responding. The results reveal an empirical link between persona and empathy in human conversations and may suggest that persona has a greater impact on empathetic conversations than non-empathetic ones.

Abstract

The global market size of conversational assistants (chatbots) is expected to grow to USD 9.4 billion by 2024, according to MarketsandMarkets. Despite the wide use of chatbots, leakage of personal information through chatbots poses serious privacy concerns for their users. In this work, we propose to protect personal information by warning users of detected suspicious sentences generated by conversational assistants. The detection task is formulated as an alignment optimization problem and a new dataset `PERSONA-LEAKAGE` is collected for evaluation. In this paper, we propose two novel constrained alignment models, which consistently outperform baseline methods on `PERSONA-LEAKAGE`[1]. Moreover, we conduct analysis on the behavior of recently proposed personalized chit-chat dialogue systems. The empirical results show that those systems suffer more from personal information disclosure than the widely used Seq2Seq model and the language model. In those cases, a significant number of information leaking utterances can be detected by our models with high precision.

1 Introduction

According to Opus Research[2], 4.5 billion dollars will be invested in conversational assistants (chatbots) by 2021. Among diverse types of chatbots, Google Duplex, first introduced at Google I/O 2018, represents the kind of AI personal assistants (PAs) that *act on behalf of* people to perform simple tasks, such as making reservations at restaurants and hair salons. In order to successfully complete those tasks, PAs are granted the access to personal information (PI) of their owners, such as number of children, working hours, home address, and vacation plans. Thus, these PAs pose privacy concerns when they communicate with real-life people, or other bots in natural language.

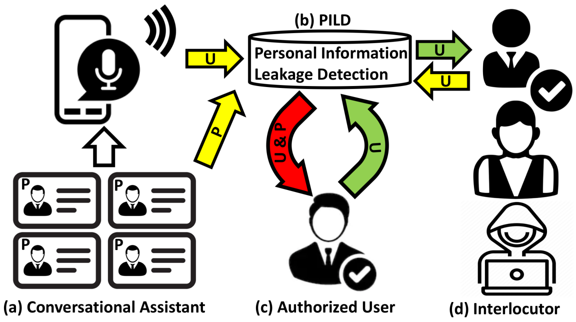

Figure 1: Given utterances (U) and personal information descriptions (P) from a conversational assistant (a), PILD module (b) detects risky utterances with corresponding personal information and sends a warning (red arrow) to an authorized user (c). The authorized user manually approve or reject the utterances. Then, only the approved utterances (green arrow) are sent to interlocutors (d) who could be authorized or malicious.

Another major source of personal information leakage is online social networks, which store a huge amount of possibly sensitive information on users and their interactions (Zhang et al., 2010). However, a recent study shows that *none* of the popular social network platforms (Facebook, Wechat, Google+, etc) have developed a perfectly non-leaky privacy protection mechanism (Yu et al., 2018). In addition, internet users (including a vast number of children and teenagers) often show a phenomenon called *privacy paradox*, which states that even users with high level of privacy concerns do not always take appropriate actions although those measures are fairly easy to perform (Norberg et al., 2007). As an unfortunate example, children's privacy is often unconsciously compromised by their parents' online behaviour, such as online posting and mes-

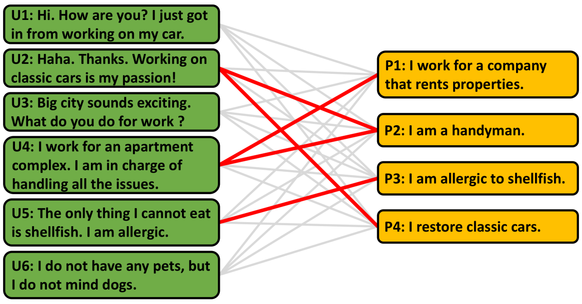
saging (Minkus et al., 2015).

An ideal privacy protection solution is *not* to stop using PAs or discourage online socialization, but to have the ability to *control the dissemination of personal information* (Yu et al., 2018). Personal information can be dispersed through various types of media. In this work, we focus on natural language utterances in conversations articulated by PAs or humans. The ways of controlling such textual information vary significantly w.r.t. platforms, PAs, user preferences, and social circles. Since there is no universally applicable control strategy, we take the first step towards privacy protection by designing a Personal Information Leakage Detection module (PILD) that *warns* users or *alerts* PAs whenever an utterance is associated with personal information, as illustrated in Figure 1. The warning module gives authorized users the capability to control information leakage from the start. Then, it is up to users and the design of PAs to decide how they deal with utterances leaking personal information. PAs will communicate with other interlocutors using secure or approved utterances.

We formulate detection of utterances causing personal information leakage as a text alignment problem, which aims to link information leaking utterances to the corresponding textual descriptions of personal information. We consider personal information provided in text, because i) user profiles on popular social network platforms include a significant proportion of textual descriptions, and ii) it is natural for users to share their information with PAs in natural language. Figure 2 demonstrates an example of aligning utterances in a dialogue with a set of personal information descriptions. Those red lines depict the ground-truth alignments between utterances and personal information descriptions. The true alignments are sparse as not all utterances leak personal information, e.g., U1, U3 and U6. Meanwhile, an utterance may be associated with more than one descriptions of personal information, e.g., U2 and U4, and vice versa.

In the absence of direct supervision signals, we explore low annotation-cost solutions to this text alignment problem by considering a weakly supervised setting. In this setting, we only know *who speaks what* and what are the PI descriptions of each interlocutor during training, without knowing true alignments. The additional challenges are imposed by the complex relationships between utterances and descriptions of PI, which could be sparse alignment, and one-to-one, one-to-many, many-to-one, or many-to-many mapping.



(a) Utterance Set (b) Alignment (c) Personal Information Description Set

Figure 2: The alignment (b) of an utterance set (a) and a personal information description set (c) by a user. The matched sentence-level utterance-PI pairs are highlighted using red lines.

To address the aforementioned challenges, we propose two models SHARP-MAX and SPARSE-MAX by formulating the text alignment problem as constrained optimization problems. The training procedure takes the form of contrastive learning (Mnih and Kavukcuoglu, 2013; Dai and Lin, 2017). Herein, we encourage aligning an utterance with the descriptions of its interlocutor subject to sparsity constraints, while penalizing its alignments with those of other speakers. Thus, sentence-level alignments are not employed during training.

The main contributions are the following:

- We propose to protect privacy in conversation using PILD. Due to the lack of datasets for the new task, we construct a testing dataset PERSONA-LEAKAGE by extending the test set of the personalized dialogue corpus PERSONA (Zhang et al., 2018) with alignment annotations through crowdsourcing.
- Under weakly supervised setting, we propose two novel alignment models SHARP-MAX and SPARSE-MAX, which leverage coarse grained alignment signals to deliver sparse solutions. Our experiments on PERSONA-LEAKAGE show that our models achieve superior performance than competitive baselines.
- We empirically evaluated four representative dialogue models as PAs on PERSONA-LEAKAGE by letting them act as one of the interlocutors in a dialogue. We found that more advanced dialogue

models are prone to leak higher proportion of personal information of the interlocutors they represent. Our PILD module works well on recently proposed dialogue agents.

2 Alignment Models

In this section, we formally define the problem of PI leakage detection as text alignment between utterances and descriptions of PI in the weakly supervised setting, followed by presenting the architecture shared by the two proposed alignment models SPARSE-MAX and SHARP-MAX. The two models differ in the sparsity regularization for alignments during training. We then detail the training algorithms as well as how to derive the regularizers.

2.1 Problem Statement

A dialogue between two interlocutors A and B is composed of two sets of utterances U_A and U_B. The corresponding persona profiles P_A and P_B are two sets of PI descriptions. A personalized dialogue dataset $\mathcal{D} = \{\langle U_i, P_i \rangle | i = 1, 2, \cdots, N\}$ consists of $\langle U_i, P_i \rangle$ associated with the same interlocutor i in a conversation, where $U_i = \{u_{i,j} | j = 1, 2, \cdots, n_i\}$ and $P_i = \{p_{i,k} | k = 1, 2, \cdots, m_i\}$. In the weakly supervised setting, a $\langle U_i, P_i \rangle$ from the 'same interlocutor' provides a set-level training signal for learning an alignment between the utterance set and the PI description set. An alignment is a set of links between an utterances set and an description set. This can also be viewed as identifying the edges of a bipartite graph between the two sets of vertices U_i and P_i. In the absence of alignment annotation during training, we relax the problem by learning alignment strength between $u_{i,j}$ and $p_{i,k}$ as an association score $a_{i,j,k}$, which constitute an association matrix $\mathbf{A}_i \in \mathbb{R}^{n_i \times m_i}$ for each $\langle U_i, P_i \rangle$. Then, it is up to the system design of a PA or the preference of an interlocutor to decide if an association score indicates that $p_{i,k}$ is leaked through $u_{i,j}$. For example, one can check if $a_{i,j,k}$ is above a pre-specified threshold.

2.2 Model Architecture

Recent advances in pre-trained language models, such as BERT (Devlin et al., 2019), demonstrate their strengths of encoding semantic information into the produced text representations. Thus we apply a pre-trained language model $f(\cdot)$ (BERT in this work) to convert each utterance and each PI description into its representation vectors. As a widely accepted practice, we take the representation of the [CLS] token to represent an input text. Then, we apply a projection matrix $\mathbf{M}$ to map those vectors into a semantic space shared by utterances and PI descriptions,

$$\begin{aligned} \mathbf{r}_{i,j}^{(u)} &= \mathbf{M} \cdot f(u_{i,j}) \\ \mathbf{r}_{i,k}^{(p)} &= \mathbf{M} \cdot f(p_{i,k}) \end{aligned} \tag{1}$$

The association score between an utterance $u_{i,j}$ and a PI description $p_{i,k}$ is calculated by the cosine similarity between their representations, where $\langle \cdot, \cdot \rangle$ denotes the inner product of two vectors,

$$a_{i,j,k} = \frac{\langle \mathbf{r}_{i,j}^{(u)}, \mathbf{r}_{i,k}^{(p)} \rangle}{\| \mathbf{r}_{i,j}^{(u)} \| \| \mathbf{r}_{i,k}^{(p)} \|} \tag{2}$$

As we freeze the parameters of BERT in both training and testing, the only tunable parameters of this model is the matrix $\mathbf{M}$.

2.3 Model Training

Learning an association matrix between an utterance set and a PI description set in the weakly supervised setting imposes two challenges. First, there is no ground-truth label to guide the alignment training. Second, an utterance may indicate zero, one, or multiple PI descriptions, while a PI description may also be associated with varying number of utterances.

Loss. To address the first challenge, we observe that i) a linked utterance-PI pair has high semantic relatedness; ii) the utterances in a dialogue are much more likely to correlate with the PI of its interlocutors than that of other interlocutors. The latter observation provides set-level alignment signals for contrastive learning. In light of this, we maximize the set-level aggregated associated scores for utterance-PI pairs from the same interlocutors $\langle U_i, P_i \rangle$, while minimizing those scores for the pairs from different interlocutors $\langle U_i, \widehat{P} \rangle$ and $\langle \widehat{U}, P_i \rangle$.

The second challenge imposes sparsity over the links in alignments. As it is difficult to enforce representation based cosine similarity values to approach zero, we introduce an alignment weight $w_{i,j,k}$ for each utterance-PI pair during training. The weight matrix $\mathbf{W}_i = \{w_{i,j,k}\}_{n_i \times m_i}$ puts a focus on the more reliable utterance-PI pairs and reduces the influence from irrelevant links. Then, the similarity between U_i and P_i is the weighted sum of all elements in $\mathbf{A}_i$.

$$sim(U_i, P_i) = \mathbf{W}_i \odot \mathbf{A}_i = \sum_j \sum_k w_{i,j,k} a_{i,j,k} \tag{3}$$

where $\odot$ denotes hadamard product. High weights in $\mathbf{W}_i$ will enhance the corresponding association scores during training, while low weights or zeros in $\mathbf{W}_i$ discourage participation of those corresponding scores.

By putting two ideas together, the loss for the ith training sample is defined as:

$$\begin{aligned}&\mathcal{L}(U_i, P_i) = \\ &\quad \max\{0, \alpha - sim(U_i, P_i) + sim(U_i, \widehat{P})\} + \\ &\quad \max\{0, \alpha - sim(U_i, P_i) + sim(\widehat{U}, P_i)\}\end{aligned} \tag{4}$$

where $\widehat{U}$ and $\widehat{P}$ are randomly sampled from $\mathcal{D}$, α is a hyper-parameter controlling the margin of the loss. Then the loss on training set is the sum of all example losses $\mathcal{L}(\mathcal{D}) = \sum_{i=1}^{N} \mathcal{L}(U_i, P_i)$.

Sparsity. The two models SHARP-MAX and SPARSE-MAX differ in the regularizers used in $sim(U_i, P_i)$ for learning *sparse* weight matrices $\mathbf{W}_i$. The matrices $\mathbf{W}_i$ are expected to assign zeros or low weights to irrelevant pairs, while assigning high weights to the aligned pairs. They are formulated as a constrained optimization problem of the following form,

$$\begin{aligned}&sim(S_i, P_i) = \max_{\mathbf{W}_i}\{\mathbf{W}_i \odot \mathbf{A}_i + \gamma H(\mathbf{W}_i)\} \\ &s.t. \sum_j \sum_k w_{i,j,k} = 1, \forall j, k; w_{i,j,k} \in [0, 1]\end{aligned} \tag{5}$$

where $H(\cdot)$ is a regularization term that determines the sparsity of $\mathbf{W}_i$, and $\gamma \in \mathbb{R}^+$ adjusts the degree of regularization. If $\gamma \to 0$, the solution of the above problem is to assign the weight 1 to the maximal value in $\mathbf{A}_i$. As we expect more than one links in an alignment, the regularizer should encourage more non-zero entries in $\mathbf{W}_i$. If $\gamma \to +\infty$, the solution is weights with equal values, which aggregates $\mathbf{A}_i$ by averaging all association scores.

SHARP-MAX utilizes entropy as the regularizer because uniform distribution achieves the maximum of entropy. In another words, this term encourages similar entries in $\mathbf{W}_i$.

Proposition 1. Let $\gamma \in \mathbb{R}^+$

$$H(\mathbf{W}_i) = -\sum_{j,k} w_{i,j,k} \log w_{i,j,k}$$

in Eq. (5), the solution of $\mathbf{W}_i$ is the following softmax function with temperature γ,

$$w_{i,j,k} = \frac{\exp(a_{i,j,k}/\gamma)}{\sum_j \sum_k \exp(a_{i,j,k}/\gamma)} \tag{6}$$

Proof Idea: The solution is derived by solving the Lagrangian of Eq. (5):

$$\begin{aligned}\mathcal{L}(\mathbf{W}_i, \lambda) = &\sum_j \sum_k w_{i,j,k} a_{i,j,k} \\ &- \gamma \sum_j \sum_k w_{i,j,k} \log w_{i,j,k} \\ &+ \lambda(1 - \sum_j \sum_k w_{i,j,k})\end{aligned} \tag{7}$$

Note that, when the temperature with $\gamma < 1$ is sufficiently small, the optimal $\mathbf{W}_i$ enlarges the differences of the values in $\mathbf{A}_i$ (SHARP-MAX). If $\gamma = 1$, we got the conventional softmax, which is also referred to as **SOFT-MAX** in our experiments.

SPARSE-MAX considers the squared loss on $\mathbf{W}_i$ as the regularizer, as it controls the sparsity of the matrix by encouraging equal contributions.

Proposition 2. Let $\gamma = 1$,

$$H(\mathbf{W}_i) = -\frac{1}{2} \sum_{j,k} w_{i,j,k}^2$$

in Eq. (5), the solution of $\mathbf{W}_i$ is the *sparsemax* of $\mathbf{A}_i$ (SPARSE-MAX) (Martins and Astudillo, 2016).

$$w_{i,j,k} = [a_{i,j,k} - \tau(\mathbf{A}_i)]_+ \tag{8}$$

where $\tau(\cdot)$ is a dynamic threshold function and $[t]_+ = \max\{0, t\}$.

3 Experimental Setup

3.1 PERSONA-LEAKAGE Dataset

In order to evaluate models under the weakly supervised setting, we constructed a dataset `PERSONA-LEAKAGE` as the test set by annotating the test set of the personalized dialogue corpus `PERSONA` (Zhang et al., 2018). In that corpus, each dialogue is conversed between two human interlocutors, where each interlocutor is characterized by three to five descriptions of PI. A description of PI describes one aspect of that person, e.g., 'I am a handyman'. For each dialogue, we collected link candidates by pairing each utterance of a interlocutor to each description of his PI. As a result, we constructed a set of link candidates for each interlocutor in a dialogue. For each link candidate, we asked three annotators to judge if the utterance indicates the corresponding PI description. A candidate was considered as *aligned* if at least two annotators agreed on that decision. In total, we annotated alignments for 968 dialogues, in which there are 6,894 aligned utterance-PI pairs out of 67,601 candidate pairs.

Moreover, in order to understand the user perception on sensitivity of PI, we collected a set of all possible PI descriptions in test and dev set of `PERSONA`, and asked five annotators to judge if the descriptions were sensitive or not. A PI description is considered as sensitive if annotators would suggest not to share it with strangers, given that it describes their friends. We collected 306 descriptions (31.48% among all 972 descriptions) with more than 2 sensitive annotations[3].

3.2 Baselines

We apply the scoring function of two widely used information retrieval (IR) methods **TF-IDF** and **BM25** (Manning et al., 2008; Robertson and Zaragoza, 2009), and the most recent **BERT**-based IR (Dai and Callan, 2019) to measure the association between a PI description and an utterance.

We also consider the following competitive alignment models proposed in recent works.

- **MEAN** averages the contribution of association matrix, namely uniform weights ($\frac{1}{n_i \cdot m_i}$). We consider MEAN as the solution of a special case of our optimization problem with $\gamma \rightarrow +\infty$.

- **Avg-Max** (Lee et al., 2018) uses the average of the maximum similarity scores for all PI descriptions (**Avg-Max-P**) or utterances (**Avg-Max-U**).

- **LSAP** (Linear sum assignment problem) (Hessel et al., 2019) optimizes hard alignments, where each row and column has less or equal than one link, i.e. $\forall j, \sum_k w_{i,j,k} \leq 1; \forall k, \sum_j w_{i,j,k} \leq 1; \forall j, k, w_{i,j,k} \in \{0, 1\}$.

- **OPT** (Optimal Transport) (Kusner et al., 2015) optimizes soft alignments, where weights are in $[0, 1]$ and sums of the weights on each column and row are less or equal to one, i.e. $\forall j, \sum_k w_{i,j,k} \leq 1; \forall k, \sum_j w_{i,j,k} \leq 1; \forall j, k, w_{i,j,k} \in [0, 1]$.

The weights of all alignment models are normalized to the sum of one.

3.3 Model Setting

In order to have a fair comparison, all alignment models share the same deep learning architecture which is composed of i) a pre-trained text representation model (BERT), ii) a learnable linear transformation layer, and iii) a weight computation module without back-propagation. The dimensions of pre-trained and final text representations are 768 and 256, respectively. We use Adam as optimizer for all experiments that require training. According to our preliminary experiments, we set learning rate to 0.01, batch size to 128 and train 200 epochs for all experiments.[4] We consider the hyper-parameters $\alpha \in \{0.0, 0.1, 0.2, 0.4, 0.8\}$ for all models and $\gamma \in \{1/4, 1/5, 1/6, 1/7, 1/8\}$ for Sharp-Max.

We evaluate the models by testing whether the alignment links between sets are correctly retrieved from all candidates links, following (Hessel et al., 2019). Given the ground-truth alignment between two sets, we evaluate the association matrix $\mathbf{A}_i$, by using precision at K (P@K)[5], R-Precision (Rprec), normalized discounted cumulative gain (NDCG) and mean average precision (MAP)[6]. In addition, we use Hellinger Distance (H-Dist) (Oosterhoff and van Zwet, 2012) $\frac{1}{N}\sum_i \frac{1}{2}\sum_{j,k}(\sqrt{w_{i,j,k}} - \sqrt{g_{i,j,k}})^2$ to quantify the matching rate of alignment weights $\mathbf{W}_i$ with ground-truth alignment weights $\mathbf{G}_i = \{g_{i,j,k}\}_{n_i \times m_i}$, where $g_{i,j,k}$ is normalized over j, k to sum to one.

3.4 Collection of Human-Bot Dialogue

To evaluate the performance of our model on chatbots, we collect human-bot dialogues using SOTA personalized chatbots and their competitors:

- $\mathcal{P}^2$ **Bot** (Liu et al., 2020) achieved SOTA performance on automatic metrics by incorporating mutual persona perception. $\mathcal{P}^2$ **Bot (w/ Persona)** and $\mathcal{P}^2$ **Bot (w/o Persona)** are models with and without personal information as input when generating responses.

- **Lost-In-Conversation** (Dinan et al., 2019)

---

[3] Appendix B describes more details about data collection.

[4] We have explored learning rate in $\mathcal{R} = \{0.1, 0.01, 0.001\}$ and number of training epochs in $\mathcal{E} = \{25, 50, 100, 200, 400\}$.

[5] As the average and maximum number of alignment links are 3.56 and 9 in our corpus, we choose $K \in \{1, 3, 5\}$.

Table 1: Experimental results of random guess (RANDOM), unsupervised IR models (TF-IDF, BM25, and BERT), baseline alignment models (MEAN, Avg-Max-U, Avg-Max-P, OPT and LSAP), and our proposed models (Soft-Max, Sparse-Max and Sharp-Max).

topped the human evaluations in ConvAI2 by fine-tuning a pre-trained language model GPT.

- **Seq2Seq-Attn** (Zhang et al., 2018) is an LSTM-based sequence-to-sequence model incorporateing persona via an attention module.
- **Language Model** (Zhang et al., 2018) is an LSTM-based language module for dialogue.

For each chatbot, we provided interlocutor A's dialogue history as input and bot responded as interlocutor B. We performed 60 dialogues and collected 770 utterances for each chatbot. The responses by those chatbots are analyzed in three dimensions.

- Personal Information Engagement (**PIE**) is the proportion of the utterances leaking PI,

  $$|\text{Utterances have PI Leakage}|/|\text{All Utterances}|$$

- Disclosed PI Sensitivity (**DPS**) is the ratio of sensitive PI descriptions to the leaked ones,

  $$\frac{|\text{Sensitive Disclosed PI descriptions}|}{|\text{Disclosed PI descriptions}|}$$

  .

- Hits-at-K (**Hits@K**) is the percentile of the leaked PI that can be retrieved from top $K = 5/10$ results using alignment models.

Perplexity (**PPL**) and uni-gram **F1** are supplementary metrics that reflect the performance of bots (Liu et al., 2020).

4 Empirical Results and Analysis

In this section, we analyze our experimental results. Our experiments are designed to answer the following research questions (**RQ**s),

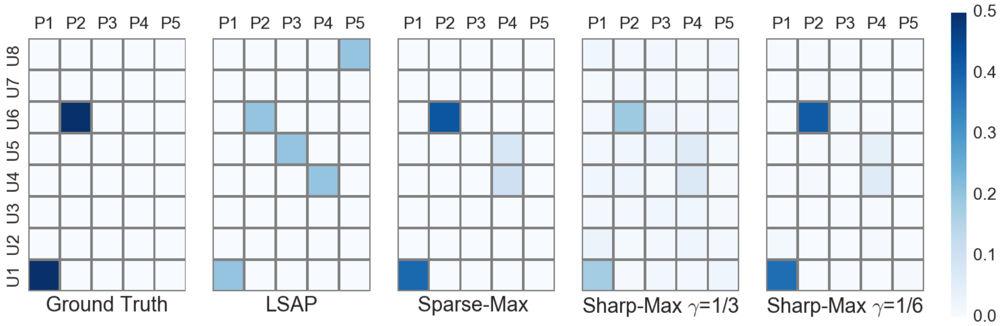
- **RQ1:** How well do our alignment models perform, in comparison with the competitive baselines?
- **RQ2:** Why do our alignment models outperform the baselines?
- **RQ3:** Do the SOTA chatbots disclose PI in dialogues, and are they sensitive? Can we use our alignment models to capture the leakage?

4.1 Model Comparison on `PERSONA-LEAKAGE`

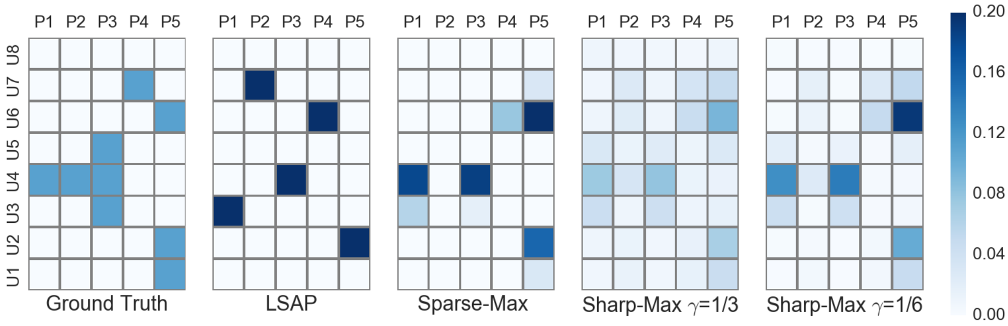
We compare our alignment models, Sharp-Max and Sparse-Max, with IR baselines and alignment baselines, in Table 1[7]. The proposed model consistently outperform baseline methods, indicating the effectiveness of our methods. H-dist is strongly correlated to other metrics, because better alignments lead to better H-dist. IR models significantly outperform random guess, showing that semantic information provided in utterances and descriptions provides strong guidance on inference. Although the naive MEAN does not enforce sparsity during training, it outperforms the unsupervised IR models with a large margin, more than

---

[7] Appendix C provides more details about hyper-parameter selection.



(a) A case with sparse alignment.



(b) A case with dense alignment.

Figure 3: Comparison of weights assigned to candidates between utterances (U1-U8) and personal information descriptions (P1-P5). (a) case 12 and (b) case 85 are test cases with sparse and dense alignments, respectively. The alignment weights of Ground Truth and LSAP are all normalized to the sum of one for each case.

10% for all scores, showing that coarse grain signal is effective for learning semantic relevant for the PI leakage. Avg-Max, OPT and LSAP further outperform MEAN with a margin more than 2% for most of the metrics, as they apply the sparsity constraints in order to focus on aligned utterances and PI descriptions during training. Although these approaches set up competitive baselines on our task, SHARP-MAX and SPARSE-MAX achieve consistent improvement on all evaluation metrics. As SPARSE-MAX cuts off the weights of irrelevant pairs, it performs the best.

4.2 Analysis on Alignment Model

We visualize the association scores of each alignment model in Figure 3, in order to qualitatively demonstrate the strengths of our models. LSAP attempts to assign a fixed number of aligned pairs, i.e. $\min\{n_i, m_i\}$, which will lead to unavoidable false positive alignment for sparse cases (U8-P5, U5-P3 and U4-P4, in Figure 3a LSAP) and false negative alignment for dense cases (U4-P1 and U4-P2, in Figure 3b LSAP). Avg-Max-P and Avg-Max-U also hold the similar drawback as the number of aligned pairs is exact the number of columns or rows, while does not depend on the cases. In contrast, SPARSE-MAX and SHARP-MAX manage to adapt the number of 'aligned pairs' (deep colored), therefore achieve alignments closer to the ground truth. For SHARP-MAX, we can adjust the sharpness of the weight matrix using sharpness parameter γ. Using sharper model with lower γ manages to alleviate the influence of the pairs with relatively low similarity scores. For SPARSE-MAX, more deterministic alignments are achieved by cutting off pairs with low association scores. Although SHARP-MAX and SPARSE-MAX do not differ much in terms of empirical performance, they are driven by different theories of regularization. The comparison between these two solutions proposed by us helps draw a conclusion that the similarity function should be designed to find a proper degree of sparsity, which does not depend much on a particular choice of regularizer.

4.3 Analysis on Personalized Chatbots

In this section, we analyze the engagement and sensitivity of chatbots in human-bot conversations. The experiments are designed to show the risk of privacy leakage when using current chatbot models. For all generated utterances, we retrieved top 10 relevant PI using SPARSE-MAX. Then we asked an-

Model	PIE	DPS	Hits@5/10	PPL ↓	F1 ↑

Seq2Seq-Attn	04.39	06.54	18.64 / 22.03	39.54	15.52
$\mathcal{P}^2$ **Bot (w/o Persona)**	08.94	10.77	51.54 / 56.15	-	17.77
Lost-In-Conversation	14.68	09.39	79.34 / 82.63	-	16.83
$\mathcal{P}^2$ **Bot (w/ Persona)**	37.19	16.86	73.62 / 77.04	18.89	19.08
Human	43.83	27.75	55.07 / 66.52	-	-

Table 2: Analysis on the responses of personalized chatbots and human interlocutors.

notators to select the leaked ones from the retrieved PI descriptions. Three annotators are asked to indicate if the utterances leak those PI descriptions. The results are summarized in Table 2. Compared with bots *without PI* as inputs, such as **Language Model** and $\mathcal{P}^2$ **Bot (w/o Persona)**, the bots *with PI* as input, namely **Lost-In-Conversation** and $\mathcal{P}^2$ **Bot (w/ Persona)**, tend to acquire higher PIE with significantly higher magnitude. PIE of $\mathcal{P}^2$ **Bot** even approaches that score of human interlocutors. DPS is correlated to PIE showing that bots with higher PIE generally disclose higher portions of sensitive PI. Although higher PIE and DPS for the chatbots *with PI* as input is expected, there is also a significant proportion of leakage for the bots without PI as input, e.g., $\mathcal{P}^2$ **Bot (w/o Persona)**. This raises serious privacy concerns in future research on PAs.

Furthermore, Hit@K measures the ability of our system for detecting PI leakage. As a warning module, our model SPARSE-MAX manages to detect most of the utterances leaking PI[8]. Our system achieves around 80% of Hit@10 on the responses generated by the two most recent and advanced chatbots, **Lost-In-Conversation** and $\mathcal{P}^2$ **Bot (w/ Persona)**.

5 Related Work

Recently, privacy and fairness started to attract more and more attention from NLP community. Sensitive information was removed from latent representations via adversarial training (Li et al., 2018; Elazar and Goldberg, 2018) and differential privacy (Fernandes et al., 2019), achieving fair decisions. Privacy-aware text rewriting methods suggested to generate new sentences with less sensitive information (Xu et al., 2019a; Emmery et al., 2018; Xu et al., 2019b; Strengers et al., 2020). Our work serves as a component that detects the sentences requires rewriting. Another line of research aims to identify mentions of pre-defined semantic categories indicating sensitive information in text (Microsoft; Bevendorff et al., 2019), such as bank account and phone number. In our setting, sensitive information can be expressed in any syntactic structures, including events conveyed in whole sentences, such as "I have got less than 5 hours of sleep each night for years" is associated with the persona "I have sleep disorders for many years.". The setting of our work is more general, as we focus on open-domain personal information written in natural language, which is not limited to mentions of fixed semantic categories in sentences or sensitivity labels of sentences.

Our work places an emphasis on privacy concerns in conversations (Huang et al., 2020; Ischen et al., 2019; Gao et al., 2018; Tur et al., 2018; Muthukrishnan et al., 2017). In recent research, several works have attempted to improve the engagement and diversity of chit-chat dialogue system (Liu et al., 2020; Tigunova et al., 2019; Wolf et al., 2019; Zhang et al., 2018) and goal-oriented dialogue system (Luo et al., 2019; Zhang et al., 2019). With the rapid development of personalized dialogue systems, PILD module is expected to address the privacy concerns (Ischen et al., 2019). Welleck et al. (2019) improved the coherence and consistency of a dialogue using Natural Language Inference (NLI) (Bowman et al., 2015). Dialogue-NLI dataset could be utilized to train retrieval models, however, it does not directly address the privacy concerns. In contrast, our dataset i) considers all possible leakage pairs, and ii) includes sensitivity annotations of all PI descriptions.

Our problem setting was inspired by an image-sentence alignment problem, given pairs of image sets and documents (Hessel et al., 2019). Similar problems were also explored in the context of align-

---

[8] According to our preliminary experiments in Appendix D, SPARSE-MAX achieves the best Hits on the whole test set of `PERSONA-LEAKAGE`.

ing image fragments with words (Lee et al., 2018; Jiang et al., 2015). In this paper, we considered utterances and PI descriptions from the *same* interlocutor as coarse-grained alignment signals, which are in the same modality.

6 Conclusions and Future Work

We formulate protection of personal information in conversations as a weakly supervised alignment between personal information and dialogue utterances. To tackle this task, we proposed two new alignment models and created a dataset `PERSONA-LEAKAGE` for evaluation. Our experimental results demonstrate the effectiveness of our methods in comparison with the competitive baselines on that dataset. Further analysis on human-bot dialogue performance demonstrated the potential privacy risks with advanced personalized dialogue techniques. This work is the first step towards fully preventing leakage of privacy in text, which still requires PAs or users to select and hide sensitive information. We hope this work and the dataset will pave the way for the research on privacy leakage in conversations. In the future, we will explore full-fledged solutions to address the privacy concerns of both humans and dialogue systems.

A Malicious Attack on Siri

We conducted an experiment using Siri installed in iPad pro, with iPadOS version 13.3.1 released in January 28 2020. An unauthorized user manage to acquire the owner's personal information by asking Siri questions. The responses by Siri are demonstrated in Figure 4. User name and home address of the facility devide owner is disclosed to the attacker, when asked *'Where do I live?'*. Name, partner and home address of the owner's parents are unveiled, when asked *'Who is my father?'*. Although Siri represented the answer in form of contact cards, we argue that such risky reactions by personal assistants could appear in natural language responses as well.

B Details for Data Collection

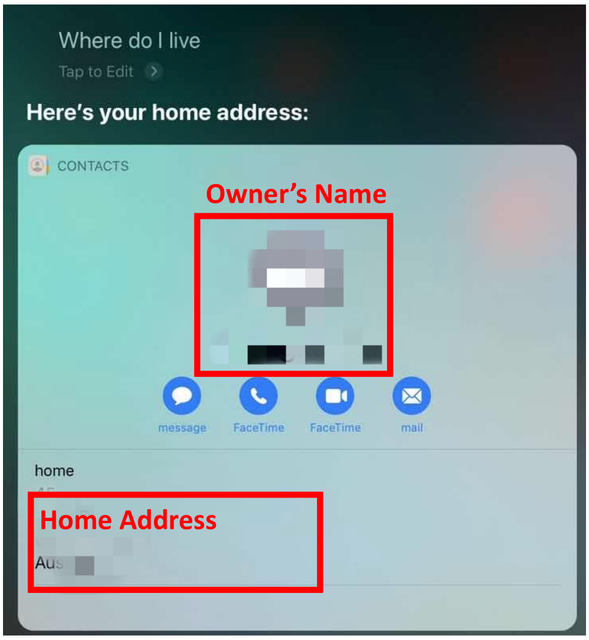
Starting from test set of `PERSONA`, our dataset basically tops up two annotations on test sets, alignment annotations on utterance-persona pairs and sensitivity annotations on all personal information statements. For both parts, we use Amazon Mechanical Turk (MTurk)[9] for crowdsourcing. We only accept results from the qualified annotators that i) have more than 90% HIT acceptance rate, ii) have finished more than 100 HITs, iii) locate in America. For further quality control, we reject 2.1% and 2.0% unreliable HITs for alignment annotation and sensitivity annotation respectively by automatically rejecting HITs that are i) not completed or ii) inconsistent in answers.

For alignment annotations, annotators were instructed to *"find the personal descriptions leaked in a conversation"* by *"select if the sentence indicates any of the provided personal descriptions or none of them"*, see task screenshot in Figure 5.

For sensitivity annotations, annotators were instructed to *"give advice to a friend who belongs to a vulnerable group"*, see task screenshot in Figure 6. Sensitive information is defined as the one that *"your friend rather not let strangers know"*.

- **Sensitive:** In most cases, your friend would rather not to tell a stranger such information. Otherwise it will do more harm than good if the information is utilized by malicious people.

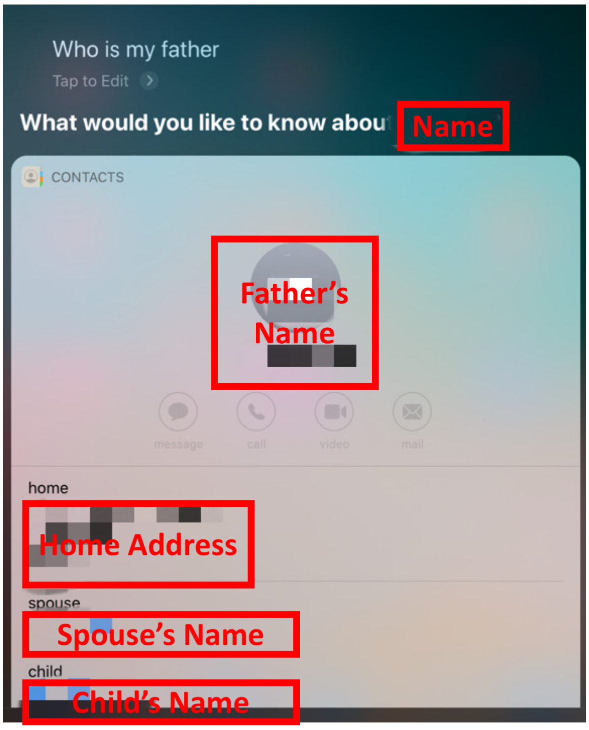
- **Non-sensitive:** In most cases, it is safe for your friend to share such information with strangers.



Where do I live

Here's your home address:

(a) Malicious Attack 1: *'Where do I live?'*.



Who is my father

What would you like to know abou

(b) Malicious Attack 2: *'Who is my father?'*.

Figure 4: Screenshots of Siri's responses to an unauthorized user, when it is inquired *'Where do I live?'* and *'Who is my father?'*. The sensitive personal information is blurred by mosaics.

Instructions

View full instructions

The task aims to find the personal descriptions leaked in a conversation. In each job, you are provided with a sentence ('**utterance**') from a conversation as well as its conversational context ('**dialogue**'). You are asked to select if the sentence indicates any of the provided personal descriptions or none of them.

Please do read full instructions for more detail!

Dialogue Context:

A: [BEGIN]	B: [BEGIN]
A: hello , how are you doing ?	B: i am great , just sitting at work . how are you
A: fine , where do you work ?	B: i am a real estate agent , how about you

A: hello , how are you doing ?

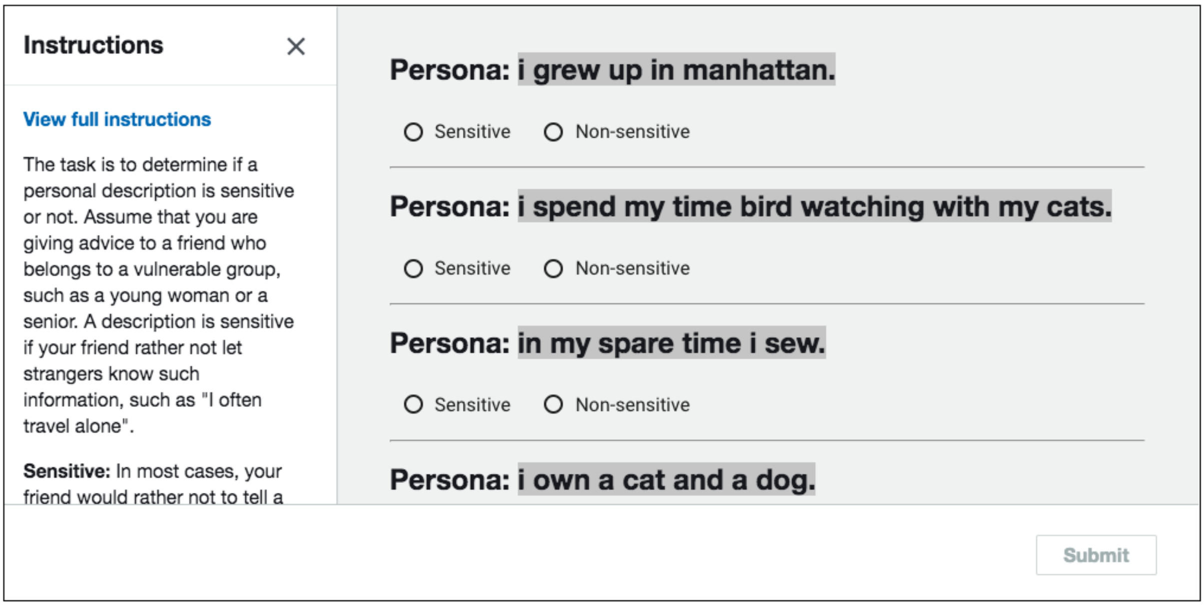
Check one or more personal descriptions that can be inferred by **A's utterance:**

☐ i work in a program that mentors troubled teens.
☐ i love italian food.
☐ i like to sing in choir.
☐ i enjoy playing softball.
☐ i have know taekwondo since i was a kid.
☐ None of the above.

B: i am great , just sitting at work . how are you

Check one or more personal descriptions that can be inferred by **B's utterance:**

Figure 5: Task screenshot for utterance-persona alignment annotation.



Instructions

View full instructions

The task is to determine if a personal description is sensitive or not. Assume that you are giving advice to a friend who belongs to a vulnerable group, such as a young woman or a senior. A description is sensitive if your friend rather not let strangers know such information, such as "I often travel alone".

Sensitive: In most cases, your friend would rather not to tell a

Persona: i grew up in manhattan.

○ Sensitive ○ Non-sensitive

Persona: i spend my time bird watching with my cats.

○ Sensitive ○ Non-sensitive

Persona: in my spare time i sew.

○ Sensitive ○ Non-sensitive

Persona: i own a cat and a dog.

Figure 6: Task screenshot for personal information sensitivity annotation.

C Hyper-parameter Selection

We provide details about the hyper-parameter selection for baseline alignment models and our models in Table 3. More details about Sharp-Max is demonstrated in Table 4.

D Hits on human-human dialogue

We compare alignment models on Dialogue60, a subset used in our paper, and DialogueTest, the whole test set of *PERSONA-LEAKAGE*. Overall, Sparse-Max achieves the best performance.

Response Selection for Multi-Party Conversations with Dynamic Topic Tracking

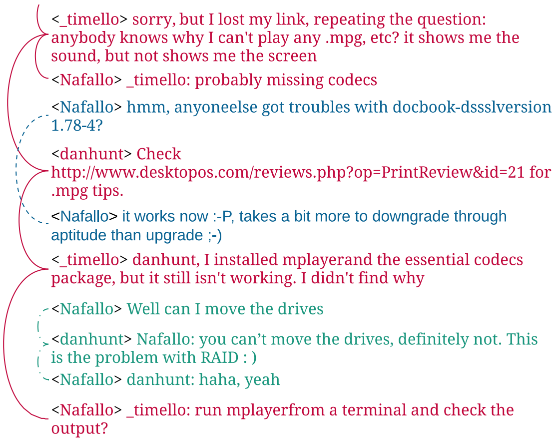
Weishi Wang[§‡], **Steven C.H. Hoi**[§], **Shafiq Joty**[§‡]
[§]Salesforce Research Asia
[‡]Nanyang Technological University, Singapore
[§]`{weishi.wang,shoi,sjoty}@salesforce.com`

Abstract

While participants in a multi-party multi-turn conversation simultaneously engage in multiple conversation topics, existing response selection methods are developed mainly focusing on a two-party single-conversation scenario. Hence, the prolongation and transition of conversation topics are ignored by current methods. In this work, we frame response selection as a dynamic topic tracking task to match the topic between the response and relevant conversation context. With this new formulation, we propose a novel multi-task learning framework that supports efficient encoding through large pretrained models with only two utterances at once to perform dynamic topic disentanglement and response selection. We also propose Topic-BERT an essential pretraining step to embed topic information into BERT with self-supervised learning. Experimental results on the DSTC-8 Ubuntu IRC dataset show state-of-the-art results in response selection and topic disentanglement tasks outperforming existing methods by a good margin.[1]

1 Introduction

In recent years, with the influx of deep learning methods in natural language processing (NLP), there has been a lot of interests in building effective task-oriented dialogue systems that can assist people in real-world business such as booking tickets, ordering food and solving technical issues (Bui, 2006). *Retrieval-based* response generation that selects a suitable response from a pool of candidates (pre-existing human responses) has become a popular approach to framing dialog. Compared to the *generation-based* systems that generate novel utterances (Serban et al., 2016), retrieval-based systems produce fluent, grammatical and informative responses (Weston et al., 2018; Henderson et al., 2019). Also compared to the traditional modular approach, it does not rely on dedicated modules for language understanding, dialog management, and generation, thus simplifying the system design. Due to these reasons, retrieval-based systems have been widely adopted in commercial dialogue systems (Gao et al., 2019; Gunasekara et al., 2019).



```
<_timello> sorry, but I lost my link, repeating the question: anybody knows why I can't play any .mpg, etc? it shows me the sound, but not shows me the screen
<Nafallo> _timello: probably missing codecs
<Nafallo> hmm, anyoneelse got troubles with docbook-dssslversion 1.78-4?
<danhunt> Check http://www.desktopos.com/reviews.php?op=PrintReview&id=21 for .mpg tips.
<Nafallo> it works now :-P, takes a bit more to downgrade through aptitude than upgrade ;-)
<_timello> danhunt, I installed mplayerand the essential codecs package, but it still isn't working. I didn't find why
<Nafallo> Well can I move the drives
<danhunt> Nafallo: you can't move the drives, definitely not. This is the problem with RAID : )
<Nafallo> danhunt: haha, yeah
<Nafallo> _timello: run mplayerfrom a terminal and check the output?
```

Figure 1: A (truncated) multi-party conversation from Ubuntu IRC log. Curved arrows show the ‘reply-to’ links between utterances. We use different colors to represent different conversation topic clusters.

Initially, researchers considered response selection in single-turn conversations, where only the last input utterance is considered as the context query (Yan et al., 2016). More recent work deals with multi-turn context, which shows improvements over the single-turn context (Lowe et al., 2015, 2017; Zhou et al., 2016; Chen and Wang, 2019; Gu et al., 2019; Zhou et al., 2018). These methods typically aim to encode the context and the candidate responses in a joint semantic space by capturing short and long range dependencies, and then retrieve the most relevant response by matching the query representation against each candidate's representation through attentions.

However, most of these works are limited to only

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6581–6591, November 16–20, 2020.

two-party conversations. As dialogue research progresses, it is necessary to study the more generic multi-party multi-turn scenario, which has become very common (e.g., Slack, Whatsapp) with the advent of Internet and mobile devices, and posits a unique set of challenges for the dialog models (Kim et al., 2019; Kummerfeld et al., 2019).

Multiple ongoing conversations seem to occur more naturally in multi-party conversations. For example, consider the conversation excerpt in Figure 1 among three participants, taken from the Ubuntu IRC corpus. There are three ongoing conversation topics as highlighted by different color, and the participants contribute to multiple topics simultaneously (e.g., `Nafallo` participates in three and `danhunt` participates in two). An effective response selection method should model such complex conversational topic dynamics in the context, for which existing methods are deficient. In particular, a proper response should match with its context in terms of the same conversation topic, while ignoring other non-relevant topics.

To address the aforementioned challenges in multi-party multi-turn dialog, we frame response selection as a dynamic topic tracking task with the intuition that the topic should remain the same as we go from the context to the response. Our formulation is also supported by the Segmented Discourse Representation Theory (SDRT) of conversations (Asher and Lascarides, 2003). Based on this new formulation, we propose a novel architecture that can incorporate other related dialog tasks such as conversation disentanglement, enabling multi-task learning in a unified framework.

Crucially, our formulation of the task needs to encode only two utterances at a time, thus allowing efficient encoding via large pretrained models like BERT (Devlin et al., 2018). Furthermore, it facilitates pretraining of BERT-like models on topic related sentence pairs to incorporate topic relevance in pretraining, which can be done on large dialog corpora with self-supervised objectives, requiring no manual topic annotations, and can benefit not only response selection but also other dialog tasks. In summary, our contributions are:

- A new formulation of the response selection task with an efficient multi-task learning framework for dynamic topic tracking, which supports efficient encoding with only two utterances at once.
- Incorporate topic prediction and topic disentanglement as auxiliary tasks within the framework. Based on the similarity of these three tasks, the objective is to match topic (topic prediction) between context utterance and response and track response's topic (topic disentanglement) across contexts to select an appropriate response.
- Propose Topic-BERT as a pretraining step to embed topic information into BERT, and use a self-supervised approach to generate topic sentence pairs from existing dialogue datasets. The incorporated topic information is shown to be a key step to our topic tracking framework.
- Apply topic attention by using topic embedding as query to obtain utterance-level embeddings for topic prediction. Then self-attention was applied to capture the contextual topic vectors for response selection and topic disentanglement.
- Evaluate the proposed models on the DSTC-8 Ubuntu IRC dataset (Kim et al., 2019), and show state-of-the-art results in both response selection and topic disentanglement outperforming the existing methods by a good margin.

2 Related Work

2.1 Response Selection

A dual encoder framework was proposed to match the context and response (Lowe et al., 2015), and the long short-term memory (LSTM) was utilized to learn the long and short term dependencies among tokens. Beyond tokens, the sentence view matching was introduced by applying a hierarchical recurrent neural network to model sentence level relationships (Zhou et al., 2016). However, context utterances and response are encoded separately without interaction; thus the semantics extracted from context are not based on the response. Recent approaches such as Sequential Matching Netowrk (SMN) (Wu et al., 2019) leverage the contextual information by matching each contextual utterance with response and the multi channel Convolutional Neural Network (CNN) was proposed to generate multiple levels of granularity of matched segment.

These hierarchy-based methods use LSTM to encode the text, which is not cost effective to capture multi-grained segment representation (Lowe et al., 2015; Zhou et al., 2016; Wu et al., 2019). A particular work on sequence-based method stand out in DSTC-7; Enhanced Sequential Inference Model (ESIM) (Chen et al., 2017) achieves the state-of-the-art performance in DSTC-7 by taking advantage of inter-sentence matching (Chen et al., 2016; Chen and Wang, 2019). It converts multi-turn dialogue setting to natural language inference setting. In addition, transformer-based approach Deep Attention Matching (DAM) solve response selection problem by attention mechanism (Zhou et al., 2018). It utilizes utterance self-attention and context-to-response cross attention to leverage the hidden representation at multi-grained level. Similar to DAM, Multi-hop Selector Network (MSN) was proposed to fuse and select relevant context utterances and match it with the response utterance (Yuan et al., 2019). In addition, Tao et al. (2019) studied the relationship between context utterance and response which indicates that the depth of interaction affect the effectiveness of the model.

Compared to LSTM-based approaches, methods based on transformers (Vaswani et al., 2017) present a promising performance in both accuracy and efficiency (Yang et al., 2020). Devlin et al. (2018) proposed BERT, a transformer-based large-scale pretrained language model, which achieves state-of-the-art performance in different NLP tasks. BERT is also a good match to response selection problem as shown by Vig and Ramea (2019). Our Topic-BERT is initialised with BERT$_{base}$ and post-trained with topic related sentence pairs.

2.2 Hard Context Retrieval

The side effect of multi-speaker multi-turn context is crucial; a lot of noise will be introduced in the context utterances. The speaker and addressee information are essential to decide the structure of conversation, thus can also benefit conversational response selection (Zhang et al., 2017; Le et al., 2019; Hu et al., 2019). A hard context retrieval method was proposed by Wu et al. (2020b) to minimize the context size, while keeping only the utterances whose speaker is the same as the response candidates or referred by the response candidates. However, it cannot guarantee clean context with a single topic of conversation. Indeed, topic tracking is necessary along with hard context retrieval.

2.3 Conversation Disentanglement

Traditional statistical learning based approaches and linguistic features have shown to be effective for conversation disentanglement (Mayfield et al., 2012; Du et al., 2016). Recent methods demonstrate that neural networks could be applied to have a better linguistic representation of the utterances to retrieve relevant conversation. Hand crafted features and pretrained word embeddings are utilized to predict the link-to relationship between utterances (Kummerfeld et al., 2019). Recently, BERT has been adapted in disentangling task to capture the semantics across utterances (Gu et al., 2020). Also, a masked transformer has been applied to learn the graphical representation of utterances based on the reply-to links (Zhu et al., 2019).

3 Task Formulation

Our Topic-BERT framework combines response selection task with two auxiliary tasks, which are topic prediction and topic disentanglement.

Response Selection Our primary task is response selection in multi-party multi-turn conversations. Let $\mathcal{D}_{rs} = \{(c_i, r_{i,j}, y_{i,j})\}_{i=1}^{|\mathcal{D}_{rs}|}$ is a response selection dataset, where j is the index of a response candidate for a context $c_i = \{u_1, u_2, \ldots, u_n\}$ with n utterances. Each utterance $u_i = \{s_i, w_{i,1}, w_{i,2}, \ldots, w_{i,m}\}$ starts with its speaker s_i and is composed of m words. Similarly, a response $r_{i,j}$ has a speaker $s_{i,j}$ and composed of n words. $y_{i,j} \in \{0, 1\}$ represents the relevance label. Our goal is to find the relevance ranking score $f_{\theta_r}(c_i, r_{i,j})$ with model parameters θ_r.

Topic Prediction For this (auxiliary) task, we assume a multi-party conversation with a single conversation topic. Let $\mathcal{D}_{tp} = \{(c_i, r_i^+, r_{i,j}^-)\}_{i=1}^{|\mathcal{D}_{tp}|}$ is a topic prediction dataset, where r_i^+ is a positive (same conversation) response and $r_{i,j}^-$ is a negative (difference conversation) response for context c_i. For our training purposes, each utterance pair from the same context constitutes (c_i, r_i^+), whereas an utterance pair from different contexts constitutes $(c_i, r_{i,j}^-)$. Our goal is to train a binary classifier $g_{\theta_t}(c_i, r_i) \in \{0, 1\}$ with model parameters θ_t.

Topic Disentanglement In this (auxiliary) task, our goal is to disentangle single conversations from a multi-party conversation based on topics. For a given conversation context $c_i = \{u_1, u_2, \ldots, u_n\}$, a set of pairwise "reply-to" annotations $\mathcal{R} = \{(u_c, u_p)_1, \ldots, (u_c, u_p)_{|\mathcal{R}|}\}$ is given, where u_p is a parent of child u_c. Our task is to compute a reply-to score $h_{\theta_d}(u_i, u_j)$ for $j \leq i$ that indicates the score for u_j being the parent of u_i, with model parameters θ_d. The individual conversations can then be constructed by following the reply-to links. Note that an utterance u_i can point to itself, which we call *self-link*. Self-links are either start of a conversation or a system message, and they play a crucial role in identifying the conversation clusters.

4 Our Topic-BERT Framework

Our framework for response selection aims to track how the conversation topics change from one utterance to another and use it for ranking the candidate responses. As shown in Fig. 2, we encode an utterance u_k from the context $c_i = \{u_1, u_2, \ldots, u_n\}$ along with a candidate response $r_{i,j}$ using our pretrained Topic-BERT encoder (§4.1). The contextual token representations in Topic-BERT encode topic relevance between the tokens of u_k and the tokens of $r_{i,j}$, while the `[CLS]` representation captures utterance-level topic relevance. We use the `[CLS]` representation as query to attend over the token representations to further enforce topic relevance in the attended topic vector $\boldsymbol{t}_k$.

We repeat this encoding process for the n utterances in the context c_i to get n different topic vectors $\boldsymbol{T}_j = \{\boldsymbol{t}_1, \ldots, \boldsymbol{t}_n\}$ that model $r_{i,j}$'s topic relevance to the each of context utterances. These topic representations are then used for the prediction tasks – topic prediction, disentanglement, and response selection. Response selection is our main task, while the other two tasks are auxiliary and optional. Since our Topic-BERT encodes two utterances at a time, the encoding process is efficient and can be used to encode larger context. The core component of our framework is the Topic-BERT pretraining as we describe next.

4.1 Topic-BERT Pretraining

One crucial advantage of our topic-based task formulation is that it allows us to pretrain BERT directly on a very relevant task in a self-supervised way, without requiring any human annotation. In other words, our goal is to pretrain BERT such that it can be used to encode relevant topic information for our task(s). For this, we assume that a single-threaded conversation between two or more participants covers a single topic and the utterance pairs in that thread can be used to pretrain our Topic-BERT with relevant self-supervised objectives.

To collect such single-threaded conversational data in an opportunistic way, we can simply adopt the heuristics (unsupervised) used by Lowe et al. (2015) to collect the popular Ubuntu Dialogue Corpus from multi-threaded chatlogs. Alternatively, we can extract two-party conversations from other sources as done in previous work (Henderson et al., 2019; Wu et al., 2020a). In our experiments, we use the data from DSTC-8 task 1 (Kim et al., 2019), which was automatically collected from Ubuntu chat logs. This dataset contains detached speaker-visible conversations between two or more participants from the Ubuntu IRC channel.

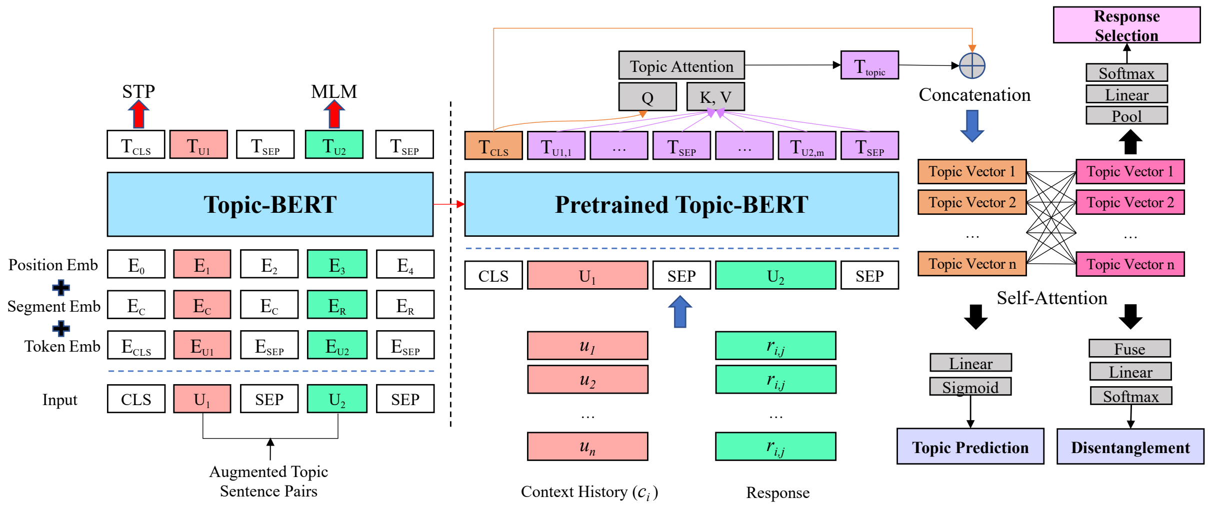
To pretrain Topic-BERT, we first initialise it with the pretrained uncased BERT$_{base}$ (Devlin et al., 2018). We treat the training setting similar to our *topic predection* task in §3. Formally, the pretraining dataset is $\mathcal{D}_{pr} = \{(u_i, r_i^+, r_{i,j}^-)\}_{i=1}^{|\mathcal{D}_{pr}|}$, where each utterance pair from the same conversation (including the true response) constitutes a positive pair (u_i, r_i^+), and for each such positive pair we randomly sample 4 negative responses $(r_{i,j}^-)$ from the 100 candidate pool to balance the positive and negative ratio. We (re)train Topic-BERT on $\mathcal{D}_{pr}$ with two self-supervised objectives as follows.

Masked Language Modeling (MLM) We follow the same MLM training of the original BERT (Devlin et al., 2018) by masking 15% of the input tokens at random, and replacing the masked word with `[MASK]` token at 80% of the time, with a random word at 10% of the time, and with the original word at 10% of the time. The MLM objective is only applied to the positive samples.

Same Topic Prediction (STP) Each training pair ((u_i, r_i^+) or $(u_i, r_{i,j}^-)$) is fed into the Topic-BERT as (`[CLS]`, $[u_1]$, `[SEP]`, $[u_2]$, `[SEP]`). Similar to the original BERT's Next Sentence Prediction (NSP) task, the position embedding, segment embedding and token embedding are added together to get input layer token representations. The token representations are then passed through multiple transformer (Vaswani et al., 2017) encoder layers, where each layer is comprised of a self-attention and a feed-forward sublayer. Different from the original BERT, Topic-BERT uses the `[CLS]` representation to predict whether the training instance is a positive (same topic) pair or a negative (different topic) pair. Thus, the `[CLS]` representation encodes topic relationship between the two utterances and will be used as the topic-aware contextual embedding to determine whether the two utterances are matched in topic.

4.2 Topic-BERT Multi-Task Framework

As shown in Fig. 2(b), the encoded representations from our Topic-BERT are passed through a topic attention layer (§4.2.1) to get the corresponding topic vectors, which are then used for the end tasks.



(a)

(b)

Figure 2: Overview of Topic-BERT architecture. (a) Topic-BERT pretraining with topic sentence pairs to incorporate utterance-utterance topic relationship. (b) Our multi-task framework which uses the pretrained Topic-BERT to enhance topic information in the encoded representations to support three downstream tasks – response selection as the main task while topic prediction and disentanglement as two auxiliary (optional) tasks.

4.2.1 Topic Attention Layer

We apply an attention layer to enhance topic information in the encoded vector. We use the Topic-BERT's `[CLS]` representation T_{CLS} as query to attend to the remaining K tokens $\{T_j\}_{j=1}^{K}$:

$$e_j = \boldsymbol{v}_a^T \tanh(\boldsymbol{W}_a T_{\text{CLS}} + \boldsymbol{U}_a T_j); \quad (1)$$

$$a_j = \frac{\exp(e_j)}{\sum_{j=1}^{K} \exp(e_i)} \quad (2)$$

$$T_{\text{topic}} = \sum_{j=1}^{K} a_j T_j \quad (3)$$

where $\boldsymbol{v}_a$, $\boldsymbol{W}_a$ and $\boldsymbol{U}_a$ are trainable parameters. The concatenation of T_{topic} and T_{CLS} constitutes the final topic vector, *i.e.,* $\boldsymbol{t} = [T_{\text{CLS}}; T_{\text{topic}}]$. We repeat this encoding process for the n utterances in the context $c_i = \{u_1, u_2, \ldots, u_n\}$ by pairing each with the candidate response $r_{i,j}$ to get n different topic vectors $\boldsymbol{T}_j = \{\boldsymbol{t}_1, \ldots, \boldsymbol{t}_n\}$. $\boldsymbol{T}_j$ represents $r_{i,j}$'s topic relevance to the context utterances, which will be fed to the task-specific layers.

4.2.2 Topic Prediction

Topic prediction is done for each utterance-response pair $(u_k, r_{i,j})$ for all $u_k \in c_i$ to decide whether u_k and $r_{i,j}$ should be in the same topic (§3). The Topic-BERT encoded topic vector corresponding to the $(u_k, r_{i,j})$ pair is $\boldsymbol{t}_k \in \boldsymbol{T}_j$. We define the binary topic classification model as:

$$g_{\theta_t}(u_k, r_{i,j}) = \text{sigmoid}(\boldsymbol{w}_p^T \boldsymbol{t}_k) \quad (4)$$

where $\boldsymbol{w}_p$ is the task-specific parameter. We use a binary cross entropy loss computed as:

$$\mathcal{L}_{\text{topic}} = -y \log(g_{\theta_t}) - (1-y)\log(1-g_{\theta_t}) \quad (5)$$

where $y \in \{0, 1\}$ is the ground truth indicating same or different topic. Note that topic prediction is an auxiliary task intended to help our main task of response selection, as we describe next.

4.2.3 Response Selection

In response selection, our goal is to measure relevance of a candidate response $r_{i,j}$ with respect to the context c_i. For this, we first apply the same hard context retrieval method proposed by Wu et al. (2020b) to filter out irrelevant utterances and to reduce the context size. Then, we put each context utterance paired with the response $r_{i,j}$ as the input to Topic-BERT to compute the corresponding topic vectors $\boldsymbol{T}_j$ through the topic attention layer.

We pass the topic vectors $\boldsymbol{T}_j \in \mathbb{R}^{n \times d}$ through a scaled dot-product self-attention layer (Vaswani et al., 2017) to learn all-pair topic relevance at the utterance level. Formally,

$$\boldsymbol{T}_j^{'} = \text{softmax}\Big(\frac{(\boldsymbol{T}_j \boldsymbol{W}_q)(\boldsymbol{T}_j \boldsymbol{W}_k)^{\top}}{\sqrt{d}}\Big)(\boldsymbol{T}_j \boldsymbol{W}_v) \quad (6)$$

where $\{\boldsymbol{W}_q, \boldsymbol{W}_k, \boldsymbol{W}_v\} \in \mathbb{R}^{n \times d}$ are the query, key and value parameters, respectively, and d denotes the hidden dimension of 768.

We add a max-pooling layer to select the most important information followed by a linear layer and a softmax to compute the relevance score of the response $r_{i,j}$ with the context c_i. Formally,

$$f_{\theta_r}(u_k, r_{i,j}) = \mathrm{softmax}(\boldsymbol{W}_r(\mathrm{maxpool}(\boldsymbol{T}_j^{'}))) \quad (7)$$

where $\boldsymbol{W}_r$ is the task-specific parameter. We use the standard cross entropy loss defined as:

$$\mathcal{L}_{\text{rs}} = -\sum_{i,j} \mathbb{1}(y_{i,j}) \log(f_{\theta_r}) \quad (8)$$

where $\mathbb{1}(y_{i,j})$ is the one-hot encoding of the ground truth label.

4.2.4 Topic Disentanglement

For topic disentanglement (§3), our goal is to find the "reply-to" links between the utterances (including the candidate response) to track which utterance is replying to which previous utterance.

For training on topic disentanglement, we simulate a sliding window over the entire (entangled) conversation. Each window constitutes a context $c_i = \{u_1, u_2, \ldots, u_n\}$ and the model is trained to find the parent of u_n in c_i, in other words, we try to find the reply-to link (u_n, u_{n_p}) for $1 \leq n_p \leq n$.

For the input to our Topic-BERT (Fig. 2b), we treat u_n as the response, thus allowing also response-response (u_n, u_n) interactions through Topic-BERT's encoding layers to facilitate *self-link* predictions (the fact that u_n can point to itself).

In the task-specific layer for disentanglement, we take the self-attended topic vectors $\boldsymbol{T}_j^{'} = \{\boldsymbol{t}_1^{'}, \ldots, \boldsymbol{t}_n^{'}\}$ as input, and separate it into two parts: context topic vectors encapsulated in $\boldsymbol{T}_c^{'} = \{\boldsymbol{t}_1^{'}, \ldots, \boldsymbol{t}_{n-1}^{'}\} \in \mathbb{R}^{(n-1)\times d}$ and the response topic vector $\boldsymbol{t}_n^{'} \in \mathbb{R}^d$. In order to model high-order interactions between the response and context utterances, we compute the differences and element-wise products between them (Chen and Wang, 2019). We duplicate the response message $\boldsymbol{t}_n^{'}$ to obtain $\boldsymbol{T}_r^{'} \in \mathbb{R}^{(n-1)\times d}$ and concatenate them as:

$$\boldsymbol{T}^{''} = [\boldsymbol{T}_r^{'}, \boldsymbol{T}_c^{'}, \boldsymbol{T}_r^{'} \odot \boldsymbol{T}_c^{'}, \boldsymbol{T}_r^{'} - \boldsymbol{T}_c^{'}] \quad (9)$$

Then, we compute the *reply-to* distribution as: $h_{\theta_d}(u_n, c_i) = \mathrm{softmax}(\boldsymbol{T}''\boldsymbol{w}_d) \in \mathbb{R}^{n\times 1}$, and optimize with the following cross-entropy loss:

$$\mathcal{L}_{\text{dis}} = -\sum_{j=1}^{n} \mathbb{1}(y_j) \log(h_{\theta_d}) \quad (10)$$

For inference, we compute $\arg\max_j h_{\theta_d}(u_n, c_i)$.

Tasks@Track2	Train Set	Val Set	Test Set
Task 1 (# Dialog)	225,367	4,827	5,529
Task 2 (# Dialog)	112,262	9,565	9,027
Task 4 (# Link)	69,395	2,607	5,187

Table 1: DSTC-8 Ubuntu Dataset Statistics.

4.2.5 Multi-task Learning

We jointly train the three tasks: response selection, topic prediction and topic disentanglement, which share the same topic attention weights to benefit each other. Response selection should benefit from dynamic topic prediction and disentanglement. Similarly, topic prediction and disentanglement should benefit from the response prediction. The overall loss is a combination of the three task losses from Equations 5, 8, and 10:

$$\mathcal{L} = \alpha\mathcal{L}_{\text{rs}} + \beta\mathcal{L}_{\text{topic}} + \gamma\mathcal{L}_{\text{dis}} \quad (11)$$

where α, β, and γ are parameters which are chosen from $[0, 0.1, 0.2, ..., 1]$ by optimizing our model response selection accuracy on dev dataset.

5 Experiments

In this section, we present our experiments, including the datasets, experimental setup, evaluation metrics, and the results with analysis.

Datasets and Setup Considering multi-party conversations, we adopt a publicly available Ubuntu dataset from DSTC-8 track 2 "NOESIS II: Predicting Responses"(Kim et al., 2019). This dataset consists of four tasks and we use the datasets from three of them, including Task 1: single-topic multi-party dialogues for response selection; Task 2: a long Ubuntu chat log with multi-party conversations of multiple on-going topics simultaneously, which is ideal for our main response selection evaluation; Task 4: multi-party chat with link annotations (used for disentanglement task). Table 1 shows the dataset statistics. More details about the datasets, experimental setups and training details can be found in Appendix.

Evaluation Metrics DSTC-8 Track 2 considered a range of metrics for comparing models. We follow their evaluation metrics and the details could be found in Appendix.

5.1 Experiment I: Response Selection

Baseline Models. We compare the proposed Topic-BERT approach with several existing and state-of-the-art approaches for response selection:

- **BERT.** We adopt the vanilla pretrained uncased $\text{BERT}_{\text{base}}$[2] as the base model, and follow (Gu et al., 2020) to post-train $\text{BERT}_{\text{base}}$ for 10 epochs on DSTC-Task 1 (response selection in a single-topic dialog). We take the whole context with the response as one input sequence. We then finetune it on Task 2's response selection for 10 more epochs. More details can be found in Appendix.
- **ToD-BERT.** This is a domain-specific pretrained BERT from Wu et al. (2020a), which is pretrained on a combination of 9 Task-oriented Dialogue datasets and surpasses BERT in several downstream response selection tasks.
- **BERT-ESIM.** This model ensembles both ESIM (Chen et al., 2017) and BERT with gradient boosting classifier, and ranks the second best in DSTC-8 response selection (Dario Bertero, 2020).
- **Adapt-BERT.** This is based on BERT model with task-related pretraining and context modeling through hard and soft context modeling, and ranks as top-1 in the DSTC-8 response selection challenge (Wu et al., 2020b).

Results. From Table 2, we can see that our Topic-BERT model outperforms the baselines by a large margin. By examining our model in detail, we found that our context filtering, self-supervised topic training and topic attention contribute positively to our model, boosting the metric of Recall@1 from 0.287 ($\text{BERT}_{\text{base}}$) to 0.696 (Topic-BERT with standalone response selection task). This shows our topic pretraining with task related data improves BERT for response selection task.

Furthermore, the performance continues to increase from 0.696 to 0.710, when we jointly train response selection and topic prediction (2nd last row), validating an effective utilization of topic information in selecting response. Then we replace topic prediction with disentanglement, which further improves from 0.710 to 0.720, showing response selection can utilize topic tracing by sharing the connection of utterances. Finally, our Topic-BERT with the multi-task learning achieves the best result (0.726) and significantly outperform the prior state-of-the-art Adapt-BERT in DSTC-8 response selection task (Kim et al., 2019).

We further compute BLEU4 SacreBLEU (Post, 2018) for the incorrectly selected responses by Topic-BERT and ToD-BERT. From Table 3, we see that responses retrieved by Topic-BERT are more relevant even if they are not the top one.

Model	**Recall@1**	**Recall@5**	**Recall@10**	**MRR**
BERT_{base}	0.287	0.503	0.572	0.351
$\text{BERT}_{\text{+post-train}}$	0.532	0.797	0.840	0.677
ToD-BERT	0.588	0.823	0.885	0.691
Adapt-BERT	0.706	0.916	0.957	0.799
Topic-BERT	**0.726**	**0.930**	**0.970**	**0.807**
−TP	0.720	0.927	0.964	0.803
−D	0.710	0.924	0.960	0.800
−TP −D	0.696	0.910	0.950	0.790

Table 2: Response selection results on DSTC-8 Ubuntu. "-TP" means our model excluding topic prediction loss and "-D" means excluding topic disentanglement loss. Adapt-BERT results are obtained from (Wu et al., 2020b), other DSTC-8 released baselines are in Appendix.

		Precision@N-gram			
Model	**BLEU4**	**N = 1**	**N = 2**	**N = 3**	**N = 4**
ToD-BERT	0.67	7.568	1.894	0.218	0.065
Topic-BERT	0.75	7.876	2.032	0.250	0.078

Table 3: BLEU4 and N-gram precision are calculated using SacreBLEU on incorrectly selected responses.

5.2 Experiment II: Topic Prediction

This experiment aims to examine how significant our Topic-BERT can improve over the baselines on the topic prediction task, which is important for both response selection and topic disentanglement.

Baseline Models.

- **BERT.** We use our post-trained $\text{BERT}_{\text{base}}$ from §5.1 and fine-tune it on Task 1 topic sentence pairs as our BERT baseline for topic prediction.
- **ToD-BERT.** We adopt our post-trained ToD-BERT and fine-tune it with our obtained topic sentences pairs as the ToD-BERT baseline.

Results. Table 4 gives the topic prediction results on DSTC-8 task-1. From the results, we can see that our Topic-BERT outperforms the baselines BERT and ToD-BERT significantly in the topic prediction task. Compared with our pretrained Topic-BERT without fine-tuning (last row), the proposed topic attention further enhances the topic matching of two utterances by improving the F-score by 1.5% (from 0.813 to 0.828). Joint training with response selection or disentanglement tasks show similar effect on topic prediction tasks, and the contextual topic information sharing by Topic-BERT

multi-task model add a marginal improvement in topic prediction. Compared with vanilla BERT, ToD-BERT (Wu et al., 2020a) makes substantial improvement for the topic prediction task, but not as significant as ours. This further confirms the importance and efficacy of our learning scheme. Meanwhile, if we compare our pretrained Topic-BERT without fine-tuning (last row) with the BERT model that does not use STP (first row), the significant improvement gives us an impression on how much our Topic-BERT benefits from the STP loss.

5.3 Experiment III: Disentanglement

This experiment aims to examine how well can Topic-BERT tackle the topic disentanglement task.

Baseline Models.

- **BERT & ToD-BERT** We use our fine-tuned BERT and ToD-BERT models in §5.2 as our baselines by taking the history of utterances $(u_1, \ldots, u_{n-1}, u_n)$ and pair each with the current utterance u_n itself from a dialogue as input. Following (Gu et al., 2020), A single-layer BiLSTM is applied to extract the cross message semantics of `[CLS]` outputs. Then we take the differences and element-wise products (Eq. 9) between the history and current utterance. Finally, a feedforward layer is used for link prediction.
- **Feed-Forward.** This is the baseline model[3] from DSTC-8 task organizers that has the best result for task 4 (Kummerfeld et al., 2019), which is trained by employing a two-layer feed-forward neural network on a set of *77 hand engineered features* combined with word average embeddings from pretrained Glove embeddings.
- **Masked Hierarchical (MH) BERT.** This is a two-stage BERT proposed by Zhu et al. (2019) to model the conversation structure, in which the low-level BERT is to capture the utterance-level contextual representation between utterances, and the high-level BERT is to model the conversation structure with an ancestor masking approach to avoid irrelevant connections.

Model	Recall10@1	Recall10@2	Recall10@5
DL2R	0.626	0.783	0.944
Multi View	0.662	0.801	0.951
$\text{SMN}_{\text{dynamic}}$	0.726	0.847	0.961
AK-DE-biGRU	0.747	0.868	0.972
DUA	0.752	0.868	0.962
DAM	0.767	0.874	0.969
IMN	0.777	0.888	0.974
ESIM	0.796	0.894	0.975
MRFN_{FLS}	0.786	0.886	0.976
BERT_{base}	0.817	0.904	0.977
BERT-DPT	0.851	0.924	0.984
Topic-BERT	**0.861**	**0.933**	**0.985**

Table 6: Response selection results on Ubuntu Corpus v1. All other results are from (Whang et al., 2019).

Results. From the results in Table 5, we can see that our Topic-BERT achieves the best result and outperforms all the BERT based baselines significantly. This shows our multi-task learning can enrich the link relationship for improving disentanglement together with topic prediction and response selection. The improvement of Topic-BERT over the baseline model using feed-forward network and hand-crafted features is relatively less, but our approach is able to avoid manual feature engineering. Many of these features are dataset/domain specific and they do not generalize across datasets/domains.

5.4 Experiment IV: Evaluation on New Task

Finally, we examine our Topic-BERT's transferability on a new task based on another Ubuntu Corpus

---

[3] `https://github.com/dstc8-track2/NOESIS-II/tree/master/subtask4`

v1 dataset by comparing with various state-of-the-art response selection methods in Table 6. Ubuntu Corpus V1 contains 1M train set, 500K validation and 500K test set (Lowe et al., 2015).

Baseline Models. Here we mainly introduce the state-of-the-art baseline: BERT-DPT (Whang et al., 2019), which fine-tunes BERT by optimizing the domain post-training (DPT) loss comprising both NSP and MLM objectives for response selection. Details of other baselines can be found in Appendix.

Results. Our Topic-BERT with standalone response selection task fine-tuned on Ubuntu Corpus v1 outperforms the state-of-the-art BERT-DPT, improved by about 1% for $\text{Recall}_{10}@1$. This result shows that the learned topic relevance in Topic-BERT can be potentially transferable to a novel task, the topic information influences the response selection positively, and our utterance-level topic tracking is effective for response selection.

6 Conclusion

This paper presented a new formulation of response selection in multi-party conversations from a novel dynamic topic tracking perspective. Based on our new formulation, we propose Topic-BERT for response selection in multi-party conversations, which consists of two steps: (1) a topic-based pre-training to embed topic information into BERT with self-supervised learning, and (2) a multi-task learning on our pretrained model by jointly training response selection and dynamic topic prediction and disentanglement tasks. Empirically the proposed Topic-BERT achieved the state-of-the-art results on the DSTC8 Ubuntu IRC datasets.

Abstract

Human dialogues are scenario-based and appropriate responses generally relate to the latent context knowledge entailed by the specific scenario. To enable responses that are more meaningful and context-specific, we propose to improve generative dialogue systems from the scenario perspective, where both dialogue history and *future conversation* are taken into account to implicitly reconstruct the scenario knowledge. More importantly, the conversation scenarios are further internalized using imitation learning framework, where the conventional dialogue model that has no access to future conversations is effectively regularized by transferring the scenario knowledge contained in hierarchical supervising signals from the scenario-based dialogue model, so that the future conversation is not required in actual inference. Extensive evaluations show that our approach significantly outperforms state-of-the-art baselines on diversity and relevance, and expresses scenario-specific knowledge.

1 Introduction

Neural dialogue generation has drawn increasing attention due to its vast commercial values and practical demands. Typically, given the dialogue history, neural dialogue models, such as plain Seq2Seq model (Sutskever et al., 2014) and Transformer (Vaswani et al., 2017), learn to predict responses via maximum likelihood estimation (Vinyals and Le, 2015; Shang et al., 2015).

Different from other sequence generation tasks, such as machine translation and paraphrase generation, the dialogue generation task can be regarded as a loose-coupling task, which has much freedom in the semantic and the linguistic aspects of the generated responses. However, it is often hard for the existing models to handle such freedom, compared to the fact that humans have no problem in giving specific yet varied responses even for open-ended dialogue history (Shen et al., 2018; Csaky et al., 2019). One important reason is that we can extend the given dialogue with many possible scenarios of enriched, imaginative background information from our experience and world knowledge, to which existing systems have no access.

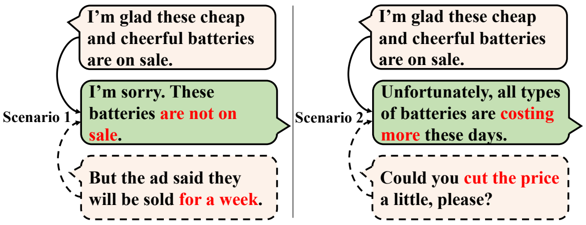

Figure 1: Examples of one dialogue history and its different responses followed by related future conversations. Different responses imply various conversation scenarios, which can be inferred by different relevant future conversations.

It is beneficial for the dialogue systems to build upon such scenarios to facilitate dialogue generation. However, manually annotating the scenario contexts is intractable in terms of both difficulty and quantity. In turn, we find that such scenarios are naturally contained in existing multi-turn dialogue corpora, where the entire dialogue of both dialogue history and future conversation with respect to the current utterance implicitly represents a specific dialogue scenario. An example is given in Figure 1. For Scenario 1, "for a week" in the future conversation suggests the response is related to time. For Scenario 2, "cut the price" indicates that the response contains price information.

Therefore, we reconstruct the dialogue task that only relies on dialogue history into a scenario-based response generation task. In order to enrich the conversation scenario, we employ future conversations together with dialogue histories to learn implicit conversation scenarios, which provide more

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6592–6604,
November 16–20, 2020. ©2020 Association for Computational Linguistics

semantic constraints to guide the response generation. We further propose a novel model to handle this new type of training data consisting of $\{$*implicit scenario, response*$\}$ pairs.

It should be noted that the scenario-based dialogue model relies on future conversations that are inaccessible in inference. Rather than simply searching the training corpora for possible scenarios, we propose an imitation learning framework to drive the conventional dialogue model to absorb the corresponding scenario knowledge from the scenario-based dialogue model. Specifically, the scenario-based dialogue model serves as a teacher, and the conventional dialogue model that relies solely on dialogue history serves as a student that mimics the outputs of the teacher. Under the regularization of scenario knowledge, the student is effectively guided towards a wider local minimum that represents better generalization performance (Chaudhari et al., 2017; Keskar et al., 2017). To facilitate knowledge transfer, the student mimics the teacher on every layer instead of just the top layer, which alleviates the delayed supervised signal problem using hierarchical semantic information in the teacher (Li et al., 2019a). Besides containing the information of future conversations, the distilled knowledge (Hinton et al., 2015) is also a less noisy and more "deterministic" supervised signal in comparison to real-world responses (Lee et al., 2018; Guo et al., 2019), which provides the student with smoother sequence trajectories that are easier to fit.

We highlight our contributions as follows:

- We introduce future conversations together with dialogue histories to learn implicit conversation scenarios, which provide more semantic constraints to drive the responses to be meaningful and relevant to the real-world scenario-specific knowledge.
- We propose an imitation learning framework that bridges the gap between training and inference in the accessibility of future conversations. We also demonstrate why imitation learning works and further how to enhance the imitation learning.
- Our model achieves better results than state-of-the-art baselines on four datasets. Extensive analysis demonstrates the effectiveness and the scalability of the implicit conversation scenarios and the proposed imitation learning framework.

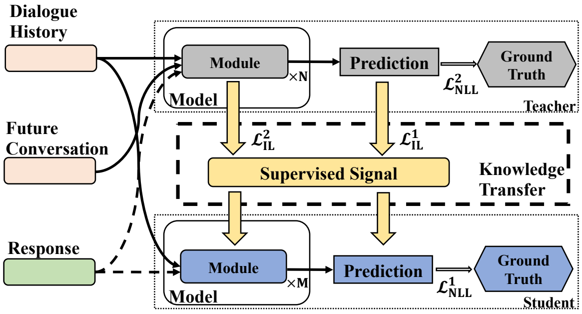

Figure 2: Illustration of the imitation learning framework transferring scenario knowledge from the teacher to the student. Top (Teacher): the scenario-based dialogue model. Bottom (Student): the conventional dialogue model.

2 Proposed Approach

In this section, we first introduce the scenario-based dialogue model, then describe the imitation learning framework shown in Figure 2, and finally present the training objective.

2.1 Scenario-Based Dialogue Model

The conventional dialogue model takes a sequence of dialogue history $X = \{x_1, \ldots, x_T\}$ as input, and generates a response $Y = \{y_1, \ldots, y_{T'}\}$ word by word, where T and T' represent the length of source side and target side respectively. The maximum likelihood estimation is usually used to train the model, which can also be expressed as minimizing the negative log-likelihood:

$$\mathcal{L}^1_{\text{NLL}}(\theta_1) = -\sum_{i=1}^{T'}\sum_{k=1}^{|\mathcal{V}|} \mathbb{I}\{y_i = k\}\cdot \log p(y_i = k | y_{<i}, X_h; \theta_1), \tag{1}$$

where $|\mathcal{V}|$ is the size of vocabulary, θ_1 is a set of parameters, and X_h represents the input sequence that is from dialogue history.

However, dialogue task allows responses to continue the dialogue topic from many aspects or even introduce a new topic depending on various conversation scenarios or semantic constraints, which dramatically increases the difficulty of prediction without any specific scenario information besides the hints from the given dialogue history. Moreover, labeling the scarce scenario information is labor-consuming and impractical. Instead, we resort to easy-to-access but underutilized future conversations that exist in all multi-turn dialogue corpora. By combining the dialogue history and its corresponding future conversation, we introduce the implicit conversation scenario into existing dialogue models to provide more semantic constraints and reduce the difficulty of prediction.

Concretely, we enforce the model to use implicit conversation scenarios to generate responses from two aspects. Different from previous dialogue models only based on the dialogue history X_h to predict the response Y, the future conversation X_f is also considered as part of input so that the model can look ahead and predict more purposefully. Intuitively, our training pair $\{(X_h, X_f), Y\}$ induces the model to imitate humans to produce the scenario-specific response.

We also redesign the sequence generation architecture to handle the proposed training pair. The attention module in each layer calculates the weight of the contextualized token representations from the encoder based on the information that has been generated in the decoder, and then returns the context c_h. In order to consider the future conversation X_f, we apply another encoder to produce the contextualized token representations of X_f, which will be further extracted as the context c_f by the attention module. The new encoder shares the parameters with the original encoder. Meanwhile, the output of the attention module is the concatenation of the past context c_h and the future context c_f. Finally, the training criterion is formulated as the following negative log-likelihood:

$$\mathcal{L}^2_{\text{NLL}}(\theta_2) = -\sum_{i=1}^{T'}\sum_{k=1}^{|\mathcal{V}|} \mathbb{I}\{y_i = k\}\cdot \log p(y_i = k|y_{<i}, X_h, X_f; \theta_2), \tag{2}$$

where θ_2 is a set of parameters to minimize the NLL loss for the scenario-based dialogue model.

2.2 Imitation Learning

In inference, future conversations are inaccessible, which means implicit conversation scenarios cannot be constructed. Thus, the performance improvement from the scenario-based dialogue model cannot facilitate the generation of high-quality responses in practice. In order to bridge this gap between training and inference, we propose an imitation learning framework, in which we regard the scenario-based dialogue model as a teacher and the conventional dialogue model as a student. Through step-by-step imitation, including fine-grained prediction imitation and intermediate representation imitation, scenario knowledge distilled from the teacher regularizes the student to reach a robust local minimum and obtain significant generalization performance in inference.

2.2.1 Fine-Grained Prediction Imitation

Compared with the ground-truth labels, the soft predictions (i.e., the probability distribution from the output layer) contain more fine-grained and valuable information, such as the similarity of labels and potential future conversations. Moreover, the soft predictions provide less noisy and more "deterministic" targets that are easy to mimic. To transfer knowledge from the teacher, instead of taking the one-hot representation of Y as the target, we minimize the cross-entropy of the predicted probability distribution between the teacher and the student:

$$\mathcal{L}^1_{\text{IL}}(\theta_1, \theta_2) = -\sum_{i=1}^{T'}\sum_{k=1}^{|\mathcal{V}|} p(y_i = k|y_{<i}, X_h, X_f; \theta_2)\cdot \log p(y_i = k|y_{<i}, X_h; \theta_1) \tag{3}$$

2.2.2 Intermediate Representation Imitation

Only transferring knowledge from the output layer has a limited effect on the student to use implicit conversation scenarios. When the student network is very deep, the supervised signals from the output layer hardly conduct an effective update and regularization on the parameters of intermediate layers, which will make the imitation learning framework quickly reach saturation (Romero et al., 2015; Sun et al., 2019). This problem prevents the student from scaling to deeper models to further improve the model performance.

To tackle this problem, we extend the range of imitation learning from the soft predictions in the output layer to the output h of intermediate layers to guide the imitation process. Specifically, we penalize the discrepancy of hidden states in intermediate layers between the teacher and the student:

$$\mathcal{L}^2_{\text{IL}}(\theta_1, \theta_2) = \sum_{i=1}^{T'}\sum_{l=1}^{|\mathcal{O}|} f\big(h^t_{il}(X_h, X_f; \theta_2), h^s_{il}(X_h; \theta_1)\big), \tag{4}$$

where $|\mathcal{O}|$ is the number of intermediate layers, h^t_{il} and h^s_{il} are the outputs of intermediate layers in the teacher and the student respectively, and $f(\cdot)$ is the measurement function.

$$f(\cdot) = \begin{cases} \phi(h^s_{il}, h^t_{il}), & \text{if } \phi(h^s_{il}, h^t_{il}) \geq \alpha; \\ 0, & \text{else .} \end{cases} \tag{5}$$

where $\phi(\cdot)$ is the mean-squared-error (MSE) loss. Because we observe that directly applying the MSE loss as an additional loss hurts the stability of the imitation learning process, we set a scalar threshold α to loose this constraint.

2.3 Training

Combining the NLL loss in Equation (1) with the IL losses in Equation (3) and Equation (4), the final objective function of the student is formulated as:

$$\mathcal{L} = \mathcal{L}^{1}_{NLL} + \lambda_1(\mathcal{L}^{1}_{\mathrm{IL}} + \mathcal{L}^{2}_{\mathrm{IL}}), \tag{6}$$

where λ_1 is a hyper-parameter that balances the importance of the NLL loss and the IL losses.

Because the scenario knowledge is only transferred from the teacher by hierarchical supervised signals, our imitation framework has the following three advantages: (1) Compared with the fine-tuning style of knowledge transfer (Dai and Le, 2015; Howard and Ruder, 2018), the proposed imitation framework does not affect the teacher, i.e., the knowledge learned from the teacher will not be forgotten. (2) The proposed method is model agnostic. Thus, the imitation object can be extended from one teacher to multiple teachers, such as incorporating a language model besides the scenario-based dialogue model. (3) The imitation process does not change the current objective function, which means the previous work of modifying objective function can serve as a complementary to improve the model performance further.

3 Experiment

3.1 Datasets

DailyDialog It is provided by Li et al. (2017b), which contains various dialogue topics about daily life. We randomly select 27K, 2.5K, and 1.5K pairs for training, validation, and testing.

PersonaChat It is gathered by assigning two Amazon Turkers with their personas to chat with each other (Zhang et al., 2018a). We only use the conversation section and split it to 67K, 8.5K, and 8K pairs for training, validation, and testing.

OpenSubtitles It is collected from movie subtitles and consists of more than 60M scripted lines (Lison and Tiedemann, 2016). We randomly extract 1500K, 50K, and 25K pairs for training, validation, and testing.

For all datasets, every seven consecutive dialogue turns form a training example, in which the first three turns, the middle turn, and the last three turns are taken as *dialogue history*, *response*, and *future conversation*, respectively.

We also conducted the experiment on a multi-domain goal-oriented dataset called **MultiWOZ**, which is simplified by us as a general dialogue generation task. The detailed description of MultiWOZ and data pre-processing is provided in Appendix A.

3.2 Baselines

We re-implemented two classes of six baselines for comparison. The detailed settings of baselines are provided in Appendix B.

LSTM-Based One class is based on LSTM, including **Seq2Seq+Att**, which contains a vanilla Seq2Seq model (Sutskever et al., 2014) with attention mechanism (Bahdanau et al., 2015), **VHRED+BOW** (Serban et al., 2017), which introduces a continuous latent variable attached to the response information into HRED (Serban et al., 2016) and applies BOW loss (Zhao et al., 2017) as a complementary with KL annealing, and **NEXUS** (Shen et al., 2018), which further uses the future conversation to incorporate more scenario information into the latent variable.

Transformer-Based The other class is based on **Transformer** (Vaswani et al., 2017), including itself, **ReCoSa** (Zhang et al., 2019a), and **CHMAM** (Tao et al., 2018), which consists of Multi-Head Attention Mechanism (MHAM) and an attention weight regularizer. Both ReCoSa and CHMAM aim to extract more relevant and diverse scenario information from dialogue history.

3.3 Experiment Settings

Based on the performance including the loss and metrics on the validation dataset, we trained baselines and our models with the following hyper-parameters. According to the scale of the dataset, the vocabulary sizes for OpenSubtitles, DailyDialog, PersonaChat, and MultiWOZ are set to 50k, 20k, 20k, and 18k, respectively. We use separate word embeddings for the encoder and the decoder, and the word embedding dimension is 256. All the parameters are initialized randomly from a normal distribution $\mathcal{N}(0, 0.0001)$. All models are trained using Adam (Kingma and Ba, 2015) with a learning rate of 0.001 and gradient clipping at 2.0. The batch size is 128. The hyper-parameters in our proposed appraoch are set as $\alpha = 0.01$ and $\lambda_1 = 2.0$. Our models, i.e., **RegDG**, the imitating student conventional model, and **Transformer-IF**, the imitated teacher scenario-based model, are based on Transformer.

3.4 Evaluation Metrics

We conducted both automatic and human evaluation to compare the performance of the models.

Automatic Evaluation The evaluation of open-domain dialogue generation has no well-defined automatic metrics. Thus, we employ two kinds of automatic metrics to evaluate all models. The reference-based metrics, perplexity (**PPL**), **BLEU** (%) (Papineni et al., 2002), and the embedding metrics (including embedding average (**AVE**), embedding greedy (**GRE**), embedding extrema (**EXT**)) (Liu et al., 2016), and coherence (**COH**) (Xu et al., 2018b), are widely adopted to reflect the *grammaticality and semantic relevance* of the responses (Serban et al., 2017; Csaky et al., 2019). The count-based metrics, distinct (**Dist-**$\{$**1,2,3**$\}$ (%)) (Li et al., 2016) and KL divergence (Csaky et al., 2019), are used to evaluate the *lexical diversity* and the *distribution distance* of the responses (Xu et al., 2018a; Zhang et al., 2018b). We report the unigram and bigram version of KL divergence, i.e., $\boldsymbol{D_{kl}^{u}}$ and $\boldsymbol{D_{kl}^{b}}$. Please refer to Appendix C for the detailed settings of automatic metrics.

Human Evaluation We conducted human evaluation to assess the quality of response. We randomly selected 200 test examples from each dataset and asked three annotators to judge which generated response in each pair (RegDG and baseline) is better (i.e., win, lose or tie) in terms of **Diversity** (how much the generated response contains meaningful information), **Relevance** (how likely the generated response is coherent to both dialogue history and future conversation), and **Fluency** (how likely the generated response is from human).

3.5 Experimental Results

Automatic Evaluation The results obtained at the lowest point of the validation loss are shown in Table 1. Our proposed model significantly outperforms all baselines on all datasets. The LSTM-based baselines obtain better performance than Transformer-based baselines in terms of diversity, distribution distance, and relevance, while they lose in grammaticality. It suggests that the LSTM-based model still has a certain advantage in the loose coupling dialogue task. Compared with CHMAM, ReCoSa achieves higher scores on BLEU and embedding metrics but weaker results on Dist-$\{1,2,3\}$ and KL divergence, which means that only extracting scenario information from dialogue history cannot provide sufficient semantic constraints to improve model performance across all metrics. Although NEXUS and VHRED+BOW enrich the latent variable and bring more diversity and relevance, they show a distinct decline in PPL. It verifies that our method not only effectively uses the implicit conversation scenario to boost the performance but also indeed transfers this advantage to the inference phase. The improvements of our model on all datasets are significant with $p \leq 0.01$ (t-test). The results of MultiWOZ, reported in Appendix D, show similar improvements.

Table 2: The human evaluation results. Our model has higher percentages of Win than the baselines.

Human Evaluation The results are shown in Table 2. We only report the results of VHRED+BOW, NEXUS, ReCoSa, and CHMAM, which are more related to our work. From the results, we can observe that our model performs better than baselines in all datasets. In particular, our model obtains the most significant win-lose difference on diversity, which demonstrates that the implicit conversation scenario induces the response containing more tokens that are meaningful. We calculate the Fleiss's kappa (Fleiss, 1971) to measure the inter-annotator agreement, and the results are mainly distributed in $[0.4, 0.6]$ (i.e., moderate agreement range) with the significance $p \leq 0.01$.

3.6 Experimental Analysis

In this section, we further quantitatively analyze the effectiveness of future conversations and explore why imitation learning works and how to enhance it. For limited space, we select a set of complementary metrics, Dist-{1,2,3}, PPL, and BLEU, to report the results. The rest of the results is in Appendix F.

3.6.1 Case Study

Table 3 presents some generated responses. The responses generated by baselines are usually dull and meaningless, while the responses generated by our model show diverse and coherent semantic information that indicates distinct relations with those topics in future conversation. The improvements of our model demonstrate the effectiveness of implicit conversation scenarios and our imitation learning framework. Due to limited space, we provide more examples in Appendix E.

3.6.2 Ablation Study

We evaluate the performance of our method without fine-grained prediction imitation (**FPI**) or intermediate representation imitation (**IRI**). The ablation study results, reported in Table 4, show that both types of imitation are beneficial for knowledge transfer. Without IRI, the model converges to a weaker performance than RegDG.

Dialogue history: Well, I am. How much will that cost? // The pass is free. // I don't have to pay for anything?
Seq2Seq+Att: I don't like it. **VHRED+BOW:** Yes, I'm sorry. **NEXUS:** Yes, we have to pay the cash, please. **Transformer:** I don't know what I want to do. **ReCoSa:** I'm going to check out this magazine. **CHMAM:** I want to get a deposit. **RegDG:** You need to pay for the monthly sticker.
Future Conversation: How much is the monthly sticker? // It's $ 24 for each month. // I'll take the student bus pass.

Dialogue history: We're considering of ordering 200 computers, but I'm wondering about the price you'll possibly offer. // Our price will be not less than $ 5000. // Your price is higher than I expected. Could you give us a little discount?
Seq2Seq+Att: Yes, I'm afraid I'm going to get it. **VHRED+BOW:** Yes, we have a credit card. **NEXUS:** Yes, I need to order the price, but I need to pay the goods in the price. **Transformer:** I see. I'll take it. **ReCoSa:** Well, we have to pay a discount for our products. **CHMAM:** Yes, we'll take a 20%. **RegDG:** I'm afraid I can't. We don't have any reduction of quality.
Future Conversation: But the price is always negotiable and you should consider our quantity of order. // Well, what would you suggest? // Could you make it $ 4500.

Table 3: Examples of the generated responses. The responses generated by our model imply the implicit conversation scenario and contain meaningful information.

3.6.3 Effect of Future Conversation

Effect of the Informativeness of Future Conversation We first investigate the situation under which future conversations benefit the generation of high-quality responses. Intuitively, if the true responses or the future conversations are general safe responses, the future conversions contribute little useful information to current dialogue, thereby playing a limited role in the current response prediction. Thus, we classify examples into two sets, i.e., **Uninformative** and **Other**. Specifically, Un-

Models	Dist-1 ↑	Dist-2 ↑	Dist-3 ↑	PPL ↓	BLEU ↑

Models	Similarity
Seq2Seq+Att	0.553
VHRED+BOW	0.689
NEXUS	0.700
Transformer	0.594
ReCoSa	0.633
CHMAM	0.656
RegDG	**0.732**

Table 7: Effect of regularization reflected by cosine similarity between the generated and real-world word distributions.

informative includes the examples in which the {*dialogue history, response*} or the {*response, future conversation*} is a many-to-one pair. Generally, the second sequence in many-to-one pairs is dull and meaningless (Csaky et al., 2019). To determine the many-to-one pairs, we need to judge whether sentences are of the same meaning and we adopt three measures, that is, whether if the strings match (**Exact Match**), the words overlap more than 80% (**Word Overlap**), or the sentences are in the same embedding cluster (**Sent. Cluster**). For the detailed settings of the above strategies, please refer to Appendix F.

Table 5 shows the results of Transformer-IF on DailyDialog. We can see that the average of all metric improvements of Transformer-IF on the Uninformative set is lower than the Other set, which verifies the assumption that the informativeness of the future conversation supplementing the conversation scenario is crucial to the proposed approach.

Effect of the Capacity of Future Conversation In order to demonstrate the impact of the information content of the implicit conversation scenario on model performance, we conducted the training and testing of both Transformer and Transformer-IF on DailyDailog (1-1-1) and DailyDailog (3-1-3), respectively. "3-1-3" represents that both dialogue history and future conversation consist of three turns, and response only contains one turn. "1-1-1" represents that all sequences in the training examples consist of one turn.

The results are shown in Table 6. Compared with the results on DailyDialog (1-1-1), both models on DailyDialog (3-1-3) achieve overall improvements. The absolute improvements in multi-turn conversation are higher than those in single-turn conversation, which means that Transformer-IF performs better when the implicit conversation scenario contains rich semantic information. Because the automatic metrics may still improve after the lowest point of validation loss (Csaky et al., 2019), the results of both models after 50 epochs of training are reported in Appendix F. It can be observed that Transformer-IF still substantially outperforms Transformer across all metrics under this setting.

3.6.4 Effect of Imitation Learning

Why does the imitation learning work? According to observations in previous work (Chaudhari et al., 2017; Keskar et al., 2017), the model generalization is related to the width of the local minimum achieved by the model. Wider local minima suggests that the model can effectively resist perturbations and obtain better performance on unseen datasets. Therefore, we inject perturbations into the student to judge whether it is guided to a wider local minimum based on the regularization of knowledge transfer. Specifically, we add Gaussian noise with varying magnitude to the parameters of the trained model and observe the perplexity drop on the test set. The results in Figure 3 show that the perplexity of all baselines rapidly increases while the perplexity of our student model grows slowly,

Models	Dist-1 ↑	Dist-2 ↑	Dist-3 ↑	PPL ↓	BLEU ↑
RegDG	1.1	4.4	9.2	**80.61**	**19.1**
+ Word-Emb	1.6	6.5	12.6	101.73	18.4
+ Encoder	**1.8**	**7.8**	**17.7**	118.00	17.9

Table 8: Results using the hard transfer. With more hard-transferred modules, the diversity gradually improves, while the relevance gradually weakens.

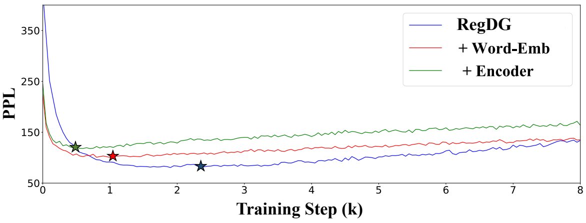

Figure 4: Convergence analysis of the hard transfer. The convergence is faster with more hard-transferred modules.

indicating that the student model reaches a wider local minimum to gain better generalization.

We also analyze the word distributions of the generated responses to intuitively reflect the effect of regularization from imitation learning. Concretely, we use a vector to represent all generated responses, and each element in the vector represents the frequency of a word. Only 2350 most frequent words are considered as Feng et al. (2020). Then, we calculate the distance between the word distributions from each model and the real-world data. From Table 7, it can be seen that our model significantly outperforms plain Transformer and other baselines, which indicates that knowledge transfer effectively regularizes the model so that the model avoids sticking in a relatively centralized word distribution.

Models	Dist-1 ↑	Dist-2 ↑	Dist-3 ↑	PPL ↓	BLEU ↑
RegDG	1.1	4.4	9.2	80.61	19.1
+ LM	**1.3**	**5.0**	**9.6**	**79.31**	**19.4**

Table 9: Results of multiple teachers on DailyDialog. With the help of a pre-trained LM, the performance is improved consistently.

Can imitation learning be accelerated? Before the student mimics the teacher, the teacher is usually well pre-trained. According to our observation, this is a redundant workflow that almost doubles the training time. It is worse if we should train a larger model on a huge dataset. In order to accelerate the training process, instead of transferring knowledge via supervised signals to train a student from scratch, we initialize the specified module of the student directly using the parameters of the teacher, and the transferred parameters are kept from updates during the training process. We call this the **hard transfer**. We first apply the hard transfer operation on word embedding (Word-Emb), and further extend it to the encoder. The results of DailyDialog in Table 8 indicate that the performance has been further improved on the diversity with a slight drop on the relevance. Figure 4 shows the variation curve of PPL on the validation set with the training step. The full results are provided in Appendix F. With more hard-transferred modules, the model reaches the lowest point of validation loss faster. It demonstrates that the hard transfer distinctly accelerates the convergence.

Do multiple teachers work? To take advantage of more diverse and richer prior knowledge, we consider extending the teacher from one to many. We pre-train a transformer-based language model as another teacher. The results are shown in Table 9 with full results in Appendix F. It is clear that with the help of the language model, the student further improves on all metrics, except for a weak decline in relevance, because the language model conducts unconditional sequence generation and does not consider the mapping between the dialogue history and the response. We defer the exploration of balancing multiple teachers in future work.

4 Related Work

Diversified Dialogue Generation Recently, various researches have focused on neural dialogue models to generate diverse, informative, and relevant responses. One line of research attempts to extract relevant contexts from redundant dialogue history accurately (Xing et al., 2018; Tao et al., 2018; Zhang et al., 2019a). Another line of research tries to explicitly incorporate a latent variable to inject the variability of response in the decoding process (Serban et al., 2017; Zhao et al., 2017). Shen et al. (2018); Gu et al. (2019); Gao et al. (2019) further enriched the latent variable approach. Also, some works redesigned the objective function or automatically learned it by adversarial learning (Li et al., 2016, 2017a; Xu et al., 2018a; Feng et al., 2020), which improves diversity but brings a fragile training process. Finally, some researchers have adapted external knowledge, such as topic information (Xing et al., 2017), persona (Zhang et al., 2018a), knowledge base (Ghazvininejad et al., 2018). Unlike the above models to predict responses given a dialogue history, our method combines the future conversation with the dialogue history as the implicit conversation scenario, which contains comprehensive background information to guide the response generation.

Imitation Learning Imitation learning, acquiring skills from observing demonstrations, has proven to be promising in structured prediction, such as alleviating the exposure bias problem (Bengio et al., 2015; Zhang et al., 2019b), transferring knowledge to guide non-autoregressive translation model (Gu et al., 2018; Wei et al., 2019), and automatically learning the reward of the dialogue system (Li et al., 2019b). In our work, the conventional dialogue model as a student mimics the scenario-based dialogue model on both the output layer and intermediate layers.

5 Conclusion

In this work, we introduce the future conversation with the corresponding dialogue history to learn the implicit conversation scenario, which entails latent context knowledge and specifies how people interact in the real world. To incorporate such scenario knowledge without requiring future conversation in inference, we propose an imitation learning framework. The scenario-based teacher model first learns to generate responses with access to both the future conversation and the dialogue history and then a conventional student model is trained to imitate the teacher by hierarchical supervisory signals. As a result, the student is effectively regularized to reach a robust local minimum that represents better generalization performance. Evaluation on four datasets demonstrates the effectiveness and the scalability of our approach, compared to the state-of-the-art baselines. The proposed framework enables the generation of responses that pertain more closely to the scenario indicated by the given dialogue history. Moreover, detailed analyses illustrate how imitating implicit scenarios regularizes the student model. For future work, we will incorporate pre-trained models into our framework (e.g., BERT as a teacher and GPT as a student) to further unlock the performance improvement and explore how to balance diverse prior knowledge from multiple teachers.

A Datasets

MultiWOZ This dataset is a large-scale multi-turn conversation corpus that contains highly natural conversation across 7 goal-oriented scenarios written by human (Budzianowski et al., 2018). It is split to 58K, 15K, and 5K pairs for training, validation, and testing, respectively.

Two rules are applied to process the four datasets in the experiment:

1. Every seven consecutive dialogue turns form a training example, in which the first three turns, the middle turn, and the last three turns are taken as *dialogue history*, *response*, and *future conversation*, respectively.
2. The lengths of response, dialogue history, and future conversation are limited to $[5, 25]$, $[25, 80]$ and $[25, 80]$, respectively.

B Baselines

Seq2Seq+Att We use a plain Seq2Seq model (Sutskever et al., 2014) with attention mechanism (Bahdanau et al., 2015). The encoder consists of a 2-layer bidirectional LSTM with 256 hidden units. The decoder is based on a 4-layer unidirectional LSTM with 256 hidden units. This baseline is enhanced with multiple techniques from related work and should be considered as a strong baseline.

VHRED+BOW VHRED is proposed by Serban et al. (2017), which introduces conditional variational auto-encoder (CVAE) into the HRED model (Serban et al., 2016) with a continuous latent variable attached to the response. We also adopt the BOW loss (Zhao et al., 2017) as a complementary with KL annealing. The latent variable is 256.

NEXUS NEXUS (Shen et al., 2018) enriches the latent variable with both dialogue history and future conversation through mutual information maximization.

Transformer Transformer (Vaswani et al., 2017) is based solely on the attention mechanism. The number of blocks and heads is 2 and 4, respectively. The hidden size is set to 256. The dimension of the feed-forward layer is 1024.

ReCoSa ReCoSa is proposed by Zhang et al. (2019a), which consists of a word-level LSTM encoder, a self-attention based context-level encoder, and a self-attention based context-response decoder.

CHMAM CHMAM (Tao et al., 2018) applies Multi-Head Attention Mechanism (MHAM) to capture multiple semantic aspects from the dialogue history with a regularizer penalizing the redundancy of attention weight vectors across different aspects of the source sequence.

We adopt residual connection, Layer Normalization (Ba et al., 2016), and Dropout in the LSTM-based baselines, which significantly boost the performance of Seq2Seq+Att, VHRED+BOW, and NEXUS. RegDG and Transformer-IF use the same settings as Transformer. The parameters of Transformer-IF are kept fixed during imitation learning.

Table 10: The automatic evaluation results at the lowest point of the validation loss. "↑" means higher is better. "↓" means lower is better.

C Automatic Evaluation Metrics

Embedding Metrics The word embedding used in embedding metrics is pre-trained on each dataset using fasttext.

Perplexity We calculate the perplexity of each individual sentence and then calculate the average perplexity, which is different from the other way that takes the whole test set (or each batch of data) as one long sentence and then calculates the perplexity (e.g., the official code of Zhao et al. (2017)). The score calculated by the former way is usually larger than the latter one. The difference will increase as the test set (or the size of each batch) gets larger.

KL Divergence It calculates the KL divergence $D_{kl} = {}^{1}\!/\!_{|U_r|} \sum_{w \in U_r} \log_2 {}^{p_r(w)}\!/\!_{p_m(w)}$ for each reference response between the reference and the generated response sets, where p_r and p_m are estimated based on the reference response set and the generated response set respectively.

D Automatic Evaluation on MultiWOZ

Table 10 shows the automatic evaluation results on MultiWOZ. Our model beats all baselines on 9 out of 11 metrics.

E Case Study

We provide more generated examples in Table 11.

F Experimental Analysis

Effect of the Informativeness of Future Conversation We use the cosine similarity as the similarity measure and set 0.8 and 0.98 as the thresholds for one-turn sequence and three-turn sequence, respectively. The sentence embedding used in single-pass algorithm is the sum of word embedding with a corresponding weight estimated on the training set. We also adopt the k-means algorithm, which achieves similar clustering proportion.

Effect of the Capacity of Future Conversation Table 12 demonstrates that our model works better when the implicit scenario contains rich information. Table 13 indicates that our model still outperforms Transformer after a fixed epochs (50) of training.

Effect of Imitation Learning Table 14 and Table 15 report the full version of the experimental results in Section 3.6.4.

Dialogue history: Sure. The fitting room is on your right. // It fits well. I like it a lot. What do you think? // You look pretty in red.
Seq2Seq+Att: I don't know. I don't want to do that. **VHRED+BOW:** Oh, I don't know. **NEXUS:** I don't know it. **Transformer:** No, I don't think it's too heavy. **ReCoSa:** I think I'll have a glass of wine. **CHMAM:** It looks like this one. **RegDG:** I'll take it. How much is it?
Future Conversation: $ 29.99. // Okay, I'll take it. Thank you very much for your help. // You're welcome.
Dialogue history: First off, I'm going to need a pound of ground beef. // A pound of ground beef is $ 2.48. // That's perfect.
Seq2Seq+Att: How much do you need to do for the next week? **VHRED+BOW:** How much do you want? **NEXUS:** How much do you like? **Transformer:** How much do you want to get? **ReCoSa:** I'm going to need to get a ticket. **CHMAM:** What kind of ground would you like? **RegDG:** What kind of chicken do you want?
Future Conversation: I'm also going to need three pounds of chicken breasts. // The chicken breasts cost $ 4.05 per pound. // What's the total price for the chicken?
Dialogue history: How much dose it cost for a bus pass? // It'll be $ 65 for a monthly pass. // Is there anything cheaper than that?
Seq2Seq+Att: Yes, I have to take a taxi. **VHRED+BOW:** Well, it's the same thing. **NEXUS:** That's right. How much do you want to pay the bus? **Transformer:** I'm not sure. **ReCoSa:** It's about two years ago. **CHMAM:** We'll get a student pass. **RegDG:** You can take a student pass.
Future Conversation: Well, I am. How much will that cost? // The pass is free. // I don't have to pay for anything?
Dialogue history: I don't want to have a specific title. I just want to enjoy what I am doing. // That sounds very reasonable. // It's the most important thing to me.
Seq2Seq+Att: I don't know that. **VHRED+BOW:** Well, I'll have a good idea. You can have a good idea. **NEXUS:** What do you have to do? **Transformer:** I don't know. But i don't know what to do. **ReCoSa:** I think I should get a part-time job. **CHMAM:** What kind of relationship do you have? **RegDG:** But you know that that's a good idea. I think you should have a good impression on the job.
Future Conversation: That obviously depends on how things go. Whether I'm suited to the firm and firm to me. // Tell me about some of your recent goals and what you do to achieve them. // I want to put my knowledge and experience to use in a challenging position. In order to achieve this goal, I just want work step by step.

Abstract

Being able to perform in-depth chat with humans in a closed domain is a precondition before an open-domain chatbot can ever be claimed. In this work, we take a close look at the movie domain and present a large-scale high-quality corpus with fine-grained annotations in hope of pushing the limit of movie-domain chatbots. We propose a unified, readily scalable neural approach which reconciles all subtasks like intent prediction and knowledge retrieval. The model is first pretrained on the huge general-domain data, then finetuned on our corpus. We show this simple neural approach trained on high-quality data is able to outperform commercial systems replying on complex rules. On both the static and interactive tests, we find responses generated by our system exhibits remarkably good engagement and sensibleness close to human-written ones. We further analyze the limits of our work and point out potential directions for future work [1].

1 Introduction

Being able to converse like humans in a *closed domain* is a precondition before an intelligent open-domain chatbot, which further requires transiting among various domains, can be designed (Gao et al., 2019; Su et al., 2020). Nonetheless, even if constrained in a specific domain, current chatbots are still far from satisfactory. Unlike task-oriented systems that can be relatively well-resolved with handcrafted templates, human conversations feature a complex mixture of QA, chitchat, recommendation, etc. without pre-specified goals or conversational patterns (Dodge et al., 2016; Akasaki and Kaji, 2017; Shen et al., 2018). Selecting proper domain knowledge to support response generation at all the different situations is challenging (Milward and Beveridge, 2003; Lian et al., 2019; Shen et al., 2019). In this work, we direct our focus to the movie domain and present a *large-scale, crowd-sourced Chinese dataset with fine-grained annotations* in hope of boosting the study towards a human-like closed-domain chatbot.

A variety of dialogue datasets with grounded domain knowledge have already been proposed. However, they are collected either through (1) online forum crawling (Dodge et al., 2016; Ghazvininejad et al., 2018; Liu et al., 2018; Zhou et al., 2018a; Qin et al., 2019), which are noisy, multi-party, mostly contain only single-exchange QA, or (2) crowd-sourced (Zhu et al., 2017; Zhou et al., 2018b; Moon et al., 2019; Wu et al., 2019), which are small-scale and often created in an overconstrained setting like teacher-student (Moghe et al., 2018). Even for datasets crowd-sourced in unconstrained scenarios, suggestive domain knowledge is provided for humans before an utterance is provided. This would inevitably prompt humans to utilize these knowledge deliberately, yielding unnatural conversations simply connecting the knowledge (Dinan et al., 2019; Zhou et al., 2020). We show examples from other datasets in Appendix Table 10. In comparison, our dataset has the following advantages:

1. **Natural**: Crowdworkers chat in a free environment without further constraint or prompt in order to mimic the human daily conversations to the largest extent.

2. **Large-scale**: It covers 270k human dialogues with over 3M utterances, which is *at least one order of magnitude larger* than all the other crowd-sourced datasets.

3. **Annotated**: Utterances are labeled with entity information and dialogue acts classified into

November 16–20, 2020.

15 fine-grained aspects, based on which linked into different types of knowledge.

Different from previous crowd-sourced works, our annotation process is conducted posteriori so that it will not interfere with human conversations, e.g., prompt them to overuse suggested knowledge.

Built upon our dataset, we propose a *simple unified language model approach* to push the limits of movie-domain chatbots. The model is first pretrained on 2.2B words collected from various general-domain conversational resources, then fine-tuned on the movie dataset with additional knowledge and dialogue acts incorporated. We pool all components like intent prediction and knowledge retrieval into a sequence prediction task and solve them with a unified language model architecture. It avoids designing complex systems for individual components separately and all subtasks can be easily trained simultaneously (Hosseini-Asl et al., 2020; Peng et al., 2020). We show our simple unified approach outperforms strong baselines for each separate subtask. Knowledge retrieval, dialogue acts prediction and general-domain pretrain benefit from each other and altogether bring improvement to the generation quality. In the online interactive test, our best model succeeds at chatting with humans for 11.4 turns without being detected to be a machine, outperforming even commercial chatbots Mitsuku [2] and Microsoft XiaoIce [3] which further rely on complex rules. By analyzing the limitations of our model, we find it especially has difficulty at dealing with in-depth discussions over long turns. Future research can consider employing larger knowledge base or explicit state tracking.

In summary, our main contributions are (1) presenting a high-quality, large-scale Chinese conversational corpus with fine-grained annotations in the movie domain to benefit future study, (2) showing that a simple unified neural model trained on the high-quality dataset can approach human performance and even outperform commercial systems replying on complex rules, and (3) studying the shortcomings of current techniques, providing suggestive directions for future research.

2 Dataset Construction

The dataset construction consist of (1) crowd-sourcing the dialogues, (2) annotating dialog acts and entities and (3) linking utterances into grounded knowledge. We explain these three steps in order and present the dataset statistics in the end.

Dialogue Crowd-sourcing We obtain the dialogue dataset through a two-phase Wizard-of-Oz-style collection (Kelley, 1984; Dahlbäck et al., 1993). In the first phase, we run small-scale pilot studies and examine the quality of collected conversations. Based on the examination, we created tutorials and qualification tests. They are used to train and qualify crowd-workers for the second phase. During this second phase, we consistently monitor the collected dialogue datasets and perform periodic quality check on samples from every individual work pairs. If more than 5% from one pair are considered invalid, their collections will be removed. Before a conversation started, two workers are paired and a movie is chosen agreed by both [4]. We constrain at least one of them to have watched the movie to make sure the conversation is contentful [5]. The annotators are especially instructed to (1) behave naturally as in daily life, (2) avoid dirty words and (3) talk differently in each conversation. Duplicate conversations will be removed if more than 70% of their contents are overlapped. To encourage diverse movies, we further set an upper limit to forbid one movie from being talked about for more than 100 times.

The whole collecting process lasts two months. In the end, 245 participants are involved with 66,424 movies being talked about in total.

Dialogue Act and Entity Annotation Following prior work, we base our annotation schema on the ISO 24617-2 standard (Bunt et al., 2010, 2012). Table 1 shows our annotation schema, counts, descriptions, and brief examples. The dialogue acts (DAs) are organized in a hierarchical structure. The first layer makes distinctions on three concepts: objective facts, recommendations and subjective feelings. Each concept can either be either requested or informed during the conversation. We further define an "*Other*" class to include actions that do not belong to any of the three concepts, like some general non-contentful greetings or echos. The second layer includes 15 finer-grained aspects covering most popular topics being discussed. Every first-layer DA (except *Other*) will be further group it into one of these 15 aspects, e.g., the de-

Aspects: Type
Mov_Tracker: *The Legend of 1900*

一部意大利拍的英语电影，讲一位天才钢琴师一辈子都住轮船上
An English film made in Italy, where a talented pianist lived on the ship all his life

DA: Inform_fact
Aspects: Region, Language, Plot
Mov_Tracker: *The Legend of 1900*

Region: Italy | **Language:** English | **Plot:** "a talented pianist lived on the ship all his life"

这么离奇的故事，为什么他不离开那艘船呢
Such a bizarre story, why didn't he leave that boat?

DA: Inform_feeling, Request_fact
Aspect: Plot
Mov_Tracker: *The Legend of 1900*

Plot: "why didn't he leave that boat"

他把这里当成了他的精神家园，所以船要被炸掉他都不肯离开
He regarded this as his spiritual home, so when the last ship was about to be blown up, he refused to leave

DA: Inform_feeling, Inform_fact
Aspects: Plot
Mov_Tracker: *The Legend of 1900*

Plot: "when the last ship was about to be blown up, he refused to leave"
Comment: *What he cannot leave is not the boat, but the spiritual home that nurtured him.*

就像阿甘正传一样。现代社会很少有人能和世俗割裂去追求自己的精神世界
Just like in Forrest Gump. Few people in modern society can separate themselves from the world to pursue their own spiritual world

DA: Inform_feeling
Aspects: Name
Mov_Tracker: *Forrest Gump*

Name: Forrest Gump | **Comment:** *The negative perspective of 1900 may represent the director's reflection on modern civilization.*

Figure 1: An example of our dataset. The annotations include dialogue act, aspects and movie tracker and grounded knowledge.

tailed DA of the first example in Table 1 will be request_fact_director. If one utterance contains multiple dialogue acts, we order the dialogue acts based on their turn of appearance in the utterance. As for the named entity recognition, we labeled 5 kinds of entities: movie names, director, actor, type and role (first 5 aspects).

To speed up the annotation process, we first define a set of handcrafted regular expressions, which covers most frequent patterns at each class, to train a DA and NER classifier . The annotators are instructed to post-correct the auto-labeled dialogues instead of doing everything from scratch. The classifiers are trained with online learning (Sahoo et al., 2018) to keep improving the accuracy and lower down the frequency of post-correction in consequence. As we observe, this semi-automated way significantly speeds up the labeling process. All the dataset is finished labeling within three weeks with 188 annotators involved.

Knowledge Linkage We extract fact knowledge from the structured table in Douban Movie [6] , a popular Chinese platform for movies. The knowledge is organized in the form of key-value pairs, where the key corresponds to the 15 aspects defined by us. Some aspects, like lines or music, are not directly available from the structured table. We extract these missing information from other sources and combine it into our knowledge base. For utterances labeld as *inform/request_fact*, we link them to the key-value pairs from the same aspect. Apart from the objective knowledge, we also crawl movie comments from Douban Movie to support the generation of responses expressing subjective feelings. These comments can be a good supplementary to provide knowledge that can be hardly organized in the structured form (Moghe et al., 2018). For utterances labeled as *inform/request_feeling*, we compare them with Douban comments from the same movie and compute the similarity score based on weighted average of edit distance, Jaccard distance, tf-idf, sentence vector cosine similarity, common words and entities. Each utterance is linked to the most similar comment with a threshold cutoff. In the end, 51.7% of the utterances about feelings have grounded comments. For utterances about recommendations, we simply ground them to the men-

Dialogue Act	Count(%)	Linked	Description	Example
Request_fact	8.62	Fact	Request facts.	Who directed this movie?
Request_recommend	4.91	None	Ask recommendations.	Which other movies do you recommend?
Request_feeling	4.98	Comment	Request feelings.	How do you like its theme music?
Inform_fact	24.85	Fact	Inform facts.	Wong Kar-Wai directed this movie.
Inform_recommend	4.56	Movie	Give recommendations.	I can also recommend *Titanic*!
Inform_feeling	28.95	Comment	Convey feelings	Its music reminds me of my childhood!
Other	23.10	None	Greetings, echos, etc.	hahaha.
Aspects: name, director, actor, type, role, region, time, plot, line, award, gross, rating, website, music, others				

Table 1: Counts, type of linked knowledge, descriptions and examples of the dialogue acts. *Examples are shown only in translated English for space limit.* Each dialogue act (except *other*) is paired with one of the 15 aspects. Details descriptions and statistics of the aspects are in Appendix Table 11.

tioned movie entities [7], and no grounded knowledge is linked for utterances labeled as *Other*. An example of our annotation is presented in Table 1.

	Train	Valid	Test/s	Test/u
Dialogues	221,526	12,307	6154	6154
Utterances	2,702,618	153,591	79,978	74,463
Turns/D	12.2	12.5	13.0	12.1
Tokens/U	14.9	12.6	13.5	15.9
Movies	59,449	3,146	1454	1454

Table 2: Number of dialogues, utterances, turns per dialogues, tokens per utterance and movies in the train, valid, test (seen movies) and test (unseen movies) dataset.

Dataset Statistics The final dialogue dataset we collect consists of 246,141 dialogues with 3,010,650 turns, which we divide into 221,526 for train, 12,307 for validation, and 12,308 for test. The test set is split into test/seen for movies seen in the training set, and Test/unseen for unseen movies, each covers conversations about 1454 movies. The training set covers 59,449 movies with 12.2 turn per dialogue in average. Each turn contains 14.9 tokens. Data statistics can be found in Table 2.

3 Model Architecture

Language models have demonstrated impressive performance as a universal learner across NLP tasks (Shen et al., 2017; Peters et al., 2018; Radford et al., 2019; Brown et al., 2020). Inspired by this, our dialogue generation model is implemented as a Transformer-based language model like GPT2 (Radford et al., 2019; Zhang et al., 2019). It contains a pipeline process of movie tracker, intent prediction, knowledge retrieval and text generation. Unlike in traditional task-oriented systems where subtasks are decomposed separately, we opt for *a simple and unified approach by casting all subtasks into sequence prediction*. A special token is injected in the beginning to indicate which subtask to perform (Hosseini-Asl et al., 2020; Peng et al., 2020). Table 3 shows the schema representation for different components. The condition and the target are concatenated into a single sequence and then fed into the language model to train. For example, the task of predicting the intent given the dialogue context will be transformed into “[context] *dialogue context* [intent] *DA sequence*”, where the *DA sequence* will be predicted conditioned on “[context] *dialogue context* [intent]”.

Context	[context] *dialogue context*
Fact	[fact] *key-value pair(s)*
Comment	[comment] *movie comment(s)*
Recommend	[recommend] *movie name(s)*
Track	[tracker] *[inherit] or a new movie name*
Intent	[intent] *DA sequence*
Retrieve	[retrieve] *knowledge*
Response	[response] *response*

Table 3: A schematic representation of the different components. Upper parts are the conditions and lower parts are the targets. The condition and target are concatenated into a single sequence then fed into the language model.

General-domain Pretrain The model is first pretrained on a mixed general-domain conversational corpus crawled from various sources like

---

[7] We only consider recommending *movies* as for the DA about recommendation. Recommending other aspects require assembling recommendation systems of different domains, which is beyond the scope of this paper.

douban [8], tieba [9], zhihu [10] and weibo [11]. The pretrained corpus covers 468M conversations with 2.2B words. Each training instance is processed in the form of "[context] *dialogue context* [response] *response*" where *response* will be predicted given "[context] *dialogue context* [response]". The objective is a mixture of maximum likelihood and unlikelihood training (He and Glass, 2019; Li et al., 2019), which we find help reduce repeated and incoherent generations as observed in Adiwardana et al. (2020). The unlikelihood training minimizes the likelihood of 1) randomly sampled responses from the corpus and 2) repeated bigrams from the previous generated tokens.

Movie Tracker The movie tracker is like the belief state tracker in task-oriented systems (Henderson et al., 2013). It is used to track which movie will be talked about in the next utterance. Conditioned on the dialogue context, we feed a special token [tracker] to the decoder. The decoder should decide whether to inherit the movie talked about in the last utterance or switch to a new movie. The target would be "[tracker] [*inherit*]" or "[tracker] *new movie name*" if transiting to a new movie. The initial state is an empty indicator [*None*].

Intent Prediction The intent prediction is also cast as a sequence prediction task. Compared with the traditional way of multi-label classification, casting it as sequence prediction is better at addressing the coexistence of multiple DAs and capturing the sequential dependencies among the hierarchy (Raffel et al., 2019; Vedula et al., 2020). For example, to predict the DAs of the 4th utterance in Figure 1, the sequence fed to the language model will be "[context] *dialogue context* [intent] *inform, feeling, plot, request, fact, plot*". By this means, before predicting a DA, the model can condition on both the dialogue context and its previous DAs to improve the accuracy.

Knowledge Retrieval The knowledge retrieval component is similar to the classical DSSM model (Huang et al., 2013). We replace the MLP with our language model encoder to get the embedding for knowledge. Note that we only select knowledge from the current movie, which can be obtained from the movie tracker, so it is possible to run exact softmax over all knowledge candidates and maximize the likelihood of the ground truth. We condition on both the dialogue context and the intent. The sequence fed to the language model would be "[context] *dialogue context* [intent] *DA sequence* [retrieve] *knowledge*" where *knowledge* will be predicted. When an utterance is not linked with any knowledge, it will predict a *None* token.

Parameters	Layers	Dimension	Heads
117M	12	768	12
345M	24	1024	16
762M	36	1280	20

Table 4: Architecture hyperparameters for the 3 model sizes.

Text Generation The text generation is conditioned on the dialogue context, intent and the retrieved knowledge. All the conditions are concatenated into a long sequence. The knowledge can be fact, comment, movie names of mixture of them according to the DA of the utterance. For example, if grounded on comment knowledge, "[context] *dialogue context* [intent] *DA sequence* [comment] *comment* [response]" will be fed to the language model to generate the response. To make it consistent with the pretrained general-domain dialogue, the position embedding of the decoded response will skip the concatenated intent and knowledge and directly follow the dialogue context. We find this beneficial when combined with pretrained models. The objective also follows the pretrained model mixing maximum lilkelihood and unlikelihood training.

4 Experiment Setting

We tokenize the Text in the unit of Chinese characters and keep all unique non-Chinese unique tokens appearing for more than 5 times. The whole vocabulary contains 13,317 words. We train our model on 24 Nvidia V100 GPUs (32GB) with three different model sizes as shown in Table 4. The batch size is fixed as 64 per GPU. The context length is truncated to be 300 words. We optimize models with the Adam gradient descent and a drop out rate of 0.1. For the 117/345M model, the learning rate is set as $1.5e-4$ with a linear warm up of 3600 steps. For 762M model, the learning rate is $1.25e-4$ with a 2400-step linear warm up. Models are trained for 150k steps on the pretraining corpus and we observe no overfitting for all. For decoding, we employ Nucleus Sampling with $p = 0.9$ (Holtzman et al., 2020). All experiments are done with

Table 5: The perplexity, BLEU score and distinct uni/bi-grams of our model with different sizes. Results are reported for seen/unseen movies respectively. Each line adds one more condition on top of the above one.

PyTorch (Paszke et al., 2019).

5 Results and Analysis

Automatic Evaluation In Table 5, we report the perplexity, BLEU scores and distinct uni/bigrams for three model sizes. To investigate the effects of incorporating annotations and pretraining, we start from a basic model which trains from scratch on our movie corpus. At each time, we add one more condition to see its influence. The results show a clear tendency of gradual improvement as more conditions are added to the training. Adding knowledge especially boosts the performance, which is understandable considering movie-domain chats usually contain many movie-specific rare names. Without knowledge grounding, it can hardly predict the correct tokens. Pretraining on general-domain conversations can improve both the overlap with ground truth. The distinct uni/bigrams also consistently increase, implying the model can learn useful patterns in the pretrained corpus to enrich its generations in the movie domain. In unseen testset, the performance generally drops for all, especially for models without knowledge grounding as they have to make up facts and comments for totally unseen movies in the training set.

Table 6 measures the accuracy of predicting dialogue act (DA), aspect and movie tracker of our model. Our models are all pretrained with general-domain corpus beforehand. Apart from being trained only to predict the individual tasks, we include the results where all subtasks are co-trained end-to-end in the last line. We compare our models with the Chinese RoBERTa (Liu et al., 2019), which has achieved SOTA performance on Chinese NLU tasks. We use its optimized version for Chinese which is pretrained by masking full Chinese words (Cui et al., 2019) [12]. RoBERTa does the movie tracking by performing softmax over the recognized named entities. For dialogue acts, we deal with DA1 (inform/request/other) and DA2(fact/feeling/recommend) separately. As can be observed, our simple unified approach for all subtasks does not come at the expense of the accuracy. When all subtasks are co-trained, the performance is further boosted, indicating the multitask training paradigm can benefit individual tasks.

Model	DA1	DA2	Aspect	Movie
RoBERTa	75.8	64.0	44.3	90.7
117M	76.7	66.3	43.8	88.9
345M	82.5	71.5	46.1	90.3
762M	82.9	73.4	51.4	**92.1**
762M (co-train)	**84.5**	**76.5**	**54.3**	91.7

Table 6: Accuracy of dialogue act, aspect and movie tracker.

Model	Fact	Comment	Recommend	
	Hit@1	Hit@1	Hit@1/5

762M	0.518	0.120	0.053	0.086
+ DA	**0.543**	**0.158**	**0.066**	**0.104**

Table 7: Hit rates of knowledge retrieval.

Table 7 measures the performance of retrieving fact knowledge, movie comments and recommen-

---

[12] https://huggingface.co/hfl/chinese-RoBERTa-wwm-ext

dation respectively. We report the hit@1 and hit@5 scores for them (Zhang et al., 2018). We compare our model with a random baseline, bag-of-word (BOW) and the Bert (Devlin et al., 2019) model (we pass sentences through Bert and derive a fixed-sized vector by averaging the outputs from the second-to-last layer (May et al., 2019)). The BOW and Bert model are finetuned with our knowledge linkage annotations. We find that our unified model again outperforms all baseline approaches. Adding the DA as a condition further helps. Fact retrieval has the highest hit rate as it is well structured and easy to match. Recommendation, on the other hand, is very hard to predict. As an accurate recommendation system is clearly beyond the scope of this paper, it is understandable that our simple way fails to provide satisfying recommendations.

Metric	Agreement (%)	Fleiss'k score
Sensibleness	71.5 ± 3.4	0.473
Engagement	64.2 ± 2.3	0.438
Informativeness	79.2 ± 3.1	0.576

Table 8: Crowd worker agreement scores.

Human Evaluation Automatically evaluating dialogue systems are known to be extremely hard (Liu et al., 2016; Su et al., 2018). We further conduct a set of static and interactive human evaluations. We focus on evaluate the machine-generated response from four perspectives. Apart from the oft-used metrics (1) **Sensibleness (Sens)** and (2) **Engagement (Enga)** for open-domain chatbots, we further evaluate on (3) **Factuality (Fact)** and (4) **Informativeness (Info)** to see if models can actively provide informative responses based on movie facts. Details are in Appendix B. As evaluating factuality requires specific movie knowledge, this metric is only evaluated by the same person who produced the dialogue. The other metrics are evaluated by 3 workers each. Table 8 shows the agreement scores. The agreement is reasonable considering the evaluations are subjective. The results are the majority votes of the binary scores.

In the static evaluation, we sample 300 responses for each model from the test set (mixing seen and unseen). The responses can come from any turn in a conversation. We show the results in Figure 2. Our largest model with 762M is clearly preferred by human evaluators on almost all metrics and approaches human performance. By training a larger model and increasing the training size, the gap might be further closed.

In the interactive evaluation, humans can chat with any topic but restricted in the movie domain. We conduct an online Turing test where one side is always a human participant not aware whom he is talking with. The other side could be either Mitsuku, XiaoIce [13], our model (762M with pretraining) or a real human. Mitsuku interacts in English, so we hire only English native speakers for the experiment. We collect 100 conversations for all models. Humans can stop interacting once they (1) find the other side is a machine or (2) reaches the maximum turn of 20. Responses from all models are later passed to the third party to judge the scores. The results are shown on the right of Figure 2. Our model outperforms Mitsuku and XiaoIce by a large margin. As Mitsuku and XiaoIce are designed to be open-domain chatbots, restricting to be on the movie domain will give our model some natural advantage. We can also notice that Mitsuku and XiaoIce *almost never produce fake facts*. The cost is the extremely low ratio of informative responses since they tend to behave over-safely and will only answer it when they are 100% sure. Our model is closer to humans in that sense. It will converse actively at some risk of containing fact errors.

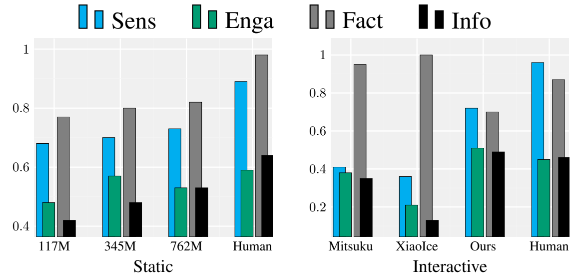

Figure 2: Results of static/interactive human evaluation.

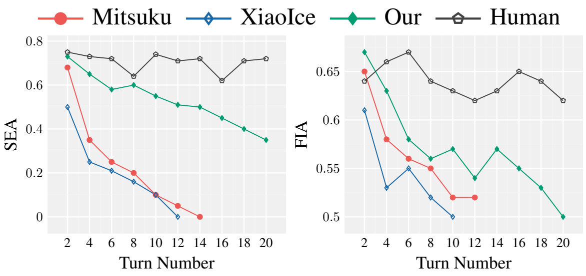

Figure 3: Change of SEA and FIA as the turn proceeds.

---

[13] We use its chat service through Weibo. It will sometimes generate responses containing keywords like "XiaoIce". We manually replace it to prevent disclosing its identity.

	MovieChats	[request_fact_role] [role: 哈利波特...] 哈利波特是谁演的呀(Who played the role of Harry Potter)

Table 9: Examples of interactions with our model. First two are failing cases from the interactive evaluation. Last one shows how the response can be controlled by feeding different DA and aspects.

Distance from Human Performance In the interactive evaluation, compared with human performance, our model loses a bit on sensibleness and factuality but wins on the other two. To investigate where our model fails, figure 3 visualizes the change of **SSA** (Sensibleness-Engagement average) and **FIA** (Factuality-Informativeness average) when the conversational turn proceeds. A good chatbot should balance well these skills (Adiwardana et al., 2020). SEA can reflect how it behaves as a general chatbot while FIA can better test its capability at incorporating domain knowledge. We can see a clear trend of decrease for all models. As for human performance, however, the score is quite consistent across turn rounds, implying a large improvement space for current models to **deal with multi-turn context**.

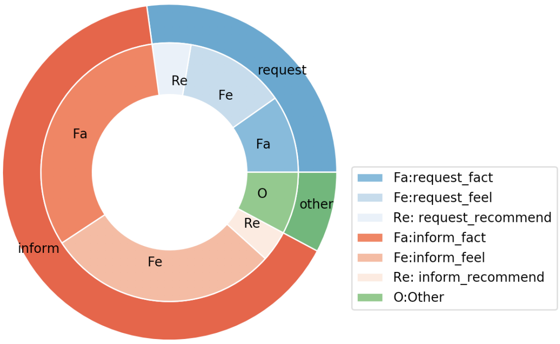

Figure 4: Dying distribution of DAs in interactive evaluation.

In figure 4, we further show the "dying distribution" of our model, namely, in which DA our model fails to pass the Turing test and thereby "dies". Unsurprisingly, we can see the system fails mostly when informing facts or feelings. Only a small portion are from non-grounded chitchats (*other*). This suggests the most crucial bottleneck lies in the **interaction with movie-specific knowledge and seamlessly incorporating it into the response generation**. We show some snippets of interactions with our model in Table 9. The first two are failing cases labeled by humans as not factual and sensible. We can see the model struggles at replying to too specific facts. This is understandable since our knowledge base only provide short introductions and cannot cover all what happened in the movie. The second case shows its shortcoming at handing long-range consistency. It still recommends the current movie when the user asks about "which *other movie*". Employing larger knowledge bases and explicitly tracking the states by a checklist (Kiddon et al., 2016) might potentially alleviate both issue. We also provide examples for controllable generations where the DA and aspect are manually assigned. As observed, the model shows decent performance at fitting both the dialogue context and specified conditions. This can be helpful when finer-grained control is needed.

6 Conclusion

We present MovieChats: a movie-domain chatbot built upon a large-scale, high-quality conversational corpus with fine-grained annotations. The model can be trained end-to-end with a simple unified language model architecture. We show that our model, powered by well-defined knowledge grounding, is able to approach human performance in some perspective, though still lagged behind when it comes to dealing with detailed knowledge or long-turn consistency.

Table 10: Comparison between our dataset and others.

A Dataset Collection

Table 10 shows examples comparing our dataset and the others. As observed, forum conversations are mostly single-turn QA or comments. Current crowd-sourced datasets are either collected on constrained scenarios (the scenario in (Zhou et al., 2018b) fixed the roles in a conversation as one introducer and one listener), or unconstrained but prompting people to deliberately connect knowledge. Our dataset simulates real-life conversations to the largest extent.

We classify the utterances into one of 15 aspects. The definitions, counts, and examples of them are shown in Table 11. When annotating the corpus, tutorials and examples are provided to the annotators, we show some examples of in the following tables. All the examples are provided only in Chinese as that is the native language among annotators.

Aspects	**Count(%)**	**Description**	**Example**
电影名(name)	17.41	Name of a movie.	Its name is so funny
导演(director)	2.44	Director of a movie.	Who played Jack in the movie?
演员(actor)	9.24	Actor of a movie.	I wonder who picked him as the leading actor.
类型(type)	7.12	Type of a movie.	I don't really like horror movies.
角色(role)	10.01	Role of a movie.	I like Bumblebee, he is cute.
区域(region)	2.95	Region of a movie.	Is it a Japanese movie?
上映时间(time)	2.02	Release time of a movie.	I remember it was in 1997, still at high school.
剧情(plot)	24.30	Plot of a movie.	What happened to him?
台词(line)	1.51	Line of a movie.	That line becomes a popular word that year.
奖项(awards)	1.17	Award of a movie.	It won a lot of awards that year.
票房(gross)	1.00	Gross of a movie.	I doubt if its gross will be satisfying.
评分(rating)	4.04	Rating of a movie.	It's clearly the best mivie I've watched.
资源(website)	1.25	Website of a movie.	You can watch it on iqiyi.com!
音乐(music)	2.19	Music in the movie.	Its theme song is "my heart will go on".
其他(other)	12.31	Other aspects.	I like her costume so much!

Table 11: Counts, descriptions and examples of the aspects. *Examples are shown only in translated English for space limit.*

B Human Evaluation

As for the four human evaluation metrics. The first two will focus only on the conversational backbones without considering domain knowledge. The second two will check if the responses can provide informative and correct responses powered by domain knowledge. The detailed definitions of them are:

A: 一直有听到《千与千寻》，却未曾真的看过这部电影	告知事实_类型; 告知感受_其他
B: 怎么不去看	其他
A: 话说你看了吗	其他
B: 看了，挺感动的	告知感受_其他
A: 主要讲什么的	请求事实_剧情
B: 一个小女孩，千寻，不畏艰难救了自己的父母和朋友	告知事实_角色; 告知事实_剧情
A: 海报里的小女孩看起来还很小	告知事实_角色
B: 所以啊，觉很她很勇敢	告知感受_其他
A: 听上去好像还挺好看的	告知感受_评分
B: 是啊，你快去看看吧	其他

A: 发现一部有点年代感的电影	告知感受_其他
B: 你说什么类型的	请求事实_类型
A: 特别反映现在的问题女人的地位	告知事实_剧情
B: 啥电影	请求事实_电影名
A: 菊豆，巩俐演的	告知事实_电影名告知事实_演员名
B: 卧槽，她啊实力派啊自带气质真的	告知感受_演员名
A: 对啊我才看完	其他
B: 怎么样	请求感受_剧情
A: 有点点压抑，还是觉得我们现在的生活幸福	告知感受_剧情
B: 哈哈哈我也去看看	其他

A: 《蚁人》你看了没有	告知事实电影名
B: 蚁人绝对是最接地气的超级英雄！	告知事实_角色
A: 从小偷变英雄（因为是没有超能力吗？）	告知事实_其他
B: 好看死了！！每天炸纽约炸香港炸洛杉矶都看醉了！	告知感受_评分
A: 在玩具房里的打斗戏太有意思了！	告知事实_剧情; 告知感受_评分
B: 笑点也挺多的，看得我很开心。	告知感受_评分
A: Paul不是最帅的但绝对是最有味道的！	告知事实_角色
B: 就是最后十秒钟变星际穿越!真心吐槽	告知事实_剧情
A: 各种官方自带吐槽和自黑恶搞真是入戏不过三秒	告知感受_其他
B: 哈哈哈，确实是	其他

A: 你有没有看过多啦A梦的电影吗	告知事实_电影名
B: 你说的是哪一部？！	请求事实_电影名
A: 大雄的月球探险记	告知事实_电影名
B: 对啊，多啦A梦小时候最喜欢了，口袋里面什么都有	告知事实_剧情
A: 哈哈对，这里面他们去月球找玉兔，作者想象力很丰富！	告知事实_剧情
B: 后半部分其实有点融梗《星球大战》+《阿丽塔》	告知事实_电影名
A: 但也没有看出来有什么违和点啊	告知感受_评分
B: 恩呢，那倒是一直是萌物与科普，以及不变的友情。	告知感受_剧情
A: 最后胖虎把那个东西送给那个小孩的时候就哭了	告知事实_剧情
B: 你也一样嘛?	其他
A: 对啊对啊，就是蓝胖子的口袋东西太多了吧	告知事实剧情
B: 哈哈当然全都靠道具	告知事实剧情

1. Sensibleness: If the response makes sense given the dialogue context. *Specific domain knowledge is ignored.* For example, if the user asks “Who directed the movie Inception?”, the bot replies “Steven Spielberg! I like him so much!!” The answer is wrong but still considered sensible given the context.
2. Engagement: If the response is engaging for the user to follow. The definition is generally similar to diversity, or interestingness metric used for open-domain chitchat. If the bot simply passively replies messages like “That’s good” or “No idea”, it will be marked as non-engaging.
3. Factuality: Factuality checks the information correctness in case the model fabricate wrong facts. This is orthogonal to the above metrics. The response can be factual but not sensible or the other way around. The same for Engagement.
4. Informativeness: Informativeness checks if the response contains new information about the movie. If the bot replies sth like “That’s so interesting, I’ve never heard of that!”. It is considered specific yet non-informative, because the bot provides no new information.

Intuitively a good closed-domain chatbot should balance well all these skills. Sensibleness plus engagement can evaluate its general performance as a chatbot. Factuality and informativeness can evaluate its capability at actively injecting appropriate domain knowledge into the dialogue.

All the three metrics are evaluated by three crow-workers each except for factuality. As evaluating factuality requires in-depth knowledge about one movie, it is quite difficult for random human evaluators to judge them. Even if we filter to only keep people who have watched a movie, it is hard to guarantee they can recall all the scenes in the movie. Therefore, the factuality check is only done by the person who performed this dialogue. In the static evaluation, it is evaluated by the annotator who produced the reference response. In the interactive evaluation, it is evaluated by the person who chat with the bot. It is nevertheless not accurate though. However, if the bot can cheat the human into believing its false information, it can also somehow be considered a “success”. We provide examples for guiding the human evaluators in Table 12.

Table 13 shows some interactive examples with humans. We observe Mitsuku can XiaoIce perform decently in single-turn exchanges but strongly struggle at understanding multi-turn user intents. Most conversations stop at turn 4 and will not move on.

Conversation	**Score**
Input: Do you know who directed the movie Inception? Bot: I know! It was Christopher Nolan! I like him so much!	Sensibleness = 1; Engagement = 1 Factuality = 1, Informativeness = 1
Input: Do you know who directed the movie Inception? Bot: The movie is amazing to imagine about a dream within a dream.	Sensibleness = 0; Engagement = 1 Factuality = 1, Informativeness = 1
Input: Do you know who directed the movie Inception? Bot: Christopher Nolan.	Sensibleness = 1; Engagement = 0 Factuality = 1, Informativeness = 1
Input: Do you know who directed the movie Inception? Bot: I know! It was Steven Spielberg! I like him so much!	Sensibleness = 1; Engagement = 1 Factuality = 0, Informativeness = 1
Input: Do you know who directed the movie Inception? Bot: I don’t remember. Do you like it?	Sensibleness = 1; Engagement = 1 Factuality = 1, Informativeness = 0
Input: Do you know who directed the movie Inception? Bot: Steven Spielberg.	Sensibleness = 1; Engagement = 0 Factuality = 0, Informativeness = 1

Table 12: Examples for human evaluation scores.

Mistsuku	**XiaoIce**	**Ours**
User: Do you know who directed the movie Inception?	*User*: 你喜欢看感人的电影吗	*User*: 你喜欢看感人的电影吗
Bot: No idea. I will guess at Steven Spielberg.	*Bot*: 我喜欢更加另类一些的	*Bot*: 喜欢啊，你有什么推荐吗
User: Maybe, it does look like his style.	*User*: 比如呢	*User*: 我不是药神很感人
Bot: Interesting comparison.	*Bot*: 比如？	*Bot*: 确实是一部很良心的电影
User:have you watched any movies recently?	*User*:泰坦尼克号主角是谁	*User*: 确实，徐峥演的也好
Bot: My favourite movie is Terminator. Have you seen it?	*Bot*:这我还真知道，莱昂纳多·迪卡普里奥主演的	*Bot*: 徐峥的演绎一直很走心
User:not really, what is it about?	*User*:那是谁导演了呢	*User*:不过我最喜欢的还是里面的小黄毛
Bot:If not that, what?	*Bot*:你想让我说什么？	*Bot*: 小黄毛好难啊，太不容易了
User: I like the Avengers series so much	*User*:你看过大话西游吗	*User*:我看电影的时候他死那段给我哭完了
Bot: Yes. My favourite is Iron Man, as he's a kind of robot. You like Avengers.	*Bot*: 你可以再说一遍吗	*Bot*: 看完你有什么感想呢
User: Exactly! Can't accept he died in the end, sigh		*User*:最大的病就是穷病啊
Bot:You and I are on the same wavelength. I often wonder if it can.		*Bot*: 确实是这样，希望我们能平安
		User:平安是最大的幸福了
		Bot: 我觉得还行

Conundrums in Entity Coreference Resolution: Making Sense of the State of the Art

Jing Lu and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
Richardson, TX 75083-0688
{ljwinnie,vince}@hlt.utdallas.edu

Abstract

Despite the significant progress on entity coreference resolution observed in recent years, there is a general lack of understanding of what has been improved. We present an empirical analysis of state-of-the-art resolvers with the goal of providing the general NLP audience with a better understanding of the state of the art and coreference researchers with directions for future research.

1 Introduction

The advent of the neural NLP era has revolutionized virtually all areas of NLP research. For entity coreference, many issues that were once thought to be important no longer appear to be particularly relevant to the current research agenda. Specifically, while a decade ago coreference researchers have focused on developing computational models that are complex (e.g., structured models (Fernandes et al., 2012; Björkelund and Kuhn, 2014; Martschat and Strube, 2015)) and knowledge-rich (e.g., those that encode world knowledge (Ponzetto and Strube, 2007; Rahman and Ng, 2011a; Hajishirzi et al., 2013)), nowadays virtually all state-of-the-art resolvers employ a simple model (i.e., the mention-ranking model, which was developed more than a decade ago (Denis and Baldridge, 2008))[1] and a fairly simple input representation (i.e., contextualized word embeddings) in conjunction with a mechanism for learning representations of entity mention spans such that coreferent mentions have similar representations (Lee et al., 2017, 2018; Kantor and Globerson, 2019; Joshi et al., 2019).

Despite significant progress in the past few years in terms of performance numbers, what seems to be missing is an understanding of what has been improved. The lack of understanding has long been a concern shared by coreference researchers, even before the neural revolution in NLP. This has led to several attempts to analyze coreference resolvers over the years (Stoyanov et al., 2009; Kummerfeld and Klein, 2013). With the development of neural resolvers, however, this concern has become more serious than ever: the fact that significant progress can be made via learning mention representations with a simple neural mention-ranking model that employs a fairly simple input representation for a task as challenging as coreference resolution (CR) is somewhat contrary to common wisdom.

In light of this apparent conundrum, we present an empirical analysis of state-of-the-art entity coreference resolvers through four major sets of experiments in this paper, with the goal of gaining insights into their behaviors. We believe that our analysis will not only provide the general NLP audience with a better understanding of the state of the art, but also provide coreference researchers with directions for future research.

2 Evaluation Setup

In this section, we describe the datasets, the evaluation metrics, the state-of-the-art resolvers and the hyperparameters used in our experiments.

Datasets. We report results on three coreference datasets. The NIST-sponsored ACE evaluations resulted in several datasets. We use ACE 2005 (Walker et al., 2006), the last one in the series. The ACE 2005 organizers have only made the official training set (but not the official test set) publicly available, so previous work defined different train-test splits over the official training set. We employ the same train-test split as Bansal and Klein (2012).

KBP is another series of NIST-sponsored evaluations in the mid 2010s. KBP does not have any evaluations on entity CR, but to support high-level

---

[1] The first learning-based resolver is a pairwise ranker (Connolly et al., 1994), which was extended by Denis and Baldridge (2008) to rank more than two candidate antecedents at a time.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6620–6631,
November 16–20, 2020.

	ACE			OntoNotes			KBP		
	Train	Dev	Test	Train	Dev	Test	Train	Dev	Test
#docs	365	117	117	2802	343	348	360	97	168
#mentions	34481	11126	9261	155558	19155	19764	40628	10983	13860
#chains	11963	3798	3050	35142	4545	4532	14332	3942	5482

Table 1: Dataset statistics in terms of the number of documents, mentions, and coreference chains.

information extraction tasks (e.g., event extraction, event CR), the organizers have made available several corpora that include entity coreference annotations. For training, we use three such corpora (LDC2015E29, LDC2015E68, and LDC2016E64). For evaluation, the KBP 2017 organizers have made available the official test set for the event CR task (LDC2017E51), which also include entity coreference annotations. We use it as our test set.

OntoNotes (Hovy et al., 2006), which was developed circa 2006, is the most widely-used dataset for entity coreference evaluations. It has a standard train-dev-test split. Unlike in ACE and KBP, singleton clusters are not annotated in OntoNotes.

The key difference between these three corpora is that OntoNotes supports "unrestricted" CR, meaning that coreference links are annotated between entity mentions without regard to their entity types. In contrast, coreference links are only annotated between mentions belonging to one of the seven entity types in ACE and one of the five entity types in KBP. Statistics on these corpora are shown in Table 1.

Evaluation metrics. Following the convention established in the CoNLL 2011 and 2012 shared tasks (Pradhan et al., 2011, 2012), we use as our primary coreference evaluation measure the CoNLL score, which is the unweighted average of the F-scores provided by three popular metrics, the link-based MUC metric (Vilain et al., 1995), the mention-based B^3 metric (Bagga and Baldwin, 1998), and the entity-based $CEAF_e$ metric (Luo, 2005). We obtain these scores using the official CoNLL scorer (Pradhan et al., 2014).[2]

Mention detection (MD) is the task of extracting the mentions in a text needed for entity CR. A key observation made in the CoNLL shared tasks was that the performance of resolvers was limited by MD, so it is important to examine the extent to which MD performance has improved over the years. We report performance in terms of recall, precision, and F-score, considering that a system mention is correctly detected if and only if it has an exact match in boundary with a gold mention.

Systems. We evaluate five variants of three state-of-the-art neural resolvers, all of which employ a ranking model where all candidate antecedents are ranked against each other for a given anaphor.

The first resolver, the Stanford neural resolver (Clark and Manning, 2016)[3], takes as input a set of entity mentions identified for a given document by a rule-based MD system and trains using reinforcement learning a simple mention ranker consisting of three hidden layers of ReLU units and a final layer that is fully-connected.

The other two resolvers are developed by Lee et al. (2018)[4] and Joshi et al. (2019)[5]. Both are *span-based* models, which have two key characteristics. First, mention spans are identified as part of CR, so this mitigates the propagation of errors from MD to CR. Second, *representations* of entity mention spans are learned so that coreferent mentions have similar representations. The key differences between these resolvers are: (1) in Lee et al. the input instances correspond to the sentences in the given document, whereas in Joshi et al. the input instances correspond to fixed-length non-overlapping segments of the input document[6]; (2) Lee et al. use a LSTM, whereas Joshi et al. use a transformer; and (3) the pretrained embeddings are different.

For each of these resolvers, we derive two variants. Specifically, Lee et al. (2018) employ GloVe+ELMo embeddings, but to better understand the effect of the contextual information provided by ELMo embeddings (Peters et al., 2018) on CR performance, we evaluate a version of Lee et al. using only GloVe embeddings (Pennington et al., 2014). We will henceforth refer to these two versions of Lee et al. as ELMo (i.e., ELMo+GloVe) and GloVe, respectively. Joshi

---

[2] LEA (Moosavi and Strube, 2016) is a coreference evaluation metric recently designed to address the shortcomings associated with B^3 and $CEAF_e$, but we found no difference in the performance trends in our experiments according to CoNLL and LEA. See the Appendix for the LEA results.

Table 2: Best hyperparameters obtained on the development sets for each span-based resolver.

et al. (2019) employ embeddings pretrained using a new method called SpanBERT (Joshi et al., 2020), which is designed to better represent text *spans* than BERT. The two variants of Joshi et al. differ in the transformer. Specifically, SpanBERT-base (henceforth SpanBERT-b) employs a simple transformer while SpanBERT-large (henceforth SpanBERT-l) employs a more complex transformer.

We use the publicly-available implementation of each of these resolvers. There is one caveat, however. Recall that the span-based resolvers were all evaluated on OntoNotes. Since singleton clusters are not annotated in OntoNotes, all singleton clusters predicted by a resolver are removed from its output before it is sent to the scoring program. In contrast, singleton clusters that contain mentions belonging to one of the ACE/KBP entity types are annotated in ACE/KBP, so these mentions should not be removed from a resolver's output. However, span-based resolvers cannot distinguish between spans that correspond to entity mentions and those that do not. To address this problem, we extend the span-based models so that they are jointly trained to predict entity mention spans and coreference links. Specifically, the feedforward neural network that is responsible for scoring a span in these models currently do not receive *direct* feedback on whether a span corresponds to an entity mention. We first turn it into a mention detector by training it in a supervised manner using the negative cross entropy loss, so that it predicts a positive mention score for a span if and only if the span corresponds to an entity mention. Then, to jointly learn MD and CR in the span-based resolvers, we employ a loss function that is the unweighted sum of the coreference loss and the MD loss.

Hyperparameter tuning. To ensure a fair comparison of the resolvers, we tune their hyperparameters to maximize the CoNLL score on development data. Note, however, that the authors of Stanford, ELMo, SpanBERT-b, and SpanBERT-l reported the best hyperparameter settings on OntoNotes in the original papers (Lee et al., 2018; Joshi et al., 2019), so we simply use them in our experiments and focus on tuning the hyperparameters for the remaining cases. We adopt the set of hyperparameters to be tuned from the original papers.

For Stanford, there are three hyperparameters to tune: α_{WL}, α_{FA}, and α_{FN}. These are the weights associated with three different types of mistakes made by the coreference model. Following Clark and Manning (2016), we fix α_{WL} = 1.0 and search for α_{FA} and α_{FN} out of $\{0.1, 0.2, \ldots, 1.5\}$ using a variant of grid search. For ACE, (α_{WL}, α_{FA}, α_{FN}) = (1.0, 0.5, 1.0) is the best configuration, and for KBP, the best configuration is (1.0, 0.5, 0.8). For OntoNotes, we use the configuration found by Clark and Manning, which is (1.0, 0.5, 0.8).

For GloVe and ELMo, we have five hyperparameters to tune. Specifically, we search for: (1) max span width (i.e., maximum number of words in a candidate span) out of $\{10, 20, 30\}$; (2) max top antecedents (i.e., maximum number of candidate antecedents) out of $\{35, 40, 45, 50\}$; (3) max training sentences out of $\{25, 50, 75, 100\}$; (4) task learning rate out of {5e-4, 1e-3, 2e-3}; and (5) top span ratio (i.e., the fraction of top spans that survive the filtering) out of $\{0.3, 0.35, 0.4, 0.45, 0.5\}$. For the two SpanBERT resolvers, we have seven hyperparameters to tune. For three of the hyperparameters (max span width, max top antecedents, and top span ratio), the ranges are the same as those used in GloVE and ELMo. For the remaining four, we search for: (1) max training segments out of $\{3, 4, 5\}$; (2) max segment length out of $\{128, 256, 384, 512\}$; (3) SpanBERT learning rate out of {1e-5, 2e-5}; and (4) task learning rate out of {1e-4, 2e-4, 3e-4}. Table 2 shows the best hyperparameter setting of each span-based model on each dataset.

3 Performance across Datasets

We first provide the reader with a high-level understanding of the state of the art by analyzing the five

		ACE				OntoNotes				KBP			
	System	CoNLL	MUC	Sing.	MD	CoNLL	MUC	Sing.	MD	CoNLL	MUC	Sing.	MD
1	Stanford	38.6	57.9	56.8	50.6	65.5	74.3	–	80.1	26.2	48.8	42.8	26.4
2	GloVe	68.0	76.6	67.0	87.4	68.1	76.7	–	82.0	65.9	71.3	63.2	82.4
3	ELMo	71.8	79.5	70.1	90.4	73.0	80.5	–	85.1	69.7	73.8	67.5	85.3
4	SpanBERT-b	75.7	83.1	71.5	91.6	77.4	83.7	–	87.1	71.3	75.6	67.5	86.3
5	SpanBERT-l	78.9	85.4	75.1	92.3	79.6	85.3	–	88.2	75.8	80.1	71.1	88.5

Table 3: Results of the resolvers on the three coreference datasets.

resolvers' performance on the three datasets.

Performance across datasets. Results on the three datasets, which are reported in terms of the CoNLL score, are shown in the CoNLL column in Table 3.[7] Although the five resolvers have been evaluated solely on OntoNotes, their relative performances are consistent across the datasets. In particular, the use of ELMo embeddings enables ELMo to outperform GloVe by 3.8–4.9% points. SpanBERT-b outperforms ELMo by 1.6–4.4% points, and SpanBERT-l further outperforms SpanBERT-b by 2.2–4.5% points.

Source of performance improvements. Do the above improvements stem from improved recognition of coreference links, or improved recognition of singleton clusters, or both? To understand whether these resolvers have improved in terms of *link* prediction, we examine the MUC F-scores (see the MUC column), which are computed solely on coreference links. As we can see, the MUC scores are consistently increasing down the table across all datasets, meaning that later systems are indeed doing better at identifying coreference links. To understand whether later resolvers are also better at identifying singleton clusters, we show in the Singleton column the percentage of singleton clusters that are correctly *recalled*. Again, the scores are increasing down the table, and the degree of improvement is particularly large from GloVe to ELMo and from SpanBERT-b to SpanBERT-l.

Mention detection performance. First, MD performance has improved significantly over the years. SpanBERT-l achieves an F-score of 88.2 in MD on OntoNotes, which is significantly higher than the best MD F-score achieved in the CoNLL-2012 shared task (77.7). Note that Stanford's mention detector performs substantially worse than those of the other resolvers, especially on ACE and KBP. The reason is that Stanford employs a rule-based MD system that was initially developed when the Stanford NLP Group participated in the CoNLL-2011 shared task, whereas in the other resolvers MD is jointly trained with CR. Overall, MD performance appears to have a significant impact on CR performance. In particular, joint MD and CR in the span-based resolvers seems to be a driving force behind the rapid coreference performance improvements we have seen in recent years.

4 Using Oracles

Can the performance of coreference resolvers be further improved if we improve MD? Being able to answer this kind of questions is important: if further improvements in MD can result in significant gains in coreference performance, then future research efforts should perhaps be focused on MD.

To answer this kind of questions, we perform oracle experiments. Specifically, we provide a resolver with a particular type of perfect information (e.g., using gold mentions as input) and see how much performance improvement can be obtained.

4.1 Gold Mention Boundaries

Our first oracle experiment concerns training and testing our resolvers on gold mention boundaries. While this experiment has been conducted over the years by numerous researchers (e.g., Peng et al. (2015), Zhang et al. (2018)), we are primarily interested in understanding whether further improving an MD component that already has an F-score of more than 85% can improve coreference performance. For the four span-based models, we disable the component in the span representation layer that is responsible for proposing spans (i.e, mention boundaries) and instruct them to use gold mention spans instead. Note, however, that the representation of a span will be learned during training. In other words, although all resolvers are given gold mention spans, the span representations that will be used during resolution will still be different for different span-based resolvers.

Results, expressed in terms of the CoNLL score, are shown in the Gold Mention Boundaries col-

---

[7] Owing to space limitations, we show only the most important scores in Table 3. The detailed results (e.g., B^3 and $CEAF_e$ results) can be found in the Appendix.

		Gold Mention Boundaries			Perfect Anaphoricity			Gold Entity Types		
	System	ACE	Onto.	KBP	ACE	Onto.	KBP	ACE	Onto.	KBP
1	Stanford	76.3	83.7	80.0	40.3	73.4	29.2	39.5	71.8	27.7
2	GloVe	79.3	86.1	81.6	71.5	76.2	69.8	69.6	71.4	67.9
3	ELMo	81.8	87.2	83.5	76.1	82.0	73.8	73.3	76.7	71.6
4	SpanBERT-b	84.9	90.5	85.7	79.3	84.4	76.3	77.4	79.3	73.8
5	SpanBERT-l	87.3	91.9	88.0	82.8	86.9	80.1	80.4	81.4	77.6

Table 4: CoNLL scores of the resolvers using gold mention boundaries, perfect anaphoricity, and gold entity types.

umn in Table 4. First, despite recent significant improvement in MD, these results suggest that coreference performance can still be significantly improved just by improving MD: for the best resolver (SpanBERT-l), the CoNLL score can be improved by 8.4–12.3% points. Second, the relative performances of the resolvers are consistent across the three datasets: the CoNLL scores increase as we go down the table. Since the four span-based resolvers use essentially the same (mention-ranking) model for resolution and the same algorithm for weight updates, their performance differences can be attributed largely to differences in the pretrained embeddings and the encoder. In addition, these results suggest that the coreference performance improvements we observed in recent years can be attributed to not only improved mention (boundary) detection but also improved resolution accuracy presumably as a result of better span representations.

4.2 Perfect Anaphoricity

Anaphoricity determination, a.k.a. discourse-new detection (Poesio et al., 2004), is the task of determining whether a mention is coreferent with another mention that appears earlier in the text. Being able to identify non-anaphoric mentions could improve the precision of coreference resolvers, as any antecedent chosen for them is erroneous.

In this oracle experiment, we provide a resolver with perfect anaphoricity information, meaning that we know for every entity mention whether it is anaphoric or not. We use this perfect anaphoricity information during resolution: we will resolve all and only those mentions that are anaphoric.

Results are shown in the Perfect Anaphoricity column of Table 4. A few points deserve mention. First, all resolvers improved on all datasets when provided with perfect anaphoricity information. These results imply that anaphoricity determination remains an important issue in CR research, and further improvements in anaphoricity can improve CR. However, the gains that state-of-the-art resolvers can achieve by improving anaphoricity determination are generally smaller than those by improving MD: the CoNLL scores of the span-based resolvers increase by 3.5–4.3% points on ACE, 4.4–9% points on OntoNotes, and 3.9–5% points on KBP. This is understandable, as MD is likely to improve both coreference precision and recall, whereas anaphoricity determination can only improve precision. Note that Stanford's poor performance on ACE and KBP is due to poor MD.

4.3 Gold Entity Types

In this experiment, we assume that a resolver is given gold entity types (i.e., semantic classes) such as PERSON, ORGANIZATION, and LOCATION. The set of entity types to be provided is corpus-dependent. As mentioned before, ACE and KBP only have seven and five entity types respectively. In OntoNotes, however, only named entities are annotated with (one of 18) entity types. Consequently, we automatically derive entity types for pronouns and nominals using gold coreference chains: if a pronoun or a nominal appears in a coreference cluster that contains a name, we derive its entity type from that of the name. This method allows us to derive the entity type of 36.4% of the nominals and 70% of the pronouns. Any pronoun or nominal whose entity type cannot be derived using this method will be assigned the entity type UNKNOWN. While this method does not provide full coverage, we will still be able to examine whether having access to perfect entity types on a subset of the mentions will enable us to improve the performance of a resolver on OntoNotes.

We use entity types during resolution. We disallow a candidate antecedent to be selected as the antecedent for a given anaphor if they have different entity types. Results are shown in the Gold Entity Types column in Table 4. As we can see, all resolvers improved on all datasets when provided with gold entity types. Compared with the gains achieved using gold mention spans or perfect anaphoricity, the gains that come with the use of gold entity types are smaller: for the span-based resolvers, the CoNLL scores increase by 1.5–1.7% points on ACE, 1.8–3.7% points on OntoNotes, and 1.9–2.5% points on KBP. In other words, state-of-the-art resolvers can be improved by improving the determination of entity types.

These results are particularly interesting in light of a conundrum in entity CR: while some researchers have reported successes with improving entity CR using automatically computed semantic information (Ng, 2007), there have also been numerous failed attempts (Kehler et al., 2004; Durrett and Klein, 2013; Sapena et al., 2013). Although the semantic information we use in this paper is restricted to gold entity types, our results suggest that hand-annotated semantic information is indeed useful, and the (non-)utility of semantics for CR reported in earlier work could be attributed to the noise inherent in computing semantic information.

5 Results on Resolution Classes

To gain additional insights into the state-of-the-art resolvers, we analyze their performance on different types of entity mentions. More specifically, motivated by Stoyanov et al. (2009), we partition the *gold* mentions into different *resolution classes*. While previous work has focused mainly on three coarse-grained resolution classes (namely, pronouns, names, and nominal mentions), we employ the 13 fine-grained resolution classes defined by Rahman and Ng (2011b), as discussed below.

Names. Four classes are defined for gold names. (1) **e**: a name is assigned to this *exact string match* class if there is a preceding mention such that the two are coreferent and are the same string; (2) **p**: a name is assigned to this *partial string match* class if there is a preceding mention such that the two are coreferent and have some content words in common; (3) **n**: a name is assigned to this *no string match* class if there is no preceding mention such that the two are coreferent and have some content words in common; and (4) **na**: a name is assigned to this *non-anaphor* class if it is not coreferent with any preceding mention.

Nominal mentions. Four analogous resolution classes are defined for gold mentions whose head is a nominal: (5) **e**; (6) **p**; (7) **n**; and (8) **na**.

Pronouns. We have three pronoun classes. (9) **1/2**: 1st and 2nd person pronouns; (10) **G3**: gendered 3rd person pronouns (e.g., *she*); (11) **U3**: ungendered 3rd person pronouns; (12) **oa**: any anaphoric pronouns that do not belong to (9), (10), and (11) (e.g., relative pronouns); and (13) **na**: non-anaphoric pronouns (e.g., pleonastic pronouns).

Table 5 shows the performance of each resolver on each resolution class. To avoid overwhelming the reader, we only show the results of ELMo and SpanBERT-l, which will allow us to gain insights into what made SpanBERT-l better. Specifically, for each resolution class C, we show each resolver's MD recall (percentage of gold mentions in C that are correctly recalled) under **MD** and its resolution accuracy (percentage of correctly identified anaphors in C that are correctly resolved)[8] under **RA**. Under **Size** we show the percentage of gold mentions belonging to each resolution class.

First, if we consider only the three coarse-grained resolution classes, the results are perhaps not surprising: name resolution is the easiest and nominal resolution is the hardest.

Second, consider the 13 fine-grained resolution classes. By design, the names and the nominals in the 'e' class should be easier to resolve than those in 'p', which in turn should be easier to resolve than those in 'n'. The results are consistent with this intuition. Results on the anaphoric pronoun classes are also consistent with our intuition: 3rd person gendered pronouns are the easiest to resolve, followed by 1st/2nd person gendered pronouns and then ungendered 3rd person pronouns.

Third, these results reveal that the difficulty of anaphoricity determination stems primarily from pronouns: while resolution accuracies on non-anaphoric names and nominal mentions are above 89%, those on non-anaphoric pronouns are only between 65.9% and 77.6%. Note that we consider a non-anaphoric mention correctly "resolved" if it is resolved to the dummy antecedent.

Finally, SpanBERT-l has better resolution accuracies than ELMo for all resolution classes on all datasets. Encouragingly, the harder a resolution class is, the bigger the improvement is. These results clearly show that we are making progress on resolving anaphors that are traditionally considered difficult to resolve. Note that part of this improvement can be attributed to improved MD, which increases the likelihood that the correct antecedent of an anaphor is present in its list of candidate antecedents. Additional experiments are needed to determine the impact of improved MD on improvement in resolution accuracies, however.

---

[8] In other words, the resolution accuracy does not depend on anaphor recall and precision.

Table 5: Results on resolution classes.

6 Sensitivity to Perturbed Inputs

Next, we conduct a series of experiments that involve perturbing the input. In each experiment, we (1) replace a certain kind of words/phrases in each training document with other words/phrases, (2) train a coreference model on these perturbed training documents, and (3) evaluate the output. Our goal is to gain insights into the behavior of state-of-the-art resolvers by examining how sensitive their performance is to perturbations in the input. Specifically, if performance drops significantly when a particular kind of words/phrases is replaced, that means the replaced words/phrases are important in the model learning process. Note that perturbations are only applied to the training documents; no changes are made to the test documents.

We divide the different kinds of perturbations into two broad categories, mention-internal perturbations and mention-external perturbations.

6.1 Mention-internal Perturbations

Mention-internal perturbations involve making changes to the words within an entity mention.

6.1.1 Perturbations to Names

We consider two kinds of perturbations to names.

Unseen names. We replace each name in a training document with a name that will highly unlikely appear in any test set. With this replacement, all the names in the test set will be unseen w.r.t. the training set. When trained on this perturbed training set, we can determine the extent to which the algorithms for learning coreference resolvers rely on memorizing seen names (as opposed to generalizing from their contexts) when performing MD and CR. Specifically, if a learner memorizes a lot, it will likely perform poorly on MD (i.e., its recall will suffer) and subsequently CR.

Perturbation Type	Example
Unseen names	Mr. Smith → Mr. Htims
Names of a different type	John Smith → New York
Unseen nominals	activist → tsivitca
Nominals of a different type	actor → plane
Nominals of the same type	wife → grandmother
Unseen verbs	support → troppus
Seen verbs	acquire → believe
Unseen adj/adv	directly → yltcerid
Seen adj/adv	organic → shredded

Table 6: Perturbation examples.

We perform name replacement in a deterministic manner: we replace each word in a name with another word in which the order of its characters is reversed. Note that person prefixes (e.g., "Mr."), organization words and suffixes ("Airlines", "Inc."), and location nouns (e,g, "River") will not be replaced, as the goal is to introduce unseen names rather than change the type of a name.[9] In addition, any word in a name that appears in a nominal mention in the training set will not be replaced. For instance, the word "Church" in "Baptist Church" appears in a nominal in the training set and therefore will not be replaced. This is done to ensure that only the "name" part of a mention will be changed to something that is not previously seen.[10]

Names of a different type. In this experiment, we replace each name, ne_1, in a training document with another name, ne_2, that satisfies two conditions. First, ne_2, like ne_1, should appear in the training set. This ensures that the number of names in the test set that will be unseen w.r.t. the train-

---

[9] These lists are available in the Appendix.

[10] Examples of this and other kinds of perturbations are shown in Table 6.

ing set will not change. Second, the two names should have different entity types. Importantly, the replacement is deterministic, meaning that (1) all occurrences of ne_1 will be replaced with the same name (i.e., ne_2), and (2) any name coreferent with ne_1 (but are not lexically identical to ne_1, such as "Trump" and "President Trump") will be replaced with a name coreferent with ne_2. These conditions together ensure that only the names and their types will change, but their coreference relationships will not. Note that the choice of ne_2 is random subject to these conditions. Due to the randomness involved in the selection of ne_2, we repeat the experiment three times and report the average result.

With this replacement, the resulting training documents may no longer make sense to a human reader, as a PERSON name may appear in a context for an ORGANIZATION name. In particular, the contexts in which a certain type of names (e.g., PERSON) appear in the training set will be different from those in which these names appear in the test set. This experiment will allow us to determine the extent to which a resolver makes use of contextual information when identifying coreference links involving names: if it makes heavy use of contextual information, we should see a considerable drop in resolver performance.

6.1.2 Perturbations to Nominal Mentions

We consider three kinds of perturbations to nominal mentions to determine the roles they play.

Unseen nominals. This experiment has the same setup as the "Unseen names" experiment above, except that we replace each nominal mention in the training set with another mention in which we reverse the order of the characters of each of its words. Note that this is a mention-internal perturbation, meaning that we replace all and only those nominals that are annotated as entity mentions, not all nominals in the training set.

Nominals of a different type. This experiment has the same setup as the "Names of a different type" experiment above, except that we replace nominal mentions rather than names. As in the previous experiment, we replace each nominal that is annotated as an entity mention in the training set.

Nominals of the same type. This experiment has the same setup as the "Nominals of a different type" experiment above, except that the nominal mention being replaced must have the same entity type as its replacement. This kind of perturbation is "milder" than the previous kind of perturbation, as a PERSON mention will continue to appear in a PERSON context after the replacement. In other words, if a machine learner does not pay attention to the semantic compatibility between a nominal mention and its context, then we should see little performance difference when a resolver is trained on this training set vs. the previous training set (i.e., the one from "Nominals of a different type").

6.2 Mention-external Perturbations

Mention-external perturbations involve making changes to the words outside a mention.

6.2.1 Perturbations to Verbs

We consider two kinds of perturbations to verbs to determine the role they play in resolution.

Unseen verbs. This experiment has the same setup as the two "Unseen" experiments above, except that we replace each verb in the training set that is not part of an entity mention.

Seen verbs. This experiment has the same setup as the "Names of a different type" experiment above, except that we replace verbs outside of entity mentions rather than names. In particular, the new verb is not constrained to have the same type as the verb being replaced: it can be any verb taken from the training set. Nevertheless, the replacement is deterministic: all occurrences of a given verb will be replaced with the same verb.

6.2.2 Perturbations to Adjectives & Adverbs

We consider two kinds of perturbations to adjectives and adverbs to determine the roles they play.

Unseen adjectives and adverbs. This experiment has the same setup as the three "Unseen" experiments above, except that we replace each adjective and adverb in the training set that is not part of an entity mention.

Seen adjectives and adverbs. This experiment has the same setup as the "Seen verbs" experiment above, except that we replace adjectives and adverbs outside of entity mentions rather than verbs.

6.3 Perturbation Results

Results of these experiments on the three datasets are shown in Table 7. As in Table 5, we only show the results of ELMo and SpanBERT-l. For each resolver, we show its CR CoNLL score and its MD F-score. To facilitate comparison, we show in row 1 the performance of the resolvers when the input is not perturbed.

		ACE				OntoNotes				KBP			
		ELMo		SpanB-l		ELMo		SpanB-l		ELMo		SpanB-l	
	Perturbation Type	CR	MD	CR	MD	CR	MD	CR	MD	CR	MD	CR	MD
1	No Perturbation	71.8	90.4	78.9	92.3	73.0	85.1	79.6	88.2	69.7	85.3	75.8	88.5
2	NAM-Unseen	68.4	88.6	74.9	90.8	46.2	63.3	65.7	77.2	62.1	79.7	65.7	79.7
3	NAM-DiffType	69.5	89.5	75.7	91.1	58.8	75.2	72.7	83.5	64.3	82.5	67.2	81.4

10	Adj/Adv-Seen	69.8	88.8	76.9	91.3	70.1	83.0	76.3	86.7	68.5	84.8	74.0	86.6

Table 7: Perturbation results.

A few points deserve mention. First, mention-internal perturbations (rows 2–6) triggered larger deterioration in CR performance than mention-external perturbations. These results suggest that the resolvers rely more on the mentions themselves than their contexts for resolution, which should not be surprising. Among the mention-internal perturbations, the biggest CR performance drops occur with the Unseen perturbations (rows 2 and 4), particularly those involving unseen names, followed by perturbations involving the replacement of a seen name or nominal with a different type. A closer inspection of the results reveals that there is a strong correlation between CR performance and MD performance: larger drops in CR performance are always accompanied by larger drops in MD performance. This sheds light on why the Unseen perturbations triggered the largest drop in CR performance: when all the names or nominal mentions in the test set are not seen in the training set, the mention detector is likely to perform poorly on the test set. In contrast, when they are replaced by mentions of a different entity type, the percentage of unseen mentions in the test set doesn't change, thus posing fewer problems for the mention detector.

As for the mention-external perturbations, no clear patterns emerged: while verb replacement (rows 7–8) has a greater impact than adjective and adverb replacement (rows 9–10) for OntoNotes, the same observation cannot be made for the other datasets. Moreover, while replacing a word with another seen word is generally expected to cause less harm to MD (and thus CR) performance than replacing a word with an unseen word, these experiments show that this is not necessarily the case. These results seem to suggest that the mention span learner is not particularly sensitive to the verbs, adjectives and adverbs that appear in the context.

Third, it is not easy to conclude which resolver is more robust to perturbations. While the drops in CR performance on ACE are fairly mild for both resolvers, we see bigger CR performance drops on the other two datasets. In particular, ELMo suffers from a bigger drop in performance than SpanBERT-l on OntoNotes, whereas the reverse is true on KBP.

Finally, while the two resolvers' MD performances are similar, SpanBERT-l's CR performance is always superior to ELMo's. These results reveal once again that the mention representations learned by SpanBERT-l are indeed better than those by ELMo as far as resolution is concerned.

7 Conclusions

While space limitations preclude a reiteration of all the observations we have made, we believe the key conclusions are: (1) the relative performances of the resolvers are consistent across datasets; (2) for each resolver, higher mention detection performance always yields better coreference performance; (3) the newest resolvers perform better because of not only improved mention detection, but also improved mention span representations, and they improved the resolution of both easy- and difficult-to-resolve anaphors; (4) all resolvers can be improved by improving mention detection, anaphoricity determination, and entity type detection; and (5) our perturbation results suggest that coreference performance is most sensitive to those words/phrases in the input that have the greatest impact on mention detection performance.

A Lists of Prefixes and Suffixes

Table 8 shows the list of person prefixes, organization words and suffixes, and location nouns used in the perturbation experiments.

B Results from Different Evaluation Metrics

Recall that owing to space limitations, results of the different resolvers are only expressed in terms of the CoNLL score, the MUC F-score, the percentage of singleton clusters being recalled, and the mention detection F-score. Table 9 provides the detailed results on coreference expressed in terms of recall (R), precision (P) and F-score (F) that are via different evaluation metrics (i.e., MUC, B^3, $CEAF_e$, and LEA). In addition, mention detection performance is expressed in terms of R, P, and F.

As can be seen, regardless of which coreference evaluation metric is used, F-score consistently increases down the table for each dataset. These results provide suggestive evidence that the improvements achieved by each resolver over the previous ones are robust. As for mention detection, improvements in F-score are largely accompanied by improvements in both recall and precision.

Semantic Role Labeling Guided Multi-turn Dialogue ReWriter

Abstract

For multi-turn dialogue rewriting, the capacity of effectively modeling the linguistic knowledge in dialog context and getting rid of the noises is essential to improve its performance. Existing attentive models attend to all words without prior focus, which results in inaccurate concentration on some dispensable words. In this paper, we propose to use semantic role labeling (SRL), which highlights the core semantic information of *who* did *what* to *whom*, to provide additional guidance for the rewriter model. Experiments show that this information significantly improves a RoBERTa-based model that already outperforms previous state-of-the-art systems.

1 Introduction

Recent research (Vinyals and Le, 2015; Li et al., 2016; Serban et al., 2017; Zhao et al., 2017; Shao et al., 2017) on dialogue generation has been achieving impressive progress for making single-turn responses, while producing coherent multi-turn replies still remains extremely challenging. One important factor that contributes to this difficulty is coreference and information omission, where mention is dropped or replaced by a pronoun for simplicity. These phenomena dramatically introduce the requirements for long-distance reasoning, as they frequently occurred in our daily conversations, especially in pro-drop languages like Chinese and Japanese.

To tackle these problems, sentence rewriting was introduced to ease the burden of dialogue models by simplifying the multi-turn dialogue modeling into a single-turn problem. Several approaches (Su et al., 2019; Zhang et al., 2019; Elgohary et al., 2019) have been proposed to address the rewriting task. Conceptually, these models follow the conventional encoder-decoder architecture that first encodes the dialogue context into a distributional representation and then decodes it to the rewritten utterance. Their decoders mainly use global attention methods that attends to all words in the dialogue context without prior focus, which may result in inaccurate concentration on some dispensable words. We also observe that the accuracy of their models significantly decreases when working on long dialogue contexts. This observation is expected since if the text is lengthy, it would be quite difficult for deep learning models to understand as it suffers from noise and pays vague attention to the text components.

Utterance 1	需要粤语 (I may need Cantonese.)
Utterance 2	粤语$_{\textbf{ARG0}}$是普通话$_{\textbf{ARG1}}$吗 (Is Cantonese Mandarin ?)
Utterance 3	不算$_{\textbf{predicate}}$吧 (Maybe Not.)
Utterance $3'$	粤语不算普通话吧 (Cantonese may be not Mandarin.)

Table 1: One example of multi-turn dialogue. The goal of dialogue rewriting is to rewrite utterance 3 into $3'$.

Motivated by these observations, we propose to incorporate the information of Semantic role labeling (SRL) (Gildea and Jurafsky, 2002; Palmer et al., 2010) to improve sentence rewriting. SRL is broadly used to identify the predicate-argument structures of a sentence, where these structures could capture the main semantic information of *who* did *what* to *whom*. As a result, we believe that it can pick out the important words, which are semantically most related to the utterance that needs to be rewritten. As shown in Table 1, our SRL system is able to find that the ARG0 and ARG1 of "不算"(is not) are "粤语"(Cantonese) and "普通话"(Mandarin), respectively. Consequently, our rewriting model can correctly generate the correct output (utterance $3'$), which covers all dropped information. We can see that SRL can guide our

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6632–6639,

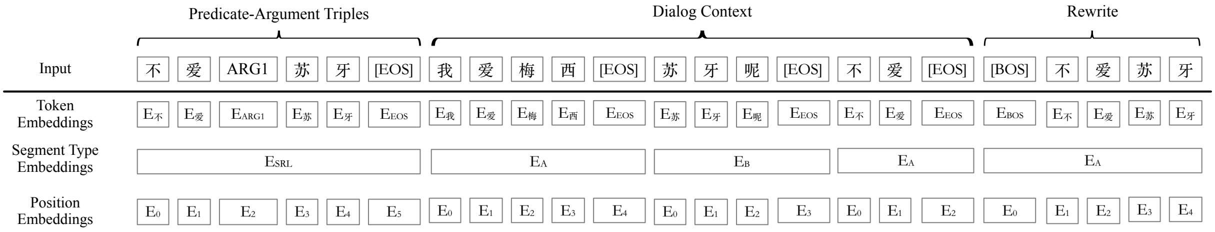

Figure 1: The input representation of a running example. We should point out that some tuples that do not contain words in the rewritten utterances could also be used as input predicate-argument triples.

rewriting model to focus on the semantically important words in the dialogue history, especially the omitted information that appears in previous turns.

For more details, we first take an SRL parser to recognize the predicate-argument (PA) structures from dialog contexts, before encoding that semantic information into our model. Since conventional SRL benchmarks only contain sentence-level annotations, existing pretrained SRL parsers (Khashabi et al., 2018; Gardner et al., 2018) can fail to extract the cross-turn PA structures in dialogues. To address this problem, we extend the traditional SRL to the conversational scenario by additionally annotating a dialogue dataset with standard SRL labels.

Our rewriting model is based on a pre-trained RoBERTa model (Liu et al., 2019) that takes the outputs of SRL parsing and dialogue history as its inputs, before generating rewriting outputs word by word. Experimental results show that even without the SRL information, our model already outperforms previous state-of-the-art models by a large margin. Augmenting the SRL information, the model performance is further improved significantly *without* adding any new parameters.

2 Task Definition

Formally, an input for dialogue rewriting is a dialogue session $c = (u_1, ..., u_N)$ of N utterances, and u_N is the most recent utterance that needs to be revised. The output is r, the resulting utterance after recovering all coreference and omitted information in u_N. Our goal is to learn a model that can automatically rewrite u_N based on the dialogue context.

3 Model

Given a dialogue context c, we first apply an SRL parser to identify the predicate-argument structures z; then conditioned on c and z, the rewritten utterance is generated as $p(r|c, z)$. The backbone of our infrastructure is similar to the transformer blocks in Dong et al. (2019), which supports both bi-directional encoding and uni-directional decoding flexibly via specific self-attention masks. Specifically, we concatenate z, c and r as a sequence, feeding them into our model for training; during decoding, our model takes the z and c before generating the rewritten utterance word by word. Our model uses a pre-trained Chinese RoBERTa (Liu et al., 2019) for rich features.

3.1 Conversational SRL

SRL has long been treated as a sentence-internal task, and its major benchmarks (Carreras and Màrquez, 2005; Pradhan et al., 2013) contains only sentence-level annotations. We extend SRL to fit the conversational scenario by allowing SRL parsers to search for potential arguments over the whole conversation. As there is no publicly available data with paragraph-level SRL annotations, we directly annotate inter- and cross-utterance arguments for predicates on a public dialogue dataset, Duconv (Wu et al., 2019)[1]. Specifically, we annotated 3,000 dialogue sessions, including 33,673 predicates in 27,198 utterances. Among them, 21.89% arguments are not in the same turn with their predicates, respectively. Considering existing standard SRL benchmarks may also be helpful, we first pre-train our SRL model (Shi and Lin, 2019) on the training set of CoNLL 2012 (117,089 examples) and fine-tune it on our annotations. In our experiments, we employ this conversational SRL model to recognize the predicate-argument structures for the dialogue context.

3.2 Input Representation for ReWriter

For each token, its input representation is obtained by summing the embeddings for word, semantic role and position. One example is shown in Fig-

---

[1] More annotation details could be found in the Appendix.

	BLEU-1	BLEU-2	BLEU-4	ROUGE-1	ROUGE-2	ROUGE-L	EM
Trans-Gen	78.18	70.31	51.85	83.1	67.84	81.98	24.12

Table 2: Evaluation results on the datset of Su et al. (2019).

ure 1 and details are described in the following:

- The input is the concatenation of PA structures, dialog context, and rewritten utterance. Note that a PA structure is essentially in a tree format, where the root is a predicate and its children are corresponding semantic arguments. For the linearization, we decomposing each PA structure into several triples of the form <*predicate*, *role*, *argument*> and concatenate them in a random order. A special end-of-utterance token (i.e., [EOS]) is appended to the end of each utterance for separation. Another begin-of-utterance token (i.e., [BOS]) is also added at the beginning of the rewritten utterance. The final hidden state of the last token in the final layer is used to predict the next token during generation.
- We expand the segment-type embeddings of BERT to distinguish different types of tokens. In particular, the type embedding E_A is added for the rewritten utterance, as well as dialogue utterances generated by the same speaker in the context; the type embedding E_B is used for the other speaker; E_{SRL} is used as the type embedding of the tokens in predicate-argument triples. Position embeddings are added according to the token position in each utterance. The input embedding is the summation of word embedding, segment embedding, and position embedding.

3.3 Attention Mask

Similar to TransferTransfo (Wolf et al., 2019), we apply a future mask on the rewritten sequence, that is, the tokens in the rewritten utterance only attend on previous tokens in self-attention layers. Recall that, we linearize a PA structure into a concatenation sequence of triples. Since these triples are randomly ordered, it may inevitably introduce noisy information when using a sequence encoder. To better reflect its structural information, we elaborate the attention mask on PA sequence: the tokens in the same PA triple have bidirectional attentions while tokens in different PA triples can not attend each other. And the position embeddings of tokens in the PA sequence are added according to their positions in each distinct triple rather than the total PA sequence. In experiments, we find using these two designs help our model to more efficiently use the SRL information. We leave a more detailed discussion in Session 4.

3.4 Training

We employ the NLL loss to train our model:

$$\mathcal{L} = -\sum_{t=1}^{T} \log p(r_t | c, z, r_{<t}; \boldsymbol{\theta})$$

where $\boldsymbol{\theta}$ represents the model parameters, T is the length of the target response r, and $r_{<t}$ denotes previously generated words.

4 Experiments

We evaluate our model on two rewrite datasets, which are built by Su et al. (2019) and Pan et al. (2019). Both of these two datasets are generated by crawling multi-turn conversational data from several popular Chinese social media platforms. Specifically, the dataset of Su et al. (2019) contains 17,890 examples, which are further split as 80%/10%/10% for training/development/testing, respectively. The dataset of Pan et al. (2019) contains 204k examples, where 194k/5k/5k are for training/developement/testing.

The hyper-parameters used in our model are listed as follows. The network parameters of our model are initialized using RoBERTa. The batch size is set to 32. We use Adam (Kingma and Ba, 2014) with learning rate 5e-5 to update parameters.

Results and Discussion. Following previous works, we used BLEU, ROUGE, and the exact

	B1	B2	R1	R2
Trans-Pointer	84.70	81.70	89.00	80.90
BERT	85.21	82.51	89.53	**83.18**
BERT + SRL	**85.77**	**82.85**	**89.59**	83.08

Table 3: Evaluation results on the datset of Pan et al. (2019). B_n represents n-gram BLEU score and R_n represents n-gram ROUGE score.

match score (EM) (the percentage of decoded sequences that exactly match the human references). We implemented three baselines that use the same transformer-based encoder but differ in the choice of the decoder. Specifically, *Trans-Gen* uses a pure generation decoder which generates words from a fixed vocabulary; *Trans-Pointer* applies a pure pointer-based decoder (Vinyals et al., 2015) which can only copy the word from the input; *Trans-Hybrid* uses a hybrid pointer+generation decoder as in See et al. (2017), which can either copy the words from the input or generate words from a fixed vocabulary. Table 2 and Table 3 summarizes the results of our model and these baselines.

We can see that even without the SRL information, our model still significantly outperforms these baselines on two datasets, indicating that adapting a pre-trained language model could greatly improve the performance of such a generation task. We can also see that the model with the pointer-based decoder achieves better performance than the generation-based and the hybrid one, which is similar to the observation as in Su et al. (2019). This result is expected since there is a high chance the coreference or omission could be perfectly resolved by only using previous dialogue turns. In addition, we find that incorporating the SRL information can further improve the performance by at 1.45 BLEU-1 and 1.6 BLEU-2 points, achieving the state-of-the-art performances on the dataset of Su et al. (2019).

Let us first look at the impact of attention mask design on our model. To incorporate the SRL information into our model, we view the linearized predicate-argument structures as a regular utterance (say u_{pa}) and append it in the front of the input. We experimented with two choices of attention masks. Specifically, the first one is a bidirectional mask (referred as Bi-mask), that is, words in u_{pa} could attend each other; the second one (referred as Triple-mask) only allows words to attend its neighbors in the same triple, i.e., words in different triples are not visible to each other. From Table 2, we can see that the latter one is significantly better than the first one. We think the main reason is that the second design independently encode each predicate-argument triple, which prevents the unnecessary triple-internal attentions, better mimicking the SRL structures.

Since our framework works in a pipeline fashion, one bottleneck of our system can lie in the performance of the SRL parser. One natural question is how accurate our SRL parser can be and how much performance improvement for the rewriter model we could have by introducing the SRL information. To investigate this, we employ a conventional SRL parser[2] to analyze the gold rewritten utterance. These extracted PA structures are *considered* as gold SRL annotations to measure the accuracy of our conversational SRL parser. In particular, we evaluate our SRL parser on the micro-averaged F1 over the (*predicate*, *argument*, *label*) tuples. We find our SRL parser achieves 75.66 precision, 74.47 recall, and 75.06 F_1. On the other hand, we use the gold SRL results instead of our SRL parsing results to train and test the model (referred as BERT+Gold-SRL). From Table 2, we can see that all evaluation scores are significantly improved. This result indicates that the performance of our rewriter model is highly relevant to the SRL parser, and the performance of our current SRL parser is still far from satisfactory, which we leave for future work.

We also investigate which type of dialogues our model could benefit from incorporating SRL information? By analyzing the dialogues and our predicted rewritten utterances, we find that the SRL information mainly improves the performance on the dialogues that require information completion. One omitted information is considered as properly completed if the rewritten utterance recovers the omitted words. We find the SRL parser naturally offers important guidance into the selection of omitted words. Examples of rewritten utterances are shown in the Appendix.

Recall that, there is one additional scope option to apply the SRL parser to extract PA structures, i.e., only working on the last utterance that needs to be rewritten. We evaluate this option on our dataset (referred as BERT+Partial-SRL) and results are shown in Table 2. We can see that reducing the SRL scope may slightly hurt the perfor-

---

[2] This SRL parser is trained on the CoNLL-2012 dataset.

mance, which we think is due to that larger SRL scope could provide additional guidance for the rewriter model.

5 Conclusions

In this paper, we introduce a novel SRL-guided framework for enhancing dialogue rewriting. For this purpose, we adapted traditional SRL to the conversational scenario by annotating cross-turn annotations on 3,000 dialogues. Experimental results showed that introducing SRL could significantly improve the rewriting performance without adding extra model parameters.

A Conversational SRL Dataset

In this section, we first introduce the dialog set that we annotate on and then discuss more details about the annotation.

A.1 Dialogue Dataset: DuConv

DuConv is a publicly available knowledge-driven dialogue dataset, focusing on the domain of movies and stars. It consists of 30k dialogues with 270k dialogue turns and provides a corresponding knowledge graph (KG) .

A.2 Semantic Roles

We follow PropBank (Carreras and Màrquez, 2005), the most widely used standard for annotating predicate-argument structures. It has 32 standard semantic roles. By analyzing the conversation dataset, we adopt 9 core semantic roles in our dialogue SRL:

- Numbered arguments (`ARG0-ARG4`): Arguments defining verb-specific roles. Their semantics depends on the verb and the verb usage in a sentence, or verb sense. In general, `ARG0` stands for the *agent* and `ARG1` corresponds to the *patient* or *theme* of the proposition, and these two are the most frequent roles. Numbered arguments reflect either the arguments that are required for the valency of a predicate, or if not required, those that occur with high-frequency in actual usage.
- Adjuncts: General arguments that any verb may take optionally. In PropBank, there are 13 types of adjuncts, while in our dataset we only consider the most frequent four types of adjuncts, i.e., `AM-LOC`, `AM-TMP`, `AM-PRP` and `AM-NEG`. Specifically, the locative modifiers (`AM-LOC`) indicate where the action takes place. The temporal arguments (`AM-TMP`) show when an action takes place, such as 很快 (soon) or 马上 (immediately). Note that, the adverbs of frequency (e.g., 偶尔 (sometimes), 总是 (always)), adverbs of duration (e.g., 过两天 (in two days)) and repetition (e.g., 又 (again)) are also labeled as `AM-TMP`. Purpose clauses (`AM-PRP`) are used to show the motivation for an action. Clauses beginning with 为了 (in order to) and 因为 (because) are canonical purpose clauses. `AM-NEG` is used for elements such as '没有' (not) and '绝不' (no longer).

A.3 Annotation Details

There are two main types of semantic roles: span based (Ouchi et al., 2018; Tan et al., 2018) and dependency based (Li et al., 2019). The former involves the start and end boundaries for each component, and the latter only considers the head word in a dependency tree for each component. We follow the span-based form, which has been adopted by most previous work.

	Overall Ratio	Cross-turn Ratio
`ARG0`	42.1%	22.9%
`ARG1`	40.2%	16.9%
`ARG2`	10.1%	30.2%
`ARG3`	3.0%	24.8%
`ARG4`	0.3%	41.4%
`AM-TMP`	3.2%	0.3%
`AM-LOC`	1.0%	2.1%
`AM-PRP`	0.1%	4.0%

Table 4: Percent of each type of argument and its cross-turn ratio (shown inside parenthesis).

Preprocessing For each dialogue session, we first convert it to a paragraph by concatenating each utterance in the dialogue history. We then use Stanford CoreNLP (Manning et al., 2014) for sentence segmentation, tokenizing, and POS-tagging. We identify verbs by POS tag with heuristics to filter out auxiliary verbs.

Labeling instructions We ask five annotators who are familiar with PropBank semantic roles to annotate these dialogue sessions. Following the span-based annotation standard, annotators label the index ranges for each predicate and its arguments. In contrast to the standard sentence-level SRL, conversational SRL aims to additionally address the ellipsis and anaphora problems, which frequently occurred in the dialogue scenario. To this end, the annotators are instructed that a *valid* annotation must satisfy the following criteria: (1) the argument should only appear in the current or previous turns; (2) the argument should not be assigned to a pronoun unless its reference could not be found in previous turns; (3) if the argument is the speaker or listener, it should be explicitly assigned to the special token we used to indicate the speaker (i.e., A or B). (4) in cases when there exit multiple choices for labeling an argument, we select the one that is the closest to the predicate.

Statistics We annotated 3,000 dialogue sessions from DuConv (33,673 predicates in 27,198 utterances). Table 4 analyzes our datasets by listing the percent of each argument type and its cross-turn ratio. We can see that, for all the three datasets, ar-

	Example #1
Utterance 1	十一种孤独$_{\textbf{ARG0}}$作者是谁 (Who is the author of Eleven Kinds & of Loneliness ?)
Utterance 2	理查德耶茨，对吧 (Richard Yates, right ?)
Utterance 3	这本书讲$_{\textbf{predicate}}$的啥$_{\textbf{ARG1}}$ (What is this book talking about?)
Gold:	**十一种孤独讲的啥** (What is Eleven Kinds of Loneliness talking about?)
BERT:	**理查德耶茨讲的啥** (What is Richard Yates talking about?)
BERT + SRL:	**十一种孤独讲的啥** (What is Eleven Kinds of Loneliness talking about?)
	Example #2
Utterance 1	济南大学$_{\textbf{ARG0}}$ (University of Jinan.)
Utterance 2	南京一所著名工科强校 (It is a famous school of engineering in Nanjing.)
Utterance 3	不, 它在$_{\textbf{predicate}}$济南$_{\textbf{ARG1}}$ (No, it is in Jinan.)
Gold:	**不, 济南大学在济南** (No, the University of Jinan is in Jinan.)
BERT:	**不, 济南大学在济南大学** (No, the University of Jinan is in Jinan University.)
BERT + SRL:	**不，济南大学在济南** (No, the University of Jinan is in Jinan.)

Table 5: Examples of multi-turn dialogue. The outputs of our SRL model are annotated in the utterances.

guments `ARG0`, `ARG1` and `ARG2` count for the major proportion of the arguments. For adjunct-type arguments, `AM-TMP` and `AM-LOC` appear more than `AM-PRP`. It is likely because humans tend to avoid mentioning reasons for simplicity. Besides, the adjunct-type arguments have very low cross-turn ratios. This fits our intuition that humans usually mention the time and location when describing an event or a piece of news.

B Examples of Model Prediction

Table 5 gives some running examples of our model predictions. We can see that with accurate SRL guidance, our model could generate better utterances.

Continuity of Topic, Interaction, and Query: Learning to Quote in Online Conversations

Abstract

Quotations are crucial for successful explanations and persuasions in interpersonal communications. However, finding what to quote in a conversation is challenging for both humans and machines. This work studies automatic quotation generation in an online conversation and explores how *language consistency* affects whether a quotation fits the given context. Here, we capture the contextual consistency of a quotation in terms of latent topics, interactions with the dialogue history, and coherence to the query turn's existing content. Further, an encoder-decoder neural framework is employed to continue the context with a quotation via language generation. Experiment results on two large-scale datasets in English and Chinese demonstrate that our quotation generation model outperforms the state-of-the-art models. Further analysis shows that topic, interaction, and query consistency are all helpful to learn how to quote in online conversations.

1 Introduction

Quotations, or quotes, are memorable phrases or sentences widely echoed to spread patterns of wisdom (Booten and Hearst, 2016). They are derived from the ancient art of rhetoric and now appearing in various daily activities, ranging from formal writings (Tan et al., 2015) to everyday conversations (Lee et al., 2016), all help us present clear, beautiful, and persuasive language. However, for many individuals, writing a suitable quotation that fits the ongoing contexts is a daunting task. The issue becomes more pressing for quoting in online conversations where quick responses are usually needed on mobile devices (Lee et al., 2016).

To help online users find what to quote in the discussions they are involved in, our work studies how to recommend an ongoing conversation with a quote and ensure its continuity of senses with the existing contexts. For task illustration, Figure 1 displays a Reddit conversation snippet centered around the worthiness to buy a Scuf controller. To argue against $T4$'s viewpoint, we see the query turn quotes *Tusser*'s old saying for showing that buying a controller is a waste of money. As can be observed, it is important for a quotation recommendation model to capture the key points being discussed (reflected by words like "money" and "dumb" here) and align them to words in the quotation to be predicted (such as "fool" and "money"), which allows to quote something relevant and consistent to the previous concern.

> $[T1]$: Save your money. Scuf is the biggest ripoff in gaming.
> $[T2]$: What would you suggest instead?
> $[T3]$: Just use a normal controller.
> $[T4]$: Ooooooh, I get it now...you're just dumb.
> $[Q]$: The dumb ones are the people spending over \$100 for a controller. *A fool and his money are soon parted.*

Figure 1: A Reddit conversation snippet about buying a Scuf controller. The quotation is in blue and italic. $[T1]$ to $[T4]$ are history turns while $[Q]$ is for query turn.

To predict quotations, our work explores semantic consistency of what will be quoted and what was given in the contexts. In context modeling, we distinguish the query turn (henceforth **query**) and the other turns in earlier history (henceforth **history**), where topic, interaction, and query consistency work together to determine whether a quote fits the contexts. Here **topic consistency** ensures that the words in quotation reflect the discussion topic (such as "fool" and "money" in Figure 1). **Interaction consistency** is to identify the turns in history to which the query responds (e.g., $T1$ and $T4$ in Figure 1) and guide the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6640–6650,
November 16–20, 2020. ©2020 Association for Computational Linguistics

quote to follow such interaction. **Query consistency** measures the language coherence of quote in continuing the story started by the query. For example, the quote in Figure 1 is to support the query's argument.

In previous work of quotation recommendation, there are many methods designed for formal writings (Tan et al., 2015; Liu et al., 2019); whereas much fewer efforts are made for online conversations with informal language and complex interactions in their contexts. Lee et al. (2016) use a ranking model to recommend quotes for Twitter conversations. Different from them, we attempt to generate quotations in a word-by-word manner, which allows the semantic consistency of quotes and contexts to be explored.

Concretely, we propose a neural encoder-decoder framework to predict a quotation that continues the given conversation contexts. We capture topic consistency with latent topics (i.e., word distributions), which are learned by a neural topic model (Zeng et al., 2018a) and inferred jointly with the other components. Interaction consistency is modeled with a turn-based attention over the history turns, and the query is additionally encoded to initialize the decoder's states for query consistency. To the best of our knowledge, we are the first to explore quotation generation in conversations and extensively study the effects of topic, interaction, and query consistency on this task.

Our empirical study is conducted on two large-scale datasets, one in Chinese from Weibo and the other in English from Reddit, both of which are constructed as part of this work. Experiment results show that our model significantly outperforms both the state-of-the-art model based on quote rankings (Lee et al., 2016) and the recent topic-aware encoder-decoder model for social media language generation (Wang et al., 2019a). For example, we achieve 27.2 precision@1 on Weibo compared with 24.0 by Wang et al. (2019a). Further discussions show that topic, interaction, and query consistency can all usefully indicate what to quote in online conversations. We also study how length of history and quotation affects the quoting results and find that we perform consistently better than comparison models in varying scenarios.

2 Related Work

Our work is in the line with content-based recommendation (Liu et al., 2019) or cloze-style reading comprehension (Zheng et al., 2019), which learns to put suitable text fragments (e.g., words, phrases, sentences) in the given contexts. Most prior studies explore the task in formal writings, such as citing previous work in scientific papers (He et al., 2010), quoting famous sayings in books (Tan et al., 2015, 2016), and using idioms in news articles (Liu et al., 2019; Zheng et al., 2019). The language they face is mostly formal and well-edited, while we tackle online conversations exhibiting noisy contexts and hence involving quote consistency modeling with turn interactions. Lee et al. (2016) also recommend quotations for conversations. However, they consider quotations as discrete attributes (for learning to rank) and hence largely ignore the rich information reflected by a quotation's internal word patterns. Compared with them, our model learns to quote with language generation, which can usefully exploit how words appear in both contexts and quotations.

For methodology, we are inspired by the encoder-decoder neural language generation models (Sutskever et al., 2014; Bahdanau et al., 2014). In dialogue domains, such models have achieved huge success in digesting contexts and generate microblog hashtags (Wang et al., 2019b), meeting summaries (Li et al., 2019), dialogue responses (Hu et al., 2019), etc. Here we explore how the encoder-decoder architecture works to generate quotations in conversations, which has never been studied in existing work. Our study is also related to previous research to understand conversation contexts (Ma et al., 2018; Liu and Chen, 2019; Sun et al., 2019), where it is shown to be useful to capture interaction structures (Liu and Chen, 2019) and latent topics (Zeng et al., 2019). For latent topics, we are benefited from the recent advance of neural topic models (Miao et al., 2017; Wang et al., 2019a)), which allows end-to-end topic inference in neural architectures. Nevertheless, none of the above work attempts to study the semantic consistency of quotes in conversation contexts, which is a gap our work fills in.

3 Our Quotation Generation Model

This section describes our neural encoder-decoder framework that generates quotations in conversations, whose architecture is shown in Figure 2. The encoding process works for context modeling of turn interactions (described in Section 3.1) and latent topics (presented in Section 3.2). For

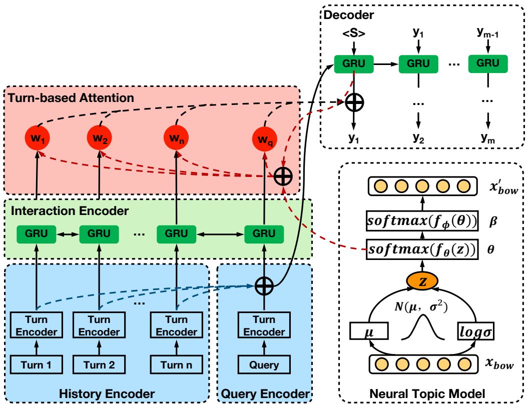

Figure 2: Our encoder-decoder framework for conversation quotation generation. It encodes turn interactions (for both query and earlier history) and latent topics in contexts. The decoder predicts quotes in aware of topic, interaction, and query consistency.

the decoding process to be discussed in Section 3.3, we predict words in quotes taking topic, interaction, and query consistency into consideration. The learning objective of the entire framework will be given at last in Section 3.4.

3.1 Interaction Modeling

To describe turn interactions, we first assume that there are m chronologically-ordered turns given as contexts and each turn T_i is formulated as a word sequence $\langle w_{i,1}, w_{i,2}, ..., w_{i,n_i}\rangle$ (n_i denotes the number of words). We consider the m-th turn as the query while others the history ($T_{history} = \langle T_1, T_2, ..., T_{m-1}\rangle$). Here we distinguish the query and its earlier history to separately explore the quote's language coherence to the query (for query consistency) and its interaction consistency to the earlier posted turns. In the following, we will describe how to encode history and query turns, and how the learned representations work together to explore conversation structure.

History Encoder. Here we describe how to encode turns in history. We first feed each word w_{ij} (the j-th word in the i-th turn) in history into an embedding layer to obtain its word vector $\boldsymbol{c}_{i,j}$. Then word vectors of the i-th turn $C_i = \langle \boldsymbol{c}_{i,1}, \boldsymbol{c}_{i,2}, ..., \boldsymbol{c}_{i,n_i}\rangle$ are further processed with a bidirectional gated recurrent unit (Bi-GRU) (Cho et al., 2014b). Its hidden states are defined as:

$$\overrightarrow{\boldsymbol{h}^c_{i,j}} = f_{GRU}(\boldsymbol{c}_{i,j}, \boldsymbol{h}^c_{i,j-1}),\ \overleftarrow{\boldsymbol{h}^c_{i,j}} = f_{GRU}(\boldsymbol{c}_{i,j}, \boldsymbol{h}^c_{i,j+1}) \tag{1}$$

The turn-level representations are hence captured by concatenating the last hidden states of both directions: $\boldsymbol{h}^c_i = [\overrightarrow{\boldsymbol{h}^c_{i,n_i}}; \overleftarrow{\boldsymbol{h}^c_{i,0}}]$. Further, we define the history representations as $\boldsymbol{h}^c = \langle \boldsymbol{h}^c_1, \boldsymbol{h}^c_2, ..., \boldsymbol{h}^c_{m-1}\rangle$, which will be further used to encode the interaction structure (described later).

Query Encoder. Similar to the way we encode each turn in history, a Bi-GRU is first employed to learn query representations $\boldsymbol{q} = \boldsymbol{h}^c_m$. Then, we identify which turns in history the query responds to for learning interaction consistency. To this end, we put a query-aware attention over the history turns and result in a context vector below:

$$\boldsymbol{c} = \sum_{i=i}^{m-1} \alpha_i \cdot \boldsymbol{h}^c_i, \quad \alpha_i = softmax(\boldsymbol{h}^c_i \cdot \boldsymbol{q}) \tag{2}$$

Afterwards, we enrich query representations with the features from history and obtain the history-aware query representations:

$$\tilde{\boldsymbol{q}} = W_q[\boldsymbol{q}; \boldsymbol{c}] + b_q \tag{3}$$

where W_q and b_q are learnable parameters.

Structure Encoder. With the representations learned above for query $\tilde{\boldsymbol{q}}$ and history $\boldsymbol{h}^c$, we can further explore how turns interact with their neighbors (henceforth conversation structure) with another Bi-GRU. It is fed with the $\langle \boldsymbol{h}^c_1, \boldsymbol{h}^c_2, ..., \boldsymbol{h}^c_{m-1}, \tilde{\boldsymbol{q}}\rangle$ sequence and the hidden states sequence $\langle \boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_{m-1}, \boldsymbol{h}_m\rangle$ is further put into a memory bank M for decoder's attentive retrieval in quotation generation (see Section 3.3).

3.2 Topic Modeling

Following the common practice (Blei et al., 2003; Miao et al., 2017), we model topics following the bag-of-words (BoW) assumption. Hence, we form a BoW vector $\mathbf{x}_{bow}$ (over vocabulary V) of the words in context to learn its discussion topic. The topic inference process is inspired by neural topic models (NTM) (Miao et al., 2017). It is based on a variational auto-encoder (VAE) (Kingma and Welling, 2013) involving an encoding and a decoding step to reconstruct the BoW of contexts.

BoW Encoding Step. This step is designed to learn a latent topic variable $\mathbf{z}$ from $\mathbf{x}_{bow}$. Here words in conversation contexts are assumed to satisfy a Gaussian distribution prior on mean μ and standard deviation σ (Miao et al., 2017). They are estimated by the following formula:

$$\mu = f_\mu(f_e(\mathbf{x}_{bow})),\ log\,\sigma = f_\sigma(f_e(\mathbf{x}_{bow})) \tag{4}$$

where $f_*(\cdot)$ is a neural perceptron performing a linear transformation activated with an ReLU function (Nair and Hinton, 2010).

BoW Decoding Step. Conditioned on the latent topic $\mathbf{z}$, we further generate words to form the BoW of each conversation $\mathbf{x}_{bow}$. Here we assume each word $w_n \in \mathbf{x}_{bow}$ is drawn from the conversation's topic mixture θ, which is a distribution vector over the topics. In the following, we show the generation story to decode $\mathbf{x}_{bow}$:

- Draw latent topic $\mathbf{z} \sim \mathcal{N}(\mu, \sigma^2)$.
- Topic mixture $\theta = softmax(f_\theta(\mathbf{z}))$.
- For the n-th word in the conversation:
  - Draw the word $w_n \sim softmax(f_\phi(\theta))$.

Here $f_*(\cdot)$ is a ReLU-activated neural perceptron defined above. The topic mixture θ will be later applied to capture topic consistency when predicting the quotation.

3.3 Quotation Generation

To predict the quotation $\boldsymbol{y}$, we first define the probability of words in it with the following formula:

$$Pr(\boldsymbol{y}|T_{history}, T_{query}) = \prod_{i=1}^{|\boldsymbol{y}|} Pr(y_i|\boldsymbol{y}_{<i}, M, \theta) \tag{5}$$

where $\boldsymbol{y}_{<i} = \langle y_1, y_2, ..., y_{i-1} \rangle$ and $|\boldsymbol{y}|$ denotes the quotation's word number. In prediction, the i-th word is generated with a likelihood $p_i = Pr(y_i|\boldsymbol{y}_{<i}, M, \theta)$, which is jointly determined by the words appearing before it ($\boldsymbol{y}_{<i}$) and the contexts features delivered by M (turn interactions described in Section 3.1) and θ (the discussion topic described in Section 3.2). Below comes more details of how we follow the semantic consistency of contexts to generate quotations.

Query Consistency. To carry on query's senses, the quotation is decoded with an unidirectional GRU initialized based on the encoded query. The initialization and later recursion of decoder's hidden states are given as:

$$\boldsymbol{h}_0^d = W_0 \tilde{\boldsymbol{q}} + b_0,\ \boldsymbol{h}_i^d = f_{GRU}(\boldsymbol{v}_i, \boldsymbol{h}_{i-1}^d) \tag{6}$$

where W_0 and b_0 are parameters to be learned. $\boldsymbol{v}_i$ is the embedded decoder input to predict the i-th word in quotation.[1] In decoding, word prediction is conducted sequentially with beam search. It results in a ranking list of output, where we take the top K for quotation matching described later.

Topic and Interaction Consistency. For modeling quote consistency of discussion topics (with θ) and turn interactions (with M), we design a turn-based attention over conversation contexts to decode the quotation. Its attention weights are computed in aware of the structure-encoded turn representations $\boldsymbol{h}_j$ from M and topic distribution θ:

$$\alpha_{ij} = \frac{exp(f_d(\boldsymbol{h}_i^d, \boldsymbol{h}_j, \theta))}{\sum_{j'=1}^{m} exp(f_d(\boldsymbol{h}_i^d, \boldsymbol{h}_{j'}, \theta))} \tag{7}$$

where $f_d(\boldsymbol{h}_i^d, \boldsymbol{h}_j, \theta)$ captures the topic-aware semantic dependency the i-th word in quotation to the j-th turn in contexts and is defined as:

$$f_d(\boldsymbol{h}_i^d, \boldsymbol{h}_j, \theta) = W_d[\boldsymbol{h}_i^d \cdot \boldsymbol{h}_j^\theta] + b_d \tag{8}$$

where $\boldsymbol{h}_j^\theta = W_\theta[\boldsymbol{h}_j; \theta] + d_\theta$, and parameters W_d, b_d, W_θ, and d_θ are all trainable. Then we give the context vector $\boldsymbol{t}_i$ conveying both topic and interaction features for the i-th word to be generated:

$$\boldsymbol{t}_i = \sum_{j=1}^{m} \alpha_{ij} \boldsymbol{h}_j. \tag{9}$$

Finally, we predict the i-th word in quotation following the distribution p_i defined to combine topic, interaction, and query consistency:

$$p_i = softmax(W_p[\boldsymbol{h}_i^d; \boldsymbol{t}_i] + b_p), \tag{10}$$

where W_p and b_p are trainable parameters.

Quotation Matching. Occasionally language generation will "create" a non-existing quotation. To avoid that, we take a post-processing step for the outputs absent in our quotation list. Following previous practice (Liu et al., 2019), we select a quote from the list with the minimum edit distance (by tokens) and consider it as the final output.

3.4 Learning Objective

For the entire framework, we design its learning objective to allow joint learning of latent topics and conversation quotations:

$$\mathcal{L} = \mathcal{L}_{NTM} + \mathcal{L}_{QGM} \tag{11}$$

Here $\mathcal{L}_{NTM}$ is the objective function of neural topic model (NTM) defined as:

$$\mathcal{L}_{NTM} = D_{KL}(p(\mathbf{z})||q(\mathbf{z}\,|\,\mathbf{x})) - \mathbb{E}_{p(\mathbf{z})}[p(\mathbf{x}\,|\,\mathbf{z})] \tag{12}$$

where $D_{KL}(\cdot)$ is the Kullback-Leibler divergence loss and $\mathbb{E}_*[\cdot]$ reflects the reconstruction loss. [2]

---

[1] In training, we do teacher forcing and feed the gold standard. In test, we feed the predicted left neighbor.

[2] Because of the space limitation, we leave out the derivation details and refer the readers to Miao et al. (2017).

As for $\mathcal{L}_{QGM}$, it is defined as the cross entropy loss over all training instances to train the quotation generation model (QGM):

$$\mathcal{L}_{QGM} = -\sum_{n=1}^{N} log(Pr(\boldsymbol{y}_n | C_n, \theta_n)) \qquad (13)$$

where N is the number of training instances. $C_n = \{T_{history}, T_{query}\}_n$ represents the contexts of the n-th conversation and θ_n is C_n's topic composition induced by NTM.

4 Experimental Setup

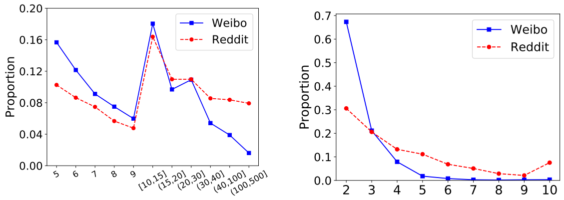
Datasets. For experiments, we construct two new datasets: one in Chinese from Weibo (a popular microblog platform in China and henceforth **Weibo**) and the other in English from Reddit (henceforth **Reddit**), which will be released upon publication. Here the raw Weibo data is released by Wang et al. (2019a) and Reddit obtained from a publicly available corpus.[3] For both Weibo and Reddit, we follow the common practice form conversations with posts and their comments (Li et al., 2015; Zeng et al., 2018b), where a post or comment is considered as a conversation turn.

To gather conversations with quotations, we maintain a quotation list and remove conversations containing no quotation from the list. For the remaining, if a conversation has multiple quotes, we construct multiple instances where one corresponds to the prediction of a quotation therein. On Weibo, we explore the quoting of Chinese *Chengyu*.[4] For Reddit, we obtain the quotation list from Wikiquote.[5] Afterwards, we remove conversation instances with quotations appearing less than 5 times to avoid sparsity (Tan et al., 2015). Finally, the datasets are randomly splitted into 80%, 10%, and 10%, for training, development, and test.

	Weibo	**Reddit**
# of quotes	1,053	1,111
Avg len of quotes	4.0	10.1
|Voc| of quotes	1,251	4,111
# of convs	19,081	44,539
Avg # of turns per conv	2.51	4.25
Avg len of turn per conv	21.6	71.8
|Voc| of convs	44,134	72,375

Table 1: Statistics of Weibo and Reddit datasets. The upper rows are for quotes and the lower rows are for conversations. The "len" refers to the number of tokens contained. "Avg # of turns" means the average turn number in context.

The statistics of the two datasets are shown in Table 1. We observe that the two datasets exhibit different statistics. For example, from the average turn number in contexts, we find Reddit users tend to quote in later turns while Weibo earlier. To further compare users' quoting behavior, we show the distribution of quotation number in Figure 3(a) and position in Figure 3(b). Figure 3(a) shows only a few quotations are commonly used in online conversations, probably because of its informal writing style. While for Figure 3(b), we find only a few Weibo conversations quote 5 turns later while the distribution on Reddit is much flatter.



(a) Frequency Distribution (b) Position Distribution

Figure 3: Quotation distribution over frequency (on the left) and position (right). X-axis: frequency (left) and context turn number (right); Y-axis: proportion of quotations (left) and conversations (right).

Preprocessing. To preprocess Weibo data, we adopted open-source Jieba toolkit[6] for Chinese word segmentation. For Reddit dataset, we employ natural language toolkit (NLTK[7]) for tokenization. In BoW preparation, all stop words and punctuation were removed following common practice to train topic models (Blei et al., 2003).

Parameter Setting. Here we describe how we set our model. In model architecture, the hidden size of all GRUs is set to 300 (bi-direction, 150 for each direction). For encoder, we adopt two layers of bidirectional GRU, and unidirectional GRU for decoder. The parameters in NTM are set up following Zeng et al. (2018a). For input, we set

---

[3] `https://files.pushshift.io/reddit/comments/`

[4] `https://en.wikipedia.org/wiki/Chengyu` Chengyu can be seen as a quotable phrase (Wang and Wang, 2013) — memorable rhetorical figures to convey wit and striking statement (Bendersky and Smith, 2012).

[7] `https://www.nltk.org`

the maximum turn length to 150 for Reddit and 200 for Weibo, and the maximum quotation length 20. Word embeddings are randomly initialized to 150-dimensional vectors. In model training, we employ Adam optimizer (Kingma and Ba, 2015), with $1e-3$ learning rate and the adoption of early stop (Caruana et al., 2001). Dropout strategy (Srivastava et al., 2014) is also used to avoid overfitting. We adopt beam search (beam size $=5$) to generate a ranking list for quote recommendation.

Evaluation Metrics. We first adopt recommendation metrics with popular information retrieval metrics Precision at K (P@K) and mean average precision (MAP) scores (Schütze et al., 2008) used. For P@K, K=1 to measure the top prediction, while for MAP we consider the top 5 outputs. Here we measure the generation models with their predictions after quotation matching (Section 3.3). Then, generation metrics are employed to evaluate word-level predictions. Here we consider both ROUGE (Lin, 2004) from summarization (F1 scores of ROUGE-1 and ROUGE-L are adopted) and BLEU (Papineni et al., 2002) from translation. To allow comparable results, generation models are measured with their original outputs (without quotation matching) while for ranking competitors, we take their top-1 ranked quotes.

Comparisons. We first adopt two weak baselines that select quotations unaware of the target conversation: 1) RANDOM: selecting quotations randomly; 2) FREQUENCY: ranking quotations with frequency. Then, we compared two ranking baselines: 3) non-neural learning to rank model (henceforth LTR) with handcrafted features proposed in Tan et al. (2015). 4) CNN-LSTM (Lee et al., 2016): previous quotation recommendation model (CNN for turn and quotation encoding and LSTM for conversation structure).

Next, we consider the encoder-decoder generation models without modeling conversation structure: 5) SEQ2SEQ (Cho et al., 2014a): using an RNN for encoding and another RNN for decoding; 6) TAKG: Seq2Seq framework incorporating latent topics for decoding. 7) the state-of-the-art (SOTA) model NCIR (Liu et al., 2019) designed for Chinese idiom generation.

Finally, the following of our variants are test: 8) IE ONLY: using interaction modeling results for decoding (w/o topic and query consistency modeling); 9) IE+QE: coupling interaction and query consistency (w/o NTM used for topic consistency); 10) IE+QE+NTM: our full model.

5 Experimental Results

In this section, we first show the main comparison results in Section 5.1. Then Section 5.2 discusses what we learn to represent consistency. Finally, Section 5.3 presents more analysis to characterize quotations in online conversations.

5.1 Main Comparison Results

Table 2 reports the main comparison results on two datasets, where our full model significantly outperforms all comparisons by a large margin. Several interesting observations can be drawn:

- *Quotation is related with context.* The poor performance of weak baselines reveals the challenging nature of quoting in online conversations. It is not possible to learn what to quote without considering context.
- *Generation models outperform Ranking.* Generation models in encoder-decoder style perform much better than ranking. It maybe attributed to generation model's ability to learn word-level mapping from source context to quotation.
- *Interaction, query, and topic consistency are all useful.* We see IE ONLY outperforms SEQ2SEQ, showing that interaction modeling helps encode indicative features from context. Likewise, the results of IE+QE are better than IE ONLY, and IE+QE+NTM better than IE+QE, both suggesting that learning query and topic consistency contribute to yield a better quotation.
- *Quoting in Reddit is more challenging than Weibo Chengyu.* All models perform worse on Reddit than Weibo. The possible reason is that Chinese Chengyu is shorter and renders a smaller vocabulary than English quotes (see Table 1).

5.2 Quotation and Consistency

We have shown our effectiveness in main results. Here we further examine our learned consistency and their effects on quoting. In the rest of this paper, without otherwise specified, *our model* is used as a short form of our full model (IE+QE+NTM). For comparison, we select TAKG for its best performance in Table 2 over all comparison models.

Interaction Consistency. To understand the positions of turns a quote is likely to respond to, we display the turn-based attention weights (Eq. 7) over turn position in Figure 4. Also shown is

Models	Weibo					Reddit

Table 2: Comparison results on Weibo and Reddit datasets (in %). RG-1 and RG-L refer to ROUGE-1 and ROUGE-L respectively. The best results in each column are in **bold**. Our full model IE+QE+NTM achieves significantly better performance than all the comparisons (paired t-test. ‡: $p < 0.05$; †: $p < 0.01$)

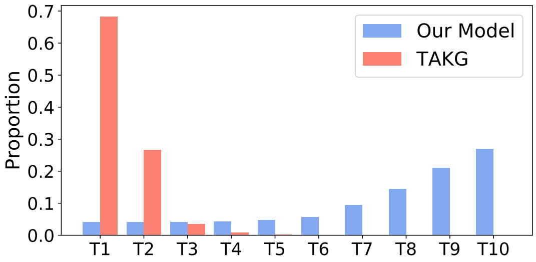

Figure 4: Attention weights over turns. X-axis: turn position; Y-axis: the normalized weight.

the attention weights from TAKG (Wang et al., 2019a) for comparison. Here we use Reddit conversations for interpretation because they involve larger turn number (see Table 1). It is seen that TAKG can only attend the first three turns while we assign higher weights to turns closer to query. In doing so, the quotes will continue senses from later history, which fits our intuition that participants tend to interact with latest information.

Query Consistency. We carry out a human evaluation to test the coherence of query and the predicted quotations. 100 conversations are sampled from Weibo and two native Chinese speakers are invited to examine whether a quote carry on the query's senses ("yes") or not ("no"). Table 3 shows the count of "yes" for the ground truth quote and the output of IE only and IE+QE. Interestingly, even ground truth quotations cannot attain over 85% "yes", probably because of the prominent misuse of quotations on social media. Nevertheless, the better performance of IE+QE compared with IE only shows the usefulness to model query consistency for ensuring quotation's language coherence to the query.

	Human 1	**Human 2**
Ground Truth	84	78
IE only	36	32
IE+QE	49	46

Table 3: Human evaluation results for the quote coherent with query (count out of 100).

Topic Consistency. Here we use the example in Figure 1 to analyze the topics we learn for modeling consistency. Recall that the conversation centers around *price and value* and the quote is used to argue that *only fools will waste the money*. We look into the top 3 latent topics (by topic mixture θ) and display their top 10 words (by likelihood) in Table 4. There appears words like "pay" and "stupied", which might help to correctly predict "fool" and "money" in the quote.

5.3 Sensitivity to Context and Quotations

In this section, we study how varying context and quotations affect our performance.

The Effects of Context. Here we examine whether longer context will result in better results.

Topic 1	*game* property child rights *pay* guy state church guys *paid*
Topic 2	fuck evidence shit guys *stupid* edit nice proof dude *dumb*
Topic 3	car *buy* cops police scrubs gun technology shot crime energy

Table 4: The top 10 words of the 3 latent topics related to the conversation in Figure 1. Words suggesting conversation's focus are in blue and italic.

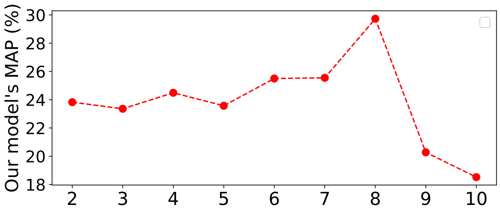

Figure 5: Our MAP scores over conversations with varying turn number. X-axis: turn number; Y-axis: MAP scores. The best results are seen for 8-turn convs.

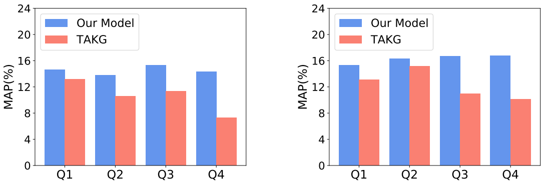
In the following, we measure context length in terms of turn number and token number.

Turn Number. Figure 5 shows our MAP scores to quote for Reddit conversations with varying turn number. Weibo results are not shown here for the limited data with turn number > 4. Generally, more turns result in better MAP, for the richer information to be captured from turn interactions. The scores drop for turn number > 8, probably because of underfitting and a more complex model might be needed for interaction modeling.

To further explore model's sensitivity to turn number, we first rank the conversations with turn number and separate them into four quartiles (Q_1, Q_2, Q_3, Q_4, in order with increasing turn number). We then train and test in each quartile, and compare the results of our model and TAKG in Figure 6(a). As can be seen, our model presents larger margin for quartiles corresponding to larger turn number, indicating our ability to encode rich information from complex turn interactions.

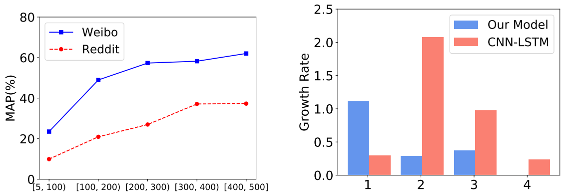
Token number. For context length measured with token number, we follow the above steps to form train and test quartiles for token number. The results are shown in Figure 6(b) where our model consistently outperform TAKG over conversation context with varying token number.

The Effects of Quotation. We further study our results to predict quotations in varying frequency



(a) Turn Number (b) Token Number

Figure 6: MAP scores (y-axis) over context length (left in turn number and right token number) in varying quantiles. For each subfigure, from left to right shows the results in Q_1 ($[0, 0.25)$), Q_2 ($[0.25, 0.5)$), Q_3 ($[0.5, 0.75)$), and Q_4 ($(0.75, 1)$).



(a) MAP on Freq. Ranges (b) Growth Rate Comparison

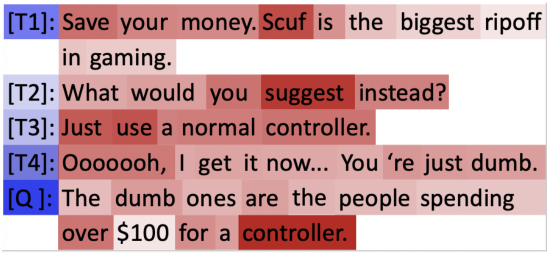
Figure 7: Left subfigure: Our MAP scores (y-axis) on different frequency range (x-axis). Right: growing rate (y-axis) on Weibo, where x-axis indicates the order of neighboring ranges.

and the MAP scores are reported in Figure 7(a). In general, higher scores are observed for more frequent quotations, as better representations can be extensively learned from training data. We also notice a slower growing rate as the frequency increases. To go into more details, we compare the growing rates with ranking model CNN+LSTM and show the results in 7(b) on Weibo (Reddit results in similar trends). In comparison, we are generally less sensitive to quotation frequency (except for very rare quotes). It is likely to be benefited from quotations' internal structure while ranking models can be largely affected by label sparsity.

5.4 Further Discussions

Here we probe into our outputs to provide more insights to quoting in conversations.

Case Study. We first present a qualitative analysis over the example in Figure 1. To analyze what the model learns, we visualize our turn-based attention and TAKG's topic-aware attention over words in Figure 8. As can be seen, TAKG focuses more on topic words "Scuf", "suggest", and "controller", all reflecting the global discussion focus



[T1]: Save your money. Scuf is the biggest ripoff in gaming.

[T2]: What would you suggest instead?

[T3]: Just use a normal controller.

[T4]: Ooooooh, I get it now... You 're just dumb.

[Q]: The dumb ones are the people spending over $100 for a controller.

Figure 8: Attention weights of our model over turns (in blue) and TAKG over words (in red).

while ignoring query's intention. Thus, it mistakenly quote "*A penny saved is a penny earned.*". Instead, we attend the query's interaction with T_1 and T_4, which results in the correct quotation.

Comparing with Human. Finally, we discuss how human performs on our task. 50 Weibo conversations were hence sampled and two human annotators (native Chinese speakers) were invited to quote a Chinese Chengyu in the given context. The two annotators give 7 and 8 correct answers respectively, which shows the task is challenging for human. Our model made 13 correct predictions, exhibiting a better ability to quote in online conversations.

6 Conclusion

We present a novel quotation generation framework for online conversations via the modeling of topic, interaction, and query consistency. Experiment results on two newly constructed online conversation datasets, Weibo and Reddit, show that our model outperforms the previous state-of-the-art models. Further discussions provide more insights on quoting in online conversations.

Abstract

Maintaining a consistent attribute profile is crucial for dialogue agents to naturally converse with humans. Existing studies on improving attribute consistency mainly explored how to incorporate attribute information in the responses, but few efforts have been made to identify the consistency relations between response and attribute profile. To facilitate the study of profile consistency identification, we create a large-scale human-annotated dataset with over 110K single-turn conversations and their key-value attribute profiles. Explicit relation between response and profile is manually labeled. We also propose a key-value structure information enriched BERT model to identify the profile consistency, and it gained improvements over strong baselines. Further evaluations on downstream tasks demonstrate that the profile consistency identification model is conducive for improving dialogue consistency.

1 Introduction

Despite the recent advancements in assigning attribute profiles to dialogue agents (Qian et al., 2018; Zhang et al., 2019), maintaining a consistent profile is still challenging for an open-domain dialogue agent. Existing works mainly emphasize the incorporation of attribute information in the generated responses (Wolf et al., 2019; Song et al., 2019; Zheng et al., 2020). Although these models have improved the response consistency by explicitly modeling the profiles, they still face the consistency issue (Welleck et al., 2019). One important reason is that they cannot identify the consistency relations between response and profile.

As shown in Figure 1, the attribute word *Beijing* is incorporated in the first two responses, but only R_1 is semantically consistent with the speaker's profile. For example, R_2 "I also hope to visit *Beijing* one day." implies that the speaker has never been to Beijing, which contradicts the speaker's profile. On the other hand, although R_3 does not contain the attribute word *Beijing*, we could still infer from the words *Tsinghua University* that the speaker's current location entails the profile. Existing studies (Qian et al., 2018; Zheng et al., 2019) train dialogue agents to produce plausible responses that contain attribute information, but still cannot teach agents to understand the differences of consistency relations in these responses.

Name	*Elena*
Gender	*Female*
Current Location	*Beijing*
Constellation	*Aquarius*
Age	*Post-90s*

Query: I will go to Beijing tomorrow.

R1: I am glad you could come to *Beijing*.

R2: I also hope to visit *Beijing* one day.

R3: I'll show you around Tsinghua University.

🟩 ***Entailed*** 🟥 ***Contradicted***

Figure 1: Left: the key-value attribute profiles of the dialogue agent. Right: a dialogue query with different responses that might be related to the attribute profiles. Among these responses, R_1 entails the current location profile, while R_2 contradicts the profile. Although R_3 does not contain the attribute word *Beijing*, we could still understand R_3 entails the current location.

Welleck et al. (2019) made an early step towards reducing the dialogue consistency identification to natural language inference (NLI) (Bowman et al., 2015), where they learn a mapping from two dialogue utterances to an entailment category. All utterances in Welleck et al. (2019) are natural sentences from the PersonaChat dataset (Zhang et al., 2018). However, structured attribute profiles, such as key-value pairs, are ubiquitous in real-world dialogue systems (Shum et al., 2018). Compared with natural sentences, structured profiles have fixed attribute keys from different domains and specific attribute values from limited candidates. The structure information is also essential to a better understanding of the profile. To endow agents with the ability to identify structured profile consistency, we

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6651–6662,
November 16–20, 2020.

need a new dataset with fine-grained labels between response and profile, as well as a model that can leverage the structure information in the profile.

In this work, we introduce a human-annotated dataset, named Key-value Profile Identification (KvPI), with over 110K single-turn conversations and corresponding attribute profiles. Three representative domains, gender, location, and constellation, are involved in the human annotation. We hire an annotation team to (1) label the relation (*entailed*, *contradicted*, or *irrelevant*) between each conversation and structured profile, and (2) find out the detailed attribute information in each response.

With the annotated KvPI dataset, we set up different baseline models, and propose a key-value structure information enriched BERT (KvBERT) model, which leverages dependency structures in profiles to enrich the contextual representations. Experimental results show that KvBERT obtains significant improvements over strong baselines. We further test the KvBERT model on two downstream tasks, including a reranking task (Welleck et al., 2019) and a consistency prediction task (Dziri et al., 2019). Evaluation results show that (1) the KvBERT reranking improves response consistency, and (2) the KvBERT consistency prediction has a good agreement with human annotation.

Our contributions are summarized as below:

- A KvPI dataset is introduced, which has over 110K fine-grained consistency annotations between responses and their key-value profiles.
- A KvBERT model is proposed for consistency identification, which gained significant improvements over strong baselines.
- Evaluations on downstream tasks show that the profile consistency identification model could be complementary to dialogue models.

2 Dataset Preparation

In this section, we describe the collection and annotation process of the KvPI dataset: (1) how we collect high-quality conversations and profiles; (2) how we define the consistency relations between responses and profiles; and (3) how we annotate consistency relations for the collected data.

2.1 Data Collection

To study the profile consistency identification problem, we use data from Weibo[1], a popular and plentiful Chinese social media, in which people routinely respond to different posts and have publicly available profiles, such as gender and location. We follow the protocol of the previous profile-based dialogue dataset (Qian et al., 2018; Zheng et al., 2019) to collect Weibo post-response pairs, together with users' available profiles. Here we filter out overly long or short pairs and finally obtain a tuple pool that contains about 30 million tuples, which are in a $\{$*profile*, *post*, *response*$\}$ format. Each profile includes three popular attributes: gender, location and constellation, and organized in a key-value format. For instance, $\{$gender: *female*, location:*Beijing*, constellation: *Aquarius*$\}$. This format is widely applied in real-world dialogue systems, such as Bowden et al. (2017), Shum et al. (2018), and Pichl et al. (2018).

Since our goal is to identify explicit consistency relations between response and profile, we filter out the tuples whose response has no profile-related information by employing a pre-trained classifier and heuristic rules. Finally, we obtain about 150K profile-related tuples after filtering.

2.2 Consistency Relations

We define three types of consistency relation between the response and profile under the open-domain dialogue setting, which is different from the entailment categories in natural language inference (Bowman et al., 2015; Welleck et al., 2019):

Entailed The response is exactly talking about the dialogue agent's attribute information, and the attribute is consistent with its key-value profile.

Contradicted Although the response is talking about the dialogue agent's attribute information, it is contradicted to at least one of the given key-value pairs. For example, given the profile "$\{$location: *Beijing*$\}$", "I am in Seattle" is contradicted to the profile, while "She lives in Seattle" is not, because the latter is not talking about the dialogue agent's attribute.

Irrelevant The response contains profile-related information, but the information does not reveal the dialogue agent's own attributes. As exemplified above, "She lives in Seattle" is irrelevant, rather than contradicted, to the dialogue agent's profile "$\{$location: *Beijing*$\}$". Another example is "I'm interested in the history of Beijing". Although there is the attribute word "Beijing", this response still does not reveal the dialogue agent's location.

---

Profile	**Post**	**Response**	**Domain**	**Annotated Attribute**	**Label**
Constell: Aries Loc: Henan Anyang Gender: Female	Bro, are you also a Scorpio? 兄弟，你也天蝎啊?	I'm an Aries bullied by Scorpio 我是被天蝎欺负的白羊座	Constell	{Constell: Aries}	E
Constell: Scorpio Loc: Beijing Gender: Female	Too cold and you girls will catch cold 女孩子贪凉容易感冒	Are you confused? I'm not a girl! I am a middle-aged woman! 搞错了吧?人家不是女孩!是中年少女!	Gender	{Gender: Female}	E
Constell: Leo Loc: Jiangsu Gender: Male	I am not here 我没在啊	Emm..I thought you came to Suzhou 嗯..还以为你来苏州了	Loc	{Loc: Jiangsu Suzhou}	E
Constell: Virgo Loc: Shaanxi Xi'an Gender: Male	Did you build it on the site? 你们工地建的?	Impossible! We are in Hancheng, but the brand is in Xi'an 不可能啦!我们在韩城，这块牌子在西安	Loc	{Loc: Shaanxi Hancheng}	C
Constell: Taurus Loc: Guangdong Gender: Male	I don't know how to fix the computer 我不知道怎么修电脑	Go to find your boyfriend ha ha 找你男人去哈哈	Gender	None	I
Constell: Gemini Loc: Fujian Gender: Female	What kind of food do you want? 你想要什么好吃的呀?	I want the Taiwan soy-braised pork 想吃台湾红烧肉	Loc	None	I

Table 1: Examples of KvPI dataset. These sentences are in Chinese, and we translated them into English. Constell and Loc are short for constellation and location. E, C, I denote Entailed, Contradicted, and Irrelevant, respectively.

2.3 Human Annotation

The definitions in Sec 2.2 are also applied in the human annotation process. We hire an annotation team to (1) review whether the response is profile-related, and (2) annotate the fine-grained information, including consistency labels, domains, and detailed attributes in each response. To ensure quality, each tuple is annotated by three people, and the annotation process lasts nearly four months.

In the annotation process, about 10K tuples are filtered out due to no profile-related information in their responses, and we obtain 140K valid tuples with explicit annotations of consistency relation.

2.4 Quality Control

To control the quality of the annotated dataset, we introduce different verification methods:

First, in the annotation process, we review 200 randomly sampled tuples every 10,000 annotations. We assign a "gold" label to each tuple and then decided whether the whole annotation batch should be accepted or re-annotated according to the disagreement rate. With tolerance to the different understandings of the dialogue response, we set an empirical acceptance threshold of disagreement rate to 10%. For the majority of annotated batches, the disagreement rate varies from 3% to 7%.

The second verification is conducted by paid annotators. Each consistency label is verified by two annotators. The tuples with a low inter-annotator agreement in their labels are directly discarded from the final dataset. Finally, we obtain 118,540 tuples in the KvPI dataset.

From the final dataset, we randomly sampled 2,000 profile-response pairs to two new annotators. These pairs are also annotated as entailed, contradicted, and irrelevant, as in the completed annotation process. Following Bowman et al. (2015), we calculated the Fleiss' Kappa among the previous labels and two new labels and obtained a kappa of 0.857, which means *almost perfect agreement* (Landis and Koch, 1977). This result shows that the completed annotation is of good quality.

3 The KvPI Dataset

We present some examples of the final KvPI dataset in Table 1. The dataset, together with trained models, will be open-sourced for public usage.

3.1 Dataset Organization

The KvPI dataset consists of single-turn conversations and profiles, labeled as entailed, contradicted, or irrelevant. Attributes in the dataset profiles come from three domains, including gender, location, and constellation. The profile is organized in a key-value format, for example, {gender: *female*, location: *Beijing*, constellation: *Leo*}.

Gender This domain includes responses that have evidence indicating they are from men or women. Both explicit gender evidence, such as

Domains	Entail	Contr	Irrelv	Len(E)	Len(C)	Len(I)	Train	Valid	Test	Overall
Gender	8,270	6,858	16,201	20.5	20.6	20.8	25,329	3,000	3,000	31,329
Location	18,468	17,777	28,759	15.8	15.9	17.5	53,004	6,000	6,000	65,004
Constell	6,376	6,365	9,466	14.5	14.6	16.7	18,207	2,000	2,000	22,207
Total	33,114	31,000	54,426	16.7	16.7	18.3	96,540	11,000	11,000	118,540

Table 2: Basic statistics of the KvPI dataset. We depict the statistics from the perspective of three domains. Entail, Contr, and Irrelv are short for Entailment(E), Contradiction(C), and Irrelevant(I), respectively.

"I am a girl", and implicit gender evidence, such as "I'm hanging out with my boyfriend", are included.

Location This domain includes responses talking about the locations. Besides the accurate matching of location, data in this domain also needs common sense reasoning, such as whether a city belongs to a province, as shown in the third example in Table 1.

Constellation This domain includes different responses that talk about the constellation. A good number of the responses contain more than one constellation word.

Both entailed and irrelevant cases in the KvPI dataset are directly obtained from the annotation results. To balance the number of cases in each relation, we collect the contradicted cases from two sources: (1) the annotated contradicted tuples, and (2) the rewritten entailed tuples. Possible reasons for the originally contradicted cases are that users may forget to update their profiles, or they are intended to present different information about themselves. Data from the first source accounts for about two-thirds of the total contradicted cases. The other part comes from entailed cases. Their profiles have been rewritten to different attributes, with a minimal edit-distance principle, so that they turn into contradicted. Cases from this source are treated as new data in the annotation process. Unqualified rewritten data is discarded.

3.2 Statistics

Table 2 summarizes the main statistics of the KvPI dataset. The first and third groups in Table 2 count the number of unique tuples in the dataset. Here a tuple refers to a group of data consisting of a key-value profile, a post, a dialogue response, as well as the corresponding domain, the annotated attribute, and the label of consistency relation. The tuple examples can be seen in Table 1. For the second group, it only calculates the average number of tokens in the dialogue responses.

4 Profile Consistency Identification

4.1 Problem Definition

To equip dialogue agents with the ability to identify consistency, we need to build a profile consistency identification model. This model learns to identify the relation of {entailed, contradicted, irrelevant} between a (profile, response) pair. Formally, our goal is to learn a mapping function $\mathcal{F}$, and $\mathcal{F}(P,R) \in \{e,c,i\}$, where P=$\{k_1 : v_1, ..., k_n : v_n\}$, $R = w_1, w_2, ..., w_m$. Here P denotes the key-value profile, and R denotes the response with m words. e, c, i denote the consistency relations.

4.2 Motivation

The main challenge of identifying profile consistency lies in how to model the key-value profiles effectively. Such structured profiles have a common dependency structure, which differs from the natural sentences. For example, from the profile { gender: *female*, location: *Beijing*, constellation: *Leo*}, we can clearly see three dependency relations: female → gender, Beijing → location, and Leo → constellation. Moreover, gender, location, and constellation will define the information in the *kv-profile*. Here we can see a hierarchical structure of the key-value profiles, as illustrated in Figure 2. More importantly, no matter how the values change, this structure will stay unchanged.

Although large pre-trained models such as BERT implicitly capture dependency information more or less (Clark et al., 2019), we argue that such implicit syntactic information may not be enough to support a powerful contextual representation for reasoning on the highly structured key-value profiles, according to the meaningless dependency parsing results generated by BERT on the structured profiles.

These observations motivate us to incorporate the explicit structure of profiles directly. To this end, we design the KvBERT, which integrates both language representation from BERT and structure representation from tree-LSTM (Zhu et al., 2015).

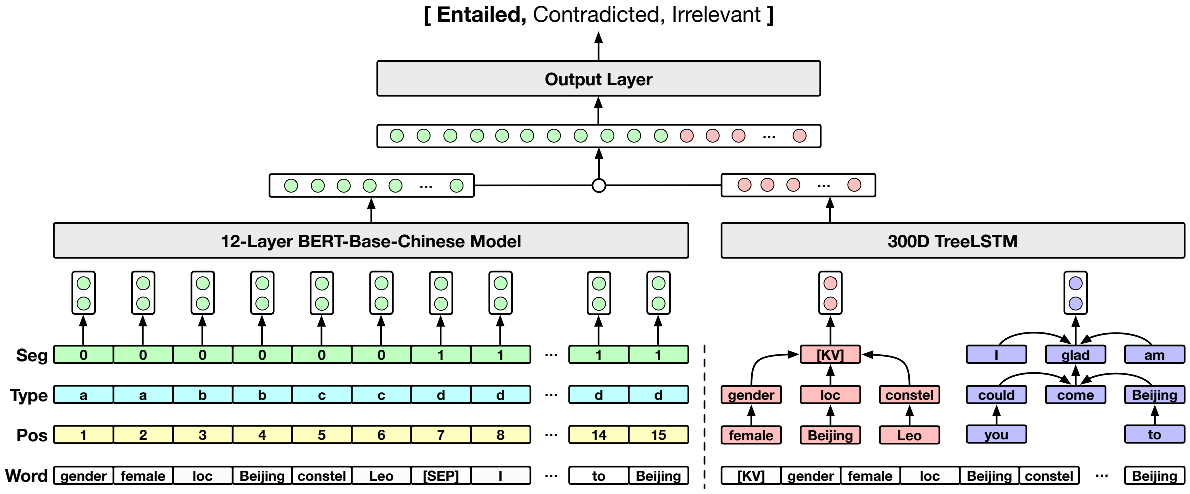

Figure 2: The overall framework of the KvBERT model. Examples in this figure: the key-value profile is { gender: *female*, location: *Beijing*, constellation: *Leo*}, and the dialogue response is "*I am glad you could come to Beijing*".

4.3 Model Brief

Figure 2 shows the overall framework of the KvBERT model. On the BERT side, we linearize the key-value pairs into a sequence and treating the responses as another sequence[2]. The input embedding is the sum of four embeddings, including an additional type embedding (Chen et al., 2020) to inform the model of different key-value pairs, as shown in Figure 2. Here we omit the well-known formulations of BERT (Devlin et al., 2019) for brevity. We can get a contextual representation for the linearized sequence through the BERT model.

On the tree-LSTM side, the profiles are parsed to predefined structure, as discussed in Sec 4.2. An example of this structure can be seen in the red part of the Figure 2. In parallel, the responses are passed to a trained parser to fetch the dependency structure. Then the tree-LSTM encodes two structures to corresponding embeddings. Three operations are performed to aggregate information from two embeddings: element-wise multiplication, element-wise difference, and concatenation. The aggregated embedding is followed up by a linear layer to form the final structure representation.

At last, the sentence representation and structure representation are concatenated to form the joint representation for the final linear output layer.

4.4 The Dependency Structures

In our model, the dependency structure for profiles is predefined, and for the response, it is obtained from a trained parser. To complete the structure in the profile, we add a special [KV] token on the top of the dependency structure of the profile. As a result, the [KV] token aggregates information from its child key-value nodes. In contrast, there is no universal dependency structure in the responses. To obtain the structures in the responses, we trained a parser on CDT5.0 (Chineses dependency treebank), achieving 90.72% and 88.38% unlabeled and labeled attachment score. All structure predictions are made in the data preprocessing stage.

A tree-LSTM unit encodes multiple child units or multiple descendant units in a recursive process. Due to the length limit, we recommend readers to get the details from Zhu et al. (2015). For both the predefined structures and the parsed structures, we apply the same depth-first encoding strategy, from every leaf node to the root node, to aggregate the structure information.

5 Experiments

In this section, we first evaluate the performance of the proposed KvBERT model on identifying profile consistency. After that, we test the trained KvBERT model on two downstream tasks, including a reranking task and a consistency prediction task, to analyze how well the proposed approach performs under practical applications.

5.1 Experiment Settings

In our experiments, we train the KvBERT based on the 12-layer BERT-Base-Chinese model, with an embedding and hidden dimension of 768. For the tree-LSTM, we set embedding size to 300 and

---

[2] Our data collection scheme ensures that all responses contain profile information, which frees the modeling of post.

Table 3: Evaluation results on the KvPI dataset. In brackets is the standard deviation of three runs, scaled by 10^{-3}.

output dimension to 50. The dimension of the final representation is 818. The tree-LSTM is firstly pre-trained on the KvPI dataset for 13 epochs and then jointly finetuned with BERT representations for 3 epochs. The KvBERT model is implemented in *PyTorch*. More setting details are in the appendix.

5.2 Identifying Profile Consistency

We compare the performance of a variety of baseline models on identifying profile consistency:

Feature-based classifier Our goal of setting this baseline was to better understand the difficulty of identifying profile consistency, rather than necessarily a state-of-the-art model. Here we choose SVM as the classifier, with unigram features and bigram features, i.e., **SVM+uni+bi**. Additionally, the overlaps between profile values and responses are extracted as another feature, which is the **SVM+uni+bi+overlap**.

Rnn-based NLI model ESIM (Chen et al., 2017) is a powerful natural language inference model, which enhanced the interactions in the LSTM. This model was applied in Welleck et al. (2019) and achieved the best results. Therefore, we set **ESIM** as the rnn baseline for our experiments.

Pretrained models Large pre-trained transformers have been shown effective for natural language understanding tasks. We choose the Generative Pre-trained Transformer, i.e. **GPT** (Radford et al., 2018), and Bidirectional Encoder Representations from Transformers, i.e. **BERT** (Devlin et al., 2019) as our pre-trained baselines. Chen et al. (2020) proposed a **TableBERT** model, which models structured table information within the BERT framework. We take this model as another pre-trained baseline. We did not explore other pre-trained models in this work, due to the expensive computational costs in preparing their Chinese models. We leave the exploration as future work.

Considering the previous works are designed for natural sentences, for the sake of a fair and thorough comparison, we use templates to convert the key-value profiles into natural sentences. The methods experimented on the converted dataset is marked by a suffix "**-template**". And the comparative experiments on the original KvPI dataset are marked by "**-kv**", which linearizes the original key-value profiles, the same as Sec 4.3. Other models are directly evaluated on the original KvPI dataset.

For evaluations, despite the whole dataset that includes all three domains, we are also interested in the model's performance on each individual domain[3]. We use **accuracy** (acc), which has been widely applied in the natural language inference tasks, to measure the overall performance on each domain. To have a better look at the model's ability on identifying different consistency relations, we also calculate the f1-score of three relations under the same domain, i.e., **entail-f1**, **contr-f1**, and **irrelv-f1**. The accuracy and f1-score are calculated by using toolkits from *sklearn*.

We report the averaged best results of three different runs on each domain in Table 3. With the explicit modeling of profile structures, our KvBERT achieves the best performance on all metrics across all domains. More importantly, KvBERT is the only model whose all metrics are over 90% on the KvPI test set, especially compared with strong pre-trained baselines. Moreover, we also obtain 3.1% absolute improvements on the overall accuracy to the latest TableBERT model (Chen et al., 2020).

We noticed an interesting phenomenon between the BERT-kv and BERT-template: the performance of BERT-template on all three individual domains are better than the BERT-kv's. Nevertheless, on the overall test set, their performances are entirely reversed. One possible reason is that the converted profile loses the structure information. Even for the powerful BERT model, this kind of information still affects the overall performance.

5.3 Testing on Downstream Tasks

Now that the KvBERT achieves good performance on the KvPI dataset, we want to test the abilities of the proposed approach further. Similar to the evaluations of pre-trained language models, we evaluate the abilities of our trained KvBERT model on two downstream tasks, with the assistance of human annotation.

Here we consider two types of dialogue models, i.e., retrieval model and generation model. We test the KvBERT on two tasks: (1) Reranking the top 20 responses from a retrieval model, to see whether the profile consistency is improved (Welleck et al., 2019). (2) Given the responses from state-of-the-art generative dialogue models, to see how well the KvBERT's consistency prediction agrees with the human annotation (Dziri et al., 2019).

Domains		Entail (%)	Contr (%)	Irrelv (%)
Gen	top-1	56.0 / 57.0	9.0 / 9.0	35.0 / 34.0
	top-5	43.2 / 51.0	9.2 / 7.8	47.6 / 41.2
Con	top-1	22.0 / 30.0	20.0 / 6.0	58.0 / 64.0
	top-5	29.8 / 32.4	18.4 / 8.2	51.8 / 59.4
Loc	top-1	10.0 / 11.0	33.0 / 11.0	57.0 / 78.0
	top-5	8.6 / 12.2	34.0 / 11.6	57.4 / 76.2

Table 4: Human annotations for the profile consistency of the retrieved responses **before / after** reranking.

To build the testbeds of different dialogue models, we use the Chinese PersonalDialog (Zheng et al., 2019) dataset, which consists of over 20 million dialogues from Weibo, together with diversified profile traits and interests tags of the user.

Further, we manually create 100 test samples for each domain, and we abbreviate the test set in this section as **Gen** (gender), **Loc** (location), and **Con** (constellation). Thus there are 300 test samples in total. Each test sample consists of a (profile, post) pair, where the attribute keys are the same as in the KvPI dataset. Moreover, we confirm that these posts will lead to domain-specific responses.

Task I: Reranking Retrieved Responses

We build the retrieval model using *pylucene*. To retrieve responses, we index both profiles and responses in the PersonalDialog dataset, with weights 0.15 and 0.85 for the profile and response, respectively. We retrieve the top 20 candidate responses for each testing sample, and then these responses are reranked by the trained KvBERT model, according to the order *Entailed >Irrelevant >Contradicted*. Within the same category, the model confidence will determine the order. Among the 20 responses from one test sample, the top 5 responses, both before and after reranking, are annotated by three people into entailed (Entail), contradicted (Contr), and irrelevant (Irrelv).

We report the statistics of annotation results in Table 4 and show some reranking examples in the appendix. Besides the entailed responses, the irrelevant ones are more acceptable than the contradicted ones. As we can see, the KvBERT reranking improves profile consistency, either by increasing the rate of entailment or by decreasing the rate of contradiction. The annotation results also concur with our intuition: selecting a proper response with the right location is difficult for the retrieval models.

---

[3] Models on each domain are trained separately.

	Gender				Constellation				Location			
	ent-f1	con-f1	irr-f1	κ	ent-f1	con-f1	irr-f1	κ	ent-f1	con-f1	irr-f1	κ
AR	97.0%	79.2%	69.6%	0.777	94.7%	78.8%	72.4%	0.744	94.3%	96.3%	90.9%	0.913
TT	96.7%	75.0%	66.7%	0.736	91.4%	72.2%	65.5%	0.659	90.7%	96.1%	69.6%	0.847

Table 5: F1-score of model prediction against human annotation, with Cohen's Kappa to measure the agreements.

Task II: Consistency Prediction

In this task, we want to test how well the KvBERT's consistency prediction agrees with the human annotation on generated responses. We implement two state-of-the-art profile-based dialogue generation models as the testbeds for this task, including the TransferTransfo (Wolf et al., 2019) (**TT**) and AttentionRouting (Zheng et al., 2020) (**AR**). Both models are based on pre-trained transformers. First, we pre-train two models on 4G Chinese news data and finetune them on the PersonalDialog dataset. Then we use the trained models to generate responses on the test data Gen, Con, Loc, respectively.

The collected responses are annotated into entailed, contradicted, and irrelevant by three annotators. The annotation instructions are the same as in Sec 2.2. In parallel, the KvBERT also predicts the relations between each profile and response.

We first report the f1-score of model prediction against the human annotation in Table 5. We also report Cohen's Kappa (Cohen, 1960) between human annotations and model prediction to measure their agreements directly. All metrics are calculated by *sklearn*. From the f1-scores, we can see that the model predictions are similar to the human annotations in most cases. And the κ coefficients show the good agreements more directly, where κ between 0.6 and 0.8 indicates *substantial agreement*, and over 0.8 indicates *almost perfect agreement* (Landis and Koch, 1977).

Responses from the generative models are in a different distribution from the training data, due to the model learning process. Still, the KvBERT obtains good agreements with humans. It shows the good generalization ability of the proposed method.

5.4 Effects of the Structure Information

Another important question is whether the structure information is always helpful. To analyze this, we sampled 9 treeLSTM checkpoints, with accuracy on the KvPI test set from 13.4% to 83.4%. The accuracy could be an indicator of how well the structure information has been captured. Then we trained 9 different KvBERT models with initialization from the 9 treeLSTMs and get final accuracies on the KvPI test set. We depict the treeLSTM accuracy and KvBERT accuracy, as well as a seventh-degree polynomial curve fitting the 9 data points, in Figure 3. And there is a performance baseline shown by the dashed horizontal line, which has no structure information.

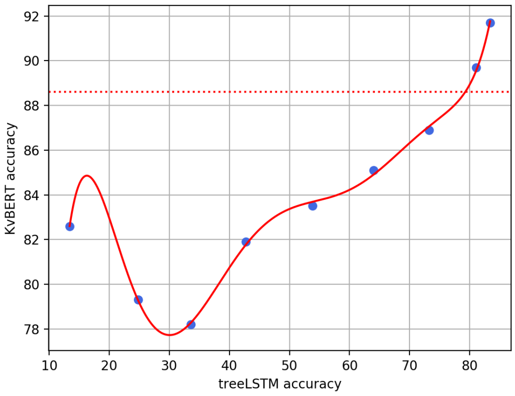

Figure 3: The red dashed line in the horizontal direction is the TableBERT accuracy, which has no structural information. The depicted curve is fitted by a seventh-degree polynomial.

As we can see, not all the structural information contributes to the final performance. When the treeLSTM is at a low accuracy, the performance of the KvBERT model is inferior to that of the baseline model. Especially when the accuracy of treeLSTM is lower than 30%, the final performance is even getting worse when the accuracy of treeLSTM grows. And only when the accuracy of treeLSTM is higher than about 80%, can the final performance be improved, as illustrated in Figure 3.

5.5 Reproducibility

The code, data, and trained model are available at https://github.com/songhaoyu/KvPI.

6 Related Work

This work is closely related to the researches in natural language inference (Bowman et al., 2015). NLI aims to determine whether a natural language hypothesis can be inferred from a natural language premise (Bowman et al., 2015; Williams et al., 2018; Khot et al., 2018; Welleck et al., 2019). Besides the natural language evidence, Suhr et al. (2017) and Suhr et al. (2019) proposed to use images as the evidence for statement verification under the multi-modal setting. A more recent related work is the Chen et al. (2020), who proposed to use semi-structured Wikipedia tables as evidence. The difference between our work and Chen et al. (2020) is noticeable: open-domain dialogues have unique language patterns, and the key-value profiles are highly structured, as analyzed in Sec 4.2. To the best of our knowledge, this is the first work that explores the identification of consistency between dialogue responses and structured profiles.

Another line of research related to this work is the personalized dialogue generation task (Zhang et al., 2018; Qian et al., 2018; Zheng et al., 2019; Song et al., 2020a,b). This task seeks to improve personality consistency by incorporating persona information in the generated responses. For this purpose, several personalized dialogue datasets have been introduced in recent years, such as PersonaChat (Zhang et al., 2018) and PersonalDialog (Zheng et al., 2019). These datasets successfully inform models of how to incorporate attribute related information in the responses, but still can not teach models how to identify the consistency relations between their response and profile.

7 Conclusion and Discussion

In this work, we introduce a large-scale annotated dataset to facilitate the study of profile consistency identification in open-domain dialogues. We leverage the structure information in profiles to enrich the BERT representations and obtain significant performance improvements over strong baselines. We further test the proposed method on two downstream tasks. Evaluation results show the effectiveness of the proposed approach.

We believe KvPI will be a useful resource for the research of open-domain dialogue consistency. Although there has been a lot of dialogue generation models in this field, most of them still can't understand the consistency relationship in the generation process. One of the major bottlenecks is the lack of data. Because the KvPI dataset has paired key-value profiles and dialogues, it can also be a high-quality resource for personalized dialogue generation tasks. Furthermore, because we have fine-grained consistency labels, this dataset also provides an opportunity to leverage natural language understanding models to assist dialogue generation models. We hope that the data will aid training dialogue agents to be more consistent.

The red box indicates the information which leads to the contradiction. In the responses after reranking, we can see that the more consistent responses are in the front, which accords with our strategy: *entailed* > *irrelevant* > *contradicted*.

An Element-aware Multi-representation Model for Law Article Prediction

Abstract

Existing works have proved that using law articles as external knowledge can improve the performance of the Legal Judgment Prediction. However, they do not fully use law article information and most of the current work is only for single label samples. In this paper, we propose a Law Article Element-aware Multi-representation Model (LEMM), which can make full use of law article information and can be used for multi-label samples. The model uses the labeled elements of law articles to extract fact description features from multiple angles. It generates multiple representations of a fact for classification. Every label has a law-aware fact representation to encode more information. To capture the dependencies between law articles, the model also introduces a self-attention mechanism between multiple representations. Compared with baseline models like TopJudge, this model improves the accuracy of 5.84%, the macro F1 of 6.42%, and the micro F1 of 4.28%.

1 Introduction

Legal Judgment Prediction(LJP) aims to predict a law case's judgment results given a fact description text. LJP mainly contains three sub-tasks, law article prediction, charge prediction, and terms of penalty prediction. In the civil law system, the correct prediction of law article prediction can help improve the accuracy of charge prediction(Luo et al., 2017). The investigation of law article prediction has significant meaning for LJP.

The law article prediction aims to predict the case's relevant law articles given the fact description (hereinafter abbreviated fact) of a case. In the law article prediction, law articles play an essential role as external information. Luo et al. (2017) uses some candidate law articles to improve the performance of the charge prediction task. However, current researches have two main limitations. One is that certain law articles are considerably similar which makes them difficult to distinguish. Using the representation of overall law articles to extract fact information is not intuitive enough. Another one is that most of the works (Zhong et al., 2018a; Yang et al., 2019; Liu et al., 2019) only predict on single label examples. Meanwhile, in the actual judgment, many cases contain multiple relevant law articles(Zhong et al., 2018b).

Human judge process mainly compares the elements of law article with the case description(Hu et al., 2018), such as the subject of crime (person or specific identity), the object of the crime (person or thing), the purpose and motive of the crime, the harmful behavior, the adverse result, and the crime scene (time or place).

To make full use of the law article information and reduce the confusion in distinguishing different law articles, we have designed a Law Article Element-aware Multi-representation Model (LEMM). LEMM is more related to human cognitive logic and more intuitive based on the law element. We call it LEMM because it extracts fact features specifically by using law article elements and generates multiple law-aware fact representations. Each label has a particular fact representation in classification, which benefits the law article prediction task. Using one vector to distinguish correct law article is inappropriate because the number of relevant law articles is more than 100. Considering law-aware fact representation takes law article as an individual unit, and there are some dependencies between law articles, we capture the relationship between them via the self-attention mechanism. Our LEMM model makes an excellent performance in all evaluation indicators.

Law article

Article 165 of the Criminal Law: [crime of illegally operating similar businesses] The directors and managers of state-owned companies and enterprises use the convenience of their positions to run their own businesses or for others to run businesses similar to the companies and enterprises they serve, and obtain illegal benefits. A fixed term of imprisonment of not more than three years or detention shall be imposed concurrently or with a single fine; if the amount is particularly large, it shall be imprisoned for more than three years but less than seven years and fined.

labeled information

number: 165
charge 1:
charge name: crime of illegally operating similar businesses
crime subject: directors and managers of state-owned companies and enterprises
crime object: the same kind of business as the company or enterprise
purpose and motive: obtain illegal benefits
harmful behavior: operate the same kind of business on your own or for others
harmful result: obtain illegal benefits, huge amount
crime occasion: None
supplementary explanation: None

Figure 1: Labeled Law Article

2 Structurally Labeling the Law Articles

Judging whether the law article and case are relevant mainly depends on whether the key elements (including the subject, object, purpose, motive, the harmful behavior, the result of the harm, and the circumstances of the crime) are consistent with the law. Therefore, we divide the law articles into seven elements: 1. the crime subject, 2. the crime object, 3. the purpose and motive of the crime, 4. the harmful behavior, 5. the harmful result, 6. the crime occasion and 7. the supplementary explanation. Since a law article may contain multiple crimes, such law article has multiple groups of elements which correspond to different crimes. As shown in Figure 1, we first divide the content of the law according to the crime and then label the various elements. For elements that are not specified or restricted, we mark them as None. We label 183 candidate law articles of the CAIL dataset (Xiao et al., 2018), which contains a total of 202 crimes.

3 LEMM Model

The fact is a word sequence $\{w_1, w_2, \ldots, w_m\}$. The model uses labeled law articles to help extract features of the fact. The labeled law articles contain the name of crime and the elements of the crime. The name of crime is a word sequence: $\{w_1, w_2, \ldots, w_n\}$. The elements of crime contain seven word sequences: $\{ele_1, ele_2, \ldots, ele_7\}$, where ele_i is $\{w_1, w_2, \ldots, w_{ik}\}$.

Our model contains five components:

Encoder: encode law article elements and fact.

Feature Extraction: use element representations to extract word-level and document-level fact representation by attention mechanism.

Fusion: fuse the word-level and document-level fact representation to law-aware representations.

Relation Extraction: extract the dependencies between law articles by self-attention.

Classification: classify whether the law article is relevant.

3.1 Encoder

The Encoder component contains two encoders, which are element encoder and fact encoder.

3.1.1 Element Encoder

Element Encoder uses BiGRU (Cho et al., 2014) to encoder crime name and crime elements. It takes the hidden state of the last token as the representation of the input. This process is shown as below:

$$ch = BiGRU_{crime}(\{w_1, w_2, \ldots, w_n\}) \quad (1)$$

$$ele_i = BiGRU_i(\{w_1, w_2, \ldots, w_{ik}\}) \quad (2)$$

3.1.2 Fact Encoder

Fact Encoder also uses BiGRU. It takes the hidden state of the last token as document level representation of the fact F and each hidden state as corresponding word representation x_i.

$$F = \{\overleftarrow{h_0}; \overrightarrow{h_m}\} \quad (3)$$

$$x_i = \{\overleftarrow{h_i}; \overrightarrow{h_i}\} \quad (4)$$

$$\overrightarrow{h_i}, \overleftarrow{h_i} = \overrightarrow{GRU}(\overrightarrow{h_{i-1}}, e_i), \overleftarrow{GRU}(\overleftarrow{h_{i+1}}, e_i) \quad (5)$$

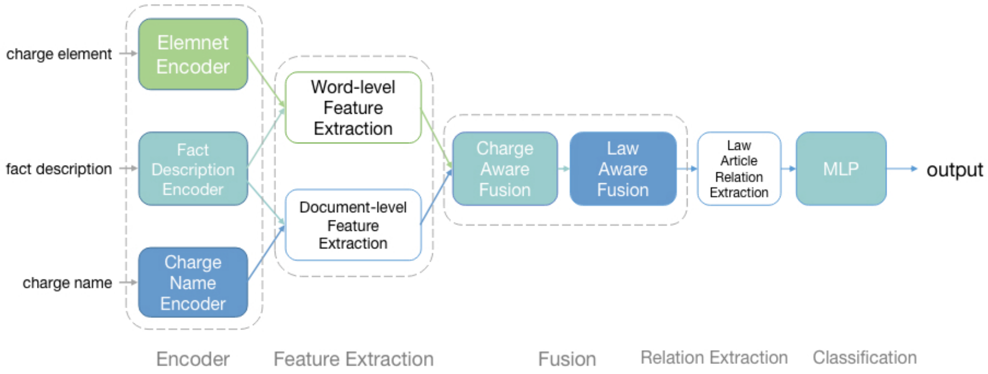

Figure 2: Overview of our LEMM for law article prediction

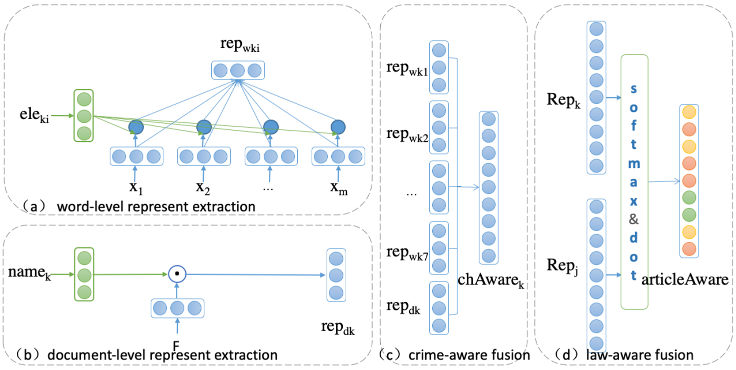

Figure 3: The components of LEMM for law article prediction

3.2 Feature Extraction

Different from Luo et al. (2017) which uses fact information to extract features of law article, we use law elements to extract features of fact and generate multiple representations for one fact. Feature Extraction contains word-level features and document-level features.

3.2.1 Word-level Feature Extraction

We use each law article element as a query to generate word-level representations of the fact by attention mechanism. The calculation is shown as below, where rep_{wi} is the word-level representation of fact extracted by ele_i and f is a non-linear function.

$$\alpha_{ij} = \frac{exp(f_{elei}(ele_i^T) f_x(x_j))}{\sum_{k=1}^{m} exp(f_{elei}(ele_i^T) f_x(x_k))} \tag{6}$$

$$rep_{wi} = \sum_{j=1}^{m} \alpha_{ij} x_j \tag{7}$$

3.2.2 Document-level Feature Extraction

To further strengthen the interaction between the fact and the law articles, we also use crime name representations to extract the document-level features of the fact rep_d via element-wise product.

$$rep_d = f_{ch}(ch) \cdot f_F(F) \tag{8}$$

3.3 Fusion

The Fusion is used to fuse word-level representation and document-level representation. Considering the word-level representations are based on the crime element, the document-level representations are affected by crime name, and crime belongs to law article, we do the crime-level Fusion firstly and then do the law article-level Fusion.

3.3.1 Crime-aware Fusion

We use linear fusion to fuse crime name and the seven elements corresponding to the crime. The document-level case description representation generated by the crime name and the word-level case description representation generated by the elements of the crime are concatenated and put into a linear function for fusion.

$$chAware = f([rep_d; rep_{w1}; \ldots; rep_{w7}]) \tag{9}$$

f is a linear function and $[;]$ means concatenate. $chAware$ is crime-aware representation.

3.3.2 Law-aware Fusion

The Law-aware Fusion is to fuse crime-aware representation based on a law article unit. Some of the law articles only contain one crime, so that we take the crime-aware representation as the article-aware representation.

$$articleAware_s = chAware_u \tag{10}$$

$articleAware$ is the fact representation generated by k-th law article and $chAware_u$ is the fact representation generated by u-th crime. The $crime_u$ belongs to $lawarticle_s$ and the $lawarticle_s$ only has one crime u in content.

When multiple crimes occur in one law article, we hope to select the prominent features of crime-aware presentation. Considering that $argmax$ will cause for failing to return gradients, we use $softmax$ instead.

$$s_{mvt} = \frac{exp(chAware_{vt})}{\sum_{i \in m} exp(chAware_{it})} \tag{11}$$

$$articleAware_m = \sum_{i \in m} s_i \cdot chAware_i \tag{12}$$

$chAware_{vt}$ is the t-th position of the v-th crime-aware representation vector. s_{mvt} is the $softmax$ score of the t-th position of the v-th crime-aware representation.

3.4 Relation Extraction

Considering the entire process from the Encoder to the Feature Extraction, and then to the Fusion, each law article is regarded as an independent individual. So far we have not taken the interaction between law articles into consideration. To extract the interaction between law articles , we use the self-attention mechanism (Vaswani et al., 2017) to calculate the interaction between them.

$$q_i, k_i, v_i = W^T_{(q,k,v)} articleAware_i + b_{(q,k,v)} \tag{13}$$

$$\beta_{ij} = \frac{exp(q_j^T k_i)}{\sum_{n=1}^{|k|} exp(q_j^T k_n)} \tag{14}$$

$$input_i = \sum_{j=1}^{|k|} \beta_i v_j \tag{15}$$

$input_i$ is the new fact representation used to discriminate whether the i-th law article is relevant.

3.5 Classification

We have generated multiple article-aware representations for one fact, and each representation $input_i$ corresponds to a law article. We will use these representations to make classification respectively. Each label has a vector for prediction, which helps to retain more feature information. Unlike other multi-label classifications, where a threshold selects the $softmax$ output results, we use multiple binary classifications.

$$out_i = sigmoid(MLP(input_i)) \tag{16}$$

MLP is a multi-layer perceptron.

4 Experiments

This part includes data selection, experimental parameter setting, baseline model, and detailed experimental results.

4.1 Dataset and Evaluation

We use CAIL 2018 small dataset (Xiao et al., 2018). CAIL(Chinese AI and Law Challenge) is a criminal case dataset for competition released by the Supreme People's Court of China. The details of CAIL can be found in Xiao et al. (2018). Considering the serious long-tail distribution of the sample in the dataset, we only select the samples with more than 300 occurrences of the relevant law. To study the model's performance on low-frequency samples, we also conducted experiments on the complete small dataset.

We use the correct rate, micro/macro accuracy, precision, recall, and F1 as evaluation indicators.

4.2 Experimental Parameter Setting

We use the $Thulac$ (Li and Sun, 2009) tool to segment words, and use $CBOW$ (Rong, 2014) to train word vector on the training data and law article content. The dimension of the word vector is 300. Due to the enormous length of the fact, we only keep the first 256 words of fact. The hidden size is 512. The optimizer is Adam, and the learning rate is 2e-4.

4.3 Experimental Results

We compared our model with LSTM(Cheng et al., 2016), BiLSTM, CNN(Kim, 2014), and the current state-of-the-art TopJudge model. The hidden size is 512, the max word length is 256, the kernel size is [3, 3, 3], and the pooling size is [3, 3, 3].

Model	**Acc**	**Macro**			**Micro**		
		P	**R**	**F1**	**P**	**R**	**F1**
TopJudge	71.41	81.20	73.88	76.04	80.31	79.40	79.85
CNN	71.36	78.60	73.88	75.54	79.32	78.89	79.10
LSTM	72.08	80.51	76.58	77.66	79.87	80.42	80.14
BiLSTM	72.27	79.45	78.01	78.07	78.59	81.81	80.17
LEMM	**77.25**	**83.91**	**82.11**	**82.46**	**83.73**	**84.55**	**84.13**

Table 1: Results on CAIL 2018 small (filtered)

Model	**Acc**	**Macro**			**Micro**		
		P	**R**	**F1**	**P**	**R**	**F1**
TopJudge	65.45	61.11	46.65	50.17	78.13	72.47	75.19
CNN	67.18	62.55	51.02	53.91	77.66	75.20	76.41
LSTM	68.99	64.52	56.71	58.57	77.05	78.26	77.65
BiLSTM	70.32	65.07	59.63	60.51	76.73	80.53	78.58
LEMM	**72.13**	**73.53**	**61.21**	**64.69**	**81.47**	**81.65**	**81.56**

Table 2: Results on CAIL 2018 small (whole)

We tested our model on the complete and filtered CAIL small dataset. The experimental results are shown in Tabel 1 and Tabel 2. The experiment results show:

(1) Our model has achieved outstanding performance in all evaluation indicators. Compared with TopJudge, our model has achieved 12.42% and 3.34% improvement in macro accuracy and micro accuracy respectively, and 14.56% and 9.18% improvement in macro recall and micro recall respectively.

(2) The performance of TopJudge(current state-of-the-art model) on the two datasets is worse than that of LSTM and BiLSTM. Base on the result, we suspect that joint learning of TopJudge's three subtasks causes more error propagation, and terms of penalty prediction is greatly affected by external factors.

4.4 Ablation Experiment

We compared the LEMM model with some variant models on the screened dataset. The experimental results are shown in Tabel 3. -R means to remove the law article relationship extraction module. The model fact-art puts the entire word sequence of the law article into BiGRU for encoding and use the law article representation to extract features of the fact.

Model	**Acc**	**Macro**			**Micro**		
		P	**R**	**F1**	**P**	**R**	**F1**
LEMM	**77.25**	**83.91**	**82.11**	**82.46**	**83.73**	**84.55**	**84.13**
- R	75.85	85.13	78.77	81.18	84.48	82.93	83.70
fact-art	72.68	83.05	79.66	80.62	82.06	82.88	82.47

Table 3: Ablation Experiment Results

The ablation experiment shows that the law article relationship significantly contributes to the improvement of the accuracy rate and recall rate. Nevertheless, the precision of the model has been slightly dropped with law article relationship. There might be some noise information in extracting the relationships, which affects the accuracy of the model.

The performance has a sharp drop without manual labeling law article elements. This verifies the labeled law article information is useful in extracting facts.

5 Conclusion

We propose a model that predicts relevant law articles on multi-label samples by simulating the human judging process. Our proposed LEMM model uses elements of the manually labeled law articles to generate multiple representations of a fact. It uses self-attention to capture dependencies between law articles and makes a unique representation for each candidate label for prediction. The experiments verify that the element-aware multi-representation can better extract features of the factual information and the dependencies between law articles are beneficial to the law article prediction task. The model achieves state-of-the-art performance in benchmark datasets. It also fills the gap between experimental and practical applications on multi-label samples.

Abstract

Knowledge graph reasoning is a critical task in natural language processing. The task becomes more challenging on temporal knowledge graphs, where each fact is associated with a timestamp. Most existing methods focus on reasoning at past timestamps and they are not able to predict facts happening in the future. This paper proposes Recurrent Event Network (RE-NET), a novel autoregressive architecture for predicting future interactions. The occurrence of a fact (event) is modeled as a probability distribution conditioned on temporal sequences of past knowledge graphs. Specifically, our RE-NET employs a recurrent event encoder to encode past facts, and uses a neighborhood aggregator to model the connection of facts at the same timestamp. Future facts can then be inferred in a sequential manner based on the two modules. We evaluate our proposed method via link prediction at future times on five public datasets. Through extensive experiments, we demonstrate the strength of RE-NET, especially on multi-step inference over future timestamps, and achieve state-of-the-art performance on all five datasets[1].

1 Introduction

Knowledge graphs (KGs), which store real-world facts, are vital in various natural language processing applications (Bordes et al., 2013; Schlichtkrull et al., 2018; Kazemi et al., 2019). Due to the high cost of annotating facts, most knowledge graphs are far from complete, and thus predicting missing facts (a.k.a., knowledge graph reasoning) becomes an important task. Most existing efforts study reasoning on standard knowledge graphs, where each fact is represented as a triple of subject entity, object entity and the relation between them. However, in practice, each fact may not be true forever, and hence it is useful to associate each fact with a timestamp as a constraint, yielding a temporal knowledge graph (TKG). Fig. 1 shows example subgraphs of a temporal knowledge graph. Despite the ubiquitousness of TKGs, methods for reasoning over such kind of data are relatively unexplored.

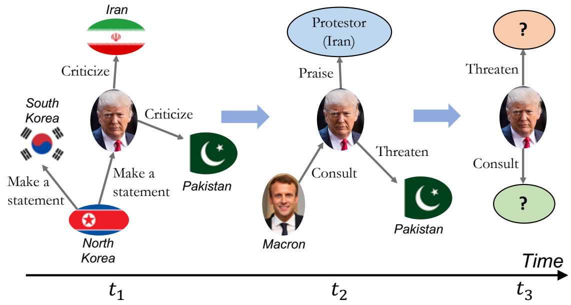

Figure 1: **Example temporal knowledge subgraphs.** Each edge or interaction between entities is associated with temporal information and a set of interactions build a multi-relational graph at each time. Our task is to predict interactions and build graphs at future times.

Given a temporal knowledge graph with timestamps varying from t_0 to t_T, TKG reasoning primarily has two settings - *interpolation* and *extrapolation*. In the *interpolation* setting, new facts are predicted for time t such that $t_0 \leq t \leq t_T$ (García-Durán et al., 2018; Leblay and Chekol, 2018; Dasgupta et al., 2018). In contrast, *extrapolation* reasoning, as a less studied setting, focuses on predicting new facts (*e.g.*, unseen events) over timestamps t that are greater than t_T (*i.e.*, $t > t_T$). The extrapolation setting is of particular interests in TKG reasoning as it helps populate the knowledge graph over future timestamps and facilitates forecasting emerging events (Muthiah et al., 2015; Phillips et al., 2017; Korkmaz et al., 2015).

Recent attempts to solve the extrapolation TKG reasoning problem are Know-Evolve (Trivedi et al., 2017) and its extension DyRep (Trivedi

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6669–6683,
November 16–20, 2020.

et al., 2019), which predict future events assuming ground truths of the preceding events are *given* at inference time. As a result, these methods are unable to predict events sequentially *over future timestamps* without ground truths of the preceding events–*i.e.*, a practical requirement when deploying such reasoning systems for event forecasting (Morstatter et al., 2019). Moreover, these approaches do not model *concurrent events* occurring within the same time window (e.g., a day, or 12 hours), despite their prevalence in real-world event data (Boschee et al., 2015; Leetaru and Schrodt, 2013). Thus, it is desirable to have a principled method that can extrapolate graph structures over future timestamps by modeling the concurrent events within a time window as a *local* graph.

To this end, we propose an autoregressive architecture, called Recurrent Event Network (RE-NET), for modeling temporal knowledge graphs. Key ideas of RE-NET are based on: (1) predicting future events over multiple time stamps can be formulated as a sequential and multi-step inference problem; (2) temporally adjacent events may carry related semantics and informative patterns, which can further help predict future events (i.e., *temporal information*); and (3) multiple events may co-occur within the same time window and exhibit structural dependencies between entities (i.e., *local graph structural information*).

Given these observations, RE-NET defines the joint probability distribution of all events in a TKG in an autoregressive fashion. The probability distribution of the concurrent events at the current time step is conditioned on all the preceding events (see Fig. 2 for an illustration). Specifically, a *recurrent event encoder* summarizes information of the past event sequences, and a *neighborhood aggregator* aggregates the information of concurrent events within the same time window. With the summarized information, our decoder defines the joint probability of a current event. Inference for predicting future events can be achieved by sampling graphs over time in a sequential manner.

We evaluate our proposed method on five public TKG datasets via a temporal (extrapolation) link prediction task, by testing the performance of multi-step inference over time. Experimental results demonstrate that RE-NET outperforms state-of-the-art models of both static and temporal knowledge graph reasoning, showing its better capability to model temporal, multi-relational graph data. We further show that RE-NET can perform effective multi-step inference to predict unseen entity relationships in a distant future.

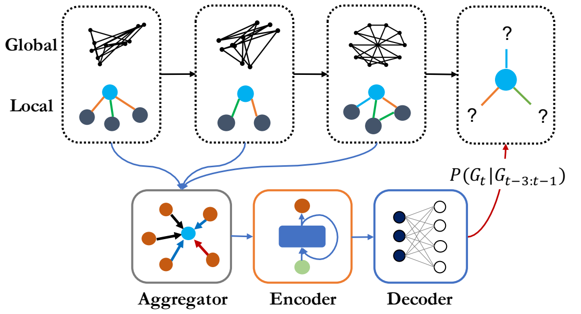

Figure 2: **Illustration of the Recurrent Event Network architecture.** The aggregator encodes the global graph structure and the local neighborhood, capturing global and local information respectively. The recurrent event encoder updates its state with the sequence of encoded representations of graph structures. The MLP decoder defines the probability of a current graph.

2 Problem Formulation

We first describe notations for building our model and problem definition, and then we define the joint distribution of temporal events.

Notations and Problem Definition. We consider a *temporal knowledge graph* as a multi-relational, directed graph with time-stamped edges between nodes (entities). An *event* is defined as a time-stamped edge, *i.e.*, (subject entity, relation, object entity, time) and is denoted by a quadruple $(\mathrm{s}, \mathrm{r}, \mathrm{o}, t)$ or $(\mathrm{s}_t, \mathrm{r}_t, \mathrm{o}_t)$. We denote a set of events at time t as G_t. In our setup, the timestamps are discrete integers and used for the relative order of graphs or events. A TKG is built upon *a sequence of event quadruples* ordered ascending based on their timestamps, *i.e.*, $\{G_t\}_t = \{(\mathrm{s}_i, \mathrm{r}_i, \mathrm{o}_i, t_i)\}_i$ $(t_i < t_j, \forall i < j)$, where each time-stamped edge has a direction pointing from the subject entity to the object entity.[2] The goal of *learning generative models of events* is to learn a distribution $p(G)$ over TKGs, based on a set of observed event sets $\{G_1, ..., G_t\}$.

Approach Overview. The key idea of our approach is to learn temporal dependency from the sequence of graphs and local structural dependency from the neighborhood (Fig. 2). Formally, we represent TKGs as sequences, and then build an autoregressive generative model on the sequences. To this

---

[2] The same triple $(\mathrm{s}, \mathrm{r}, \mathrm{o})$ may occur multiple times in different timestamps, yielding different event quadruples.

end, RE-NET defines the joint probability of concurrent events (or a graph), which is conditioned on all the previous events. Specifically, RE-NET consists of a Recurrent Neural Network (RNN) as a recurrent event encoding module and a neighborhood aggregation module to capture the information of graph structures. We first start with the definition of joint distribution of temporal events.

Modeling Joint Distribution of Temporal Events. We define the joint distribution of all the events $G = \{G_1, ..., G_T\}$ in an autoregressive manner. Basically, we decompose the joint distribution into a sequence of conditional distributions, $p(G_t|G_{t-m:t-1})$), where we assume the probability of the events at a time step, G_t, depends on the events at the previous m steps, $G_{t-m:t-1}$. For each conditional distribution $p(G_t|G_{t-m:t-1})$, we further assume that the events in G_t are mutually independent given the previous events $G_{t-m:t-1}$. In this way, the joint distribution can be rewritten as follows:

$$\begin{aligned} p(G) &= \prod_t \prod_{(\mathrm{s}_t,\mathrm{r}_t,\mathrm{o}_t)\in G_t} p(\mathrm{s}_t, \mathrm{r}_t, \mathrm{o}_t|G_{t-m:t-1}) \\ &= \prod_t \prod_{(\mathrm{s}_t,\mathrm{r}_t,\mathrm{o}_t)\in G_t} p(\mathrm{s}_t|G_{t-m:t-1}) \cdot p(\mathrm{r}_t|\mathrm{s}_t, G_{t-m:t-1}) \\ &\qquad\qquad \cdot p(\mathrm{o}_t|\mathrm{s}_t, \mathrm{r}_t, G_{t-m:t-1}). \end{aligned} \quad (1)$$

From these probabilities, we generate triplets as follows. Given all the past events $G_{t-m:t-1}$, we first sample a subject entity s_t through $p(\mathrm{s}_t|G_{t-m:t-1})$. Then we generate a relation r_t with $p(\mathrm{r}_t|\mathrm{s}_t, G_{t-m:t-1})$, and finally the object entity o_t is generated by $p(\mathrm{o}_t|\mathrm{s}_t, \mathrm{r}_t, G_{t-m:t-1})$.[3]

Next, we introduce how these probabilities are defined and parameterized in our method.

3 Recurrent Event Network

In this section, we introduce our proposed method, Recurrent Event Network (RE-NET). RE-NET consists of a Recurrent Neural Network (RNN) as a recurrent event encoder (Sec. 3.1) for temporal dependency and a neighborhood aggregator (Sec. 3.2) for graph structural dependency. We also discuss parameter learning of RE-NET and define multi-step inference for distant future by sampling intermediate graphs in a sequential manner (Sec. 3.3).

3.1 Recurrent Event Encoder

To parameterize the probability for each event, RE-NET introduces a set of *global* representations as well as *local* representations. The global representation $\boldsymbol{H}_t$ summarizes the global information from the entire graph until time stamp t, which reflects the global preference on the upcoming events. In contrast, the local representations focus more on each subject entity s or each pair of subject entity and relation (s, r), which capture the knowledge specifically related to those entities and relations. We denote the above local representations as $\boldsymbol{h}_t(\mathrm{s})$ and $\boldsymbol{h}_t(\mathrm{s}, \mathrm{r})$, respectively. The global and local representations capture different aspects of knowledge from the knowledge graph, which are naturally complementary, allowing us to model the generative process of the graph in a more effective way.

Based on the above representations, RE-NET parameterizes $p(\mathrm{o}_t|\mathrm{s}, \mathrm{r}, G_{t-m:t-1})$ in the following way:

$$p(\mathrm{o}_t|\mathrm{s}, \mathrm{r}, G_{t-m:t-1}) \propto \exp\left([\boldsymbol{e}_\mathrm{s} : \boldsymbol{e}_\mathrm{r} : \boldsymbol{h}_{t-1}(\mathrm{s}, \mathrm{r})]^\top \cdot \boldsymbol{w}_{\mathrm{o}_t}\right), \quad (2)$$

where $\boldsymbol{e}_\mathrm{s}, \boldsymbol{e}_\mathrm{r} \in \mathbb{R}^d$ are learnable embedding vectors specified for subject entity s and relation r. $\boldsymbol{h}_{t-1}(\mathrm{s}, \mathrm{r}) \in \mathbb{R}^d$ is the local representation for (s, r) obtained at time stamp $(t-1)$. Intuitively, $\boldsymbol{e}_\mathrm{s}$ and $\boldsymbol{e}_\mathrm{r}$ can be understood as static embedding vectors for subject entity s and relation r, whereas $\boldsymbol{h}_{t-1}(\mathrm{s}, \mathrm{r})$ is dynamically updated at each time stamp. By concatenating both the static and dynamic representations, RE-NET can effectively capture the semantic of (s, r) up to time stamp $(t-1)$. Based on that, we further compute the probability of different object entities o_t by passing the encoding into our multi-layer perceptron (MLP) decoder. We define the MLP decoder as a linear softmax classifier parameterized by $\{\boldsymbol{w}_{\mathrm{o}_t}\}$.

Similarly, we define probabilities for relations and subjects as follows:

$$p(\mathrm{r}_t|\mathrm{s}, G_{t-m:t-1}) \propto \exp\left([\boldsymbol{e}_\mathrm{s} : \boldsymbol{h}_{t-1}(\mathrm{s})]^\top \cdot \boldsymbol{w}_{\mathrm{r}_t}\right), \quad (3)$$

$$p(\mathrm{s}_t|G_{t-m:t-1}) \propto \exp\left(\boldsymbol{H}_{t-1}^\top \cdot \boldsymbol{w}_{\mathrm{s}_t}\right), \quad (4)$$

where $\boldsymbol{h}_{t-1}(\mathrm{s})$ focuses on the local information about s in the past, and $\boldsymbol{H}_{t-1} \in \mathbb{R}^d$ is a vector representation to encode global graph structures $G_{t-1:t-m}$. To predict what relations a subject entity will interact with $p(\mathrm{r}_t|\mathrm{s}, G_{t-m:t-1})$, we treat the static representation $\boldsymbol{e}_\mathrm{s}$ as well as the dynamic representation $\boldsymbol{h}_{t-1}(\mathrm{s})$ as features, and feed them into a multi-layer perceptron (MLP) decoder parameterized by $\boldsymbol{w}_{\mathrm{r}_t}$. Besides, to predict the distribution of subject entities at time stamp t (i.e., $p(\mathrm{s}_t|G_{t-m:t-1})$), we treat the global representation

---

[3] We can also first sample an object entity in this process. Details are omitted for brevity.

$\boldsymbol{H}_{t-1}$ as a feature, as it summarizes the global information from all the past graphs until time stamp $t-1$, which reflects the global preference on the upcoming events at time stamp t.

The global representation $\boldsymbol{H}_t$ is expected to preserve the global information about all the graphs up to time stamp t. The local representations $\boldsymbol{h}_t(\mathrm{s},\mathrm{r})$ and $\boldsymbol{h}_t(\mathrm{s})$ emphasize more on the local events related to each entity and relation. Thus we define them as follows:

$$\boldsymbol{H}_t = \mathrm{RNN}^1(g(G_t), \boldsymbol{H}_{t-1}), \tag{5}$$

$$\boldsymbol{h}_t(\mathrm{s},\mathrm{r}) = \mathrm{RNN}^2(g(\mathrm{N}_t^{(\mathrm{s})}), \boldsymbol{H}_t, \boldsymbol{h}_{t-1}(\mathrm{s},\mathrm{r})), \tag{6}$$

$$\boldsymbol{h}_t(\mathrm{s}) = \mathrm{RNN}^3(g(\mathrm{N}_t^{(\mathrm{s})}), \boldsymbol{H}_t, \boldsymbol{h}_{t-1}(\mathrm{s})), \tag{7}$$

where g is an aggregate function which will be discussed in Section 3.2 and $\mathrm{N}_t^{(\mathrm{s})}$ stands for all the events related to s at the current time step t. We leverage a recurrent model RNN (Cho et al., 2014) to update them. The global representation takes the global graph structure $g(G_t)$ as an input. $g(G_t)$ is an aggregation over all the events G_t at time t. We define $g(G_t) = \max(\{g(\mathrm{N}_t^{(s)})\}_s)$, which is an element-wise max-pooling operation over all $g(\mathrm{N}_t^{(\mathrm{s})})$. The $g(\mathrm{N}_t^{(\mathrm{s})})$ captures the local graph structure for subject entity s. The local representations are different from the global representations in two ways. First, the local representations focus more on each entity and relation, and hence we aggregate information from events $\mathrm{N}_t^{(\mathrm{s})}$ that are related to the entity. Second, to allow RE-NET to better characterize the relationships between different entities, we treat the global representation $\boldsymbol{H}_t$ as an extra feature in the definition, which acts as a bridge to connect different entities.

In the next section, we introduce how we design g in RE-NET.

3.2 Neighborhood Aggregators

In this section, we first introduce two simple aggregation functions: a mean pooling aggregator and an attentive pooling aggregator. These two simple aggregators only collect neighboring entities under the same relation r. Then we introduce a more powerful aggregation function: a multi-relational aggregator. We depict comparison on aggregators in Fig. 3.

Mean Pooling Aggregator. The baseline aggregator simply takes the element-wise mean of representations in $\{\boldsymbol{e}_\mathrm{o} : \mathrm{o} \in \mathrm{N}_t^{(\mathrm{s},\mathrm{r})}\}$, where $\mathrm{N}_t^{(\mathrm{s},\mathrm{r})}$ is the set of objects that interacted with s under r at t. But the mean aggregator treats all neighboring objects equally, and thus ignores the different importance of each neighbor entity.

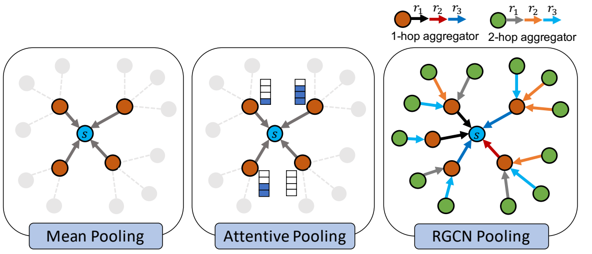

Figure 3: **Comparison of neighborhood aggregators.** The blue node corresponds to node s, red nodes are 1-hop neighbors, and green nodes are 2-hop neighbors. Different colored edges are different relations. Mean and attentive pooling aggregators do not differentiate different relations and do not encode 2-hop neighbors, whereas RGCN aggregator can incorporate information from multi-relational and multi-hop neighbors.

Attentive Pooling Aggregator. We define an attentive aggregator based on the additive attention introduced in (Bahdanau et al., 2015) to distinguish the important entities for (s,r). The aggregate function is defined as $g(\mathrm{N}_t^{(\mathrm{s},\mathrm{r})}) = \sum_{\mathrm{o}\in\mathrm{N}_t^{(\mathrm{s},\mathrm{r})}} \alpha_\mathrm{o}\boldsymbol{e}_\mathrm{o}$, where $\alpha_\mathrm{o} = \mathrm{softmax}(\mathbf{v}^\top \tanh(\boldsymbol{W}(\boldsymbol{e}_\mathrm{s};\boldsymbol{e}_\mathrm{r};\boldsymbol{e}_\mathrm{o})))$. $\mathbf{v} \in \mathbb{R}^d$ and $\boldsymbol{W} \in \mathbb{R}^{d\times 3d}$ are trainable weight matrices. By adding the attention function of the subject and the relation, the weight can determine how relevant each object entity is to the subject and the relation.

Multi-Relational Graph (RGCN) Aggregator. We introduce a multi-relational graph aggregator from (Schlichtkrull et al., 2018). This is a general aggregator that can incorporate information from multi-relational and multi-hop neighbors. Formally, the aggregator is defined as follows:

$$g(\mathrm{N}_t^{(\mathrm{s})}) = \mathbf{h}_s^{(l+1)} = \sigma\Big(\sum_{\mathrm{r}\in R}\sum_{\mathrm{o}\in\mathrm{N}_t^{(\mathrm{s},\mathrm{r})}} \frac{1}{c_s}\boldsymbol{W}_r^{(l)}\mathbf{h}_\mathrm{o}^{(l)} + \boldsymbol{W}_0^{(l)}\mathbf{h}_s^{(l)}\Big), \tag{8}$$

where initial hidden representations for each node ($\mathbf{h}_o^{(0)}$) are set to trainable embedding vectors ($\boldsymbol{e}_\mathrm{o}$) for each node and c_s is a normalizing factor. Details are described in Section B of appendix.

3.3 Parameter Learning and Inference

In this section, we discuss how RE-NET is trained and infers events over multiple time stamps.

Parameter Learning via Event Predictions. An object entity prediction given (s,r) can be viewed as a multi-class classification task, where each class corresponds to each object entity. Similarly, relation prediction given s and subject entity prediction

Algorithm 1: Learning algorithm of RE-NET

```
Input: Observed graph sequence: $\{G_1, ..., G_t\}$,
       Number of events to sample at each step: $M$.
Output: An estimation of the conditional distribution
        $p(G_{t+\Delta t}|G_{:t})$.
1 $t' \leftarrow t + 1$
2 while $t' \leq t + \Delta t$ do
3     Sample $M$ number of s $\sim p(\mathrm{s}|\hat{G}_{t+1:t'-1}, G_{:t})$
        by equation (4).
4     Pick top-$k$ triples
        $\{(\mathrm{s}_1, \mathrm{r}_1, \mathrm{o}_1, t'), ..., (\mathrm{s}_k, \mathrm{r}_k, \mathrm{o}_k, t')\}$ ranked by
        $p(\mathrm{s}, \mathrm{r}, \mathrm{o}|\hat{G}_{t+1:t'-1}, G_{:t})$.
5     $\hat{G}_{t'} \leftarrow \{(\mathrm{s}_1, \mathrm{r}_1, \mathrm{o}_1, t'), ..., (\mathrm{s}_k, \mathrm{r}_k, \mathrm{o}_k, t')\}$
6     $t' \leftarrow t' + 1$
7 Estimate the probability of each event
    $p(\mathrm{s}, \mathrm{r}, \mathrm{o}|\hat{G}_{t+1:t+\Delta t-1}, G_{:t})$.
8 Estimate the joint distribution of all events
    $p(G_{t+\Delta t}|\hat{G}_{t+1:t+\Delta t-1}, G_{:t})$ by equation (1).
9 return $p(G_{t+\Delta t}|\hat{G}_{t+1:t+\Delta t-1}, G_{:t})$ as an estimation.
```

can be considered as a multi-class classification task. Here we omit the notations for preceding events for brevity. Thus, the loss function is as follows:

$$\mathcal{L} = -\sum_{(\mathrm{s},\mathrm{r},\mathrm{o},t)\in G} \log p(\mathrm{o}_t|\mathrm{s}_t, \mathrm{r}_t) + \lambda_1 \log p(\mathrm{r}_t|\mathrm{s}_t) + \lambda_2 \log p(\mathrm{s}_t), \tag{9}$$

where G is set of events, and λ_1 and λ_2 are importance parameters that control the importance of each loss term. λ_1 and λ_2 can be chosen depending on the task. If a task aims to predict o given (s, r), then we can give small values to λ_1 and λ_2.

Multi-step Inference over Time. RE-NET seeks to predict the forthcoming events based on the previous observations. Suppose that the current time is t and we aim to predict events at time $t + \Delta t$ where $\Delta t > 0$. Then the problem of multi-step inference can be formalized as inferring the conditional probability $p(G_{t+\Delta t}|G_{:t})$. The problem is nontrivial as we need to integrate over all $G_{t+1:t+\Delta t-1}$. To achieve efficient inference, we draw a sample of $G_{t+1:t+\Delta t-1}$, and estimate the conditional probability as follows:

$$\begin{aligned}
&p(G_{t+\Delta t}|G_{:t}) \\
&= \sum_{G_{t+1:t+\Delta t-1}} p(G_{t+\Delta t}, G_{t+1:t+\Delta t-1}|G_{:t}) \\
&= \sum_{G_{t+1:t+\Delta t-1}} p(G_{t+\Delta t}|G_{:t+\Delta t-1}) \cdots p(G_{t+1}|G_{:t}) \\
&= \mathbb{E}_{G_{t+1:t+\Delta t-1}|G_{:t}}[p(G_{t+\Delta t}|G_{:t+\Delta t-1})] \\
&\simeq p(G_{t+\Delta t}|\hat{G}_{t+1:t+\Delta t-1}, G_{:t}).
\end{aligned}$$

Intuitively, one starts with computing $p(G_{t+1}|G_{:t})$, and drawing a sample $\hat{G}_{t+1}$ from the conditional distribution. With this sample, one can further compute $p(G_{t+2}|\hat{G}_{t+1}, G_{:t})$. By iteratively computing the conditional distribution for $G_{t'}$ and drawing a sample from it, one can eventually estimate $p(G_{t+\Delta t}|G_{:t})$ as $p(G_{t+\Delta t}|\hat{G}_{t+1:t+\Delta t-1}, G_{:t})$. Although we can improve the estimation by drawing multiple graph samples at each step, RE-NET already performs very well with a single sample, and thus we only draw one sample graph at each step for better efficiency. Based on the estimation of the conditional distribution, we can further predict events that are likely to form in the future. We summarize the detailed inference algorithm in Algorithm 1; we first sample M number of s (line 3) and pick top-k triples (line 4). Then we build a graph at time t' (line 5) to generate a graph. The time complexity of the algorithm is described in Section C of appendix.

4 Experiments

Evaluating the quality of generated graphs is non-trivial, especially for knowledge graphs (Theis et al., 2015). In our experiments, we evaluate the proposed method on a *extrapolation* link prediction task on TKGs. The task of predicting future links aims to predict unseen relationships with object entities given $(\mathrm{s}, \mathrm{r}, ?, t)$ (or subject entities given $(?, \mathrm{r}, \mathrm{o}, t)$) at future time t, based on the past observed events in the TKG. Essentially, the task is a ranking problem over all the events $(\mathrm{s}, \mathrm{r}, ?, t)$ (or $(?, \mathrm{r}, \mathrm{o}, t)$). RE-NET can approach this problem by computing the probability of each event in a distant future with the inference algorithm in Algorithm 1, and further rank all the events according to their probabilities. Note that we are only given a training set as ground truth at inference and we do not use any ground truth in the test set for the next time step predictions when performing multi-step inference. This is the main difference from previous work; they use previous ground truth in the test set.

We evaluate our proposed method on three benchmark tasks: (1) predicting future events on three event-based datasets; (2) predicting future facts on two knowledge graphs which include facts with time spans, and (3) studying ablation of our proposed method. Section 4.1 summarizes the datasets. In all these experiments, we perform predictions on time stamps that are not observed during training.

Table 1: Performance comparison on temporal link prediction (average metrics in % over 5 runs) on three event-based TKG datasets (ICEWS18, GDELT, and ICEWS14) and two public knowledge graphs (WIKI and YAGO). RE-NET achieves the best results.

Figure 4: **Performance of temporal link prediction over future timestamps with filtered Hits@3.** RE-NET consistently outperforms the baselines.

4.1 Experimental Setup

We compare the performance of our model against various traditional models for knowledge graphs, as well as some recent temporal reasoning models on five public datasets.

Datasets. We use five TKG datasets in our experiments: 1) three event-based TKGs: ICEWS18 (Boschee et al., 2015), ICEWS14 (Trivedi et al., 2017), and GDELT (Leetaru and Schrodt, 2013); and 2) two knowledge graphs where temporally associated facts have meta-facts as $(\mathrm{s}, \mathrm{r}, \mathrm{o}, [t_s, t_e])$ where t_s is the starting time point and t_e is the ending time point: WIKI (Leblay and Chekol, 2018) and YAGO (Mahdisoltani et al., 2014).

Evaluation Setting and Metrics. For each dataset except ICEWS14[4], we split it into three subsets, i.e., train(80%)/valid(10%)/test(10%), by time stamps. Thus, (time stamps of train) $<$ (time stamps of valid) $<$ (time stamps of test). We report a filtered version of Mean Reciprocal Ranks (MRR) and Hits@3/10. Similar to the definition of filtered setting in (Bordes et al., 2013), during evaluation, we remove all the valid triplets that appear in the train, valid, or test sets from the list of corrupted triplets.

Baselines. We compare our approach to baselines for static graphs and temporal graphs as follows:

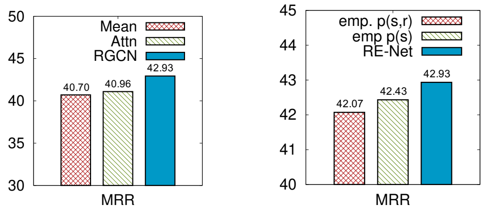
(1) ***Static Methods.*** By ignoring the edge time stamps, we construct a static, cumulative graph for all the training events, and apply multi-relational graph representation learning methods including DistMult (Yang et al., 2015), R-GCN (Schlichtkrull et al., 2018), ConvE (Dettmers et al., 2018), and RotatE (Sun et al., 2019).

(2) ***Temporal Reasoning Methods.*** We also compare state-of-the-art temporal reasoning methods for knowledge graphs, including Know-Evolve[5] (Trivedi et al., 2017), TA-DistMult (García-Durán et al., 2018), and HyTE (Dasgupta et al., 2018). TA-DistMult and HyTE are for an interpolation task whereas we focus on an extrapolation task. To do this, we assign random values to temporal embeddings that are not observed during training. To see the effectiveness of our recurrent event encoder, we use encoders of previous work and our MLP decoder as baselines; we compare Know-Evolve, Dyrep (Trivedi et al., 2019), and GCRN (Seo

---

[4] We used the splits as provided in (Trivedi et al., 2017).

[5] *: We found a problematic formulation in Know-Evolve. Details of this issues are discussed in Section G of appendix.



(a) RE-NET with different aggregators

(b) Study of empirical $p(s)$ and $p(s, r)$

Figure 5: **Performance study on model variations.** We study the effects of (a) RE-NET with different aggregators, and (b) empirical $p(\mathrm{s})$ and $p(\mathrm{s}, \mathrm{r})$.

et al., 2017) combined with our MLP decoder, called Know-Evolve+MLP, DyRep+MLP, and R-GCRN+MLP. The GCRN utilizes Graph Gonvolutional Network (Kipf and Welling, 2016). Instead, we use RGCN (Schlichtkrull et al., 2018) to deal with multi-relational graphs.

We also compare our method with dynamic methods on homogeneous graphs: dyngraph2vecAE (Goyal et al., 2019), tNodeEmbed (Singer et al., 2019), and EvolveRGCN (Pareja et al., 2020). These methods were proposed to predict interactions at future time on homogeneous graphs. Thus, we modified the methods to apply them on multi-relational graph.

(3) *Variants of* RE-NET. To evaluate the importance of different components of RE-NET, we varied our model in different ways: RE-NET w/o multi-step which does not update history during inference, RE-NET without the aggregator (RE-NET w/o agg.), RE-NET with a mean aggregator (RE-NET w. mean agg.), and RE-NET with an attentive aggregator (RE-NET w. attn agg.). RE-NET w/o agg. takes a zero vector instead of an aggregator. RE-NET w. GT denotes RE-NET with ground truth history.

Please refer to Section D of appendix for detailed experimental settings.

4.2 Performance Comparison on TKGs.

We compare our proposed method with other baselines. The test results are obtained by averaged metrics (5 runs) over the entire test sets on datasets.

Results on Event-based TKGs. Table 1 summarizes results on all datasets. Our proposed RE-NET outperforms all other baselines on ICEWS18 and GDELT. Static methods underperform compared to our method since they do not consider temporal factors. Also, RE-NET outperforms all other temporal methods including TA-DistMult, HyTE, and dynamic methods on homogeneous graphs. Know-Evovle+MLP significantly improves Know-Evolve, which shows effectiveness of our MLP decoder. However, there is still a large gap from our model, which also indicates effectiveness of our recurrent event encoder. R-GCRN+MLP has a similar structure to ours in that it has a recurrent encoder and an RGCN aggregator but it lacks multi-step inference, global information, and the sophisticated modeling for the recurrent encoder. Thus, it underperforms compared to our method. More importantly, none of the prior temporal methods are capable of multi-step inference, while RE-NET can sequentially infer multi-step events (Details in Section 4.3).

Results on Public KGs. Previous results have demonstrated the effectiveness of RE-NET on event-based KGs. In Table 1 we compare RE-NET with other baselines on the Public KGs WIKI and YAGO. Our proposed RE-NET outperforms all other baselines on these datasets. In these datasets, baselines show better results than in the event-based TKGs. This is due to the characteristics of the datasets; they have facts that are valid within a time span. However, our proposed method consistently outperforms the static and temporal methods, which implies that RE-NET effectively infers new events using a powerful event encoder and an aggregator, and provides accurate prediction results.

Performance of Prediction over Time. Next, we further study performance of RE-NET over time. Figs. 4 shows the performance comparisons over different time stamps on the ICEWS18, GDELT, WIKI, and YAGO datasets with filtered Hits@3 metrics. RE-NET consistently outperforms baseline methods for all different time stamps. Performance of each method fluctuate since testing entities are different at each time step. We notice that with increasing time steps, the difference between RE-NET and ConvE gets smaller as shown in Fig. 4. This is expected since further future events are harder to predict. To estimate the joint probability distribution of events in a distant future, RE-NET needs to generate a long graph sequence. The quality of generated graphs deteriorates when RE-NET generates a long graph sequence.

4.3 Ablation Study

In this section, we study the effect of variations in RE-NET on the ICEWS18 dataset. We present the results in Tables 1, 2, and Fig. 5.

Table 2: **Ablation study on the ICEWS18 and GDELT datasets.**

Method	ICEWS18			GDELT		
	MRR	H@3	H@10	MRR	H@3	H@10
RE-NET w/o agg.	33.46	35.98	46.62	38.10	41.26	51.61
RE-NET w/o multi-step	40.05	42.60	52.92	38.72	42.52	52.78
RE-NET	42.93	45.47	55.80	40.42	43.40	53.70
RE-NET w. GT	44.33	46.83	57.27	41.80	45.71	56.03

Different Aggregators. In Table 2, we observe that RE-NET w/o agg. hurts model quality, suggesting that introducing aggregators makes the model capable of dealing with concurrent events and improves performance. Table 1 and Fig. 5a show the performance of RE-NET with different aggregators. Among them, RGCN aggregator outperforms other aggregators. This aggregator has the advantage of exploring multi-relational neighbors. Also, RE-NET with an attentive aggregator shows better performance than RE-NET with a mean aggregator, which implies that giving different attention weights to each neighbor helps predictions.

Multi-step Inference. In Table 2, we observe that RE-NET outperforms RE-NET w/o multi-step. The latter one does not update history during inference; keeps its last history in the training set. So it is not affected by time stamps. Without the multi-step inference, the performance of RE-NET is decreased as is shown. Also we expect that RE-NET w. GT shows significant improvement when RE-NET uses ground truth of triples at the previous time step which are not allowed in our setup.

Empirical Probabilities. Here, we study the role of $p(\mathrm{s}_t|G_{t-m:t-1})$ and $p(\mathrm{r}_t|\mathrm{s}, G_{t-m:t-1})$. We denote them as $p(\mathrm{s})$ and $p(\mathrm{r})$ for brevity. $p(\mathrm{s}_t, \mathrm{r}_t|G_{t-m:t-1})$ (or simply $p(\mathrm{s}, \mathrm{r})$) is equivalent to $p(\mathrm{s})p(\mathrm{r})$. In Fig 5b, emp. $p(\mathrm{s})$ (or $p_e(\mathrm{s})$) denotes a model with empirical $p(\mathrm{s})$, defined as $p_e(\mathrm{s}) =$ (# of s-related triples) / (total # of triples). emp. $p(\mathrm{s}, \mathrm{r})$ (or $p_e(\mathrm{s}, \mathrm{r})$) denotes a model with $p_e(\mathrm{s})$ and $p_e(\mathrm{r})$,defined as $p_e(\mathrm{r}) =$ (# of r-related triples) / (total # of triples). Thus, $p_e(\mathrm{s}, \mathrm{r}) = p_e(\mathrm{s})p_e(\mathrm{r})$. Note that RE-NET use a trained $p(\mathrm{s})$ and $p(\mathrm{r})$. The results show that the trained $p(\mathrm{s})$ and $p(\mathrm{r})$ help RE-NET for multi-step predictions. $p_e(\mathrm{s})$ underperforms RE-NET, and $p_e(\mathrm{s}, \mathrm{r}) = p_e(\mathrm{s})p_e(\mathrm{r})$ shows the worst performance, suggesting that training each part of the probability in equation (1) improves performance.

5 Related Work

Temporal KG Reasoning. There have been some recent attempts on incorporating temporal information in modeling dynamic knowledge graphs, broadly categorized into two settings - *extrapolation* (Trivedi et al., 2017) and *interpolation* (García-Durán et al., 2018; Leblay and Chekol, 2018; Dasgupta et al., 2018; Goel et al., 2020; Lacroix et al., 2020). For the former setting, Know-Evolve (Trivedi et al., 2017) models the occurrence of a fact as a temporal point process. For the latter setting, several embedding-based methods have been proposed (García-Durán et al., 2018; Leblay and Chekol, 2018; Dasgupta et al., 2018; Goel et al., 2020; Lacroix et al., 2020) to model time information. They embed the associate into a low dimensional space such as relation embeddings with RNN on the text of time (García-Durán et al., 2018), time embeddings (Leblay and Chekol, 2018), temporal hyperplanes (Leblay and Chekol, 2018), diachronic entity embedding (Goel et al., 2020), and tensor decomposition (Lacroix et al., 2020). However, these models cannot predict future events, as representations of unseen time stamps are unavailable.

Temporal Modeling on Homogeneous Graphs. There are attempts on predicting future links on homogeneous graphs (Pareja et al., 2020; Goyal et al., 2018, 2019; Zhou et al., 2018; Singer et al., 2019). Some of the methods try to incorporate and learn graphical structures to predict future links (Pareja et al., 2020; Zhou et al., 2018; Singer et al., 2019), while other methods predict by reconstructing an adjacency matrix by using an autoencoder (Goyal et al., 2018, 2019). These methods seek to predict on single-relational graphs, and are designed to predict future edges in one future step (i.e., for $t + 1$). However, our work focuses on *multi-relational* knowledge graphs and aims for multi-step prediction.

Deep Autoregressive Models. Deep autoregressive models define joint probability distributions as a product of conditionals. DeepGMG (Li et al., 2018) and GraphRNN (You et al., 2018) are deep generative models of graphs and focus on generating static homogeneous graphs where there is only a single type of edge. In contrast to these studies, our work focuses on generating heterogeneous graphs, in which multiple types of edges exist, and thus our problem is more challenging. To the best of our knowledge, this is the first paper to formulate the structure inference (prediction) problem for temporal, multi-relational (knowledge) graphs in an autoregressive fashion.

6 Conclusion

To tackle the extrapolation problem, we proposed Recurrent Event Network (RE-NET) to model temporal, multi-relational, and concurrent interactions between entities. RE-NET defines the joint probability of all events, and thus is capable of inferring graphs in a sequential manner. The experiment revealed that RE-NET outperforms all the static and temporal methods and our extensive analysis shows its strength. Interesting future work includes developing a fast and efficient version of RE-NET, and modeling lasting events and performing inference on the long-lasting graph structures.

A Recurrent Neural Network

We define a recurrent event encoder based on RNN as follows:

$$\boldsymbol{h}_t(\mathrm{s},\mathrm{r}) = \mathrm{RNN}(g(\mathrm{N}_t(\mathrm{s})), \boldsymbol{H}_t, \boldsymbol{h}_{t-1}(\mathrm{s},\mathrm{r})).$$

We use Gated Recurrent Units (Cho et al., 2014) as RNN:

$$\begin{aligned}
&\boldsymbol{a}_t = [\boldsymbol{e}_{\mathrm{s}} : \boldsymbol{e}_{\mathrm{r}} : g(\mathrm{N}_t(\mathrm{s})) : \boldsymbol{H}_t]\\
&\boldsymbol{z}_t = \sigma(\boldsymbol{W}_z \boldsymbol{a}_t + \boldsymbol{U}_z \boldsymbol{h}_{t-1})\\
&\boldsymbol{r}_t = \sigma(\boldsymbol{W}_r \boldsymbol{a}_t + \boldsymbol{U}_r \boldsymbol{h}_{t-1})\\
&\boldsymbol{h}_t = (1 - \boldsymbol{z}_t) \circ \boldsymbol{h}_{t-1} + \boldsymbol{z}_t \circ \tanh(\boldsymbol{W}_h \boldsymbol{a}_t + \boldsymbol{U}_h(\boldsymbol{r}_t \circ \boldsymbol{h}_{t-1})),
\end{aligned}$$

where : is concatenation, $\sigma(\cdot)$ is an activation function, and $\circ$ is a Hadamard operator. The input is a concatenation of four vectors: subject embedding, object embedding, aggregation of neighborhood representations, and global information vector $(\boldsymbol{e}_{\mathrm{s}}, \boldsymbol{e}_{\mathrm{r}}, g(\mathrm{N}_t(\mathrm{s})), \boldsymbol{H}_t)$. $\boldsymbol{h}_t(s)$ and $\boldsymbol{H}_t$ are similarly defined. For $\boldsymbol{h}_t(s)$, a concatenation of subject embedding, aggregation of neighborhood representations, and global information vector $(\boldsymbol{e}_{\mathrm{s}}, g(\mathrm{N}_t(s)), \boldsymbol{H}_t)$ is input. For $\boldsymbol{H}_t$, aggregation of the whole graph representations $g(G_t)$ is input.

B Details of RGCN Aggregator

The RGCN aggregator is defined as follows:

$$g(\mathrm{N}_t^{(\mathrm{s})}) = \mathbf{h}_s^{(l+1)} = \sigma\Big(\sum_{\mathrm{r}\in R} \sum_{\mathrm{o}\in \mathrm{N}_t^{(\mathrm{s},\mathrm{r})}} \frac{1}{c_s} \boldsymbol{W}_r^{(l)} \mathbf{h}_{\mathrm{o}}^{(l)} + \boldsymbol{W}_0^{(l)} \mathbf{h}_s^{(l)}\Big), \tag{10}$$

where initial hidden representations for each node $(\mathbf{h}_o^{(0)})$ are set to trainable embedding vectors $(\boldsymbol{e}_{\mathrm{o}})$ for each node and c_s is a normalizing factor. Detailed

Basically, each relation can derive a local graph structure between entities, which further yield a message on each entity by aggregating information from neighbors, i.e., $\sum_{\mathrm{o}\in \mathrm{N}_t^{(\mathrm{s},\mathrm{r})}} \frac{1}{c_s} \boldsymbol{W}_r^{(l)} \mathbf{h}_{\mathrm{o}}^{(l)}$. The overall message on each entity is further computed by aggregating all the relation-specific messages, i.e., $\sum_{\mathrm{r}\in R} \sum_{\mathrm{o}\in \mathrm{N}_t^{(\mathrm{s},\mathrm{r})}} \frac{1}{c_s} \boldsymbol{W}_r^{(l)} \mathbf{h}_{\mathrm{o}}^{(l)}$. Finally, the aggregator $g(\mathrm{N}_t^{(\mathrm{s})})$ is defined by combining both the overall message and information from past steps, i.e., $\boldsymbol{W}_0^{(l)} \mathbf{h}_s^{(l)}$.

To distinguish weights between different relations, we adopt independent weight matrices $\{\boldsymbol{W}_{\mathrm{r}}^{(l)}\}$ for each relation r. Furthermore, the aggregator collects representations of multi-hop neighbors by introducing multiple layers of the neural network with each layer indexed by l. The number of layers determines the depth to which the node reaches to aggregate information from its local neighborhood.

The major issue of this aggregator is that the number of parameters grows rapidly with the number of relations. In practice, this can easily lead to overfitting on rare relations and models of very large size. Thus, we adopt the block-diagonal decomposition (Schlichtkrull et al., 2018), where each relation-specific weight matrix is decomposed into a block-diagonal by decomposing into low-dimensional matrices. $\boldsymbol{W}_r^{(l)}$ in equation (10) is defined as a block diagonal matrix, $\mathrm{diag}(\mathbf{A}_{1r}^{(l)}, ..., \mathbf{A}_{Br}^{(l)})$ where $\mathbf{A}_{kr}^{(l)} \in \mathbb{R}^{(d^{(l+1)}/B)\times(d^{(l)}/B)}$ and B is the number of basis matrices. The block decomposition reduces the number of parameters and helps prevent overfitting.

C Computational Complexity Analysis.

We analyze the time complexity of the graph generation process in Algorithm 1. Computing $p(\mathrm{s}_t | G_{t-m:t-1})$ (equation (4)) takes $O(|E|Lm)$, where $|E|$ is the maximum number of triples among $\{G_{t-m}, ..., G_{t-1}\}$, L is the number of layers of aggregation, and m is the number of the past time steps since we unroll m time steps in RNN. From this probability, we sample M number of subjects s. Computing $p(\mathrm{s}_t, \mathrm{r}_t, \mathrm{o}_t | G_{t-m:t-1})$ in equation (1) takes $O(D^L m)$, where D is the maximum degree of entities. To get probabilities of all possible triples given sampled subjects, it requires $O(M|R||O|D^L m)$ where $|R|$ is the total number of relations and $|O|$ is the total number of entities. Thus, the time complexity for generating one graph is $O(|E|Lm + M|R||O|(D^L m + \log k))$ where k is the cutoff number for picking top-k triples. The time complexity is linear to the number of entities and relations, and the number of sampled s.

D Detailed Experimental Settings

Datasets. We use five datasets: 1) three event-based temporal knowledge graphs and 2) two knowledge graphs where temporally associated facts have meta-facts as $(\mathrm{s}, \mathrm{r}, \mathrm{o}, [t_s, t_e])$ where t_s is the starting time point and t_e is the ending time point. The first group of graphs includes Integrated Crisis Early Warning System (ICEWS18 (Boschee et al., 2015) and ICEWS14 (Trivedi et al., 2017)), and Global Database of Events, Language, and

Table 3: **Dataset Statistics.**

Data	N_{train}	N_{valid}	N_{test}	N_{ent}	N_{rel}	Time gap
GDELT	1,734,399	238,765	305,241	7,691	240	15 mins
ICEWS18	373,018	45,995	49,545	23,033	256	24 hours
ICEWS14	323,895	-	341,409	12,498	260	24 hours
WIKI	539,286	67,538	63,110	12,554	24	1 year
YAGO	161,540	19,523	20,026	10,623	10	1 year

Tone (GDELT) (Leetaru and Schrodt, 2013). The second group of graphs includes WIKI (Leblay and Chekol, 2018) and YAGO (Mahdisoltani et al., 2014). Dataset statistics are described on Table 3, where N_{train}, N_{valid}, and N_{test} are the numbers of train set, valid set, and test set, respectively. N_{ent} and N_{rel} are the numbers of entities and relations. The time gap represents time granularity between adjacent events.

ICEWS18 is collected from 1/1/2018 to 10/31/2018, ICEWS14 is from 1/1/2014 to 12/31/2014, and GDELT is from 1/1/2018 to 1/31/2018. The ICEWS14 is from (Trivedi et al., 2017). We didn't use their version of the GDELT dataset since they didn't release the dataset.

WIKI and YAGO datasets have temporally associated facts $(\mathrm{s}, \mathrm{r}, \mathrm{o}, [t_s, t_e])$. We preprocess the datasets such that each fact is converted to $\{(\mathrm{s}, \mathrm{r}, \mathrm{o}, t_s), (\mathrm{s}, \mathrm{r}, \mathrm{o}, t_\mathrm{s}+1_t), ..., (\mathrm{s}, \mathrm{r}, \mathrm{o}, t_e)\}$ where 1_t is a unit time to ensure each fact has a sequence of events. Noisy events of early years are removed (before 1786 for WIKI and 1830 for YAGO).

The difference between the first group and the second group is that facts happen multiple times (even periodically) on the first group (event-based knowledge graphs) while facts last long time but are not likely to occur multiple times in the second group.

Model details of RE-NET. We use Gated Recurrent Units (Cho et al., 2014) as our recurrent event encoder, where the length of history is set as $m = 10$ which means saving past 10 event sequences. If the events related to s are sparse, we check the previous time steps until we get m previous time steps related to the entity s. We pretrain the parameters related to equations 4 and 5 due to the large size of training graphs. We use a multi-relational aggregator to compute $\boldsymbol{H}_t$. The aggregator provides hidden representations for each node and we max-pool over all hidden representations to get $\boldsymbol{H}_t$. We apply teacher forcing for model training over historical data, i.e., we use the ground truth rather than the model's own prediction as the input of the next time step during training. At inference time, RE-NET performs multi-step prediction across the time stamps in dev and test sets. In each time step, we sample 1000 $(= M)$ number of subjects and save top-1000 $(= k)$ triples to use them as a generated graph . We set the size of entity/relation embeddings to be 200 and embedding of unobserved embeddings are randomly initialized. We use two-layer RGCN in the RGCN aggregator with block dimension 2×2. The model is trained by the Adam optimizer (Kingma and Ba, 2014). We set λ_1 to 0.1, the learning rate to 0.001 and the weight decay rate to 0.00001. All experiments were done on GeForce GTX 1080 Ti.

Experimental Settings for Baseline Methods. In this section, we provide detailed settings for baselines. We use implementations of DistMult[6]. We implemented TA-DistMult based on the implementation of Distmult. For TA-DistMult, We use temporal tokens with the vocabulary of year, month and day on the ICEWS dataset and the vocabulary of year, month, day, hour and minute on the GDELT dataset. We use use a binary cross-entropy loss for DistMult and TA-DistMult. We validate the embedding size among 100 and 200. We set the batch size to 1024, margin to 1.0, negative sampling ratio to 1, and use the Adam optimizer.

We use the implementation of HyTE[7]. We use every timestamp as a hyperplane. The embedding size is set to 128, the negative sampling ratio to 5, and margin to 1.0. We use time agnostic negative sampling (TANS) for entity prediction, and the Adam optimizer.

We use the codes for ConvE[8] and use implementation by Deep Graph Library[9]. Embedding sizes are 200 for both methods. We use 1 to all negative sampling for ConvE and use 10 negative sampling ratio for RGCN, and use the Adam optimizer for both methods. We use the codes for

Know-Evolve[10]. For Know-Evolve, we fix the issue in their codes. Issues are described in Section G. We follow their default settings.

We use the code for RotatE[11]. The hidden layer/embedding size is set to 100, and batch size 256; other values follow the best values for the larger FB15K dataset configurations supplied by the author. The author reports filtered metrics only, so we added the implementation of the raw setting.

Experimental Settings for Dynamic Methods. We compare our method with dynamic methods on homogeneous graphs: dyngraph2vecAE (Goyal et al., 2019), tNodeEmbed (Singer et al., 2019), and EvolveGCN-O (Pareja et al., 2020). These methods were proposed to predict interactions at a future time on homogeneous graphs, while our proposed method is for predicting interactions on multi-relational graphs (or knowledge graphs). Furthermore, those methods predict links at one future time stamp, whereas our method seeks to predict interactions at multiple future time stamps. We modified some methods to apply them on multi-relational graphs as follows. We adopt R-GCN (Schlichtkrull et al., 2018) for EvolveGCN-O and call it EvolveRGCN. We convert knowledge graphs into homogeneous graphs for dyngraph2vecAE. The idea of this method is to reconstruct an adjacency matrix using an auto-encoder and regard it as a future adjacency matrix. If we keep relations, relation-specific adjacency matrices will be extremely sparse; the method learns to reconstruct near-zero adjacency matrices. tNodeEmbed is a temporal method on homogeneous graphs. To use this on multi-relational graphs, we first train entity embeddings with DistMult and set these as initial embeddings for entities in tNodeEmbed. Also we give entity embeddings as input to LSTM of tNodeEmbed. We concatenate output of LSTM and relation embeddings to predict objects. We did not modified other methods since it is not trivial to extend the methods.

E Additional Experiments

E.1 Results with Raw Metrics

Table 4 shows the performance comparison on ICEWS18, GDELT, ICEWS14 with raw settings. Our proposed RE-NET outperforms all other baselines.

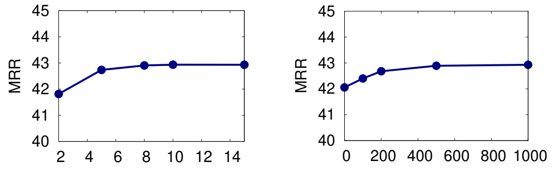
E.2 Sensitivity Analysis

In this section, we study the parameter sensitivity of RE-NET including the length of history for the event encoder, cutoff position k for events to generate a graph, the number of layers of the RGCN

---

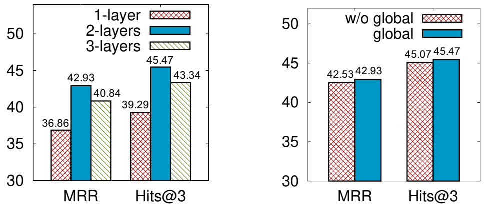
[10] https://github.com/rstriv/Know-Evolve

[11] https://github.com/DeepGraphLearning/KnowledgeGraphEmbedding



(a) Length of past history

(b) Cutoff position k



(c) # layers of RGCN

(d) Effect of global representations

Figure 7: **Parameter sensitivity on RE-NET.** We study the effects of (a) length of RNN history in event sequence encoder, and (b) cutoff position at inference time, (c) number of RGCN layers in neighborhood aggregation, and (d) effect of the global representation from a global graph structure.

aggregator, and effect of the global representation from a global graph structure. We report the performance change of RE-NET on the ICEWS18 dataset by varying the hyper-parameters (Figs. 7 and 7c).

Length of Past History in Recurrent Event Encoder. The recurrent event encoder takes the sequence of past interactions up to m graph sequences or previous histories. Fig. 7a shows the performance with various lengths of past histories. When RE-NET uses longer histories, MRR is getting higher. However, the MRR is not likely to go higher when the length of history is 5 and over.

Cut-off Position k at Inference. To generate a graph at each time, we cut off top-k triples on ranking results. In Fig. 7b, when k is 0, RE-NET does not generate graphs for estimating $p(G_{t+\Delta t}|G_{:t})$, i.e., RE-NET performs single-step predictions, and it shows the lowest result. When k is larger, the performance is getting higher and it is saturated after 500. We notice that the conditional distribution $p(G_{t+\Delta t}|G_{:t})$ can be approximated by $p(G_{t+\Delta t}|\hat{G}_{t+1:t+\Delta t-1}, G_{:t})$ by using a larger cutoff position.

Layers of RGCN Aggregator. The number of layers in the aggregator means the depth to which the node reaches. Fig. 7c shows the performance according to different numbers of layers of RGCN. 2-layered RGCN improves the performance considerably compared to 1-layered RGCN since 2-layered RGCN aggregates more information. However, RE-NET with 3-layered RGCN underperforms RE-NET with 2-layered RGCN. We conjecture that the bigger parameter space leads to overfitting.

Global Information. We further observe that representations from global graph structures help the predictions. Fig. 7d shows effectiveness of a representation of global graph structures. The improvement is marginal, but we consider that global representations at different time steps give distinct information beyond local graph structures.

F Case Study

In this section, we study RE-NET's predictions. Its predictions depend on interaction histories. We categorize histories into three cases: (1) consistent interactions with an object, (2) a specific temporal pattern, and (3) irrelevant history (Fig. 8). RE-NET can learn (1) and (2) cases, so it achieves high performances. For the first case, RE-NET can predict the answer because it consistently interacts with an object. However, static methods are prone to predicting different entities which are observed under relation ”Accuse” in training set. The second case shows specific temporal patterns on relations: (Arrest, o) $\rightarrow$ (Use force, o). Without knowing this pattern, one method might predict “Businessman” instead of “Men”. RE-NET is able to learn these temporal patterns so it can predict the second case. Lastly, the third case shows irrelevant history to the answer and the history is not helpful to predictions. RE-NET fails to predict the third case.

G Implementation Issues of Know-Evolve

We found a problematic formulation in the Know-Evolve model and codes. The intensity function (equation 3 in (Trivedi et al., 2017)) is defined as $\lambda_r^{s,r}(t|\bar{t}) = f(g_r^{s,r}(\bar{t}))(t-\bar{t})$, where $g(\cdot)$ is a score function, t is current time, and $\bar{t}$ is the most recent time point when either subject or object entity was involved in an event. This intensity function is used in inference to rank entity candidates. However, they don't consider concurrent event at the same time stamps, and thus $\bar{t}$ will become t after one event. For example, we have events $e_1 = (s, r, o_1, t_1), e_2 = (s, r, o_2, t_1)$. After e_1, $\bar{t}$ will become t (subject s's most recent time point), and thus the value of intensity function for e_2 will be 0. This is problematic in inference since if $t = \bar{t}$, then the intensity function will always

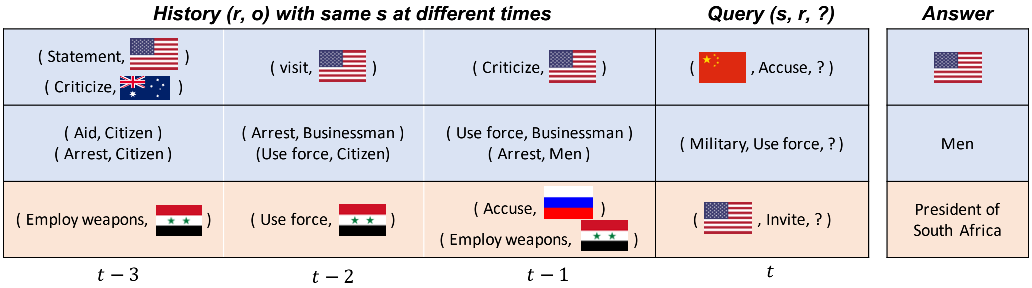


Figure 8: **Case study of RE-NET's predictions.** RE-NET's predictions depend on interaction histories. Interaction histories are categorized into three cases: (1) consistent interactions with an object, (2) a specific temporal pattern, and (3) irrelevant history. RE-NET achieves good performances on the first two cases, and poor performances on the third case.

be 0 regardless of entity candidates. In inference, all object candidates are ranked by the intensity function. But all intensity scores for all candidates will be 0 since $t = \bar{t}$, which means all candidates have the same 0 score. In their code, they give the highest ranks (first rank) for all entities including the ground truth object in this case. Thus, we fixed their code for a fair comparison; we give an average rank to entities who have the same scores.

Multi-resolution Annotations for Emoji Prediction

Weicheng Ma[1], Ruibo Liu[2], Lili Wang[3], and Soroush Vosoughi[4]

Abstract

Emojis are able to express various linguistic components, including emotions, sentiments, events, etc. Predicting the proper emojis associated with text provides a way to summarize the text accurately, and it has been proven to be a good auxiliary task to many Natural Language Understanding (NLU) tasks. Labels in existing emoji prediction datasets are all passage-based and are usually under the multi-class classification setting. However, in many cases, one single emoji cannot fully cover the theme of a piece of text. It is thus useful to infer the part of text related to each emoji. The lack of multi-label and aspect-level emoji prediction datasets is one of the bottlenecks for this task. This paper annotates an emoji prediction dataset with passage-level multi-class/multi-label, and aspect-level multi-class annotations. We also present a novel annotation method with which we generate the aspect-level annotations. The annotations are generated heuristically, taking advantage of the self-attention mechanism in Transformer networks. We validate the annotations both automatically and manually to ensure their quality. We also benchmark the dataset with a pre-trained BERT model.

1 Introduction

Emojis have become crucial components of written language. Emojis were initially designed to express emotions or feelings, e.g., 😊 for a smiley face, and they have grown to be a large family of over 2,000 icons over the years which can express not only emotions but a wide range of objects or actions, e.g., 🎁 for a gift and 🎉 for celebrations. Compared to words, emojis have the merit of preserving information more densely. For example, 😂 carries the same meaning as the phrase "laughing with tears in eyes". Additionally, the byte-level encoding of subtle linguistic expressions makes it easier to discriminate complicated feelings, e.g., the bond between 😂 and 😭 is clearly weaker than their phrasal explanations "laughing with tears in eyes" and "crying loudly" due to the similarity between "tear" and "crying". These characteristics of emojis aid in accurate summarization of text, thus benefiting natural language understanding (NLU) tasks.

Felbo et al. (2017) define the emoji prediction task by finding the most appropriate emoji(s) summarizing a piece of text. They also show with experiments that language representations learned on the emoji prediction task can boost the performance of emotion recognition, sentiment analysis, and sarcasm detection tasks. Consequently, using emoji prediction as a bridge to solve other natural language processing (NLP) tasks appears to be effective and promising. However, the emoji prediction task is yet far from being well established. First and foremost, as a classification task, there is not a set of labels agreed upon by previous research. To the best of our knowledge, all the existing papers on emoji prediction use either a handcrafted emoji set (Felbo et al., 2017) or the most frequent emojis in their individual datasets (Barbieri et al., 2018c,b). Handcrafted emoji sets are usually limited in size and topics (usually limited to emotional emojis), while frequency-based emoji sets are dataset-specific. The lack of a standard label set makes it difficult to evaluate and compare emoji prediction models, hampering the research on emoji prediction and its interactions with other NLP tasks. To solve this problem, we use an emoji list from the unicode office [1] as the label set for the emoji prediction task. This emoji list includes 1,467 emojis in total, ordered by the median frequency of their use from multiple resources. We believe using this emoji list is good

November 16–20, 2020.

for standardizing the task since it is open to all researchers and is not influenced by how we sample the data.

The second problem with emoji prediction is that existing labeled datasets are either too small in scale or not publicly available. This often results from the policy of social media platforms on using their data and the constantly changing nature of posts on these platforms, e.g., post deletion and edits. To address the problem of data unavailability or expiration, we annotate the PAN-19 Celebrity Profiling corpus (Wiegmann et al., 2019), a tweet-based corpus, which is large and available to all researchers. We provide three types of annotations in this paper. Existing emoji prediction datasets are almost all annotated on the passage-level under the multi-class classification setting, which means each record contains exactly one tweet and one emoji. While we also release this type of annotation, we additionally provide passage-level multi-label and aspect-level multi-class classification annotations. Annotations for the passage-level multi-label classification setting are similar to the multi-class setting, but with possibly multiple emojis in each record (i.e., a tweet could be associated with multiple emojis). We introduce aspect-level labels to the emoji prediction task to enable a finer-grained analysis of the functions of emojis in tweets. Each emoji in these annotations points to a span of its corresponding text instead of the entire tweet. Text fractions associated with different emojis in the same tweet may overlap with each other.

Given the large size of our dataset, all three types of annotations are generated automatically using heuristics or with the help of a Transformer-based model. The assumption underlying the passage-level annotations is that the text fully covers the meanings of emojis in a tweet. Thus we extract the emojis appearing in the text as passage-level labels, as (Felbo et al., 2017) do. Under the multi-class classification setting, a record is duplicated and assigned different emojis if it contains multiple emojis. The aspect-level annotations are created based on passage-level multi-class classification labels. Since the attention maps in a Transformer-based model reflect the interrelations of each word pair, we are able to evaluate the contribution of each word to a predicted emoji under the multi-class classification setting. We then combine the labels based on tweets to form the aspect-level multi-class annotations for the dataset. We will introduce the annotation methods in more detail in Section 3.2.

The contributions of this paper are three-fold.
First, we provide a large emoji list to be used as a label set for the emoji prediction task. These emojis are all frequently-used and meaningful, benefiting further research on the emoji prediction task and its connections to other NLP tasks.
Second, we introduce a data annotation method based on the self-attention mechanism in Transformer networks (Vaswani et al., 2017). The method is designed specifically for annotating aspect-based labels and can potentially be used on any NLP task.
Third, we provide three types of annotations for emoji prediction based on a publicly available tweet dataset. Besides the commonly used tweet-level[2] multi-class classification labels, our annotations include passage-level multi-label and aspect-level multi-class classification labels for better understanding of the linguistic roles of emojis.

We release a carefully curated (both manually and automatically) emoji prediction dataset based on the 64 top-ranked emojis in our emoji list. [3]

2 Related Work

The study of emoji usage in textual data has seen a rise in recent years. Most related research are done over Twitter, Gab, or Microblog data since the use of emojis is more common on social media. Mahajan and Shaikh (2019) compared the way emojis were used in Twitter and Gab posts, and they claimed that emojis with negative sentiment scores were more frequently used on Gab than the other. The use of emojis on Twitter also appeared to be more balanced compared to Gab in posts related to the same event, i.e., the most frequent emoji counts for 19.79% of total emoji usage on Gab and 6.28% on Twitter. We base our research on a Twitter dataset for the balanced emoji usage and more neutral points of view.

Since the amount of unique emojis was large, early research treated emojis as special word-level tokens and examined the linguistic roles with coarse-grained classification objectives, for example, predicting whether an emoji was used redundantly in its context (Donato and Paggio, 2018)

---

[2] In this paper, we use tweet-level and passage-based annotations interchangeably.

[3] Available upon request.

or classifying the linguistic purposes of emojis (Na'aman et al., 2017). With the help of Recurrent Neural Networks (RNNs), Felbo et al. (2017) and Barbieri et al. (2018c) could predict proper emojis from tweet posts. Going one step further, Barbieri et al. (2018a) combined image and text features for predicting emojis. Due to the overly large amount of data required to train neural-network-based classifiers with tens or even hundreds of labels, most emoji prediction datasets were labeled automatically, using heuristics or pre-defined rules. The logic previous researchers used to label these datasets were simple, assuming that every emoji appearing in a social media post qualified as a label of the text. Our work also relies on this assumption since the data we use consists of tweets posted by authorized accounts, who are not likely to often use emojis arbitrarily or randomly. We also extend the annotation method to be able to generate more complex, aspect-level annotations automatically.

Additionally, it is commonly agreed that emojis are closely related to emotions, sentiments, sarcasm, irony, etc. Felbo et al. (2017) showed that the language representations learned from the emoji prediction task were useful in emotion recognition, sentiment analysis, and sarcasm detection tasks. Hayati et al. (2019) designed experiments to show the interconnections between emoji usage and ironic expressions. Singh et al. (2019) also evaluated the influence of emojis on irony detection and sentiment analysis tasks, but they replaced emojis with descriptive text in this process. Based on previous knowledge about emojis and the emoji prediction task, we also use sentiment analysis, emotion recognition, and formality classification tasks to validate the quality of our annotations in this paper.

3 Annotation Method

We annotate tweets for the emoji prediction task in this paper. For clarity, we refer to each tweet in the dataset by $t = \{w_1, w_2, ..., w_n\}$ of length n and an emoji set $E = \{e_1, e_2, ..., e_m\}$ of size m, where w_i is the $i-th$ word in t and e_j is the $j-th$ emoji in E. The three settings of this task are formally defined as follows.

Passage-level multi-class classification: Predict the best e_j most closely related to t.

Passage-level multi-label classification: Predict whether each $e_j \in E$ is associated with t closely enough.

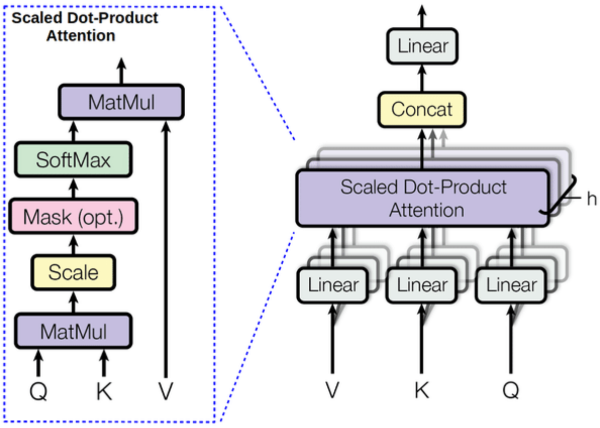

Figure 1: Interpretation of a self-attention head. Q, K, and V are query, key, and value matrices, respectively. The figure is cited from Vaswani et al. (2017).

Aspect-level multi-class classification: Given t and p subsets of t, each denoted as $s_q = \{w'_1, w'_2, ..., w'_k\}$ where $w'_l \in t$ for all $1 \leq l \leq k$ and $1 \leq q \leq p$, predict the best e_j mostly closely related to s_q.

This is an extension to our earlier work (Ma et al., 2020) in which tweets are labeled on passage-level only, and no official emoji list is used to standardize the annotations. The passage-level classification datasets are annotated directly using the emojis appearing in each tweet. Under the multi-class classification setting, we duplicate the tweets if they are bond to multiple emojis and use one emoji to label each copy. For the aspect-level annotations, each record is identified by a tweet and an aspect text piece. We generate the aspect-level annotations with the help of a Transformer-based model. Emojis are removed from the text in all three settings in case that neural models trained on our datasets directly copy and paste the emojis from text into predictions.

3.1 Transformer Networks

The core of Transformer networks is the self-attention mechanism. Figure 1 displays the structure of a self-attention head. In an attention head, each word gets its query, key, and value vectors by multiplying the Q, K, and V matrices with its representation vector. The attention score vector of a word is generated with the dot product between its query vector and the key vector of all the words in the same tweet. We get the attention map by stacking the attention vectors together. In a Transformer-based model, there are usually multiple attention heads on each layer (16 in the bert-large-cased model we use). According to past studies about Transformer networks, the highest layers of a Transformer model encode mainly task-specific features for predictions (Kovaleva et al., 2019), while shallower layers extract fundamental and low-level linguistic features (e.g., the middle Transformer layers attend mostly to syntactic features (Vig and Belinkov, 2019; Hewitt and Manning, 2019)). Thus we rely on the mean of all the attention maps on the last layer of a Transformer-based model to represent the token-level interrelations corresponding to each emoji label.

BERT (Devlin et al., 2019) is a family of pre-trained Transformer-based models. In BERT architecture, predictions are conditioned on the representation of the "[CLS]" token on its last layer. Thus, we are able to evaluate the contribution of each word to the final prediction by looking at how heavily the "[CLS]" token attends on the other words. To be specific, we use the pre-trained bert-large-cased model in all our experiments. It is worth noting that any self-attention-based neural model potentially fits our annotation framework. We pick the bert-large-cased model in our experiments because it performs the best on the 64-label single- and multi-label emoji prediction tasks, beating the bert-base models and two XLNet models.

3.2 Attention-based Automatic Annotation Method

Based on the observation that important tokens to a prediction made by BERT are heavily attended by the "[CLS]" token, we design the following steps in sequence, to annotate an aspect-level multi-class emoji prediction dataset.

3.2.1 Data Preparation

We use the 64 top-ranked emojis in our emoji list to annotate an aspect-level dataset. The selected emojis are shown in Table 1. We limit to the 64 emojis to allow for manual quality inspections of the annotations. As the first step, we remove tweets not containing any of the 64 emojis. Tweets shorter than five words are also discarded since most short tweets are formed only by mentions, retweets, URLs, and hashtags. This may unavoidably remove some meaningful short tweets, e.g., "Good night.". But generally, these tweets form one aspect as a whole, reducing the aspect-level annotations to tweet-level annotations. URLs and hashtags are replaced with #URL# and #HASHTAG# tokens as well to reduce noise. To avoid dominating classes in the dataset, we balance the number of records in each class by reducing the number of tweets associated with frequent emojis. We set the threshold to be 10,000 records. Tweets having labels in the classes with less than 10,000 instances are all preserved, while the rest are randomly pruned. Table 1 also displays the number of times each emoji appears in the balanced dataset. Duplicated emojis in the same tweet do not count

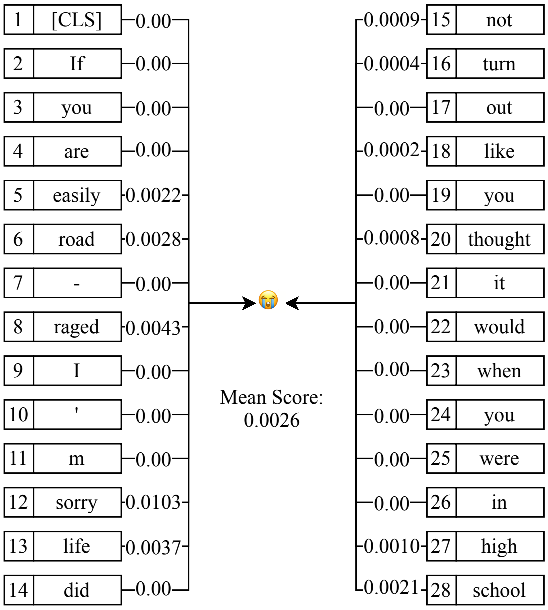

Figure 2: Attention score distribution in an example sentence regarding one specific emoji (the loudly crying face).

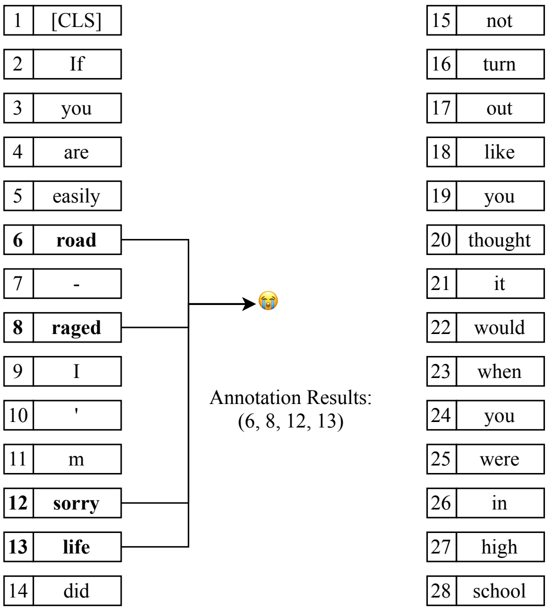

Figure 3: An example of aspect-level annotation results. Bold words connected to the emoji are annotated as the aspect for the given emoji.

Table 2: The evaluation scores of a bert-large-cased model on 64 binary classification datasets we construct. The scores are in terms of F-1 score. The emojis are sorted by frequency.

for multiple occurrences.

The bert-large-cased model achieves 41.44% in F-1 score when evaluated on the entire dataset under the multi-class classification setting, which is too low to generate proper aspect-level annotations. To enable the model to learn better representations of the tweets in this dataset, we split our dataset into 64 binary classification subsets. In each subset, we choose all the tweets labeled with one specific emoji as positive examples. We generate equal numbers of negative examples by randomly sampling the same amount of tweets from the other emoji groups. For example, as there are 76,301 tweets labeled with the ❤️ emoji in our dataset, we sample 1,211 tweets randomly from tweets labeled with every of the rest 63 emojis to form the negative examples. This results in a binary classification dataset for ❤️ with 152,594 records. The same process is repeated to generate 64 binary classification datasets.

3.2.2 Model Fine-tuning

The bert-large-cased model is pre-trained on large text corpora. We fine-tune and evaluate the model on each binary classification dataset. The entire datasets are used as both the training and test data since the positive and negative instances in these datasets are perfectly balanced, and because we expect the model to overfit on the datasets. The experiments are done on one RTX Titan GPU for an average of 3 hours per experiment. As is shown in Table 2, the evaluation scores of the BERT model range from 80.30% to 97.32% in F-1 score in our experiments. The scores show that the BERT model is good enough for annotating a high-quality aspect-level emoji prediction dataset.

3.2.3 Word Scoring

After the model is fine-tuned on each binary classification dataset, we evaluate the model on the dataset again and use the attention map on the last layer of the model on positive instances to annotate them. Recall that for BERT models, the attention score between the "[CLS]" token and each other token reflects the token's contribution to the prediction. It is worth noting that BERT tokenizes words into tokens using Byte Pair Encoding (BPE) in its preprocessing step. For readability, we re-combine the subword tokens into words and average their scores to generate word-level attention scores. Assuming the model always makes correct predictions, the attention weights can model the relatedness of each word to the labeled emoji. Though our model cannot always generate correct predictions, we discard the annotations generated from wrong predictions in the final release of the dataset as the majority of data is annotated correctly.

3.2.4 Thresholding

As the last step of annotating the dataset, we generate the annotations from the attention scores. Figure 2 shows one example sentence with attention scores to an emoji attached to the words. We first set the scores of stopwords and punctuation marks to 0 to avoid including them in the annotations. After that, we use the mean attention score on the remaining words in each tweet as the threshold to select important words from the text. The tweet in Figure 2 is annotated as in Figure 3 after thresholding, for example. After the annotations are generated, we group the records based on tweets to form the aspect-level multi-class classification dataset.

4 Emoji Prediction Dataset

One of the goals of this paper is to annotate the PAN-19 Celebrity Profiling dataset for emoji prediction. We refer to the newly-annotated dataset as Multi-Resolution Emoji Prediction (MREP) Dataset since it contains both passage-level and aspect-level annotations. When releasing the data, we randomly split the dataset into train, dev, and test datasets with 80%, 10%, and 10% of the data amount, respectively. The random seed we use for this separation is 29936.

Table 3 displays one record in our dataset with its three sets of labels. The label set of our dataset is constructed by the 64 emojis in Table 1. Sentences are labeled by single emojis under the tweet-based multi-class classification setting. The tweet-based multi-label classification annotations are emojis separated by semicolons. An annotation under the aspect-level multi-class classification setting is formed by a list of emoji indices and their corresponding text spans in the tweet. The final annotated dataset contains 1,036,131 multi-class classification records and 500,114 multi-label or aspect-level records. We benchmark our dataset using a pre-trained bert-large-cased model and show the results in Table 4. We do not benchmark our dataset with other models since no existing emoji prediction model is designed for multi-label or aspect-based predictions.

5 Annotation Quality Validation

5.1 Automatic Validation

We validate the quality of our annotations in two ways. Since it is supported by (Felbo et al., 2017) that neural models trained on a high-quality emoji prediction dataset can help improve the performances of some NLU tasks, we train a BERT model jointly on our dataset and four other datasets to automatically validate our annotations. The four datasets we use are the Stanford Sentiment Treebank (SST) (Socher et al., 2013) for sentiment analysis, GYAFC (Rao and Tetreault, 2018) for formality classification, and MELD and MELD-Dyadic (Poria et al., 2019) for emotion recognition. In the experiments, we use the MT-DNN (Liu et al., 2019) codes with a batch size of 32. The pre-trained model we use is bert-large-cased with 24 layers and 16 attention heads on each layer. We fine-tune the model for seven epochs in each experiment, with a learning rate of 0.00005. The GYAFC, MELD, and MELD-Dyadic datasets are also partitioned into train/dev/test datasets by 80%/10%/10% of the entire data using a random seed of 29936, for consistency.

The evaluation results are displayed in Table 5. Our dataset brings noticeable improvements to all the tasks we choose. This is a strong validation

Tweet	Catch all the feels with me LIVE tonight on Instagram at 8p PT when @AmericanIdol is back for Hollywood Week solos I'll take YOUR questions at the commercial breaks! #HASHTAG# #URL#

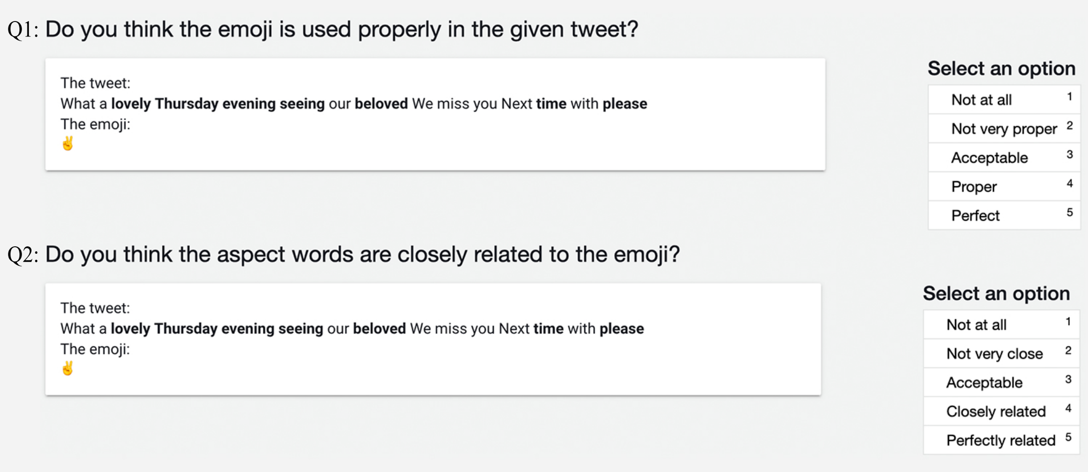
Aspect-Level	Emoji	Aspect Text Span
	🙏	(catch, all, feels, LIVE, Instagram)
	🎉	(live, tonight, Hollywood, Week)

Table 3: An example record in our labeld dataset. Multi-Class, Multi-Label and Aspect-Level corresponds to the three types of annotations, respectively. We replace all the hashtags and URLs with #HASHTAG# and #URL# tokens at the preprocessing step.



Q1: Do you think the emoji is used properly in the given tweet?

The tweet:
What a **lovely Thursday evening seeing** our **beloved** We miss you Next **time** with **please**
The emoji:
✌

Select an option

Q2: Do you think the aspect words are closely related to the emoji?

The tweet:
What a **lovely Thursday evening seeing** our **beloved** We miss you Next **time** with **please**
The emoji:
✌

Select an option

Figure 4: A preview of our Amazon Mechanical Turk questionnaire. We ask three annotators to answer the questionnaire for each annotated record.

Task	ACC	ACC@5	F-1	ACCsub
PBMC	41.88	61.95	41.44	-
PBML	99.41	-	-	27.16
ABMC	82.16	96.07	79.91	-

Table 4: Benchmark results on our dataset under three different settings. PBMC, PBML, and ABMC correspond to passage-based multi-class, passage-based multi-label, and aspect-based multi-class classification settings, respectively. ACC denotes accuracy and ACC@5 refers to accuracy of the top-5 predictions. For multi-label classification, ACC refers to the average accuracy of predicting every single emoji while ACCsub counts only exact matches.

of the high quality of our annotations. Among the three types of annotations, the aspect-level classification setting helps the most. This is probably because the emojis are better associated with the aspects, not all the words in a tweet.

Additionally, we run experiments to explore the subjectivity and randomness using similar but nuanced emojis, e.g., the ten heart-shaped emojis with different colors in our emoji list. To be specific, we construct a multi-label classification dataset using the tweets associated with the heart-shaped emojis from our PBMC dataset. We then fine-tune a bert-large-cased model on the subsampled dataset. The model achieves an F-1 score of 43.47% in this experiment, indicating that these heart-shaped emojis are as distinguishable as the other emojis. Furthermore, we cluster the heart-shaped emojis in the PBMC dataset into one class and evaluate its influence on our four downstream tasks. The fine-tuned model produces 93.69%, 85.07%, 44.05%, and 44.82% F-1 scores on the SST, GYAFC, MELD, and MELD-Dyadic datasets, respectively, slightly lower than the original PBMC dataset without emoji clustering. These experiments make it clear that similar emojis are, though sometimes unconsciously, used in differently depending on the context. Since emoji clustering does not provide additional help to downstream tasks, and because clustering the emojis increases subjectivity in creating the datasets, we do not apply

	SST		GYAFC		MELD		MELD-Dyadic	
	ACC	F-1	ACC	F-1	ACC	F-1	ACC	F-1
Single-task	93.12	93.38	88.98	88.06	65.29	44.03	63.06	44.71
+ PBMC	93.46	93.74	87.02	86.59	65.80	44.08	64.18	44.97

emoji clustering in our annotation framework or the annotated datasets.

We also run experiments by choosing the records labeled with "abstract" (e.g., emojis showing emotions) and "concrete" emojis (e.g., emojis representing objects) respectively. We arrange the "abstract" emojis in Table 7 and "concrete" emojis in Table 8. Results show that "abstract" emojis bring more improvements to the aforementioned tasks. This implies that sentiments, metaphors, and emotions may be abstract concepts, thus agreeing better with the predictions of "abstract" emojis.

5.2 Manual Validation

Since the use of emojis is very subjective in many cases, we sample 700 aspect-level annotations randomly for manual validation as well. Other than a few exceptions, the vast majority of the annotations (around 85%) look appropriate. We list four example imperfect annotations in Table 6. The most common problem with these annotations is that, since we removed stopwords from the annotations, some aspect-level labels are not complete and the meanings may change. In Tweets 1 and 2 in Table 6, for example, the words "at" and "off" are not chosen as parts of the labels. This does not affect Tweet 1 much, but for Tweet 2, the words "look forward" do not explain the usage of the 😊 emoji. We cannot leave all the stopwords as they are since they are usually heavily attended in attention maps of Transformer-based models. Being a language model, BERT unavoidably scores stopwords and punctuation marks high in attention maps due to their frequent co-occurrence with almost all the other words. Without removing the stopwords, the mean attention score will increase significantly, and useful words may not be correctly labeled without filtering them out. This can probably be avoided by using a list of phrases whose meanings change without all their component words. A postprocessing step removing only the stopwords outside the dependency path of any other aspect word may also be helpful. The annotation of Tweet 3 is not appropriate either since the text is too short to include any useful information associated with the emoji. It is possible that the user loves traveling or working, but the emotion cannot be inferred from this piece of text. Luckily, this does not happen often in our dataset (only 2 out of 700 in the sampled data fall under this category). The wise monkey emoji in Tweet 4 appears to be used randomly. This is the only instance in the sample that we do not know why it is used. The top-ranked emojis are mostly related to emotions or sentiments, the meanings of which are usually contained in the text. However, "concrete" emojis might pose more difficulty for annotation as they are sometimes used in place of words or phrases. This may cause annotation problems in the future if we expand our research to a broader range of emojis. A preprocessing step substituting all the "concrete" emojis with their descriptive texts can compensate for this problem.

To avoid bias, we also send the sampled aspect-level annotations for validation on Amazon Mechanical Turk. The questionnaire we design is shown in Figure 4. Each time a worker is given one tweet, one emoji associated with the tweet, and the text span annotated in our dataset corresponding to the emoji. We require the workers to answer two questions for each data point, namely, how well the emoji relates to the tweet and whether the selected span of text properly expresses the given emoji. Both questions are scored using a Likert scale (Joshi et al., 2015), in the range $\{1$ (worst), 2, 3 (acceptable), 4, 5 (perfect)$\}$. Each record is validated by three different workers. The answers are aggregated together by averaging them. Question 1 mainly validates the quality of tweet-level annotations in our dataset. The average score for Question 1 is 2.9 (mainly acceptable), showing that the way emojis are used in our dataset is understandable, but does not perfectly reflect how our validators use emojis in their daily lives. The results also teach us that the patterns of emojis usage differ from person to person, as the unanimous agreement rate of our validators is 26.4% for Question 1. By categorizing the scores into Poor (1, 2), Acceptable (3), and High (4, 5), however, we get a unanimous agreement rate of 93.4% for Question 1. Question 2 is designed to validate the quality of our aspect-level annotations. The average scores are 2.9 on all the records and 3.5 on the tweets having an average score greater than or equal to 3 in Question 1 (i.e., for tweets where the emoji is deemed acceptable or higher). This shows that our aspect-level annotations for tweets where the emoji is appropriate are of acceptable quality, despite the issue discussed above.

6 Conclusion and Future Work

Emoji prediction has become a popular task in the NLP community, but the lack of publicly available large-scale datasets with high-quality annotations remains a bottleneck for this task. In this paper, we annotated a publicly available Twitter dataset for the emoji prediction task. We designed an annotation method for aspect-level annotations using the self-attention mechanism in Transformer networks. This method showed great performance in labeling our dataset, and can potentially be used in other tasks as well. Our dataset contains three types of annotations, namely the passage-level multi-class and multi-label classification labels, and the aspect-level multi-class classification annotations. We validated our annotations both automatically and manually to ensure their quality. We also benchmarked our dataset using a pre-trained bert-large-cased model. Our labeled datasets are available upon request. There are two main paths for extending this work. First, the aspect-level annotation method can be applied to other NLP tasks. Second, our annotations in the emoji prediction dataset can be enhanced by including an enriched label set.

Abstract

We aim to leverage human and machine intelligence together for attention supervision. Specifically, we show that human annotation cost can be kept reasonably low, while its quality can be enhanced by machine self-supervision. Specifically, for this goal, we explore the advantage of counterfactual reasoning, over associative reasoning typically used in attention supervision. Our empirical results show that this machine-augmented human attention supervision is more effective than existing methods requiring a higher annotation cost, in text classification tasks, including sentiment analysis and news categorization.

1 Introduction

The practical importance of attention mechanism has been well-established, for both (a) improving NLP models (Vaswani et al., 2017), and also (b) enhancing human understanding of models (Serrano and Smith, 2019; Wiegreffe and Pinter, 2019).

This paper pursues the former direction, but unlike existing models, typically using attention in "unsupervised" nature. Adding human supervision to attention has been shown to improve model predictions and explanations (Jain and Wallace, 2019). For example, consider a review in (Tang et al., 2019) "*this place is small and crowded but the service is quick*". Models with unsupervised attention may attend highly on "*quick*", a generic strong signal for restaurant reviews, but one may supervise to focus on "*crowded*" to guide models to predict a negative sentiment correctly.

For this goal, *attention supervision* task (Yu et al., 2017; Liu et al., 2017) treats attention as output variables so that models can be trained to generate similar attention to human supervision. We categorize such human supervision into the following two levels:

- **Sample level rationale**: In the above example, whether to attend on *quick* or *crowded* depends on the ground-truth sentiment class. Human annotator is required to examine each training sample, and highlight important words specific to a sample and its class label.
- **Task level**: An alternative with lower annotation overhead would be annotating vocabulary, separately from training samples. That is, both *quick* and *crowded* are annotated to attend, since both have high importance for the target task of sentiment classification.

A naive belief would be assuming the former with a higher annotation cost is more effective at supervising the model's attention. Our key claim, in contrast, is that requiring **more** annotation, or, sample-specific supervision, can be less effective than requiring **less** from human then augmenting it by machine (**less-is-more**-hypothesis). Similar skepticism on asking **more**, or sample-level rationales from humans, was explored in (Bao et al., 2018), where machine attention from large additional annotations was more effective supervisions than rationales.

In this paper, we validate less-is-more without additional annotation overhead, by proposing a holistic approach of combining both human annotation and machine attention. Key distinctions from (Bao et al., 2018) are (a) humans annotate even less, and (b) without additional training resources. Specifically, we start by loosening the definition of human annotation (Camburu et al., 2018; Zhong et al., 2019) into the task-level annotation: it reduces annotation cost to the size of vocabulary, or often to zero, when public resources such as sentiment lexicon replace such annotation. We show the effectiveness of this zero-cost supervision, for both sentiment classification and news categorization scenarios, after our proposed adaptation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6695–6704,
November 16–20, 2020.

Our adaptation goal is an unsupervised adaptation of task-level human annotation to sample-level supervision signals for attention/classification models. Specifically, we propose Sample-level AttentioN Adaptation (SANA). Specifically, for self-supervising such adaptation, SANA conducts *what-if* tests per each sample, of whether the permutation on human annotation changes the machine prediction. That is, we collect the counterfactual (machine) supervisions for free, by observing whether highly attended word by human leads to the same machine prediction, compared to when such attention is counterfactually lowered. In such a case, SANA supervises to reduce the importance of the word. We validate such counterfactual signals are missing pieces for adapting word importance to sample-specific prediction.

We evaluate SANA on three popular datasets, SST2, IMDB, and 20NG. In all of the text classification datasets, SANA achieves significant improvements over baselines, using unsupervised attention or supervised with task- or sample-level human annotations, in the following four dimensions: Models supervised by SANA predict more accurately, explain causality of attention better, and are more robust over adversarial attacks, and more tolerant of the scarcity of training samples.

2 Preliminaries

2.1 Text Classification with Attention

Text classification assumes a dataset $D = \{\mathbf{x}_i, y_i\}_{i=1}^{N}$ which associates an input text $\mathbf{x}_i$ to its corresponding class label y_i. We will omit the index i when dealing with a single input sample. Let the input sequence of word features (*e.g.*, embeddings) be denoted as $\mathbf{x} = \{w_t\}_{t=1}^{T}$, where T is the length of the sequence. The sequence of hidden states produced by an encoding function f_ϕ with learnable parameters ϕ is then $\mathbf{h} = \{h_t\}_{t=1}^{T}$. Formally, $f_\phi : \mathbf{x} \rightarrow (\mathbf{h}, \hat{\alpha})$, where attention weights $\hat{\alpha} = \{\hat{\alpha}_t\}_{t=1}^{T}$ indicate a probability distribution over the hidden states (Zou et al., 2018; Yang et al., 2016). Finally, the hidden representations are fed into a function $g_\theta : (\mathbf{h}, \hat{\alpha}) \rightarrow \hat{y}$ with learnable parameters θ and a softmax layer that predicts the probabilities $\hat{y}$ over classes:

$$\hat{y} = \texttt{Softmax}(W^{\top}\tilde{\mathbf{h}} + b), \quad \theta = \{W, b\} \qquad (1)$$

where $\tilde{\mathbf{h}} = \sum_{h_t \in \mathbf{h}} \hat{\alpha}_t h_t$ and $\texttt{Softmax}(z_i) = e^{z_i} / \sum_j e^{z_j}$. The parameters ϕ and θ are trained to minimize the cross-entropy loss $L_{task}(\hat{y}, y)$ between the predicted label $\hat{y}$ and the ground-truth label y.

2.2 Attention Supervision

Attention can be treated as output variables, so that humans can supervise. Given an input sample $\mathbf{x}$, let α and $\hat{\alpha}$ be the attention labels (provided by human annotators) and the trained attention weights. Then, the loss for attention supervision is defined as the cross-entropy loss $L_{att}(\hat{\alpha}, \alpha)$ between $\hat{\alpha}$ and α. Finally, the parameters of the text classification network with attention supervision are trained to minimize both loss terms together as follows:

$$L = L_{task}(\hat{y}, y) + \mu \cdot L_{att}(\hat{\alpha}, \alpha) \qquad (2)$$

where μ is a preference weight.

Requiring humans to explicitly annotate soft labels α has been considered unrealistic (Barrett et al., 2018), and often delegated to implicit signals such as eye gaze. As an alternative to asking humans to annotate, important words for the given sample and class label have been typically annotated as rationale (Bao et al., 2018; Zhao et al., 2018). Formally, given an input sample $\mathbf{x}$ and its class label y, let $A \in \{0, 1\}^T$ be a binary vector of selecting words in $\mathbf{x}$, *i.e.*, $\forall w_t \in \mathbf{x} : A(w_t) \in \{0, 1\}$. Then, we convert the attention annotation A into a soft distribution of target attention labels α using softmax:

$$\alpha_t = \frac{\texttt{exp}(\lambda \cdot A(w_t))}{\sum_{t'=1}^{T} \texttt{exp}(\lambda \cdot A(w_{t'}))} \qquad (3)$$

where λ is a positive hyper-parameter that controls the variance of scores: when λ increases, the distribution of α becomes more skewed, guiding to attend a few of more important words.

To illustrate a rationale, when given the aforementioned review sample in Sec. 1, possible annotations for the negative label are either "this place is small and crowded but the service is quick" or "this place is small and crowded but the service is quick", where the underlines indicate the hard selection by human. Then, we can translate them into the sample-level annotation $A = [1, 1, 1, 1, 1, 1, 0, 0, 0, 0, 0]$ or $A = [0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0]$.

3 Less is More for Attention Supervision

Sample-level annotation is reportedly too expensive in many practical settings (Zhong et al., 2019), and is far difficult for humans to capture the dependency with corresponding class labels. In contrast, annotators may select important words for a target task, namely task-level attention annotation

(Def. 3.1), without looking up individual samples and their labels.

Definition 3.1 *(Task-level Attention Annotation) Assuming the existence of the vocabulary V, the vocab-level annotation $A_{task} \in \{0,1\}^{|V|}$ is a binary vector of the hard selection for words in V, i.e., $\forall w_t \in V : A_{task}(w_t) \in \{0,1\}$. Based on A_{task}, when given an input sample $\boldsymbol{x}$, we can use a proxy of the sample-level annotation A, i.e., $\forall w_t \in \boldsymbol{x} : A(w_t) = A_{task}(w_t)$.*

	Sample-level	Task-level	Reduction ratio
SST2	208K	16K	-92.3%
IMDB	5M	124K	-97.5%
20NG	232K	22K	-90.5%

Table 1: Comparison of annotation space

As shown in Tab. 1, the annotation space, which is referred to as a word set size for annotation, is 10~36 times smaller at task-level than at sample-level. Generally, the vocabulary size is far smaller than the total number of word occurrences in training samples. Our goal is thus to keep annotation cost cognitively reasonable (Zou et al., 2018; Zhao et al., 2018), leaving machine self-supervision to close the annotation quality gap (Sec. 3.1 and 3.2). Meanwhile, we present a setup of zero-cost supervision, which allows us attention supervision without any human efforts in all scenarios using public resources and tools (Sec. 3.3).

3.1 Counterfactuals as Causal Signals

Our key idea is to leverage causal signals (Johansson et al., 2016) from human annotation A (or attention labels α) of an input sample $\mathbf{x}$ to its corresponding model prediction $\hat{y}$. More specifically, we test whether two different attentions (one is original and the other is counterfactual) on the same input sample $\mathbf{x}$ lead to different prediction results $\hat{y}$. If high (original) and low (counterfactual) attention weights for an word w_t yield the same (or very similar) prediction, it provides evidence to edit the importance of word w_t in A into a lower value.

Formally, let $\hat{\alpha}$ and $\bar{\alpha}$ be the original and counterfactual attention weights, respectively, and let $\hat{y}$ and $\bar{y}_t$ be the original prediction and its counterfactual prediction with attention change (*i.e.*, from $\hat{\alpha}_t$ to $\bar{\alpha}_t$) on $w_t \in \mathbf{x}$, respectively. Then, knowing the quantity $|\hat{y} - \bar{y}_t|$, measured as the individualized treatment effect (ITE), enables measuring how much the word w_t contributes to the original prediction via attention mechanism. For this measurement, we adopt the Total Variance Distance (Jain and Wallace, 2019) between the two predictions, which is defined as follows:

$$TVD(\hat{y}, \bar{y}_t) = \frac{1}{2} \sum_{c=1}^{C} |\hat{y}^c - \bar{y}_t^c| \tag{4}$$

where c is the class index. If TVD value is too low, we can give a penalty by decaying the human annotation $A(w_t)$ with a factor of γ, which we empirically set as 0.5, to update the attention labels.

Algorithm 1 SANA

```
Input: Training dataset $D$, Task-level annotation $A$
Output: Model parameters $\{\phi, \theta\}$
Initialize attention labels $\alpha$ from $A$ ▷ Using Eq (3)
$\{\phi, \theta\} \leftarrow \mathrm{argmin}_{\phi,\theta} L(D, \alpha; \phi, \theta)$ ▷ Using Eq (2)
for $z = 1$ to $z_{max}$ do
    for each $(\boldsymbol{x}, y) \in D$ do
        $\mathbf{h}, \hat{\alpha} \leftarrow f_\phi(\mathbf{x})$
        $\hat{y} \leftarrow g_\theta(\mathbf{h}, \hat{\alpha})$
        for each $w_t \in \boldsymbol{x}$ do
            if $A(w_t) > 0$ then
                $\bar{\alpha} \leftarrow$ Counterfactuals($\hat{\alpha}, w_t$)
                $\bar{y}_t \leftarrow g_\theta(\mathbf{h}, \bar{\alpha})$
                if $TVD(\hat{y}, \bar{y}_t) < \epsilon$ then
                    $A(w_t) \leftarrow \gamma \cdot A(w_t)$
                end
            end
        end
    end
    $\lambda \leftarrow \gamma^{-1}\lambda$ ▷ In Eq (3)
    Update attention labels $\alpha$ from $A$ ▷ Using Eq (3)
    $\{\phi, \theta\} \leftarrow \mathrm{argmin}_{\phi,\theta} L(D, \alpha; \phi, \theta)$ ▷ Using Eq (2)
end
return $\{\phi, \theta\}$
```

3.2 Sample-level Attention Adaptation

Based on TVD, we propose a simple yet effective approach, Sample-level AttentioN Adaptation (SANA), to derive the sample-level machine attention from the task-level human annotation. As described in Alg. 1, SANA starts with the classification model trained with the initial attention labels α. Based on ϕ and θ, we run the classification inference several times for an input sample: one for obtaining the original attention weights $\hat{\alpha}$ and the others for *counterfactual* attention weights $\bar{\alpha}$. More specifically, we first store the hidden representations $\mathbf{h}$ and the attention weights $\hat{\alpha}$ from f_ϕ, and the original prediction $\hat{y}$. Then, for each word w_t, `Counterfactuals` returns the counterfactual attention weights $\bar{\alpha}$, by 1) copying $\hat{\alpha}$ but 2) assigning zero to the t-th dimension and 3) renormalizing as probability distribution, and we obtain its corresponding prediction result $\bar{y}_t$ by re-using $\mathbf{h}$.

Note that, since the hidden representation at time step t contextualizes a word w_t with surrounding words, we adopt perturbing only single words in SANA, not multiple words at the same time, also enjoying the computational advantage.

Finally, based on $\hat{y}$ and $\bar{y}_t$, as defined in Eq (4), we compute TVD and update the human annotation A by threshold ϵ and decay ratio γ. Once an iteration[1] is completed over the whole training corpus, we re-train the network with the updated attention annotation and labels. For the stable update, we observe that increasing the coefficient λ in Eq (3) is crucial, as TVD is not an optimal metric, preventing α from being flattened.

3.3 Zero-cost Supervision

From this point on, for task-level supervision, we assume zero-cost human annotation efforts, either by using public resources or self-supervision.

Supervision by public resources Task-level annotation are often publicly available as resources or tools. For example, sentiment lexicon (Esuli and Sebastiani, 2006) consists of sentiment words, which are important to the sentiment classification task, and named-entity recognizer (NER) (Peters et al., 2017) can collect entity words commonly attended in news categorization task. We empirically show that both lexicon and NER can be adequate substitutes for the manual task-level annotation.

Model distillation In an extreme scenario without any human annotator and public resources, inspired by self knowledge distillation (Furlanello et al., 2018), we report results for using the attention weights of the unsupervised model as a supervision. Note, however, this is highly unlikely in practice, but reported as a lower bound accuracy, when unsupervised attention noise is propagated through distillation supervision. Using SANA is even more critical in this noisy annotation scenario, to denoise attention supervision from counterfactual reasoning, which we empirically analyze this in the subsequent section.

4 Experiment Setup

4.1 Datasets

To validate the effectiveness of SANA, we use the following three text classification datasets, which are widely used (Wang et al., 2018; Jain and Wallace, 2019) and statistically diverse as well. We split the official training split into 90% and 10% as training and validation sets respectively. We expect SANA in two-sentence tasks, such as SNLI and MPQA, would be promising, which we leave as future work.

- **SST2** (Socher et al., 2013): *Stanford Sentiment Treebank* provides around 11K sentences tagged with sentiment on a scale from 1 (most negative) to 5 (most positive). We filter out neutral samples and dichotomize the remaining sentences into positive (4,5) and negative (1,2). We set the maximum sequence length as 30.

- **IMDB** (Maas et al., 2011): *IMDB Large Movie Review Corpus* is a binary sentiment classification dataset containing 50K polarized (positive or negative) movie reviews, split into half for training and testing. We set the maximum sequence length as 180.

- **20NG**: *20 Newsgroups*[2] contains around 19K documents evenly categorized into 20 different categories. Following (Jain and Wallace, 2019), we extract samples belonging to *baseball* and *hockey* classes, which we designate as 0 and 1, deriving a binary classification task (*Hockey vs Baseball*). We set the maximum sequence length as 300.

4.2 Implementation Details

For all datasets, we use skip-gram (Mikolov et al., 2013) (official GoogleNews-vectors-negative300) word embeddings with 300 dimensions. We use 1-layered GRU for each direction with hidden size of 150 for both SST2 and IMDB, and 300 for 20NG dataset, with g_θ of 300 dimension with 0.5 dropout rate. For attention mechanism, the size of trainable context vector is set to 100 for SST2 and 300 for IMDB and 20NG.

For attention supervision, we use the balancing coefficient $\mu = 1.0$ for SST2 and IMDB, and $\mu = 2.0$ for 20NG. Contrary to Zou et al. (2018), we

---

[1] $O(|D| \cdot T)$, where T is the maximum sequence length

[2] `http://qwone.com/~jason/20Newsgroups/`

observe a larger μ is more effective for the smaller dataset. We set the contrasting coefficient $\lambda = 3$ except $\lambda = 5$ for 20NG dataset. In Alg. 1, we use decay ratio $\gamma = 2.0$ and TVD threshold $\epsilon = 0.3$. In our experiments, the decay ratio is not significantly correlated with the final accuracy, but correlated more with the convergence period. Setting $\gamma = 2.0$ leads to the reported performance within $z_{max} = 5$.

For BERT, we train BERT-base architecture with a batch size of 4 over 3 epochs. We used Adam with a learning rate of 6.25e-5 and PiecewiseLinear scheduler.

All parameters are optimized until convergence, using Adam optimizer of learning rate 0.001. The learning parameters were chosen by the best performance on the validation set. In Alg. 1, the models are additionally fine-tuned over 10 epochs for each iteration. Note that learning time longer than our setting does not contribute to improving the model accuracy.

5 Results and Discussion

We now proceed to empirically validate the effectiveness of SANA, compared to unsupervised attention, and attention supervision approaches using either task-level or sample-level annotations as baselines (shortly, **unsupervised**, **task-level**, and **sample**). For task-level annotations (*e.g.*, in SANA), we adopt pre-annotated task-level annotations without any additional human efforts: for the two sentiment tasks, we use SentiWordNet (Esuli and Sebastiani, 2006), and for 20NG task, we use entities recognized by AllenNLP NER (Peters et al., 2017). We thus present the empirical findings for the following four research questions:

RQ1: Does SANA improve model accuracy?
RQ2: Does SANA improve model robustness?
RQ3: Is SANA effective for data-scarce cases?
RQ4: Does SANA improve attention explainability?

5.1 RQ1: Classification Accuracy

The main objective of this work is to improve attention supervisions for the purpose of better text classification. Thus, we evaluate the three attention methods by their contribution to the classification performance. Tab. 2 shows the classification accuracy for three classification datasets. In the table, we can observe the proposed approach, SANA with task-level annotation, outperforms all baselines in all the datasets. Among the results, SANA achieves the largest improvement over in 20NG dataset, which has the smallest training data. This suggests that SANA can also provide effective attention supervisions in data-scarce environments. To discuss this issue further, we will repeat this comparison over the varying size of training data for RQ3.

	Accuracy		
	SST2	IMDB	20NG
BERT	91.67	94.10	93.25
unsupervised			
BiGRU	83.96	88.07	86.04
model distillation			
BiGRU	83.53	86.93	85.12
+ SANA	84.35	88.03	88.23
task-level annotation			
BiGRU	85.12	89.30	87.19
+ SANA	**85.72**	**90.10**	**89.13**

Table 2: **Classification Performance:** accuracy (%) on the three classification datasets.

Our study also confirms two additional observations to our advantage– counterfactual 1) is effective even in model distillation setting and 2) meaningfully contributes to performance gains. More specifically, 1) SANA achieves 84.35% in SST2 dataset which is higher than the distillation only model, but lower than task-level supervised model. 2) this model gets 88.23% in 20NG dataset, which outperforms even task-level supervised model with 1.04 point gains. This also suggests the limitation of model distillation as supervision signals and supervision by public resources can provide better initial point for SANA than model distillation.

Our key contribution is to show zero-cost attention supervision can improve a simple model closer to a highly sophisticated model, such as BERT (Devlin et al., 2019) requiring more layers and data. This motivates us to supervise attention for BERT, though understanding of BERT internals, such as (Rogers et al., 2020), is mostly observational at this stage– Intervening with attention would be an interesting future work.

Our experimental results show that SANA works well in diverse scenarios, but we observe that the effectiveness is reduced when the length of target text increases (Figure 2) or token identifiability decreases (e.g., complex architecture): SANA more effectively works when the token identifiability is improved (by adding residual connection between two recurrent layers), achieving 0.83 point gain from 89.14%, which is larger gap than 0.47 point gain without residual connection.

5.2 RQ2: Robustness in Adversarial Attacks

Having tested for the overall performance with the original datasets, we evaluate the robustness of SANA with the the adversarial datasets. Recently, adversarial examples (Zhang et al., 2019) have been employed as an evaluation tool for model robustness: while the adversarial example conveys very similar semantics of its original sample, but with small and intentional feature perturbations to cause classification models to make false predictions. For robustness analysis, we thus test whether the attention models can keep the original predictions from adversarial examples.

This experiment consists of the following steps: First, based on the original training data, we set a basic BiGRU model (without attention mechanism) as *threat* model, which an adversarial attack method aims to deceive. Second, based on the original test data, we generate paraphrase texts by using the state-of-the-art attack method (Alzantot et al., 2018) with word-level perturbations. Third, we randomly select almost 500 paraphrase texts, which succeed in changing the prediction of *threat* model, *i.e.*, adversarial examples. Finally, we report the accuracy of the three attention models over both adversarial examples and their corresponding original samples, respectively.

Tab. 3 presents the results of adversarial attacks.[3] In the table, we can find that SANA is more robust, showing the smallest gap of the classification accuracy between the original and adversarial samples. It demonstrates that, when the network is attending to the words having causal signals to the model prediction, the network becomes more robust against adversarial attacks, which is consistent with the experimental results in Lai et al. (2019). In addition to that, we observe similar results against the white-box adversarial examples (Tsai et al., 2019), where SANA improves 3.20 and 1.80 point gains from both unsupervised and supervised attentions.

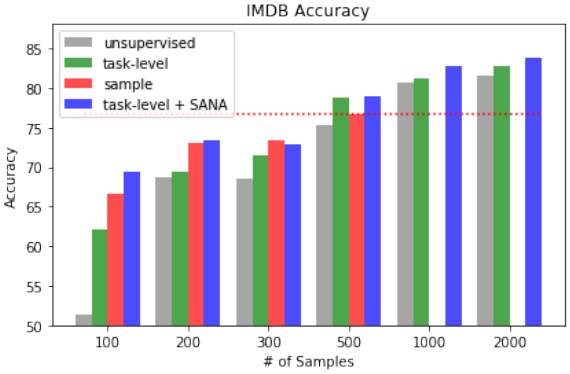

Figure 1: **Sample Effectiveness:** accuracy (%) on varying the amount of training samples in IMDB dataset.

5.3 RQ3: Sample Effectiveness

This section compares models over the varying amount of training samples in IMDB dataset, as a stress test for data-scarce scenarios.

For this experiment, we collect the sample-specific annotations from human workers. First, we randomly select 500 training samples from IMDB dataset, and ask the worker to underline the apparent rationales for the sentiment class, guided by the definition of rationale in Zhang et al. (2016). The data collection is conducted using an open annotation tool (Yang et al., 2018). Then, we build an additional method, named **sample**, which is trained with the collected sample-specific annotations.

The results are presented in Fig. 1. We notice that SANA and **sample** show much stronger performance when the training data is scarce, where similar results are reported in (Bao et al., 2018). As we expected, the attention supervision using the sample-specific annotations gets a higher accuracy than that using the task-level annotations, but cannot be scaled-up above 500 training samples, which is represented by the red reference line. In contrast, SANA improves accuracy with ≥ 1000 samples and its scalability. This result demonstrates that our counterfactual inferences successfully augment one annotation into multiple (counterfactual) attention supervisions, better regularizing from limited samples.

5.4 RQ4: Attention as Human Explanation

This section studies whether attention, after supervision, is more effective for human consumption as model explanation. Existing metrics for explainability measure whether attention correlates with (a) class prediction or (b) feature importance, discussed in the next sections respectively.

---

[3] The reason why "Original" is different from natural accuracy in Tab. 2 is that we conduct the experiments over the original samples only paired with the adversarial examples, incurring the biases in the test set.

	SST2			IMDB			20NG		
	Original	Adversarial	$\lvert\Delta\rvert$	Original	Adversarial	$\lvert\Delta\rvert$	Original	Adversarial	$\lvert\Delta\rvert$
unsupervised	47.2	47.8	0.6	68.8	64.1	4.7	47.7	48.3	0.6
task-level	50.3	48.3	2.1	69.2	65.0	**4.1**	48.7	48.2	0.5
task-level + SANA (Ours)	49.9	49.7	**0.2**	69.4	65.2	**4.1**	48.1	48.3	**0.2**

Table 3: **Adversarial Attack:** accuracy (%) for original and adversarial examples on the three classification dataset. Against the adversarial attacks, the proposed method SANA shows consistent performance with the smallest accuracy gap ($\lvert\Delta\rvert$) over all the datasets. For this evaluation, we use 485, 532, and 478 pairs of original samples and adversarial examples, in SST2, IMDB, and 20NG respectively.

5.4.1 Attention as Causal Explanation

One measure for the explainability of attention is whether each attention weight captures the causality of word and class prediction, by permuting words and observing prediction changes. If the learning is successful, such causal signals should be consistently observed in the test predictions. To validate this, we employ the attention-permutation experiments designed in (Jain and Wallace, 2019), *i.e.*, *what-if* simulation. Specifically, when given an input sample in the test phase, we look into whether the randomly mutated attention (*i.e.*, cause) from the original attention yields any changes in the corresponding prediction result (*i.e.*, effect). Here, TVD for the permutation can be regarded as a desirable evaluation measure: as TVD is lower, the (original) learned attention has a weak mapping with the model prediction, and vice versa.

The results are presented in Fig. 2, where x-axis refers to TVD values, *i.e.*, the difference of model predictions, and y-axis refers to the frequency of *what-if* simulations on their returning TVD value. To carefully analyze this, we divide the simulation results by four different intervals of input sequence length, which can be an influencing factor: as the perturbations on longer texts are unlikely to make prediction changes (Sen et al., 2020).

In this figure, we can observe that SANA has the lowest frequency on $TVD = 0$ in all cases, showing the distribution skewed to larger TVD (*i.e.*, right on x-axis) compared to baselines. Such distribution suggests that attention in SANA strongly affects model prediction by the causal signals. In unsupervised and vocab (*i.e.*, task-level), the distributions are skewed to lower TVD (*i.e.*, left on x-axis), having larger frequency on zero TVD than SANA. These patterns indicate the baselines have weak attentions loosely aligned to model predictions, motivating SANA even working well in long texts.

5.4.2 Attention as Importance Indicator

As an alternative metric of attention explainablity, (Jain and Wallace, 2019) considers the relationship between attention weights and gradient-based feature importance score of each word.

However, prior research suggests using word as a unit of importance feature is rather artificial, as word is contextualized by, and interacts with other words: (Wiegreffe and Pinter, 2019) observes such limitation, and Shapley (Chen et al., 2018) measures interaction between features for capturing dependency of arbitrary subsets.

For this purpose, we report the KL divergence between C-Shapley[4] and attention weights, $D_{\mathbb{KL}}(\texttt{Shapley}(x) \parallel \texttt{attention}(x))$. We present the results in Tab. 4, showing SANA approach is the most well correlated method with Shapley scores, well capturing word dependency.

	`unsupervised`	`task-level`	SANA
IMDB	52.62	12.69	8.86

Table 4: KL-divergence from C-Shapley

Intuitively, C-Shapley observes the interaction in n-gram, and our work, attending upon hidden representations of RNN, which are *soft* n-grams, captures similar interactions. This result manifests that, standing on self-supervision signals, our counterfactual process can improve the explanation on the contextualization ability of RNN architectures.

6 Related Work

Instead of treating attention as a by-product of model training, the following work explored how machine/human can **consume** attention for model improvement or explanation, respectively. Machine/human may also **provide** supervision. We thus categorize existing work by machine/human

---

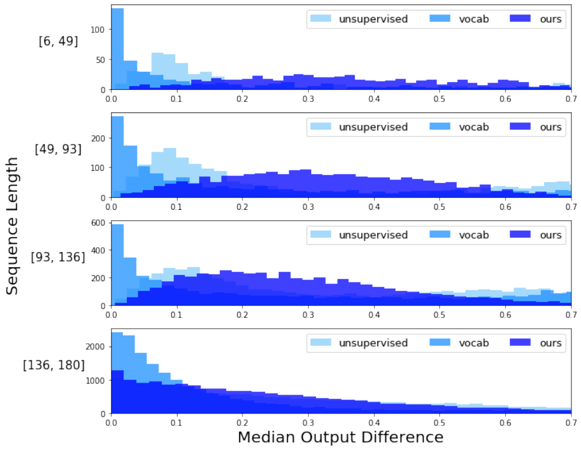
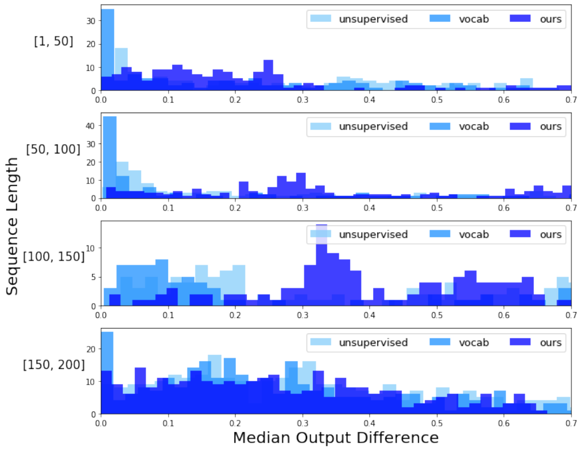
(a) SST2



(b) IMDB



(c) 20NG

Figure 2: **Attention Analysis:** x-axis refers to TVD values returned by *what-if* simulations and y-axis refers to the simulation frequency according to the returning TVD value. The compared datasets are (a) SST2 for sentence-level binary classification, (b) IMDB and (c) 20NG for document-level binary classification.

consumption and supervision. Our work falls into human providing supervision (with machine augmenting supervision) for machine consumption.

6.1 Attention to/from Human

As for human consuming attention as explanation, there has been criticism that unsupervised attention weights are too poorly correlated with the contribution of each word for machine decision (or, unfaithful) (Jain and Wallace, 2019; Serrano and Smith, 2019; Pruthi et al., 2019). Meanwhile, (Wiegreffe and Pinter, 2019) develops diagnostics to decide when attention is good enough as explanation.

As for improving human consumption, one direction focuses on better aligning models to human, another on improving annotation quality.

First, *identifiability* (Brunner et al., 2020) explains human-machine discrepancy, where token-level information is lost in model hidden states. For better alignment, (Tutek and Šnajder, 2020) utilizes masked language model (MLM) loss and (Mohankumar et al., 2020) invents orthogonal LSTM representations.

Second, toward the direction of improving annotation, (Barrett et al., 2018; Zhong et al., 2019; Bao et al., 2018) adopts sample-specific human annotations. In addition to rationales, (Zhao et al., 2018) uses event trigger words and (Kim and Kim, 2018) leverages user authenticated domains to narrow down the scope of attentions. (Strubell et al., 2018) injects word dependency relations to recognize the semantic roles in text. Such annotation overhead can be replaced by existing pre-annotated resources: (Zou et al., 2018) considers sentiment lexicon dictionary for a related task.

We pursue the second direction, but without incurring additional human annotation, by exploring the counterfactual augmentation, originated from self-supervision signals, contributing towards both accuracy and robustness of the model.

6.2 Attention to/from Machine

Machine consuming attention for higher accuracy is the most classical target scenario. (Yang et al., 2016) proposes hierarchical attention for document classification, (Chen et al., 2016) personalizes classification to user and product attributes. (Margatina et al., 2019) incorporates knowledge information to the self-attention module, *i.e.*, lexicon features.

Alternatively, machine may mine or augment attention supervision: (Tang et al., 2019) automatically mines attention supervision by masking-out highly attentive words in a progressive manner. (Choi et al., 2019) augments counterfactual observations to debias human attention supervision via instance similarity. Our work is of combining the strength of the two works: we automatically improve attention supervision via self-supervision signals, but we build it with free task-level resources.

7 Conclusion & Future Work

We studied the problem of attention supervision, and showed that requiring sample-level human supervision is often less effective than task-level alternative with lower (and often zero-) overhead. Specifically, we proposed a counterfactual signal for self-supervision, to augment task-level human annotation, into sample-level machine attention supervision, to increase both the accuracy and robustness of the model. We hope future research to explore scenarios where human intuition is not working as well as text classification, such as graph attention (Veličković et al., 2017).

Abstract

The central problem of sentence classification is to extract multi-scale n-gram features for understanding the semantic meaning of sentences. Most existing models tackle this problem by stacking CNN and RNN models, which easily leads to feature redundancy and overfitting because of relatively limited datasets. In this paper, we propose a simple yet effective model called **M**ulti-scale **O**rthogonal in**D**epend**E**nt LSTM (MODE-LSTM), which not only has effective parameters and good generalization ability, but also considers multi-scale n-gram features. We disentangle the hidden state of the LSTM into several independently updated small hidden states and apply an orthogonal constraint on their recurrent matrices. We then equip this structure with sliding windows of different sizes for extracting multi-scale n-gram features. Extensive experiments demonstrate that our model achieves better or competitive performance against state-of-the-art baselines on eight benchmark datasets. We also combine our model with BERT to further boost the generalization performance.

1 Introduction

Sentence classification (SC) is a fundamental and traditional task in natural language processing (NLP), which is widely used in many subareas, such as sentiment analysis (Wang et al., 2016a, 2018) and question classification (Shi et al., 2016). The central problem of SC is to understand the semantic meaning of a sentence by some key-phrases located at different positions (Wang et al., 2015).

CNNs excel at extracting n-gram features of sentences through a convolution operation followed by non-linear and pooling layers and have achieved impressive results in sentence classification (Kalchbrenner et al., 2014; Kim, 2014). However, the convolution operation itself is linear, which may not be sufficient to model the non-consecutive dependency of the phrase (Lei et al., 2015) and may lose the sequential information (Madasu and Anvesh Rao, 2019). As shown in Figure 1, the weighted sum of the phrase "***not** almost as **bad***" does not capture the non-consecutive dependency of "*not bad*" very well and ignores the sequential information.

I think this movie is *a bit boring* but ***not** almost as **bad***.

Figure 1: An example with variable-size phrases.

On the other hand, LSTMs (Hochreiter and Schmidhuber, 1997) are suitable for encoding structure-dependent semantics by storing previous word representations and preserving sequential information. However, LSTMs are still biased toward later words and ignoring the earlier words (Yin et al., 2017), so some current methods (Lai et al., 2015; Wang et al., 2016b; Zhang et al., 2016a; Song et al., 2018) combine the CNN and LSTM by stacking. However, merely stacking multiple layers can easily lead to feature redundancy and overfitting, because only relatively small training sets are available for SC tasks (Yin and Schütze, 2015; Guo et al., 2019). Hence, some researchers (Zhao et al., 2018a; Zhou et al., 2018; Madasu and Anvesh Rao, 2019) additionally attach an over-parameterized attention mechanism to enhance salient features and remove redundancy, but overfitting still occurs due to the increase in parameters for limited datasets.

A flexible combination method is to model non-linear mapping and non-consecutive dependency by replacing the convolution operation with a tensor product (Lei et al., 2015) or RNN unit (Shi et al., 2016; Wang, 2018). However, these methods only consider fixed-size n-gram features. This has apparent drawbacks in that there may be variable-size phrases (n-grams) in a sentence, as shown in Figure 1, we need to extract variable-size n-gram features to form a better sentence representation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6705–6715,
November 16–20, 2020.

The above observation motivates us to explore a better structure for sentence classification, balancing the capability and complexity. In this paper, we propose a lightweight model called **M**ulti-scale **O**rthogonal in**D**epend**E**nt LSTM (MODE-LSTM), which has minimal effective parameters, good generalization performance, and considers n-gram features of different scales. First, inspired by (Kuchaiev and Ginsburg, 2017), we disentangle the hidden state of LSTM into several independently updated small hidden states, which reduces the number of parameters. Furthermore, an orthogonal constraint is applied to the recurrent transition matrices of the small hidden states to improve the diversity of features. We call this structure **O**rthogonal In**D**epend**E**nt LSTM (ODE-LSTM). Then we use ODE-LSTM within a local window for extracting n-gram features instead of simply using a weighted sum as in convolution. Specifically, we introduce a Triple-S (Slide-Split-Stack) operation that splits a sentence into multiple sub-sentences by a sliding window and stacks them together. These sub-sentences are regarded as a mini-batch, which can be processed in parallel by a shared ODE-LSTM. We take the last hidden state of ODE-LSTM as the n-gram features for each sub-sentence. Furthermore, in order to capture the variable-size phrases in sentences, we use different scale windows with different initialized ODE-LSTMs to extract features of multiple scale phrases. We refer to this structure as a multi-scale ODE-LSTM (MODE-LSTM).

MODE-LSTM can extract multi-scale n-gram features like a CNN, while retaining the non-linear ability and long-term dependency of LSTMs, so it has stronger modeling ability but with fewer parameters than other methods. MODE-LSTM is analogous to a 1D CNN using multiple filters with different window sizes, but it uses recurrent transitions instead of the convolution operation. We conduct experiments on eight sentence classification datasets. The experimental results show that our proposed model achieves comparable or better results on these datasets with fewer parameters than other models. In addition, we further improve our model's generalization performance by integrating the BERT representation of the sentence.

2 Related Work

CNN-based models Kalchbrenner et al. (2014) propose a deep CNN model with a dynamic k-max pooling operation for the semantic modeling of sentences. However, a simple one-layer CNN with fine-tuned word embeddings also achieves remarkable results (Kim, 2014). Some researchers also use multiple word embeddings as inputs to further improve performance (Yin and Schütze, 2015; Zhang et al., 2016b). Xiao et al. (2018) propose a transformable CNN that can adaptively adjust the scope of the convolution filters. Although the above CNN-based methods perform excellently in extracting local semantic features, linear convolution operation limits the ability of modeling non-consecutive dependency and sequential information.

RNN-based models RNNs are suitable for processing text sequences and modeling long-term dependencies, so it is also used for sentence modeling. Recently, some work incorporate residual connections (Wang and Tian, 2016) or dense connections (Ding et al., 2018) into recurrent structures to avoid vanishing gradients. Dangovski et al. (2019) introduce a rotational unit of memory into RNNs for recalling long-distance information. Zhang et al. (2018) propose an HS-LSTM that can automatically discover structured representation in a sentence via reinforcement learning. However, these RNN-based models still display the bias problem where later words are more dominant than earlier words (Yin et al., 2017).

Hybrid models A natural strategy is to combine the advantages of CNNs and RNNs by stacking. Lai et al. (2015) equip an RNN with max-pooling to tackle the bias problem of RNNs. Zhou et al. (2015) use 1D convolutions to extract phrase features followed by an LSTM to obtain the sentence representation, and some subsequent work (Wang et al., 2016a,b; Lee and Dernoncourt, 2016) are similar. Alternatively, Zhang et al. (2016a) first model long-term dependencies using an LSTM and then apply a CNN to extract task-specific features. However, these methods simply stack multiple layers, resulting in feature redundancy and overfitting because of limited datasets (Yin and Schütze, 2015; Guo et al., 2019). Some researchers have introduced attention mechanisms (Er et al., 2016; Lin et al., 2017; Zhao et al., 2018a; Zhou et al., 2018) to enhance salient features, but this leads to a large number of parameters that overfit for small-scale datasets. A more flexible way is to combine them by replacing the convolution operation with a tensor product (Lei et al., 2015) or RNN unit (Shi et al., 2016; Wang et al., 2018), which can capture the non-linear n-gram features directly. Nevertheless, these methods currently only consider fixed-scale n-gram features.

Other models Some work (Tai et al., 2015; Liu et al., 2017; Wang et al., 2019) has used tree-LSTMs based on parse trees for sentiment analysis, but the performance depends heavily on the quality of the parser, and the parsing process itself is time-consuming. Others (Gong et al., 2018; Zhao et al., 2018b; Zheng et al., 2019) have tried using capsule networks with dynamic routing for encoding text representations.

The most relevant work to our approach is the DRNN (Wang, 2018), which also uses RNNs locally to learn semantic features. The differences between their approach and ours are: (1) The DRNN uses GRUs as the recurrent unit while we use the ODE-LSTM, which has better generalization performance. (2) We introduce the Triple-S operation to execute all sub-sentences in parallel instead of in sequence, which is faster than the DRNN. (3) We consider multi-scale n-gram features in sentences, while DRNN only considers a fixed scale.

3 Proposed Method

In the following, we start with our most straightforward model, which is a parameter-efficient structure of LSTMs to avoid over-fitting and achieve better generalization performance. This structure is then equipped with local sliding windows to learn key phrase features of the sentence, which is the central problem for understanding sentence semantics (Wang et al., 2015). Finally, we further easily extended our method to capture multi-scale features of the sentence via using different sized windows in parallel.

3.1 Orthogonal InDependEnt LSTM (ODE-LSTM)

Given a sentence of T input vectors $\{\mathbf{x}_1, \cdots, \mathbf{x}_T\}$, where $\mathbf{x}_t \in \mathbb{R}^{d_0}$, and d_0 is the dimension of input embeddings. The hidden state $\mathbf{h}_t \in \mathbb{R}^d$ of LSTM cell can be expressed as follows:

$$\begin{pmatrix}\mathbf{f}_t\\ \mathbf{i}_t\\ \mathbf{o}_t\\ \mathbf{g}_t\end{pmatrix} = \mathbf{W}\mathbf{h}_{t-1} + \mathbf{U}\mathbf{x}_t + \mathbf{b}, \tag{1}$$

$$\mathbf{c}_t = \sigma(\mathbf{f}_t) \odot \mathbf{c}_{t-1} + \sigma(\mathbf{i}_t) \odot tanh(\mathbf{g}_t), \tag{2}$$

$$\mathbf{h}_t = \sigma(\mathbf{o}_t) \odot tanh(\mathbf{c}_t), \tag{3}$$

where $\mathbf{f}_t, \mathbf{i}_t, \mathbf{o}_t$ are the forget, input and output gates respectively, and $\mathbf{g}_t$ is the candidate cell state. $\mathbf{W} \in \mathbb{R}^{4d\times d}$, $\mathbf{U} \in \mathbb{R}^{4d\times d_0}$, and $\mathbf{b} \in \mathbb{R}^{4d}$ are the learnable parameters. σ denotes the sigmoid function, and $\odot$ denotes element-wise multiplication. The number of distinct parameters in the LSTM are $4d(d_0 + d + 1)$ which are $\mathcal{O}(d^2)$. This easily leads to over-fitting for the sentence classification tasks where there are relatively limited data.

To reduce the number of parameters, inspired by (Kuchaiev and Ginsburg, 2017), we disentangle the hidden state $\mathbf{h}_t$ of the LSTM into K independently updated small hidden states. Specifically, the hidden state at time step t is composed by K small hidden states as $\widetilde{\mathbf{h}}_t = [\widetilde{\mathbf{h}}_t^1, \cdots, \widetilde{\mathbf{h}}_t^K]^\top$, where $\widetilde{\mathbf{h}}_t \in \mathbb{R}^{K\times p}, p = d/K$. The corresponding recurrent matrix is defined as $\widetilde{\mathbf{W}} = [\widetilde{\mathbf{W}}^1, \cdots, \widetilde{\mathbf{W}}^K]$, where $\widetilde{\mathbf{W}} \in \mathbb{R}^{K\times 4p\times p}$ and $\widetilde{\mathbf{W}}^k \in \mathbb{R}^{4p\times p}$. Each small hidden state $\widetilde{\mathbf{h}}_t^k$ is independently updated by an individual recurrent matrix $\widetilde{\mathbf{W}}^k$ and then merged via concatenation to constitute the hidden state $\widetilde{\mathbf{h}}_t$ at time step t. The update equation of hidden state $\widetilde{\mathbf{h}}_t$ is defined as :

$$\begin{pmatrix}\widetilde{\mathbf{f}}_t\\ \widetilde{\mathbf{i}}_t\\ \widetilde{\mathbf{o}}_t\\ \widetilde{\mathbf{g}}_t\end{pmatrix} = \widetilde{\mathbf{W}} \circledast \widetilde{\mathbf{h}}_{t-1} + \mathbf{U}\mathbf{x}_t + \mathbf{b}, \tag{4}$$

$$\widetilde{\mathbf{c}}_t = \sigma(\widetilde{\mathbf{f}}_t) \odot \widetilde{\mathbf{c}}_{t-1} + \sigma(\widetilde{\mathbf{i}}_t) \odot tanh(\widetilde{\mathbf{g}}_t), \tag{5}$$

$$\widetilde{\mathbf{h}}_t = \sigma(\widetilde{\mathbf{o}}_t) \odot tanh(\widetilde{\mathbf{c}}_t), \tag{6}$$

where $\circledast$ is the tensor-dot operation which denotes the product of two tensors along the K-axis, e.g., $\widetilde{\mathbf{W}} \circledast \widetilde{\mathbf{h}}_{t-1} = [\widetilde{\mathbf{W}}^1\widetilde{\mathbf{h}}_{t-1}^1, \cdots, \widetilde{\mathbf{W}}^K\widetilde{\mathbf{h}}_{t-1}^K]^\top$ where $\widetilde{\mathbf{W}}^k\widetilde{\mathbf{h}}_{t-1}^k \in \mathbb{R}^{4p}$. Note that standard LSTM is a special case of ODE-LSTM when $K = 1$.

The updated hidden state $\widetilde{\mathbf{h}}_t$ may be redundant if all hidden states provide similar features. To avoid this, we introduce a penalization loss that orthogonally constrains $\widetilde{\mathbf{W}}$ to explicitly encourage diversity among hidden states, inspired by (Lin et al., 2017).

$$\mathcal{L}_P = \sum_{i=1}^{K}\sum_{j=1}^{K} \|\widetilde{\mathbf{W}}\widetilde{\mathbf{W}}^\top - \mathbf{I}\|_2^2. \tag{7}$$

With the same size d of hidden states as the LSTM, ODE-LSTM reduces the number of parameters by $4d(d - p)$. The smaller p is, the more parameter reduction. Because of the disentanglement of hidden states, each small hidden state can

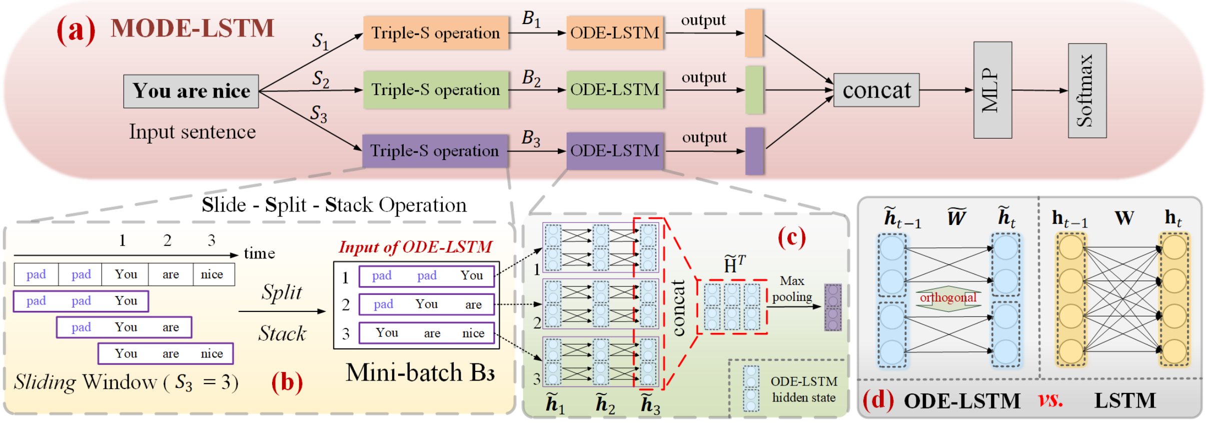

Figure 2: **(a)** The diagram of MODE-LSTM with three different scale windows $[S_1, S_2, S_3]$. The input sentence is converted into three mini-batches $[B_1, B_2, B_3]$ by the Triple-S operation. These mini-batches are respectively fed into different initialized ODE-LSTMs to extract n-gram features for each scale. **(b)** The detail of Triple-S operation. **(c)** The process of performing mini-batch B_3 for an ODE-LSTM. **(d)** The comparison of ODE-LSTM and LSTM. Here, ODE-LSTM disentangles the hidden state into two small hidden states. An orthogonal constraint is apply on the recurrent matrix $\widetilde{\mathbf{W}}$ to improve the diversity of features.

focus on a different aspect of semantics, with better generalization performance. Figure 2(d) shows the comparison between ODE-LSTM and LSTM.

3.2 Equipping ODE-LSTM with Sliding Window

The core of SC task is to understand the semantics of the sentence, which are determined by key words and variable-size phrases. Although a CNN can capture n-grams, the linear convolution operation is insufficient to model sequential information and non-consecutive dependency of sentences. Our ODE-LSTM can maintain word order, and control information preserving or forgetting through gates for modeling non-consecutive dependency. Taking the phrase “***not** almost as **bad***” as an example, the gates can selectively retain the representation of “not” and “bad” while decaying the representation of “almost” and “as”, allowing it to perceive the relation “not bad”.

Hence, we equip ODE-LSTM with a sliding window for extracting n-gram features, which means that the recurrent transition of ODE-LSTM is only performed in a local window with size S sliding along the sentence, as illustrated in the left of Figure 2(b). S is a hyperparameter. For each target position t, ODE-LSTM will sequentially process S consecutive words in the range $(t-S+1, t)$ of the sentence and generate relevant hidden states. The last hidden state $\widetilde{\mathbf{h}}_t$ output by ODE-LSTM is used as the n-gram feature of the target position:

$$\widetilde{\mathbf{h}}_t = \text{ODE-LSTM}(\mathbf{x}_{t-S+1}, \cdots, \mathbf{x}_t). \qquad (8)$$

For convenience, we reshape $\widetilde{\mathbf{h}}_t \in \mathbb{R}^{K\times p}$ to a vector of d dimension. Meanwhile, we pad $(S-1)$ zeros before the start position of the sentence to maintain consistent window size at all positions. This kind of local way is analogous to DRNN (Wang, 2018), but they process all windows sequentially, equivalent to processing a sentence of length $S \times T$ in order, which is highly time-consuming. However, we observe that all windows are independent of each other, so they can be processed in parallel by a GPU, which greatly improves the computational efficiency.

Correspondingly, we introduce a Triple-S (Slide-Split-Stack) operation to compose all the windows, as shown in Figure 2(b). First we split a sentence into multiple sub-sentences by a sliding window with size S, and then stack them together to form a mini-batch $B \in \mathbb{R}^{T\times S\times d_0}$. The mini-batch B is fed into an ODE-LSTM, obtaining the n-gram feature matrix $\widetilde{\mathbf{H}} \in \mathbb{R}^{T\times d}$, as shown in Figure 2(c):

$$\widetilde{\mathbf{H}} = [\widetilde{\mathbf{h}}_1, \cdots, \widetilde{\mathbf{h}}_T]^\top, \qquad (9)$$

where $\widetilde{\mathbf{h}}_t$ is calculated by equation (8), corresponding to the n-gram feature at t-th position. In this way, the recurrent steps of ODE-LSTM are determined by S rather than the sentence length T, so the time complexity is much lower than DRNN.

3.3 Multi-Scale ODE-LSTM (MODE-LSTM)

Sentence phrases have multiple granularities, i.e., n-gram features at different scales. Nevertheless, what we consider above uses a fixed window size S. A natural idea is to use multiple scale windows in parallel with ODE-LSTM to extract n-gram features of different scales. The Multi-scale ODE-LSTM (MODE-LSTM) model is illustrated in Figure 2(a). According to the Triple-S operation described in Section 3.2, the sentence is converted into multiple mini-batches $[B_1, \cdots, B_M]$ based on different scale window sizes $[S_1, \cdots, S_M]$, where M is the number of scales. Then, the mini-batches are fed into different ODE-LSTMs to obtain the n-gram feature matrix :

$$\widetilde{\mathbf{H}}_m = [\widetilde{\mathbf{h}}_{m,1}, \cdots, \widetilde{\mathbf{h}}_{m,T}]^{\top}, \qquad (10)$$

$$\widetilde{\mathbf{h}}_{m,t} = \text{ODE-LSTM}_m(\mathbf{x}_{t-S_m+1}, \cdots, \mathbf{x}_t), \quad (11)$$

where $\widetilde{\mathbf{H}}_m \in \mathbb{R}^{T \times d}$ denotes the n-gram feature matrix of scale S_m, $m = 1, \cdots, M$. $\widetilde{\mathbf{h}}_{m,t} \in \mathbb{R}^d$ denotes the t-th n-gram feature of scale S_m. Subsequently, we apply max pooling (MP) along the T-axis over each n-gram feature matrix to extract salient features for each scale, and then concatenate them to constitute the multi-scale feature representation $\mathbf{F} \in \mathbb{R}^{M \times d}$:

$$\mathbf{F} = [MP(\widetilde{\mathbf{H}}_1), \cdots, MP(\widetilde{\mathbf{H}}_M)]^{\top}. \qquad (12)$$

Afterward, the feature representation $\mathbf{F}$ is reshaped to a vector and fed into an MLP layer with rectified linear unit (ReLU) activation function and a softmax layer for the final classification.

3.4 Objective Function

The overall objective function includes a cross-entropy category loss and the penalization loss for all ODE-LSTMs. So it's defined as:

$$\mathcal{L} = \frac{1}{N} \sum_{n=1}^{N} \mathcal{L}_{cross}(y_n, \hat{y}_n) + \lambda \sum_{m=1}^{M} \mathcal{L}_{P_m}, \quad (13)$$

where N is the number of samples, y_n and $\hat{y}_n$ are the ground-truth label and softmax output respectively, $\mathcal{L}_{P_m}$ is penalization term for the m-th ODE-LSTM, and λ is a hyperparameter for balancing the strength of the orthogonality constraint. We minimize the above function by BPTT.

4 Experiments

4.1 Experimental Setup

Datasets To evaluate the effectiveness of our model, we conduct experiments on eight widely-studied datasets (Kim, 2014; Liu et al., 2017) for sentence classification. Statistics of these datasets are listed in Table 1. These datasets come from different topics, such as sentiment analysis, movie reviews (MR, SST2, SST5), customer reviews (CR), and idioms (IE); question type (TREC) classification; opinion (MPQA) or subjectivity (SUBJ) classification.

Dataset	c	l	ml	$Train$	Dev	$Test$
MR	2	19	53	10662	–	CV
CR	2	19	100	3775	–	CV
SUBJ	2	23	108	10000	–	CV
MPQA	2	3	34	10606	–	CV
TREC	6	10	33	5452	–	500
IE	3	16	75	2221	–	300
SST2	2	19	53	6920	872	1821
SST5	5	18	53	8544	1101	2210

Table 1: Statistics of eight datasets for sentence classification. c: Number of target classes. l: Average sentence length. ml: Maximum sentence length. $Train/Dev/Test$: Size of train/development/test set (CV means 10-fold cross validation is used).

Implementation Details We initialize the word embeddings with 300D pre-trained GloVe vectors (Pennington et al., 2014) and incorporate 50D character embeddings constructed by a convolution layer with a max pooling layer to avoid the Out-Of-Vocabulary (OOV) problem (Zhang et al., 2019). These two embeddings are then concatenated as the input embeddings and fine-tuned along with model parameters during training. We use three scale windows, [5, 10, 15], to initialize various ODE-LSTMs. K is set to 2 and the size p of each small hidden state is set to 50 for each scale. This configuration results in a 300D multi-scale feature representation for classification. For regularization, we employ dropout with a rate of 0.2 and 0.5 for input embeddings and the single MLP hidden layer, respectively. L2 regularization, with a factor of 0.001, is applied to the weights of the softmax layer. The hyperparameter λ is set to 0.01, and the batch size is set to 50. Our model is optimized by Adam with a learning rate of 1e-3. Similar to (Kim, 2014), these hyperparameters are

Table 2: Experimental accuracy comparison of our model and baselines on eight sentence classification benchmarks. "#Params" represents the approximate number of parameters except input embedddings for models. The results of models marked with * are obtained by our implementation. The input embeddings used in these baselines are the same as our models. Other parameter settings of models are consistent with their references. The remaining results are collected from the corresponding papers. The model marked with † (‡) means MODE-LSTM (with BERT$_{base}$) is significantly superior to compared model by paired t-test (Wilcoxon, 1945) at $p < 0.05$ level.

determined by a grid search on the MR dataset and are applied to the other datasets[§].

.

Baseline Methods We compare MODE-LSTM with three types of strong baselines: 1) CNN/RNN-based model: TextCNN (Kim, 2014), LSTM (Tai et al., 2015) and HM-LSTM (Zhang et al., 2018). 2) Hybrid models: C-LSTM (Zhou et al., 2015) which directly stacks CNN and LSTM, while DARLM (Zhou et al., 2018) and Self-attentive (Lin et al., 2017) additionally includes an attention mechanism for distilling important information. Relatively, DRNN (Wang, 2018) incorporates position-invariance into RNN. For a fair comparison, we use the LSTM as the basic unit of DRNN, called DLSTM. 3) Other models: tree-LSTM (Tai et al., 2015) and DC-treeLSTM (Liu et al., 2017) based on parse trees; capsuleB (Zhao et al., 2018b) and HAC (Zheng et al., 2019) based on capsule networks. In addition to the above models, we use ODE-LSTM as a baseline. We set K to 6 and the size p of small hidden states to 50 to make the number of parameters consistent with MODE-LSTM.

4.2 Experimental Results

Table 2 reports the performance of our approaches against other methods. With fewer parameters, MODE-LSTM significantly outperforms the compared models and is superior to DLSTM with an average accuracy gain over 1.0% because ours disentangles the RNN hidden states and considers multi-scale features in sentences. Meanwhile, our model achieves better or similar performance with recent state-of-the-art model HAC. HAC is a complex model that uses deep dilated convolutional layers and a capsule module at each layer. However, our model is simple yet effective, like the one-layer TextCNN. Specifically, although the parameters of TextCNN are less than ours, its parameters increase with the size of the filter window, whereas the parameters of our model are independent of the window size. ODE-LSTM also outperforms LSTM with an average accuracy gain 0.7%, which verifies

the effectiveness of disentangling the hidden states.

To investigate how our model makes a difference with others, we visualize the convergence trends in Figure 3. We observe that the direct-stacked C-LSTM (dark blue line) converges quickly on the training set but has poor performance on development or testing sets. Although the Self-Attentive (dark green line) can alleviate feature redundancy by employing the attention mechanism, overfitting still occurs due to a large number of parameters. MODE-LSTM (red line) achieves better generalization performance on development or testing sets than other models.

4.3 Combining MODE-LSTM with BERT

Recently, the pre-trained language model BERT (Devlin et al., 2018) is more effective than conventional word embeddings when fine-tuned on downstream tasks. Compared with word embeddings, BERT can learn context-dependent sentence representations. Nevertheless, recent work (Yang et al., 2018, 2019; Xu et al., 2019) has indicated that the self-attention used in BERT disperses the attention distribution and thus overlooks the essential neighboring elements and phrasal patterns. MODE-LSTM can explicitly extract multi-scale local features, which is complementary to BERT representation. Hence, we try to combine MODE-LSTM with BERT to improve the generalization performance of our model further. Concretely, the sentence is fed into BERT$_{base}$ model, and the hidden representation of the last layer of BERT$_{base}$ is used as the input embeddings of MODE-LSTM rather than GloVe and character embeddings. BERT provides contextualized sentence-level representations, which help MODE-LSTM understand sentence semantics more accurately. The detailed diagram and the hyper-parameter settings of this configuration can be found in the appendix.

We compare MODE-LSTM equipped with BERT (MODE-LSTM + BERT) with some recent strong baselines that also combine with pre-trained sentence representations, including InferSent (Conneau et al., 2017), combining ELMo with bag-of-words (BOW + ELMo) (Perone et al., 2018) or HAC (HAC + ELMo) (Zheng et al., 2019), universal sentence encoder (USE) (Cer et al., 2018), and BERT. The results are shown in the bottom row of Table 2. Using the BERT representation, MODE-LSTM can further boost the generalization performance. Although BERT already provides strong performance on almost all datasets, it may tend to ignore the local phrasal information due to the self-attention mechanism. Therefore, the combination of MODE-LSTM and BERT can further improve the prediction power, which indicates that our model can better understand the semantic meaning. Notably, our model without BERT has surpassed some pre-trained models, such as InferSent and BOW + ELMo, and is comparable to USE, verifying its effectiveness and generalization.

Scales	Pena.	Char.	MR	SUBJ	SST5

5,10,15	×	✓	83.0	94.5	51.0
5,10,15	✓	×	82.7	94.6	51.0

Table 3: Ablation study on some datasets. “Pena.” denotes penalization loss. “Char.” denotes character embeddings.

4.4 Ablation Study

In this section, we investigate to study the independent effect of each component in our proposed model. We explore the influence of the window scales, the penalization loss, and the character embeddings. The results are reported in Table 3. Com-

Examples	G.T.	TextCNN	DLSTM	Ours
1. While it 's***genuinely cool*** to hear characters talk about early ***rap records sugar*** hill gang etc ***the constant referencing*** of hip-hop arcana can ***alienate*** even the savviest audiences.	N	P	N	N
2. ***I admire it*** and yet ***cannot*** recommend it because it ***overstays its natural*** running time.	N	P	P	N

Table 4: Case study of our model compared to TextCNN and DLSTM. "G.T." is ground-truth. "N" and "P" represent Negative and Positive. Words with dotted lines, underlines, and wavy lines correspond to the important positions extracted by TextCNN, DLSTM, and MODE-LSTM respectively.

pared to using multiple windows with different scales (Row 1), using a single scale (Row 2-4) significantly reduces the accuracy. This demonstrates the necessity of integrating multi-scale windows to learn variable-size phrases in sentences. We can see that eliminating penalization loss (Row 5) or character embeddings (Row 6) also hurts the performance, which verifies that these components are beneficial to our model.

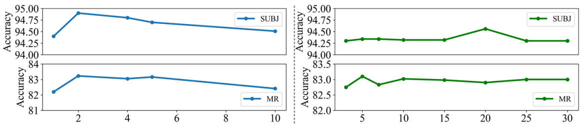
4.5 Case study

To explore why our model outperforms TextCNN and DLSTM, we display several most contributing positions in max-pooling by visualization techniques introduced in (Li et al., 2015). Table 4 shows two examples on the MR dataset. In the first example, CNN wrongly captures the key phrase *genuinely cool*. Thus the sentence is misclassified as Positive, while DLSTM and our model capture the non-consecutive dependency according to the key word *while*. Hence they attend to the second half of the sentence for correct classification. In the second sample, all the three models extract the key phrase *I admire it*, which suggests classifying the sentence as positive. Therefore, both TextCNN and DLSTM fail in this case. However, our model also extracts key phrases *cannot* and *overstays its natural* by learning multi-scale features so that it can obtain the correct answer.

4.6 Model Analysis

Impact of the value K To study the influence of the value K (the number of small hidden states), we conduct experiments on MR and SUBJ datasets. We fix the multi-scale feature representation output by MODE-LSTM to 300D and tune the value K. The larger K is, the smaller the size of the small hidden states. The results are reported in Figure 4(a). We found that $K = 2$ is a good trade-off between model accuracy and parameters. When K is too large, the hidden size is too small to provide enough features, which causes the overall performance to decrease.

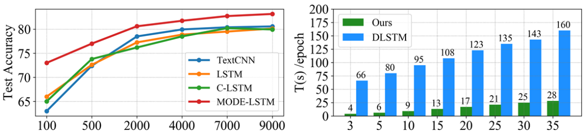
Impact of the window size We then explore the effect of window size when using only one scale window. We found that the optimal window size may be different for different datasets, as shown in Figure 4(b). The optimal window size for MR is 5, while for SUBJ, it is 20. We speculate that the reason is that the length of SUBJ sentences are longer than MR, and so long-term dependencies may be more prominent.



(a) the value K (b) the window size

Figure 4: Impact of different K and window sizes.

Impact of training set size To further verify our model's generalization, we investigate the influence of different training set sizes. The results on MR are shown in Figure 5(a). MODE-LSTM outperforms others with an accuracy gain over 8% when only having 100 training samples. As the size continues to increase, the gain gradually decreases but our model is still superior to the others.



(a) The training set sizes (b) Training speed of different window sizes

Figure 5: Effect on training set size and training time.

Training time comparison We assess the training time of our model and DLSTM on an NVIDIA GTX 1080ti GPU in Figure 5(b), testing on MR. In the case of using a single scale window, the training time for each model's epoch increases with the window size due to the recurrent structure. However, our model's training time marginally increases thanks to the ability to run in parallel by the Triple-S operation, which is $5 \sim 10 \times$ faster than DLSTM performs in sequence. Since multiple window scales are independent and parallel, the training time for our multi-scale version mainly depends on the maximum window size. For example, with the same number of parameters and a maximum window size of 15, the training time for a multi-scale version is similar to that of the single-scale version on MR (15 vs. 13, T(s)/epoch).

5 Conclusion

This study presents a novel parameter-efficient model called MODE-LSTM that can capture multi-scale n-gram features in sentences. Instead of the tradition of exploiting complicated operations by stacking CNNs and RNNs, or attaching over-parameterized attention mechanisms, our work provides a lightweight method for improving the ability of neural models for sentence classification. Through disentangling the hidden states of the LSTM and equipping the structure with multiple sliding windows of different scales, MODE-LSTM outperforms popular CNN/RNN-based methods and hybrid methods on various benchmark datasets. In future work, we plan to validate its effectiveness for aspect-level sentiment classification.

A The detailed diagram of combining MODE-LSTM with BERT

We use BERT$_{base}$ model, where the number of transformer layers is 12 and the hidden size is 784. In detail, the sentence is fed into BERT$_{base}$ model, and the hidden representation of the last layer of BERT$_{base}$ is used as the input embeddings of MODE-LSTM rather than GloVe and character embeddings. Then the BERT representation is fed into MODE-LSTM for extracting multi-scale feature representation.

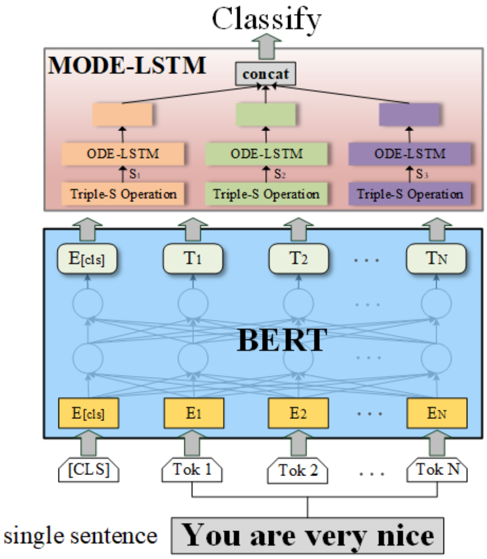

Figure 6: The diagram of combining MODE-LSTM with BERT

.

B The hyper-parameter settings of combining MODE-LSTM with BERT

The hyper-parameters of MODE-LSTM are the same as we mentioned in the experimental setup section of the main paper. That is we use three scale windows, $[5, 10, 15]$ with differently initialized ODE-LSTMs. The number of small hidden states K is set to 2 and the size p of each small hidden state is set to 50 for each scale. This configuration results in a 300D multi-scale feature representation for classification. Specifically, we tune learning rate in $\{1e-5, 3e-5, 5e-5\}$ and dropout rate in $\{0.8, 0.9\}$ for each dataset.

HSCNN: A Hybrid-Siamese Convolutional Neural Network for Extremely Imbalanced Multi-label Text Classification

Abstract

The data imbalance problem is a crucial issue for the multi-label text classification. Some existing works tackle it by proposing imbalanced loss objectives instead of the vanilla cross-entropy loss, but their performances remain limited in the cases of extremely imbalanced data. We propose a hybrid solution which adapts general networks for the head categories, and few-shot techniques for the tail categories. We propose a Hybrid-Siamese Convolutional Neural Network (HSCNN) with additional technical attributes, i.e., a multi-task architecture based on Single and Siamese networks; a category-specific similarity in the Siamese structure; a specific sampling method for training HSCNN. The results using two benchmark datasets and three loss objectives show that our method can improve the performance of Single networks with diverse loss objectives on the tail or entire categories.

1 Introduction

The data imbalance problem is a crucial issue for the multi-label text classification. In many corpora for the classification tasks, the number of instances of a category follows the long tail distribution, where many *tail categories* has only a small number of instances. To handle this problem, some works sample hard examples for training (Shrivastava et al., 2016); some works address the problem by proposing imbalance loss objectives, e.g., weighted cross-entropy loss and Focal loss (Lin et al., 2017), in place of the vanilla cross-entropy loss (Kim, 2014). Although the imbalanced loss objectives are better than the vanilla one, their performances remain limited in the cases of extremely imbalanced data because they are not designed for it, i.e., *tail (head) categories* have extremely small (large) numbers of instances.

On the one hand, the recent few-shot learning techniques (e.g., optimization-based methods (Finn et al., 2017; Munkhdalai and Yu, 2017; Mishra et al., 2018), metric-based methods (Koch et al., 2015; Vinyals et al., 2016; Snell et al., 2017)) have become popular for various NLP tasks (Yu et al., 2018; Han et al., 2018). They have already shown the capability for few-shot classifications. They thus may also perform well for tail category classification (some of the tail categories are few-shot, all have relatively small numbers of instances). On the other hand, for the head categories with many instances, general approaches such as the single CNN model (Kim, 2014; Liu et al., 2017) may be more effective in terms of performance and more efficient in terms of complexity. Therefore, our basic idea for tackling the problem of extremely imbalanced multi-label text classification is a hybrid solution that adapts a general approach (i.e., a Single network) for head categories and a few-shot approach for tail categories, so that we can take the advantages of both of them. For the few-shot approach, we select the Siamese network (Koch et al., 2015) because it is easier to integrate with different Single networks. A naïve solution is training them separately and utilizing their results on head categories and tail categories respectively as the combined classification results.

To make the hybrid solution effective, rather than a naïve combination on the results of two types of networks, we propose a Hybrid-Siamese Convolutional Neural Network (HSCNN) with additional technical properties. First, it is based on a multi-task architecture to deal with forgetting and overfitting problems when training the Siamese network. Second, the single similarity output of the vanilla Siamese structure is limited for estimating the similarities for a large number of categories and multiple categories; we thus propose a category-specific similarity in the Siamese structure. Third, we propose a specific sampling method to train the HSCNN.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6716–6722,
November 16–20, 2020.

The results using two benchmark datasets and three loss objectives (including one vanilla cross-entropy loss and two imbalanced losses) show that the proposed method can improve the performance of a Single network with diverse loss objectives on the tail categories and the entire categories. The main contributions of this paper can be summarized as follows. (1). We propose a hybrid method based on general and few-shot techniques to mitigate the extremely imbalanced multi-label text classification problem. (2). We propose a novel HSCNN model based on a multi-task architecture, a category-specific similarity, and a specific sampling method. (3). Our approach can be integrated with the imbalanced loss objectives to improve the performance; the Hybrid-Siamese architecture can extend to incorporate with other types of Single networks rather than the Single CNN network.

2 Our Approach

We denote the data as $\mathcal{D} = \{d_i\}_i$ and an instance as d_i, the category set as $\mathcal{C}$ and a category as c. The number of training instances is $\mathcal{N}$. The number of training instances of a category c is $\mathcal{N}_c$.

2.1 Single and Siamese Architectures

The Single architecture we use for multi-label text classification is similar to the CNN based models in existing works (Kim, 2014; Liu et al., 2017; Shimura et al., 2018). It includes an embedding layer, a convolutional layer and a pooling layer, and two fully connected layers. The black dashed line in Figure 1 marks a Single architecture. Note that this Single CNN network can also be replaced by other types of Single networks such as RNN, HAN (Yang et al., 2016), and so on. We utilize the CNN based one because it is one of the typical models.

We have several alternatives on the loss objectives computed by the predicted categories and true categories. Table 1 lists them. For each instance d_i, $y_{c1} = 1$ if d_i has the category c, $y_{c0} = 1 - y_{c1}$; p_{c1} is the predicted probability that d_i has category c, $p_{c0} = 1 - p_{c1}$. We use both the vanilla Binary Cross Entropy (BCE) and the imbalanced loss objectives including Weighted binary Cross Entropy (WCE) and Focal loss (Lin et al., 2017). We empirically set $\alpha_c = \log((\mathcal{N} - \mathcal{N}_c)/\mathcal{N}_c)$ for WCE loss and $\gamma = 1$ for Focal loss following the existing works (Li et al., 2020b). We do not use the Dice loss (Li et al., 2020b) because we empirically observe that it does not perform well for the multi-label text classification with a large number of categories, although it is also an imbalanced loss objective.

Loss	Objectives
BCE	$-\sum_c \sum_{v\in\{0,1\}} y_{cv} \log p_{cv}$
WCE	$-\sum_c \alpha_c \sum_{v\in\{0,1\}} y_{cv} \log p_{cv}$
Focal	$-\sum_c \sum_{v\in\{0,1\}} y_{cv} (1-p_{cv})^{\gamma} \log p_{cv}$

Table 1: Loss Objectives

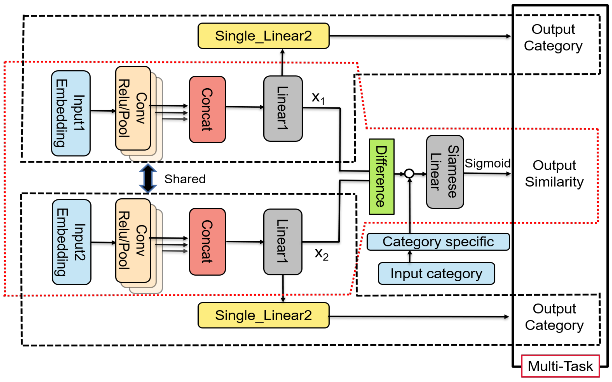

Figure 1: HSCNN Model

Siamese network (Koch et al., 2015) is a typical technique of few-shot learning. It contains two duplicated Single networks, and the inputs are two instances. The output is computed by comparing the representations extracted after the first fully connected layer of the Single network (Linear1 in Figure 1) for the two instances. Assuming that the representations of two input instances d_i and d_j are $\mathbf{x}_i$ and $\mathbf{x}_j$, there are two options on the comparison component. One option is leveraging a contrastive loss on the distance of $\mathbf{x}_i$ and $\mathbf{x}_j$. Another option (Koch et al., 2015) is utilizing a fully connected network on the difference of $\mathbf{x}_i$ and $\mathbf{x}_j$ to estimate their similarity and using a cross-entropy loss on the similarity. Because we need to estimate the similarities among a large number of categories, we select the later one to measure the rich information of the similarities. The dashed red line in Figure 1 marks a vanilla Siamese structure.

2.2 Hybrid-Siamese CNN

A naïve hybrid solution is training Single and Siamese networks separately and adapting them for head and tail categories respectively. To make the hybrid solution effective, we propose a Hybrid-Siamese Convolutional Neural Network (HSCNN) model (Figure 1) with three technical attributes.

Multi-task architecture: On the one hand, in the naïve solution, we can first train a Single network, then use it to initialize a Siamese network, and after that train the Siamese network alone. The Siamese network may forget the knowledge learned by the Single network. On the other hand, When the number of training instances is large, the number of instance pairs is squared and huge. It is infeasible to train the Siamese network with all instances pairs, and we can only sample a subset. The number of training pairs is relatively small, which results in the overfitting of the Siamese network.

To prevent the above problems, we propose a multi-task architecture based on the Single and Siamese networks. As shown in Figure 1 with black solid line, the loss function is as follows, $\mathcal{L} = \lambda_s \mathcal{L}_s + \lambda_{m_1} \mathcal{L}_{m_1} + \lambda_{m_2} \mathcal{L}_{m_2}$. $\mathcal{L}_s$ is the loss of the Siamese network, and $\mathcal{L}_m$ is the loss of a Single network. For similar pairs of input instances, $\mathcal{L}_{m_1}$ and $\mathcal{L}_{m_2}$ are the same. For dissimilar pairs, $\mathcal{L}_{m_1}$ and $\mathcal{L}_{m_2}$ are the losses for each input instance, respectively. The comparison part of the HSCNN and the Single CNN part are trained together in the multi-task architecture. The Single network part can be regarded as a constraint to avoid the forgetting and overfitting of the Siamese network part. Without loss of generality, we set λ_s=λ_{m_1}=λ_{m_2}=1.

Category-specific similarity: The Siamese structure has only a single similarity output, which is limited for estimating the similarity between a large number of categories and multiple categories. For example, if an instance has multiple categories and each category has a representation vector, it is difficult to learn a representation of this instance near the representations of all these categories through a single similarity output. Therefore, we propose a category-specific similarity in the Siamese structure to capture the rich information in the similarities.

As shown in Figure 1, HSCNN has an asymmetric structure. In addition to the inputs of two instances d_i and d_j, there is another input category c which means that d_j has category c. Given the input triplet (d_i,d_j,c), the similarity output can be explained as "whether d_i is similar with d_j on category c". Denoting the one-hot encoding of category c as $\mathbf{q}_c$, a category-specific difference is computed by $\mathbf{h} = |\mathbf{x}_i - \mathbf{x}_j| \circ \mathbf{h}_c$, where $\mathbf{h}_c = \sigma((\mathbf{w}\mathbf{q}_\mathbf{c} + \mathbf{b})/\sqrt{|\mathcal{C}|})$. σ is the ReLU activation function and $\circ$ is the elementwise multiplication. A linear layer with the sigmoid function then computes the similarity. This category-specific similarity can also be explained as a Machine Reading Comprehension (MRC) framework (Li et al., 2020a, 2019), which can improve non-MRC tasks' performance by learning additional information from the query. It is also related to the joint embedding on the instance and category (Wang et al., 2018), while ours focuses on the category-specific similarity of instances.

Sampling method: A common sampling method of the training data for a Siamese network is randomly selecting similar ((d_i,c),(d_j,c)) and dissimilar pairs ((d_i,c_i),(d_j,c_j)) with the ratio of 1:1. In this work, we generate one pair by randomly selecting the categories and selecting the instances in the categories. We set a heuristic rule to ensure that each category can be selected as least $\mathcal{T}$(e.g., ten) times. To follow the asymmetric structure of HSCNN, we propose a specific sampling method for training HSCNN. For each similar pair ((d_i,c),(d_j,c)), we generate one triplet (d_i,d_j,c) for training; for each dissimilar pair ((d_i,c_i),(d_j,c_j)), we generate two triplets (d_i,d_j,c_j) and (d_j,d_i,c_i), the ratio of similar and dissimilar pairs is thus 1:2.

We train and utilize HSCNN for classification as follows. **Training:** We first train the Single CNN separately by utilizing the raw training data in the dataset until convergence. After that, we use it to initialize HSCNN and train HSCNN by utilizing the sampled triplets as the training data. **Classification:** When using HSCNN to predict the categories of test instances, we use the Siamese part's output. For a test instance d_i and a category c, we randomly select five instances from the category c of the raw training data. We compute the mean $\bar{\mathbf{x}}^c$ of the representations of these five instances obtained by the representation extraction component. We compare the representation $\mathbf{x}_i$ of d_i with $\bar{\mathbf{x}}^c$ by the comparison component to calculate the similarity. If the similarity is higher than 0.5, we assign the category of c to d_i. Note that the option of first computing the mean representation of the five instances is not mandatory in our proposed approach. Another option for classification is first comparing d_i with each of the five instances and then using majority voting to aggregate the results. We choose the mean representation option because we obtain a little bit better results than another option. **Merge:** We finally merge the classification results of CNN and HSCNN as the results of our hybrid solution on the entire categories. We set a threshold $\mathcal{N}_\phi$ on the number of instances in a category. For tail categories ($\mathcal{N}_c < \mathcal{N}_\phi$, a subset with the instances that contain at least one tail cate-

Dataset	Train	Test	$\lvert\mathcal{C}\rvert$	$\bar{\mathcal{N}_c}$	$\mathcal{N}_c^{max}$	$\mathcal{N}_c^{min}$
RCV1	23,149	781,265	103	225	10,787	1
Delicious	12,920	3,185	983	14	3,867	12

Table 2: Data statistics. $\lvert\mathcal{C}\rvert$ is total number of categories, $\bar{\mathcal{N}_c}$ is mean of $\mathcal{N}_c$. $\mathcal{N}_c^{max}$ and $\mathcal{N}_c^{min}$ are maximum and minimum of $\mathcal{N}_c$. (URLs are in Appendix.)

gory), we use HSCNN results; For head categories ($\mathcal{N}_c \geq \mathcal{N}_\phi$), we use CNN results.

3 Experiments

3.1 Experimental Settings

The two benchmark datasets we use are the multi-label text corpus RCV1 (Lewis et al., 2004) and Delicious (Tsoumakas et al., 2008). Table 2 lists the dataset statistics. There are many categories, and the categories are extremely imbalanced on the instance numbers. We randomly split the raw training data into 75% for training and 25% for validation. We use the fastText (Joulin et al., 2017) to generate the initial word embeddings in the models. For training HSCNN, we sample 150,000 triplets for RCV1 and 300,000 triplets for Delicious; Delicious uses more triplets because it has more categories.

We mainly compare our approach with the Single CNN (black dashed line in Figure 1, named as "Sing.") in the cases of using different loss objectives list in Table 1. We also compare with additional baselines in the case of using BCE loss. "Naïve" is a hybrid solution using a vanilla Siamese network and Single network separately. "/CSS" uses HSCNN without the category-specific similarity and specific sampling. "/MT" uses HSCNN without multi-task architecture. "/CSS" and "/MT" are for the ablation test.

The parameters of the CNN architectures for all approaches refer to the ones used in exiting work (Shimura et al., 2018). The detailed parameters are list in the appendix. The evaluation metrics are Micro-F1, Macro-F1, Precision, and nDCG. For computing Precision and nDCG, we need to rank all of the categories for an instance. Here, the probabilities of head categories are obtained from the outputs of Single CNN; the similarities to a tail category is obtained from the outputs of the Siamese part of HSCNN. The probabilities of head categories and the similarities to the tail categories are not directly comparable, but the ranges of them are both in [0,1]. We just roughly rank the categories based on the probability/similarity directly. We evaluate the performance on the tail categories and the entire categories, respectively. We arbitrarily set the threshold $\mathcal{N}_\phi$ of the hybrid solutions as 100. RCV1 has 35 categories with $\mathcal{N}_c < 100$; Delicious has 472 such categories.

3.2 Experiments results

Table 3 lists the main experimental results. The left part of Table 3 shows the performance on the tail categories. First, comparing "Sing." and "Our", our approach can prominently improve the results of Single network in all cases of using vanilla or imbalanced loss objectives.

Second, comparing "Sing." and "Naïve", a "Naïve" hybrid method is even worse than "Sing.". One potential reason is that, in the head categories with a large number $\mathcal{N}$ of training instances, the number of these instances is sufficient to train a Single CNN. However, for the vanilla Siamese network, the number of potential training pairs is O($\mathcal{N}^2$), but we can only sample a small subset of them. Our multi-task component solves this problem. Another potential reason is that the vanilla Siamese network only has single similarity output and is limited for estimating the similarity for a large number of categories and multiple categories. For example, two instances that are "partially and almost" similar will have noise on the inconsistent categories if they are labeled as a similar pair. Our category-specific component solves this problem.

Third, comparing "Naïve" and "/CSS" (or "/MT" and "Our"), the proposed multi-task architecture can improve the performance. Comparing "Naïve" and "/MT" (or "/CSS" and "Our"), the proposed category-specific similarity and specific sampling can improve the performance. Using all additional technical attributes ("Our") can mutually benefit each other and improve the performance a lot.

The right part of Table 3 is the performance on entire categories. The observations on entire categories are consistent with that on tail categories. The improvement of Macro-F1 is more prominent than that of Micro-F1. It is because there are a large number of instances in head categories that influence the average computation of Micro-F1.

We also investigate the influences of different threshold $\mathcal{N}_\phi$ on the performance of entire categories. Figure 2 shows the results. Micro-F1 increases gradually as the threshold increases. Macro-F1 increases when the $\mathcal{N}_\phi$ is not too large and then decreases. It is because the numbers of training triplets are not enough for the categories with many

	450,000	5.83	1.81	24.95	8.57

Table 4: Experimental results with different number of sampled triplets for training HSCNN.

instances as the threshold $\mathcal{N}_\phi$ increases. Because the Macro-F1 scores are only worse than those of the baselines at about $\mathcal{N}_\phi > 225$ for RCV1 and $\mathcal{N}_\phi > 175$ for Delicious, the proposed HSCNN model based on few-shot technique is not only limited to few-shot categories but also performs well for the tail categories. The optimal $\mathcal{N}_\phi$ depends on the distribution of instance numbers of categories in a dataset; selecting a conservative value for $\mathcal{N}_\phi$ such as 50 or 100 is expected to obtain better results than the Single models.

Furthermore, Table 4 lists the results with different numbers of sampled triplets for training HSCNN. First, the number of sampled triplets should not be too small (e.g., RCV1 with 75,000 triplets). Second, the required number of sampled triplets to reach acceptable results depends on the dataset and possibly the number of categories, i.e., the number of categories of Delicious dataset is much larger than that of RCV1 dataset. RCV1 dataset with 150,000 already reaches a relatively high performance; Delicious dataset with 150,000 still has a relatively low performance. Third, a very large number of sampled triplets (e.g., RCV1 with 300,000 triplets) may still improve the performance but cannot improve the performance much more.

4 Conclusion

In this paper, we propose a hybrid solution with a HSCNN model for dealing with extremely imbalanced multi-label text classification. The proposed method can improve the performance of Single networks with diverse loss objectives on the tail categories or entire categories. In future work, we will try other types of Single networks (e.g., (Lai et al., 2015; Yang et al., 2016; Shimura et al., 2019)).

Abstract

This paper proposes a pre-training based automated Chinese essay scoring method. The method involves three components: *weakly supervised pre-training, supervised cross-prompt fine-tuning* and *supervised target-prompt fine-tuning*. An essay scorer is first pre-trained on a large essay dataset covering diverse topics and with coarse ratings, i.e., *good* and *poor*, which are used as a kind of weak supervision. The pre-trained essay scorer would be further fine-tuned on previously rated essays from existing prompts, which have the same score range with the target prompt and provide extra supervision. At last, the scorer is fine-tuned on the target-prompt training data. The evaluation on four prompts shows that this method can improve a state-of-the-art neural essay scorer in terms of effectiveness and domain adaptation ability, while in-depth analysis also reveals its limitations.

1 Introduction

Automated essay scoring (AES) is an important educational application of natural language processing (NLP) (Page, 1966). AES aims to automatically judge the quality of student essays, which can reduce teachers' burden on essay scoring and provide fast feedback to students.

AES is usually viewed as a supervised learning problem. Traditionally, AES systems are based on hand-crafted surface-level features (Larkey, 1998; Attali and Burstein, 2006; Chen and He, 2013; Phandi et al., 2015). Recently, neural network based representation learning has been applied and achieved superior performance compared with traditional methods (Taghipour and Ng, 2016; Cummins et al., 2016; Alikaniotis et al., 2016; Dong and Zhang, 2016; Dong et al., 2017; Tay et al., 2018).

Most of the proposed methods, no matter the feature based or the representation learning based ones, work in an in-domain setting that is to train a scorer for a specific prompt based on a set of example essays for this prompt, and use this scorer to rate more essays from the same prompt. This manner usually requires many rated examples to get acceptable performance.

Although cross-domain transferable essay scoring has gained more attention (Phandi et al., 2015; Jin et al., 2018), the progress is still limited. The possible reason may be that the available corpora for essay scoring usually cover narrow topics on a small scale, and the topics, scoring criteria, and score ranges of different prompts often vary. Since an AES system should have the ability to appreciate or criticize essays, supervised pre-training is necessary. Intuitively, if a reader has read many rated essays from different prompts, she should be more experienced to judge the quality of an essay that responds to a new prompt. At least, she should require less guidance compared to a novice.

In this work, we empirically evaluate a pre-training based method for AES. Figure 1 illustrates the main framework. Our method has three components, each of which incorporates different level supervision. The first component is **weakly supervised pre-training**. An essay scorer is pre-trained based on a large scale essay corpus. The corpus covers diverse topics and is prompt-free. The essays are collected from the Web and have been rated by anonymous teachers. The essays' ratings are converted to binary coarse ratings: *good* and *poor* for the ease of weakly supervised pre-training. The second component is **supervised cross-prompt pre-training / fine-tuning**. This component aims to exploit the supervision from the training data of other prompts to pre-train or further fine-tune an essay scorer. The third component is **supervised target-prompt fine-tuning**. The pre-trained scorer would be fine-tuned on the training data for target prompts. Since human rat-

November 16–20, 2020.

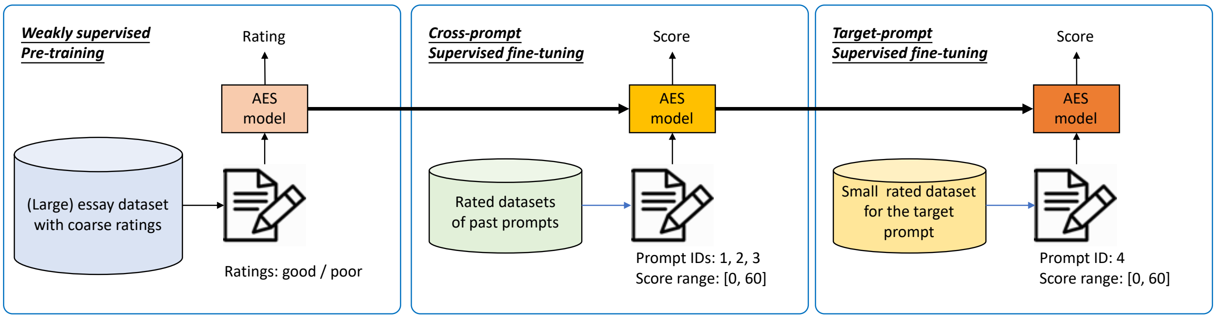

Figure 1: The proposed pre-training framework for automated essay scoring (AES).

ings are expensive to be collected, we expect the essay scorer depends on the target-prompt training data the less the better.

Although there are public available datasets in English such as the ASAP dataset.[1] These datasets usually cover only a few topics making it difficult to find datasets for pre-training and fine-tuning. As a result, we collect datasets and conduct experiments for automated Chinese essay scoring. We built a dataset with more than 85,000 essays written by junior and senior high school students for weakly supervised pre-training. We also collected nearly 4,000 essays in response to four prompts from senior high schools. These essays were carefully rated by teachers and are used for cross-prompt fine-tuning and evaluation.

Although the framework is straightforward, the evaluation demonstrates the effectiveness of the proposed method.

(1) **Higher performance in general**: The cooperation of the three components can improve the attentional recurrent convolutional neural network model (ARCNN) (Dong et al., 2017), which achieved the state-of-the-art result on the ASAP dataset. In average, the best pre-training enhanced ARCNN can achieve a 4.2% absolute improvement in QWK and 3.1% absolute improvement in Pearson coefficient compared with the ARCNN that is trained on the target-prompt training data only.

(2) **Better domain adaptation ability**: With both weakly pre-training and cross-prompt fine-tuning, our method can use 10% target-prompt training data (about 50 essays) to achieve 93.6% relative performance of the full model which is trained with 100% training data. Supervised cross-prompt fine-tuning is essential for domain adaptation though it is also expensive due to the requirement of human rated essays. With weakly pre-training only, our method can use half of the training data to achieve the same performance as the base scorer that is trained with 100% training data but without pre-training.

To the best of our knowledge, we are the first to investigate multi-stage pre-training based AES. We conduct careful analysis to gain more insights about how the method works and its limitations. Although our research focuses on Chinese, the results and observations should be useful for AES in other languages as well.

2 Related Work

AES is commonly viewed as a supervised learning problem with various feature templates (Larkey, 1998; Attali and Burstein, 2006; Chen and He, 2013; Phandi et al., 2015; Cummins et al., 2016; Song et al., 2017). These methods assume that essay quality correlates with surface-level features. The drawbacks of these methods include that the feature design and engineering are difficult and the semantic understanding of essays is limited.

Since 2016, neural network based AES systems become popular (Taghipour and Ng, 2016; Cummins et al., 2016; Alikaniotis et al., 2016; Dong and Zhang, 2016; Dong et al., 2017; Tay et al., 2018). These models obtained superior performance compared with traditional methods.

However, most of these systems are prompt-specific. New training data has to be annotated for training a new model for a new prompt.

Domain Adaptation for AES Phandi et al. (2015) proposed domain adaptation as a solution to adapt an AES system from one initial prompt to another prompt based on Bayesian linear ridge regression. Dong and Zhang (2016) demonstrated that the hierarchical CNN based model performs better in domain adaptation setting. Pilán et al. (2016); Xia et al. (2016) also attempted to incorpo-

---

[1] `https://www.kaggle.com/c/asap-aes/`

rate external knowledge for readability assessment. However, these methods mostly focused on domain adaptation from one domain to another but did not explore external resources.

Pre-training for AES Recently, pre-training language models (LM) becomes a trend (Devlin et al., 2019; Yang et al., 2019), which leads to the pre-training then fine-tuning mechanism and achieves great success in many NLP tasks.

For AES, Mim et al. (2019) proposed an unsupervised pre-training approach for evaluating the organization and argument strength of argumentative essays, where coherence modeling is used for pre-training. Rodriguez et al. (2019) attempted to apply BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019) for AES, but the results on ASAP are similar to the performance of a LSTM based scorer.

Howard and Ruder (2018) proposed the universal language model fine-tuning approach for text classification, including components such as general-domain LM pre-training, target domain LM fine-tuning and target task classifier fine-tuning. Gururangan et al. (2020) showed that task-adaptive pretraining can provide a large performance boost for ROBERTA across four domains and eight classification tasks. Motivated by previous works, this paper also adopts a multi-stage pre-training strategy by exploiting weak, distant and target oriented supervision for AES.

3 The Proposed Method

3.1 The ARCNN Model

Our base model is the attentional recurrent convolutional neural network model (ARCNN) (Dong et al., 2017), which is one of the state-of-the-art neural AES systems.

Sentence Representation A sequence of words $x = \{w_1, ..., w_N\}$ is modeled with a CNN encoder. The feature representation for the i-th word is

$$\mathbf{z}_i = f(\mathbf{W}_z \cdot [\mathbf{e}(w_i) : \mathbf{e}(w_{i+h_w-1})] + \mathbf{b}_z), \quad (1)$$

where we use `tanh` as the activation function f, $\mathbf{e}(w_i) \in \mathbb{R}^d$ is the embedding of a word, h_w is the window size in the convolutional layer, $\mathbf{W}_z$ and $\mathbf{b}_z$ are weight matrix and bias vector.

Above the convolutional layer, attention pooling is employed to get the sentence representation $\mathbf{s}$,

$$\mathbf{s} = \sum \alpha_i \mathbf{z}_i, \quad (2)$$

where,

$$\alpha_i = \frac{e^{\mathbf{W}_\alpha \cdot \mathbf{m}_i}}{\sum e^{\mathbf{W}_\alpha \cdot \mathbf{m}_i}}, \mathbf{m}_i = \mathtt{tanh}(\mathbf{W}_m \cdot \mathbf{z}_i + \mathbf{b}_m),$$

$\mathbf{W}_\alpha, \mathbf{W}_m, \mathbf{b}_m$ are parameter matrixes and bias vector for computing attentions.

Text Representation The sentence representations are modeled with a LSTM to get a sequence of hidden states $\mathbf{H} = \{\mathbf{h}_1, ..., \mathbf{h}_S\}$, where S is the number of sentences. The hidden state of the j-th sentence is

$$\mathbf{h}_j = \mathtt{LSTM}(\mathbf{s}_j, \mathbf{h}_{j-1}), \quad (3)$$

where $\mathbf{s}_j$ is the representation of the j-th sentence, and $\mathbf{h}_{j-1}$ is the hidden state of the previous step. Two LSTM encoders are applied in both directions and the bidirectional hidden representations are concatenated together to represent each sentence. The whole sequence could be represented as a fixed length vector $\mathbf{o} = \phi(\{\mathbf{h}_1, \cdots, \mathbf{h}_S\})$, where $\phi(\cdot)$ is a function to summarize hidden states. The attention mechanism are used as $\phi(\cdot)$ to get the text representation.

The Prediction Layer Finally, the rating of the essay is predicted according to

$$y = \mathtt{sigmoid}(\mathbf{w}_y \cdot \mathbf{o} + \mathbf{b}_y), \quad (4)$$

where $\mathbf{w}_y$ and $\mathbf{b}_y$ are weight vector and bias vector.

3.2 Weakly Supervised Pre-training

We attempt to explore corpora with diverse topics and weak/distant quality judgements for pre-training a general essay scorer.

3.2.1 Data Collection

We collected essays from a website LeleKetang.[2] The essays were written by Chinese students in grade 7 to12. The corpus covers diverse topics and multiple genres, including *narrative, argumentative* and *prose* essays. The average number of sentences and Chinese characters are 30 and 779.

Each essay was rated by a teacher to indicate its quality before it was uploaded to the website. The ratings range from 1 to 4, indicating *poor*, *normal*, *good* and *excellent*. However, the ratings are imbalanced. Rating 3 and rating 1 are many more than rating 2 and rating 4. The corresponding statistics are shown in Table 1.

For pre-training, we combine rating 4 and 3 to represent ***good*** essays, view rating 1 as ***poor*** essays, and remove rating 2 to ensure that the good and poor essays could be distinguished.

---

[2] `http://www.leleketang.com/zuowen/`

Ratings ↓	**#. Essays**						Sum.
Grades →	7	8	9	10	11	12	
4	132	110	263	137	83	680	1405
3	5,510	5,337	5,754	4,744	1,684	4,079	27,108
2	1,886	1,556	1,273	1,122	733	897	7,467
1 (Poor)	15,229	13,550	10,445	5,696	6,107	5,995	57,022
4+3 (Good)	5,642	5,447	6,017	4,881	1,767	4,759	28,513

Table 1: The basic statistics of the dataset used for weakly pre-training. We combine rating 3 and rating 4 as *good* essays, and use rating 1 as *poor* essays. Rating 2 is not used in this work.

3.2.2 Pre-training the ARCNN Model

Formally, we have an essay dataset $E = \{(x, y)\}$, where $y \in \{0, 1\}$ indicates a *poor* or *good* essay.

We train the ARCNN model on the dataset E to distinguish *good* and *poor* essays. The learning objective is the sum of the negative cross-entropy over all training examples.

Since the collected ratings might be noisy and are converted to coarse binary ratings, we call it ***weakly supervised pre-training (WSP)***.

Parameters	**Value**

Dimension of LSTM hidden state	128
Batch size	32
Dropout (after embedding layer) ratio	0.5
Optimizer	Adam
Learning rate	0.0001

Table 2: Hyper-parameter values.

3.3 Supervised Fine-tuning

3.3.1 Supervised Target-Prompt Fine-tuning

The WSP model is just pre-trained on the coarse ratings so that its predictions are within the range of [0,1], which is different from the score ranges in real examinations. Moreover, the essays should be closely related to the prompts. As result, the model should be fine-tuned on the training data of target prompts.

Following Dong et al. (2017), the real scores are scaled to the range $[0, 1]$ for fine-tuning:

$$y_{scaled} = \frac{\hat{y} - min}{max - min}, \tag{5}$$

where $\hat{y}$ is the real score, min and max indicate the minimum and maximum scores in the training data. In evaluation phase, the predicted scores are rescaled to integer scores in the original score range.

The token representations are fixed during fine-tuning, which is the same as the pre-training. The other parameters would be fine-tuned. We call this strategy ***WSP-Finetune***.

3.3.2 Supervised Transfer Fine-tuning

If rated essays that are from other prompts are available, such data could be used to further train our weakly pre-trained model WSP before fine-tuning the model on target prompts. We just continue to fine-tune WSP on the available prompt-specific rated datasets. Since the rating knowledge learned from cross-prompt data would be transferred for scoring target-prompt essays, we call this strategy ***supervised transfer fine-tuning (Trans)***.

To be consistent with the score range of the target prompt, we only choose the essay datasets that have the same score range with the target prompt for supervised transfer fine-tuning. The main procedure is the same as described in Section 3.3.1. We put Trans before target-prompt fine-tuning so that the complete model is noted as ***WSP-Trans-Finetune***. Of course, Trans could be also used for pre-training if the weakly supervised pre-training data is not available, noted as ***Trans-Finetune***.

4 Evaluation

4.1 Model Parameter Settings

We use the tokenizer of BERT (Devlin et al., 2019) to get tokens and token embeddings. The vocabulary size is 21,128. The dimension of token embeddings is 768. The token embeddings are fixed during both pre-training and fine-tuning phases. We segment an essay into sentences by punctuation. The length limit of each sentence is set to 50. If the length of a sentence is longer than 50, it would be truncated and the remaining part is viewed as another sentence. The detail settings of hyper-parameters are listed in Table 2.

Pre-training dataset	P	R	F1	Acc.
Dev	0.72	0.71	0.71	0.75
Test	0.71	0.70	0.70	0.74

Table 3: Results of the pre-training task on the development and test data.

4.2 Evaluation on Pre-training Task

4.2.1 Settings

Data We conducted experiments on the LeleKetang dataset. 80%, 10% and 10% of the dataset are used as the training, development and test data.

Evaluation metrics Since the coarse ratings are binary, we view pre-training as a classification problem. Macro precision(P), recall(R), F1-score (F1) and accuracy (Acc.) are used as evaluation metrics.

4.2.2 Results

Table 3 shows the experimental results on the development and test data of the pre-training dataset. The performance is moderate. The macro F1 score is about 0.74. This indicates that these essays are distinguishable on a certain degree.

Notice that the dataset covers diverse topics and different genres so that this task is not easy because different types of essays should be judged with different evaluation criteria. We also tried to incorporate genre and grade information in a multi-task learning setting for pre-training, but the results on the pre-training dataset and target prompts are not obviously better than using coarse ratings only. The acceptable results indicate that essays in different topics and genres should still share features that can indicate the quality of essays.

4.3 Evaluation on Target Prompts

4.3.1 Settings

Dataset We used four prompts which were previously used for writing test in college entrance examinations by two provinces in China, during 2012-2014. Each prompt is a short text describing an event, a quote, a fable or other background information (see Appendix A). We let students from several senior high schools write an essay according to their understandings of each prompt. The collected essays were scored by high school teachers. Each essay was scored by two teachers. The scores range from 0 to 60. If the difference between their scores is not bigger than 6 (10% of the score range), the average score would be the final score. Otherwise, a third teacher would participate in evaluation, and the average of two closest scores among the three would be the final score. This procedure is the same as the evaluation procedure in college entrance examinations. The collected essays are grouped according to prompts. The statistics of the datasets are shown in Table 4.

	# Essays	Avg. #sent.	Avg. #chars	Range
Set 1	964	24	819	0-60
Set 2	990	25	785	0-60
Set 3	866	25	781	0-60
Set 4	1,065	23	791	0-60

Table 4: Basic statistics of the target-prompt datasets.

Evaluation Metrics We use the quadratic weighted Kappa (QWK) and Pearson coefficient score as evaluation metrics. QWK is widely adopted for evaluating AES, while Pearson coefficient could reflect ranking consistency.

We conducted 5-fold cross-validation. In each run, we used 60%, 20% and 20% of a dataset for each prompt as training data, development data and test data, respectively. The average performance would be reported.

Comparisons We compare the following systems. The first set of systems are previously proposed neural AES systems, including

- Taghipour and Ng (2016): This method uses CNN for word sequence modeling and LSTM for text level modeling. The text representation is obtained through mean of time pooling.
- Dong and Zhang (2016): This method uses a hierarchical CNN structure for modeling sentence and text representations.

The second set of systems are the variations of the proposed pre-training based AES series. All variations use ARCNN as the base model.

- ARCNN: The ARCNN model is trained only based on the target-prompt training data for each prompt.
- WSP: The ARCNN model is weakly pre-trained on the LeleKetang dataset and then directly used to predict target-prompt test data without fine-tuning.
- WSP-Finetune: The weakly supervised pre-trained model is further fine-tuned based on

Model	Set1		Set2		Set3		Set4		Average

WSP-Trans-Finetune	**0.863**	**0.877**	**0.586**	0.629	**0.495**	**0.534**	**0.567**	0.606	**0.628**	**0.662**

Table 5: QWK and Pearson coefficient scores on target-prompt test sets. All models are trained or fine-tuned using the full target-prompt training data.

the target-prompt training data and development data.

- Trans: Other prompt-specific training data is used to pre-trained a model. In experiments, for each target-prompt test data, we use the training data and development data of the other three prompts for scorer training and model selection.

- Trans-Finetune: This setting further fine-tunes the Trans model based on the target-prompt training data and development data.

- WSP-Trans-Finetune: The weakly supervised pre-trained model is fine-tuned on the cross-prompt data before being fine-tuned on the target-prompt data.

4.3.2 Overall Results

Table 5 shows the performance of the previous neural AES models and the variants of our proposed pre-training based models.

ARCNN obtains competitive performance compared with the other neural scorers. The results verify that ARCNN is an effective neural essay scorer and this is also the reason that we use it as the base model for pre-training.

Our final model WSP-Trans-Finetune achieves the best performance in average and outperforms ARCNN, which is trained and test on the datasets from the same prompts. The improved QWK score and Pearson coefficient score in average are 4.4% and 3.1%. The final model also outperforms Trans-Finetune and WSP-Finetune in most cases. This results verify that the multi-stage pre-training strategy is feasible and effective for AES in general.

One issue is that the performance gain across datasets is inconsistent. The improvement on Set3 is large, while the improvement on Set4 is relatively small.

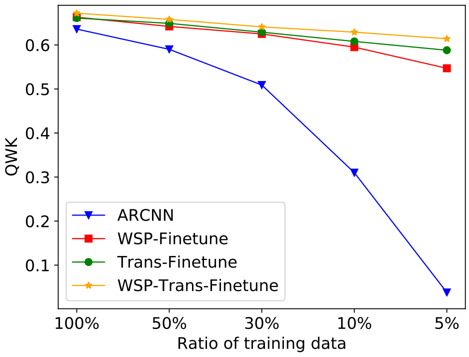
In addition, we can see that fine-tuning on the target-prompt training data is still essential. The performance of Trans decreases a lot without fine-tuning, while the WSP model is infeasible to be directly applied for scoring due to the different score ranges between pre-training and target-prompt data.

4.3.3 Analysis and Discussions

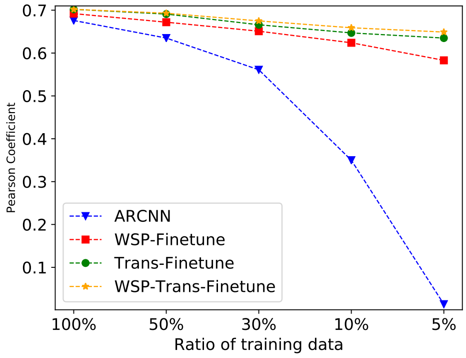
We provide more detail analysis and discussions from several aspects.

The effect of weakly supervised pre-training As shown in the last three rows in Table 5, when WSP is directly applied to score essays from target prompts, the QWK scores are very low. This is reasonable since the distribution of the coarse ratings in the pre-training dataset is far from the distribution of scores in target-prompt dataset. As a result, the differences between predicted scores and real scores are large, which lead to low QWK scores. However, the Pearson coefficient scores are not so low as QWK scores. This indicates that the weakly supervised pre-training can help capture some common indicators of the quality of essays without considering prompt specific information. After WSP is fine-tuned on the target prompts, WSP-Finetune obtains improvements on all four datasets.

The effect of supervised transfer pre-training Trans-Finetune pre-trains a model on narrow topics (3 prompts) but performs surprisingly well. Trans-Finetune may provide a kind of regularization to improve the generalization of the essay scorer. This explanation to the effectiveness of pre-training is well accepted (Erhan et al., 2010). Moreover, more training data from the same score range also helps shape the real distribution of scores and avoids overfitting to the distribution in the target-prompt training data.



(a) QWK scores.



(b) Pearson coefficient scores.

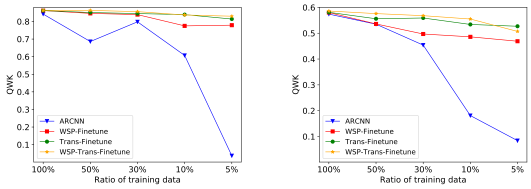
Figure 2: Average performance of training/fine-tuning with different ratio of target-prompt training data.

The combination of Trans and WSP WSP-Trans-Finetune achieves the best performance but its advantage compared with Trans-Finetune and WSP-Finetune is not very obvious, indicating that Trans and WSP benefit each other but also play similar roles.

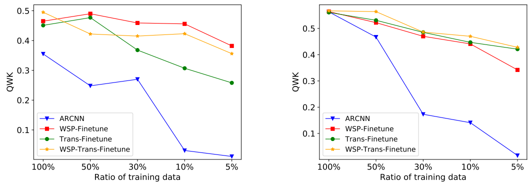
On one hand, both Trans and WSP can play a role as regularization. Because the topics are still narrow for cross-prompt pre-training so that new bias might be brought in, while WSP can help alleviate such an effect. On the other hand, WSP is trained based on coarse binary ratings. Trans can help WSP adapt the prediction distribution towards the score range of the target prompts.

Can pre-training reduce the requirement of target-prompt training data? This is a key question for this research. To answer it, we use different ratio of target-prompt training data to train ARCNN and fine-tune the pre-trained models. We sampled these subsets according to the score distribution of the whole dataset for each prompt.

Figure 2 shows the average QWK and Pearson coefficient scores over four prompts with different ratio of training data. We can see that when the size of training data decreases, the performance of ARCNN drops sharply. In contrast, all three pre-trained models, WSP-Finetune, Trans-Finetune and WSP-Trans-Finetune, achieve very consistent performance even when the ratio of used training data is small. For example, in average, WSP-Finetune can use 50% target-prompt training data to obtain similar performance compared with ARCNN trained with all training data, and use 10% target-prompt training data to obtain 93.6% performance of ARCNN. Trans-Finetune and WSP-Trans-Finetune perform even better than WSP-Finetune. The cross-prompt supervised transfer fine-tuning (Trans) is useful for domain adaptation.



(a) Set1. (b) Set2.

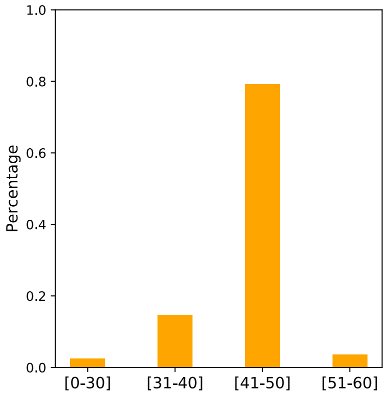


(c) Set3. (d) Set4.

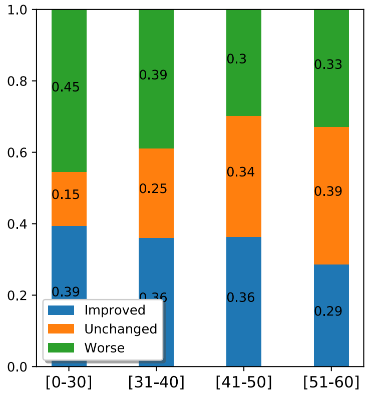
Figure 3: The QWK scores with different ratio of target-prompt training data over four prompt datasets.

Figure 3 shows the QWK scores with different ratio of target-prompt training data across four prompts in detail. We can see that the trends on four datasets are generally consistent with the average performance. The pre-training based models outperform ARCNN with a large margin when the ratio of target-prompt training data is small. WSP-Trans-Finetune performs best on 3 datasets, while WSP-Finetune performs best on 1 dataset. Trans-Finetune obtains close performance compared with WSP-Trans-Finetune.

On one hand, these observations are encouraging. It means that if we have high quality rated cross-prompt essays, the supervised transfer pre-training can help a lot for domain adaptation. But such datasets are still expensive and large scale such datasets might be not always available. Even so,



(a) Distribution of essays from different ranges.



(b) The effect of WSP-Trans-Finetune compared with ARCNN.

Figure 4: The effect of WSP-Trans-Finetue on essays from different ranges compared with ARCNN.

the weak supervision through coarse ratings can also make an impact on domain adaptation.

On the other hand, the effects of different pre-training strategies are different at different datasets. This indicates that the effects of pre-training may be also related to the properties of target prompts. Moreover, we observe that in some cases (e.g, Set1 and Set3) using fewer training data (e.g., 30%) performs better than using more training data (e.g., 50%). This may relate to the representativeness of selected subsets of essays for training.

How does pre-training affect essays from different score ranges compared with ARCNN? We divide all the essays from four datasets into four ranges according to their real scores. The distribution of scores is shown in Figure 4(a). We can see that the essay scores are concentrated in range [40-50].

We analyze the WSP-Trans-Finetune model. We define *improvement* here as reducing the differences between the predicted and real scores compared with ARCNN. Figure 4(b) shows the results. We can see that the pre-training improves the scoring ability for essays from range [40-50]. So the general performance of WSP-Trans-Finetune is good. The essays from this range are at intermediate level, written in the common way. The pre-training models may help find subtle distinctions in style to distinguish them better.

However, pre-training hurts the performance in other ranges, although the number of essays in these ranges is small. The reasons might be as follows. High score prediction is a challenge for AES, because the training examples are less than other ranges and some high score essays were written in unique ways. Essays in the range [0-40] often involve off-topic essays. The pre-training models could not help much in these cases, because they can not help capture topic information very well.

	Set1	**Set2**	**Set3**	**Set4**
mean	0.422	0.489	0.435	0.445
median	0.420	0.492	0.434	0.445
quartile deviation	0.104	0.107	**0.123**	0.115
coefficient of variation	0.180	0.156	**0.201**	0.183

Table 6: Some statistics of Jensen-Shannon divergence between topic vectors of essays on four datasets. Each essay is represented with a topic distribution vector inferred by a LDA model.

Why the performance gain is inconsistent across prompts? We observe that the effects of pre-training vary across prompts, e.g., the performance gain in Set3 and Set4 is quite different.

Qualitatively, we speculate the inconsistence is related to the distinct properties of the prompts. For example, the prompt 3 has a semi-topic setting: writing an essay to discuss "____ *to know*", where the underline part should be filled in by students. So the students discussed this from a variety of angles. In this case, the importance of target-prompt examples might be weakened and pre-training plays an important role. The prompt 4 asked students to imagine a situation if we would have an intelligent chip which knows all kinds of knowledge. In this case, a good sense of imagination and creativity may become a scoring dimension to human raters. But this dimension is difficult to be captured by AES models.

We try to find quantitative evidence to support our speculations. We analyze the topical diversity of essays within each prompt. We train a LDA model with 200 topics on the pre-training dataset and infer the topic distribution of each essay in four prompt datasets. We then compute the Jensen-Shannon divergence between every pair of essays. Table 6 shows some statistics of these values. Unfortunately, we do not find obvious regularity except that the essays from prompt 3 cover more diverse topics compared with other prompts according to the quartile deviation and the coefficient of variation. We leave the investigation of the correlation between datasets' properties and scoring performance as future work.

5 Conclusion

In this paper, we presented a pre-training based approach to automated Chinese essay scoring. Our method investigates multi-stage pre-training and incorporates multi-level supervision, including the weak supervision from large scale coarse ratings, the supervision from rated essays from other prompts and the target-prompt training data.

The experimental results show that the pre-training based approach is effective for AES in terms of both effectiveness and domain adaptation ability. We carefully analyze the effects of each component and find that: multi-stage pre-training improves the base model in general; the domain adaptation ability can be consistently improved; target-prompt fine-tuning is still indispensable but the required amount of training data can be largely reduced; weakly supervised pre-training and supervised transfer fine-tuning are both helpful.

We also observe some phenomena but do not have good explanations. For example, the performance gain across prompts is inconsistent. When the pre-trained scorer can work best should be further studied. We suggest that the prompts' properties should be investigated more for applying AES.

The proposed method has a limitation that it pays more attention to the score range that most essays are from, and may hurt the performance in other ranges. Another limitation of the method is the dependence on pre-training dataset. The pre-training dataset used in this paper is still small compared with the data used for pre-training language models. Larger pre-training dataset with supervised labels or self-supervised learning strategies could be explored. Moreover, we are interested in understanding what features or traits of essays are captured by the deep models for scoring. We plan to investigate these in future.

A Appendix

The general contents of four prompts are listed below. The students were asked to write an essay no less than 800 Chinese characters according to the prompt. There are no restrictions on title and genre.

Prompt 1: 尚先生把手机落在出租车上。他随后拨打那部手机，对方接听后立即挂断。他又发短信表示，愿意出2000元“买”回手机。一小时后，尚先生收到回复，对方要归还手机。捡到手机的人是一位年轻人。尚先生要酬谢他，但对方交还手机后就转身离去了。当天晚上，记者联系到那位年轻人，年轻人说：“我本来无意归还，但看到手机里的照片和信息，发现机主刚刚给芦山地震灾区汇去一大笔捐款，很受感动。我不能见利忘义，不能用贪心对待爱心。我也要像尚先生那样多一些真诚和友善。”

Translation of prompt 1: Mr. Shang lost his phone on the taxi. He then dialed the phone, but the other party hung up after connecting. Mr. Shang sent a message, expressing his willingness to spend 2,000 yuan to “buy” the phone back. An hour later, the other party replied and was willing to return the phone. It was a young man who picked up the phone. Mr. Shang wanted to appreciate him with money, but the young man refused. The young man said that he had no intention of returning the phone at first, but when he saw the photos and messages in the phone, he noticed that Mr. Shang just made a substantial donation to the earthquake-stricken area. He was moved and decided to return it for love and forgot the covetous thoughts.

Prompt 2: 两条小鱼一起游泳，遇到一条老鱼从另一方向游来，老鱼向他们点点头，说:“早上好，孩子们，水怎么样?”两条小鱼一怔，接着往前游。游了一会儿，其中一条小鱼看了另一条小鱼一眼，忍不住说:“水到底是什么东西?”看来，有些最常见而又不可或

缺的东西，恰恰最容易被我们忽视;有些看似简单的事情，却能够引发我们深入思考？

Translation of prompt 2: Two little fishes swam together and encountered an old fish. The old fish nodded to them and said, “Good morning, boys, how is the water?” The little fishes were puzzled and continued to swim. After a while, one of the little fish glanced at the other one and asked, “What is the water?” It seems that some common but indispensable things are often ignored; some seemingly simple things can give us a deep thought.

Prompt 3: 中国自古有“学而知之”的说法，这里的“学”，通常被理解为从师学习。韩愈就说过：“人非生而知之者，孰能无惑？惑而不从师，其为惑也，终不解矣。”随着时代的发展，我们获取知识、掌握技能或懂得道理的途径日趋多元。请结合你的心得和体验，在“____ 而知之”中的横线处填入一字，构成题目，写一篇文章，不能以“学而知之”为题。

Translation of prompt 3: There has been a saying in China since ancient times that “learning to know”. Learning here is usually understood as learning from a teacher. Han Yu once said that “no one is born to know, and everyone has confusions. If you have confusions but do not learn from a teacher, the confusions would be always there.” With the development of the times, the ways we acquire knowledge or master skills are becoming more diverse. According to your experience, fill in a word (except *learning*) above the underline in ____ *to know*, and write an essay.

Prompt 4: 也许将来有这么一天，我们发明了一种智慧芯片，有了它，任何人都能古今中外无一不知，天文地理无所不晓。比如说，你在心里默念一声“物理”，人类有史以来有关物理的一切公式、定律便纷纷浮现出来，比老师讲的还多，比书本印的还全。你逛秦淮河时，脱口一句“旧时王谢堂前燕”，旁边卖雪糕的老大娘就接茬说“飞入寻常百姓家”，还慈祥的告诉你，这首诗的作者是刘禹锡，这时一个金发碧眼的小女孩说，诗名《乌衣巷》出自唐诗，这将是怎样的情形呀！读了以上材料，你有怎样的联想或思考？请就此写一篇文章。

Translation of prompt 4: Perhaps one day in the future, we would have invented an intelligent chip. With this chip, anyone can know everything from ancient to modern times, from astronomy to geography. For example, if you meditate on *physics* in your mind, all formulas and laws related to physics in the history of mankind have emerged, more than the teachers have taught, more than the books have told. When you visit the Qinhuai River, you blurt out a sentence of a poem. An old lady who is selling ice cream would say the next sentence and kindly tells you who the author of this poem is. At the same time, a blond little girl from another country tells that the poem is from Tang poetry. How amazing it is. Based on the above materials, please write an essay about your associations and imagination.

Multi-hop Inference for Question-driven Summarization[*]

Yang Deng, Wenxuan Zhang, Wai Lam
The Chinese University of Hong Kong
`{ydeng,wxzhang,wlam}@se.cuhk.edu.hk`

Abstract

Question-driven summarization has been recently studied as an effective approach to summarizing the source document to produce concise but informative answers for non-factoid questions. In this work, we propose a novel question-driven abstractive summarization method, Multi-hop Selective Generator (MSG), to incorporate multi-hop reasoning into question-driven summarization and, meanwhile, provide justifications for the generated summaries. Specifically, we jointly model the relevance to the question and the interrelation among different sentences via a human-like multi-hop inference module, which captures important sentences for justifying the summarized answer. A gated selective pointer generator network with a multi-view coverage mechanism is designed to integrate diverse information from different perspectives. Experimental results show that the proposed method consistently outperforms state-of-the-art methods on two non-factoid QA datasets, namely WikiHow and PubMedQA.

1 Introduction

Recent years have witnessed several attempts on exploring question-driven summarization, which aims at summarizing the source document with respect to a specific question, to produce a concise but informative answer in non-factoid question answering (QA) (Tomasoni and Huang, 2010; Chan et al., 2012; Song et al., 2017). Unlike factoid QA (Rajpurkar et al., 2016), e.g., "Who is the author of Harry Potter?", whose answer is generally a single phrase or a short sentence with limited information, the answers for non-factoid questions are supposed to be more informative, involving some detailed analysis to explain or justify the final answers, such as questions in community QA (Ishida et al., 2018; Deng et al., 2020a) or explainable QA (Fan et al., 2019; Nakatsuji and Okui, 2020). As the example from PubMedQA (Jin et al., 2019) presented in Figure 1, the answer can be regarded as the summary over the document driven by the reasoning process of the given question.

Most of related studies focus on query-based summarization approaches for summarizing the query-related content from the source document (Shen and Li, 2011; Wang et al., 2013; Cao et al., 2016; Nema et al., 2017). However, these approaches fall short of tackling question-driven summarization problem in QA scenario, since the query-based summarization process is typically based on semantic relevance measurement without a careful reasoning or inference process, which is essential to question-driven summarization. Currently, question-driven summarization is mainly explored by traditional information retrieval methods to select sentences from the source document to construct the final answer (Wang et al., 2014; Song et al., 2017; Yulianti et al., 2018), which heavily rely on hand-crafted features or tedious multi-stage pipelines. Besides, compared to extractive summarization (Cao et al., 2016), abstractive methods (Nema et al., 2017) can produce more coherent and logical summaries to answer the given question. To this end, we study question-driven abstractive summarization to generate natural form of answers by summarizing the source document with respect to a specific question.

To tackle question-driven abstractive summarization, the content selection process for summarization is not only determined by the semantic relevance to the given question, but it also requires a human-like reasoning and inference process to consider the content interrelationship comprehensively and carefully across the whole source text for gener-

Question: ***Are human coronaviruses uncommon in patients with gastrointestinal illness?***

Document: <S>Coronaviruses infect numerous animal species causing a variety of illnesses including respiratory, neurologic and enteric disease. <S>***Human coronaviruses (HCoV) are mainly associated with respiratory tract disease but have been implicated in enteric disease.*** <S>***To investigate the frequency of coronaviruses in stool samples from children and adults with gastrointestinal illness by RT-PCR.*** <S>Clinical samples submitted for infectious diarrhea testing were collected from December 2007 through March 2008. <S>**RNA extraction and RT-PCR was performed for stools negative for Clostridium difficile using primer sets against HCoV-229E, HCoV-OC43, HCoV-NL63, and HCoV-HKU1.** <S>Clinical data from samples positive for coronaviruses were reviewed and recorded. <S>Samples from 479 patients were collected including 151 pediatric (< or = 18 years), and 328 adults (>18 years). <S>Of these samples, 4 patients (1.3%, 2 adult; 2 pediatric) screened positive for the presence of a coronavirus. <S>**All detected coronaviruses were identified as HCoV-HKU1.** <S>**No stools screened positive for either HCoV-229E, HCoV-NL63 or HCoV-OC43.** <S>**All HCoV-HKU1 positive samples occurred between mid-January to mid-February.** <S>**Clinical manifestations from HCoV-HKU1 positive patients included diarrhea, emesis and respiratory complaints.** <S>Three (75%) patients were admitted to the hospital with a median length of stay of 6 days. <S>

Answer: ***Coronaviruses as a group are not commonly identified in stool samples of patients presenting with gastrointestinal illness.*** **HCoV-HKU1 can be identified in stool samples from children and adults with gastrointestinal disease, with most individuals having respiratory findings as well. No stool samples screened positive for HCoV-NL63, HCoV-229E, or HCoV-OC43.**

Figure 1: An example from PubMedQA. The **highlighted** sentences illustrate the inference process when humans answer the given question. ***Italic*** represents direct matching sentences from the question. **Underlined** and **wavy-underlined** represent sentences inferred by 2nd-hop and 3rd-hop reasoning, respectively, to justify the answer.

ating the summary. For instance, in Figure 1, given the specific question, there are several **highlighted** sentences required to be concentrated for conducting summarization so as to generate the answer. It leads to the necessity of measuring the importance of each sentence, instead of regarding the source text as an undifferentiated whole. Among these **highlighted** sentences, only the ***italic*** sentences are directly related to the given question, while other **highlighted** sentences need to be inferred from their interrelationships with other sentences. In other words, the generated summary is likely to lose important information, if we only focus on the semantically relevant content to the given question. Moreover, it can be observed that one-time inference sometimes is insufficient for collecting all the required information for producing a summary. In this example, the answer is summarized from both the ***1st-hop*** and **3rd-hop** inference sentences in the document, indicating the importance of multi-hop reasoning for content selection in question-driven summarization.

In this work, we propose a question-driven abstractive summarization model, namely Multi-hop Selective Generator (MSG), which incorporates multi-hop inference to summarize abstractive answers over the source document for non-factoid questions. Concretely, the document is regarded as a hierarchical text structure to be assessed with the importance degree in both word- and sentence-level for content selection. Then we develop a multi-hop inference module to enable human-like multi-hop reasoning in question-driven summarization, which considers the semantic relevance to the question as well as the information consistency among different sentences. Finally, a gated selective pointer generator network with multi-view coverage mechanism is proposed to generate a concise but informative summary as the answer to the given question.

The main contributions of this paper can be summarized as follows: (1) We propose a novel question-driven abstractive summarization model for generating answers in non-factoid QA, which incorporates multi-hop reasoning to infer the important content for facilitating answer generation; (2) We propose a multi-view coverage mechanism to address the repetition issue along with the multi-view pointer network and generate informative answers; (3) Experimental results show that the proposed method achieves state-of-the-art performance on WikiHow and PubMedQA datasets, and it is able to provide justification sentences as the evidence for the answer.

2 Related Works

Query-based Summarization. Early works on query-based summarization focus on extracting query-related sentences to construct the summary (Lin et al., 2010; Shen and Li, 2011), which are later improved by exploiting sentence compression on the extracted sentences (Wang et al., 2013; Li and Li, 2014). Recently, some data-driven neural abstractive models are proposed to generate natural form of summaries with respect to the given query (Nema et al., 2017; Hasselqvist et al., 2017). However, current studies on query-based abstractive summarization are restricted by the lack of large-scale datasets (Baumel et al., 2016; Nema et al., 2017). One the other hand, some researchers spark a new pave of question-driven summarization in non-factoid QA (Song et al., 2017; Yulianti et al., 2018; Deng et al., 2020b), which requires the ability of reasoning or inference for supporting summarization, not merely relevance measurement, and also preserves remarkable testbeds of large-scale datasets.

Non-factoid Question Answering. Different from factoid QA that can be tackled by extracting answer spans (Rajpurkar et al., 2016) or generating short sentences (Nguyen et al., 2016; Kociský et al., 2018), non-factoid QA aims at producing relatively informative and complete answers. In the past studies, non-factoid QA focused on retrieval-based methods, such as answer sentence selection (Nakov et al., 2015) or answer ranking (Zhang et al., 2020). Recently, several efforts have been made on tackling long-answer generative question answering over supporting documents, which targets on questions that require detailed explanations (Fan et al., 2019). This kind of QA problem contains a large proportion of non-factoid questions, such as "how" or "why" type questions (Koupaee and Wang, 2018; Ishida et al., 2018; Deng et al., 2020a). Besides, some studies aim at generating a conclusion for the concerned question (Jin et al., 2019; Nakatsuji and Okui, 2020). Fan et al. (2019) propose a multi-task Seq2Seq model with the concatenation of the question and support documents to generate long-form answers. Iida et al. (2019) and Nakatsuji and Okui (2020) incorporate some background knowledge into Seq2Seq model for why questions and conclusion-centric questions. Some latest works (Feldman and El-Yaniv, 2019; Yadav et al., 2019; Nishida et al., 2019a) attempt to provide evidence or justifications for human-understandable explanation of the multi-hop inference process in factoid QA, where the inferred evidences are only treated as the middle steps for finding the answer. However, in non-factoid QA, the intermediate output is also important to form a complete answer, which requires a bridge between the multi-hop inference and summarization.

3 Proposed Framework

We propose a question-driven abstractive summarization model, namely Multi-hop Selective Generator (MSG). The overview of MSG is depicted in Figure 2, which consists of three main components: (1) *Co-attentive Encoder* (Section 3.1), (2) *Multi-hop Inference Module* (Section 3.2), and (3) *Gated Selective Generator* (Section 3.3). Moreover, *Multi-view Coverage Loss* is integrated to the overall training procedure (Section 3.4).

3.1 Co-attentive Encoder

Pre-trianed word embeddings, E_q and E_{s_i}, of the question q and each sentence s_i in the document $D = \{s_1, s_2, ..., s_n\}$ are input into the model. We first encode the question and each sentence in the document by a Bi-LSTM (Bidirectional Long Short-Term Memory Networks) shared encoder to learn the word-level contextual information, $H_q, H_{s_i} \in \mathbb{R}^{l \times d_h}$, where l and d_h denotes the sentence length and the dimension of the encoder output respectively. The overall word-level representations H_d for the document is sequentially concatenated by $[H_{s_1}, H_{s_2}, ..., H_{s_n}]$.

We compute the attention weights to align the word-level information between the question and the document sentences, and obtain the attention-weighted vectors of each word for both the question and the document sentences. For the question q and the i-th sentence s_i in the document D, we have:

$$O_{qs_i} = \tanh\left(H_q^T U H_{s_i}\right), \tag{1}$$

$$\alpha_{q_i} = \text{softmax}(\text{Max}(O_{qs_i})), \tag{2}$$

$$\alpha_{s_i} = \text{softmax}(\text{Max}({O_{qs_i}}^T)), \tag{3}$$

where $U \in \mathbb{R}^{d_h \times d_h}$ is the attention matrix to be learned; α_{q_i} and α_{s_i} are co-attention weights for the question and i-th sentence in the document.

We conduct dot product between the attention vectors and the word-level representations to generate the sentence representations for the question and the document:

$$M_q = \frac{1}{n}\sum\nolimits_{i=1}^{n} H_q^T \alpha_{q_i} \tag{4}$$

$$M_s = [H_{s_1}^T \alpha_{s_1} : ... : H_{s_n}^T \alpha_{s_n}], \tag{5}$$

where M_q and M_s denote the sentence-level representations for the question and the document.

3.2 Multi-hop Inference Module

Multi-hop Inference Module measures the degree of importance for each sentence in the document to generate the answer, through a multi-hop reasoning procedure, which contains two kinds of inference units: Attentive Unit and MAR Unit.

3.2.1 Attentive Unit

Attentive Unit basically measures the matching degree between each sentence in the document and the given question by the following vanilla attention mechanism:

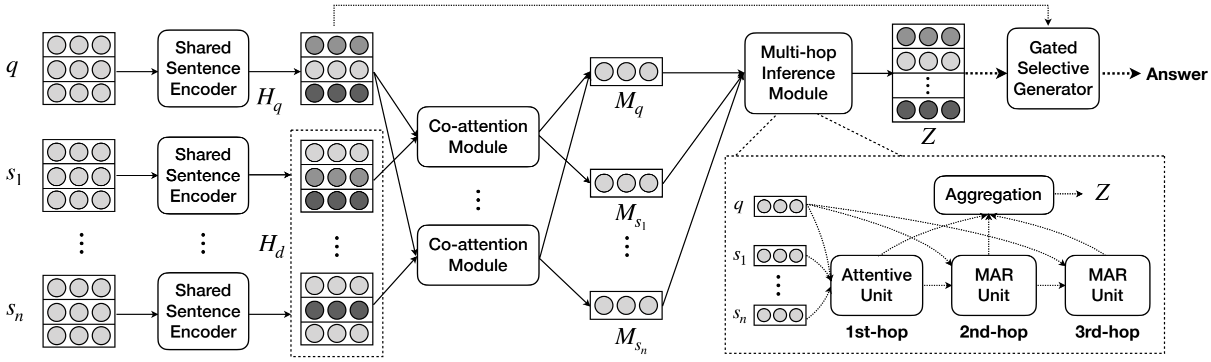

Figure 2: The overview of Multi-hop Selective Generator (MSG).

$$m_{dq} = \tanh(M_s W_m M_q), \tag{6}$$

$$\alpha_s = \text{softmax}(\omega_m^T m_{d_q}), \tag{7}$$

$$\texttt{Attentive}(M_s, M_q) = M_s \odot \alpha_s, \tag{8}$$

where W_m and ω_m are the attention matrices to be learned. α_s is the sentence-level attention weight which measures the matching degree of each document sentence with the given question. $\odot$ denotes the element-wise product for obtaining the attentive sentence-level representations for the document.

3.2.2 MAR Unit

Maximal Marginal Relevance (MMR) is an IR model that can be adopted to measure the query-relevancy and information-redundancy simultaneously for extractive summarization (Carbonell and Goldstein, 1998). However, as for the content selection in abstractive summarization, the relevance to both the question and the other sentences in the document should be taken into consideration for a high recall of selecting necessary content. Thus, we propose Maximal Absolute Relevance (MAR) to select highly salient sentences for generating the summary, which is formulated as:

$$\begin{aligned} mar_i =& \lambda \text{Sim}_1(M_{s_i}, M_q) + \\ & (1-\lambda) \max_{s_j \in D, j \neq i} \text{Sim}_2(M_{s_i}, M_{s_j}), \end{aligned} \tag{9}$$

where λ is a hyper-parameter for balancing the question-relevancy and information-consistency measurement. The relevance to the question is calculated by:

$$\text{Sim}_1(M_{s_i}, M_q) = M_{s_i} U_1 M_q, \tag{10}$$

where U_1 is a similarity matrix to be learned. We apply an attention mechanism over other sentences in the document to choose the highest relevance score, which can be regarded as the reasoning procedure where the next-hop justification sentences are supposed to be highly related to the last-hop justification sentences.

$$e_{ij} = \tanh(M_{s_i} U_2 M_{s_j}), \tag{11}$$

$$\text{Sim}_2(M_{s_i}, M_{s_j}) = \frac{exp(e_{ij})}{\sum_j exp(e_{ij})}, \tag{12}$$

where U_1 is a similarity matrix to be learned.

Then the weighted sentence representations are computed by the element-wise product of the original sentence representations and the MAR scores gated by a sigmoid function denoted as σ:

$$\textbf{MAR}(M_s, M_q) = M_s \odot \sigma(mar). \tag{13}$$

Overall, MAR Unit assigns higher weights to sentences in two situations: (i) Those sentences are correlated to the given question, due to the first term in Equation 9, (ii) Those sentences are consistent with the highly weighted justification sentences from the last hop, due to the second term.

3.2.3 Reasoning Procedure

In accordance with human-like multi-hop inference procedure, the first hop is supposed to capture the semantic-relevant sentences to the given question. Then the subsequent hops should consider not only the relevance to the question, but also the information-consistency with the previous attended sentences. Hence, the Attentive Unit is adopted as the 1st-hop inference unit, while the MAR Unit is served as the kth-hop unit, where $k > 1$. Before each hop, a Bi-LSTM layer is employed to refine the input sentence representation. For instance, a 3-hop inference procedure is as follows:

$$M_s^{(1)} = \texttt{Attentive}(\text{Bi-LSTM}(M_s), M_q), \tag{14}$$

$$M_s^{(2)} = \textbf{MAR}(\text{Bi-LSTM}(M_s^{(1)}), M_q), \tag{15}$$

$$M_s^{(3)} = \textbf{MAR}(\text{Bi-LSTM}(M_s^{(2)}), M_q). \tag{16}$$

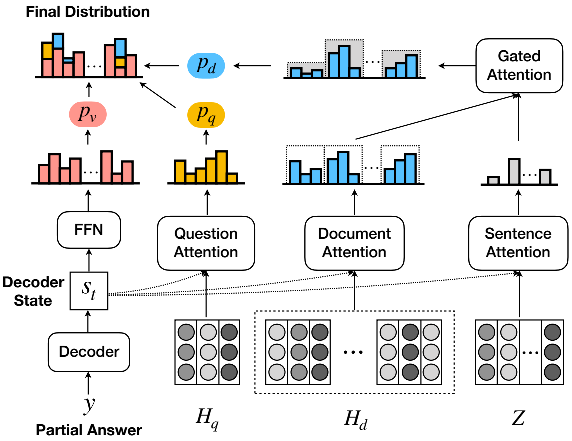

Figure 3: Gated Selective Pointer-Generator Network.

Then, we merge the 3-hop sentence representations, $\hat{M}_s = [M_s^{(1)}, M_s^{(2)}, M_s^{(3)}]$, via the following attention mechanism:

$$\alpha_h = \text{softmax}(\omega_h^T \tanh(W_h \hat{M}_s)), \tag{17}$$

$$Z = \hat{M}_s^T \alpha_h, \tag{18}$$

where W_h and ω_h are attention matrices to be learned. Z is the final sentence-level document representation for justifying the importance degree of each sentence in the decoding phase.

3.3 Gated Selective Generator

We obtain the word-level representations H_q and H_d for the question and document, respectively, from the encoding phase, and the sentence-level document representation Z via the multi-hop inference module. Figure 3 depicts the Gated Selective Pointer Generator Network in MSG.

A unidirectional LSTM is adopted as the decoder. At each step t, the decoder produces hidden state s_t with the input of the previous word w_{t-1}. The attention for each word in the question and the document, α_t^q and α_t^d, are generated by:

$$e_t^{q_j} = \omega_t^{qT} \tanh(W_q H_{q_j} + W_{qs} s_t + b_q), \tag{19}$$

$$\alpha_t^q = \text{softmax}(e_t^q), \tag{20}$$

$$e_t^{d_i} = \omega_t^{dT} \tanh(W_d H_{d_i} + W_{ds} s_t + b_d), \tag{21}$$

$$\alpha_t^d = \text{softmax}(e_t^d), \tag{22}$$

where W_q, W_{qs}, W_d, W_{ds}, ω_t^q, ω_t^d, b_q, b_d are parameters to be learned.

Then, we incorporate the multi-hop inference results Z to compute the gated attention weights β_t for each sentence in the document:

$$\beta_t = \sigma(\omega_t^{sT} \tanh(W_s Z_k + W_{ss} s_t + b_s)), \tag{23}$$

where W_s, W_{ss}, ω_t^s, b_s are parameters to be learned. We re-weight the word-level document attention scores α^d gated by the sentence-level document attention scores β to attend important justification sentences along with the decoding process:

$$\hat{\alpha}_t^{d_i} = \frac{\alpha_t^{d_i} \beta_{t,d_i \in s_k}}{\sum_i \alpha_t^{d_i} \beta_{t,d_i \in s_k}}. \tag{24}$$

Thus, the re-weighted word-level document attention $\hat{\alpha}^d$ naturally blends with the results from the multi-hop inference module to enhance the influence of those important justification sentences.

Finally, a multi-view pointer-generator architecture is designed to generate answers with multi-hop inference results as well as handle the multi-perspective out-of-vocabulary (OOV) issue. Such approach enables MSG to copy words from the question and be aware of the differential importance degree of different sentences in the document.

The attention weights α_t^q and $\hat{\alpha}_t^d$ are used to compute context vectors c_t^q and c_t^d as the probability distribution over the source words:

$$c_t^q = H_q^T \alpha_t^q, \quad c_t^d = H_d^T \hat{\alpha}_t^d. \tag{25}$$

The context vector aggregates the information from the source text for the current step. We concatenate the context vector with the decoder state s_t and pass through a linear layer to generate the answer representation h_t^s:

$$h_t^s = W_1[s_t : c_t^q : c_t^d] + b_1, \tag{26}$$

where W_1 and b_1 are parameters to be learned.

Then, the probability distribution P^v over the fixed vocabulary is obtained by passing the answer representation h_t^s through a softmax layer:

$$P^v(y_t) = \text{softmax}(W_2 h_t^s + b_2), \tag{27}$$

where W_2 and b_2 are parameters to be learned.

The final probability distribution of y_t is obtained from three views of word distributions:

$$P^q(y_t) = \sum\nolimits_{i:w_i=w} \alpha_t^{q_i}, \tag{28}$$

$$P^d(y_t) = \sum\nolimits_{i:w_i=w} \hat{\alpha}_t^{d_i}, \tag{29}$$

$$P^{all}(y_t) = [P^v(y_t), P^q(y_t), P^d(y_t)], \tag{30}$$

$$\rho = \text{softmax}(W_\rho[s_t : c_t^q : c_t^d] + b_\rho), \tag{31}$$

$$P(y_t) = \rho \cdot P^{all}(y_t), \tag{32}$$

where W_ρ and b_ρ are parameters to be learned, ρ is the multi-view pointer scalar to determine the weight of each view of the probability distribution.

3.4 End-to-end Training

Multi-view Coverage Loss. The original *coverage mechanism* (See et al., 2017) could only prevent repeated attention from one certain source text. However, the repetition problem becomes more severe, as we leverage both the question and document as the source text. Besides, similar to multi-view pointer network, coverage losses of different sources are supposed to be weighted by their contribution. Therefore, we design a multi-view coverage mechanism to address this issue as well as balance the generating and copying processes.

In each decoder timestep t, the coverage vector $c_t = \sum_{t'=0}^{t-1} a_{t'}$ is used to represent the degree of coverage so far. The coverage vector c_t will be applied to compute the attention weight α_t in Equations 19 and 21. The coverage loss is trained to penalize the repetition in updated attention weight α^t from all views. The re-normalized pointer weights $\hat{\rho} = \rho^c / \sum_{c\in\{q,d\}} \rho^c$ are employed to balance the coverage loss of different views:

$$L_{cov} = \sum \hat{\rho} \frac{1}{T} \sum_{t=1}^{T} \sum_{i} \min(\alpha_t^i, c_t^i). \quad (33)$$

Overall Loss Function. The overall model is trained to minimize the negative log likelihood and the multi-view coverage loss:

$$L = -\frac{1}{T} \sum_{t=0}^{T} \log P(w_t^*) + \lambda L_{cov}, \quad (34)$$

where λ is a hyper-parameter to balance losses.

4 Experiments

4.1 Datasets and Evaluation Metrics

We evaluate on a large-scale summarization dataset with non-factoid questions, WikiHow (Koupaee and Wang, 2018), and a non-factoid QA dataset with abstractive answers, PubMedQA (Jin et al., 2019). WikiHow is an abstractive summarization dataset collected from a community-based QA website, *WikiHow*[1], in which each sample consists of a non-factoid question, a long article, and the corresponding summary as the answer to the given question. PubMedQA is a conclusion-based biomedical QA dataset collected from *PubMed*[2] abstracts, in which each instance is composed of a question, a context, and an abstractive answer which is the summarized conclusion of the context corresponding to the question. The statistics of the WikiHow and PubMedQA datasets are shown in Table 1 [3]. We adopt ROUGE F1 (R1, R2, RL) for automatically evaluating the summarized answers. Besides, human evaluation and Distinct scores are adopted for analysis.

Dataset (train/dev/test)	WikiHow	PubMedQA
#Samples	168K / 6K / 6K	169K / 21K / 21K
Avg QLen	7.00 / 7.02 / 7.01	16.3 / 16.4 / 16.3
Avg DLen	582 / 580 / 584	238 / 238 / 239
Avg ALen	62.2 / 62.2 / 62.2	41.0 / 41.0 / 40.9
Avg #Sents/Doc	20.7 / 20.7 / 20.6	9.32 / 9.31 / 9.33

Table 1: Statictis of Dataset

4.2 Baseline Methods and Implementations

To evaluate the proposed method, we compare with several baselines and state-of-the-art methods on query-based abstractive summarization and generative QA. We first employ four widely-adopted summarization baseline methods, including two unsupervised extractive methods, **LEAD3** and **MMR**, and two abstractive methods, **S2SA** (Bahdanau et al., 2015), and **PGN** (See et al., 2017).

Then two popular query-based abstractive summarization methods are adopted for evaluation: (1) **SD**$_2$ (Nema et al., 2017), which is a sequence-to-sequence model with a query attention, and (2) **QS** (Hasselqvist et al., 2017), which incorporates question information into the pointer-generator network with the vanilla attention mechanism.

Finally, we implement two latest generative QA models for comparisons: (1) **S2S-MT** (Fan et al., 2019), which uses a multi-task Seq2Seq model with the concatenation of question and support document, and (2) **QPGN** (Deng et al., 2020a), which is a question-driven pointer-generator network with co-attention between the question and document.

We train all the models with pre-trained GloVE embeddings[4] of 300 dimensions and set the vocabulary size to 50k. During training and testing procedure, we restrict the length of generated summaries within 50 words. As for the proposed method, we train with a learning rate of 0.15 and an initial accumulator value of 0.1. The dropout rate is set to 0.5. The hidden unit sizes of the BiLSTM encoder and the LSTM decoder are all set to 256. We train our models with the batch size of 32. All other parameters are randomly initialized from [-0.05, 0.05]. Similar to the original coverage loss (See

et al., 2017), we first train the model without multi-view coverage loss for 20 epochs, and then train with it for another 5 epochs with λ as 0.1.

4.3 Performance Comparison

Table 2 summarizes the experimental results on both datasets. As for WikiHow, which is an abstractive summarization dataset with non-factoid questions, current query-based summarization (SD$_2$, QS) and generative QA approaches (S2S-MT, QPGN) barely improve the performance from traditional summarization approaches. It indicates that the question information is not fully exploited for summarization, while MSG outperforms all these methods with a noticeable margin, about 2%.

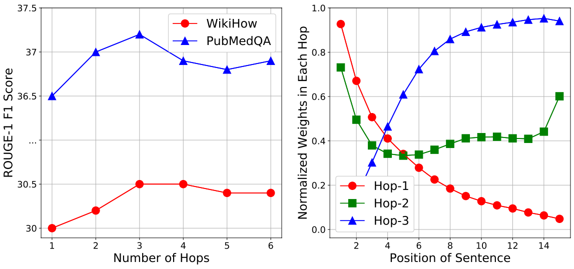
Besides, since PubMedQA is a QA dataset with abstractive answers, we can observe that QPGN, which employs special design for modeling the interaction between the question and document, achieves relatively better performance than other summarization methods. Favorably MSG raises the state-of-the-art result by about 3%. Furthermore, MSG achieves promising improvements via the multi-hop inference on these two datasets.

We conduct human evaluation to evaluate the generated answer from four aspects: (1) Informativity: how rich is the generated answer in information? (2) Conciseness: how concise is the summary? (3) Readability: how fluent and coherent is the summary? (4) Correctness: how well does the generated answer respond to the given question? We randomly sample 50 questions from two datasets and generate their answers with three query-based summarization methods, including SD$_2$, QS, QPGN and the proposed MSG. Three annotators are asked to score each generated answer with 1 to 5 (higher the better). Results are presented in Table 3. We observe that MSG consistently and substantially outperforms existing query-based summarization methods in all aspects, especially for the informativeness and correctness. The results show that MSG effectively generates concise but also informative answers, since MSG not only considers question-related information, but also captures logically necessary content for answering the given question via multi-hop reasoning. Consequently, it leads to a more precise answer.

5 Discussions

5.1 Ablation Study

We conduct ablation study to validate the effectiveness of different components in MSG as well as the detailed design for the multi-hop inference module. The upper part in Table 4 presents the ablation study on multi-hop inference module. First of all, the model performance suffers a great decrease from discarding the multi-hop inference module on two datasets, showing the necessity of incorporating the multi-hop reasoning into the question-driven summarization. In specific, the fusion of the selective sentence representations from all hops brings performance improvement, including aggre-



(a) Model Performance with Different Hops (b) Degree of Sentence Importance

Figure 4: Analysis of Multi-hop Reasoning

gating all the hops as well as applying attention to weight the importance of each hop. Besides, it also achieves better performance to apply the proposed MAR Unit as the multi-hop unit, instead of repeatedly using Attentive Unit, indicating that it is not enough to only consider the question-related information, while the interrelationship among different sentences also attaches great importance.

The second part in Table 4 presents the ablation study in terms of discarding other model components in MSG. In general, all the components contribute to the final performance to a certain extent. In detail, there are several notable observations: (1) Some existing works (Hsu et al., 2018; Nishida et al., 2019b) apply softmax function to normalize the weights of different sentences in the decoding phase, which falls short of differentiating the importance degree of each sentence. The result shows that MSG achieves better performance by employing gated attention to distinguish salient justification sentences for generating the summaries. (2) Discarding the question pointer casts a noticeably greater decrease on PubMedQA than WikiHow. We conjecture that those questions from PubMedQA contain more words available to be copied for generating precise summaries, as the statistic of the question length shown in Table 1. These results also validate the importance of multi-view PGN on question-driven abstractive summarization, which is underutilized in current methods. (3) Multi-view coverage (MVC) loss makes a great contribution to the performance by alleviating the severe repetition problem along with the multi-view PGN.

5.2 Analysis of Multi-hop Reasoning

As the results presented in Section 4.3, MSG (3-Hop) outperforms MSG (1-Hop) by 0.5% and 0.7% on WikiHow and PubMedQA, respectively, indicating the effectiveness of incorporating multi-hop reasoning in question-driven summarization. Figure 4(a) presents the model performance in terms of using different hops of reasoning. We can see that, as expected, the performance of the model begins with growth when increasing the number of hops for reasoning. However, the performance becomes generally unchanged (e.g., WikiHow) or even slightly decreases (e.g., PubMedQA) when we further increase the number of hops. In practice, it is actually unnecessary to reason for too many hops, which may cause over-fitting. And adopting 3-hops in the implementation can be regarded as a hyper-parameter that is tuned on the datasets.

In addition, we extract and normalize the sentence weights from Eq. 7&9 to analyze some characteristics of the justification sentences in multi-hop inference. Figure 4(b) summarizes the statistic result of the sentence importance degree in each hop. We observe that the most important sentences in the 1st-hop of reasoning are likely to appear at the beginning of the document, while those in the 3rd-hop are concentrated in the latter part of the document. Comparatively, the important sentences in the 2nd-hop appear equally in all positions of the document. The results show that the proposed multi-hop inference procedure of justification sentences is generally in accordance with human-like reading habits.

5.3 Case Study

We present a case study in Figure 5 with generated answers from the proposed method and some baseline methods, QPGN, QS, and SD_2, to intuitively compare these methods. With the multi-hop reasoning process in MSG, we can obtain a clear clue of how to answer the given question. As it can be observed that the reference answer is composed of the information from the ***1st-hop*** and **3rd-hop** inference sentences, it is inadequate to simply summarize the question-related content for generating the answer. For the generated summaries, there are several observations as follows: (1) MSG (3-hop) successfully summarizes the source document with all the necessary and correct information. (2) MSG (2-hop) also effectively summarizes the 1st-hop and 2nd-hop inference content in the document. However, in this case, 3-hop inference is required to answer the given question. (3) MSG (1-hop) only measures the semantic relevance to the given question, leading to an incomplete summary that is lack of some necessary content, and even introduces some general sentences due to the data-driven learning. (4) QPGN only considers the

Question: ***Does high molecular weight hyaluronan decrease oxidative DNA damage induced by EDTA in human corneal epithelial cells?***

Document: <S>***To investigate the toxic effects of Ethylenediaminetetraacetic Acid Disodium Salt (EDTA), a corneal penetration enhancer in topical ophthalmic formulations, on DNA in human corneal epithelial cells (HCEs), and to investigate whether the effect induced by EDTA can be inhibited by high molecular weight hyaluronan (HA).*** <S>Cells were exposed to EDTA in concentrations ranging from 0.00001 to 0.01% for 60 min, or 30 min high molecular weight HA pretreatment followed by EDTA treatment. <S>…<S>EDTA exhibited no adverse effect on cell viability and did not induce cell apoptosis in human corneal epithelial cells at concentrations lower than 0.01%. <S>**However, a significant increase of DNA single- and double-strand breaks was observed in a dose-dependent manner with all the concentrations of EDTA tested in HCEs.** <S> **In addition, EDTA treatment led to elevated ROS generation.** <S>**Moreover, 30 min preincubation with high molecular weight HA significantly decreased EDTA-induced ROS generation and DNA damage.** <S>

Reference Answer: ***EDTA could induce DNA damage in HCEs, probably through oxidative stress.*** **Furthermore, high molecular weight HA was an effective protective agent that had antioxidant properties and decreased DNA damage induced by EDTA.**

MSG (3-Hop): ***High molecular weight HA reduces oxidative DNA damage induced by EDTA in human corneal epithelial cells.*** **Moreover, high molecular weight HA significantly decreased EDTA-induced ROS generation and DNA damage.**

MSG (2-Hop): ***High molecular weight HA pretreatment followed by EDTA reduces oxidative DNA damage induced by EDTA in human corneal epithelial cells.*** However, a significant increase of DNA single- and double-strand breaks was observed in a dose-dependent manner with high molecular weight HA.

MSG (1-Hop): **High molecular weight HA significantly reduced EDTA-induced ROS generation and DNA damage in human corneal epithelial cells.** These results suggest that EDTA may be a potential therapeutic agent for the treatment of corneal penetration.

QPGN: ***In addition to the corneal penetration of HCEs, EDTA can induce cell apoptosis in human corneal epithelial cells, and the effect induced by EDTA in human corneal epithelial cells can be inhibited by EDTA.***

QS: EDTA induces cell apoptosis in human corneal epithelial cells, suggesting that EDTA may be a potential therapeutic agent for the treatment of corneal epithelial cells, in the prevention of DNA damage in the corneal epithelial cell population.

SD2: These results suggest that EDTA may be a potential therapeutic agent for the treatment of human corneal epithelial damage caused by EDTA in the topical ophthalmic formulation of topical ophthalmic formulations.

Figure 5: A case study with the same legend as Figure 1. The **highlighted** sentences are attended by MSG (3-hop).

semantic relevance to the given question, leading to an incomplete summary that is lack of some necessary content. (5) QS and SD_2 fail to capture the key information, resulting in generating irrelevant summaries to the given question, or producing some general sentences due to the data-driven learning. It shows the capability of MSG to implement multi-hop reasoning and provide justification sentences.

Additionally, we observe that many cases probably require more than 3-hop inference or only involve one or two hops. However, we can still evaluate how MSG works in these cases. Compared to the reference answer, MSG (3-hop) can still capture most of the useful information to generate a good summary for answering the question. Besides, MSG (2-hop) and MSG (1-hop) also manage to attend some important content in the document. In general, our model is able to only attend a single hop if one-hop is enough, while our model may regard several hops as an integral hop when more hops are required. However, the baseline methods introduce much unnecessary or even incorrect information into the summarized answers.

5.4 Duplication Analysis in Answers

We adopt Distinct scores to analyze whether the multi-view coverage mechanism can alleviate the repetition issue in the generation procedure of multi-view PGN. Figure 6 summarizes the percentage of n-grams duplication on the ground-truth answers and the generated answers with or without the original (See et al., 2017) and multi-view coverage mechanism. We observe that the original coverage mechanism can still reduce word repetition in multi-view PGN. Moreover, multi-view coverage further reduces the ratio of duplication to a great extent, since multi-view coverage not only prevents repeatedly attending to the same element in both question and document, but also balances the weight of penalty between them.

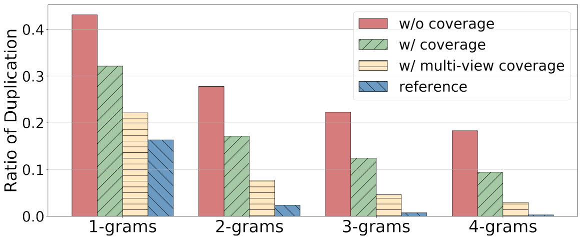


Figure 6: Duplication Analysis in Answers

6 Conclusion

We propose a novel question-driven abstractive summarization method, Multi-hop Selective Generator (MSG), to summarize concise but informative answers for non-factoid QA. We incorporate multi-hop reasoning to infer justification sentences for abstractive summarization. Experimental results show that the proposed method achieves state-of-the-art performance on two benchmark non-factoid QA datasets, namely WikiHow and PubMedQA.

Abstract

We focus on the task of reasoning over paragraph effects in situation, which requires a model to understand the cause and effect described in a background paragraph, and apply the knowledge to a novel situation. Existing works ignore the complicated reasoning process and solve it with a one-step "black box" model. Inspired by human cognitive processes, in this paper we propose a sequential approach for this task which explicitly models each step of the reasoning process with neural network modules. In particular, five reasoning modules are designed and learned in an end-to-end manner, which leads to a more interpretable model. Experimental results on the ROPES dataset demonstrate the effectiveness and explainability of our proposed approach.

1 Introduction

As a long-standing fundamental task of natural language processing, machine reading comprehension (MRC) has attracted remarkable attention recently and different MRC datasets have been studied (Rajpurkar et al., 2018; Dua et al., 2019b; Choi et al., 2018; Yang et al., 2018), among which reasoning over paragraph effects in situation (ROPES for short) is a very challenging scenario that needs to understand knowledge from a background paragraph and apply it to answer questions in a novel situation. Table 1 shows an example of the ROPES dataset (Lin et al., 2019), where the background passage states that developmental difficulties could usually be treated by using iodized salt, the situation passage describes two villages using different salt, and questions about which village having more/less people experiencing developmental difficulties need to be answered.

Background
Before iodized salt was developed, some people experienced a number of developmental difficulties, including problems with thyroid gland function and mental retardation. In the 1920s, we learned that these conditions could usually be treated easily with the addition of iodide anion to the diet. One easy way to increase iodide intake was to add the anion to table salt.
Situation
People from two villages ate lots of salt. People from Salt village used regular salt, while people from Sand village people used iodized salt in their diets, after talking to specialists.
Q&A
Q: Which village had more people experience developmental difficulties? A: Salt
Q: Which village had less people experience developmental difficulties? A: Sand

Table 1: An example from the ROPES dataset. Effect property tokens are highlighted in blue, cause property tokens in orange, and world tokens in green.

Almost all existing works (Lin et al., 2019; Khashabi et al., 2020; Dua et al., 2019a; Gardner et al., 2020) for this task adopt a standard MRC approach based on deep learning in one step: the question and a pseudo passage constructed by concatenating the background and situation are fed into a large pre-trained model (e.g. RoBERTa large), and the answer is predicted directly by the model. However, the ROPES task is more complicated than traditional MRC since it requires a model to not only understand the causes and effects described in a background paragraph, but also apply the knowledge to a novel situation. Ignoring the understanding and reasoning process hinders such models from achieving their best performance. Consequently, the best F1 (61.6%) achieved so far

November 16–20, 2020.

is far below human performance (89.0%). More importantly, such a one-step approach makes the reasoning process unexplainable, which is of great importance for complicated reasoning tasks.

We observe that human solve this kind of complicated reasoning tasks in a sequential manner with multiple steps (Evans, 1984; Sloman, 1996; Sheorey and Mokhtari, 2001; Mokhtari and Reichard, 2002; Mokhtari and Sheorey, 2002). As shown in Table 1, the background paragraph usually states the relationship between a cause property and an effect property, the situation describes multiple worlds each of which is associated with a specific value in terms of the cause property. Human usually does reasoning in a multi-step process: (1) identifying mentioned worlds, (2) identifying the cause and effect property, (3) understanding the relationship between the cause and effect property, (4) comparing identified worlds in terms of the cause property, and (5) reasoning about the comparison of mentioned worlds in terms of the effect property based on (3) and (4).

Inspired by human cognitive processes, in this paper, we propose a sequential approach that leverages neural network modules to implement each step of the above process[1]. Specifically, we define

- a *World Detection* module to identify potential worlds,
- an *Effect and Cause Detection* module to identify effect and cause property,
- a *Relation Classification* module to understand the relationship between effect and cause,
- a *Comparison* module to compare identified worlds in terms of the cause property, and
- a *Reasoning* module to infer comparison of mentioned worlds in terms of the effect property.

These modules are trained in an end-to-end manner, and auxiliary loss over intermediate latent decisions further boosts the model accuracy.

Explicitly modeling the sequential reasoning process has two advantages. First, it achieves better performance since the complicated reasoning process is decomposed into more manageable sub-tasks and each module only needs to focus on a simple sub-task. Second, intermediate outputs provide a better understanding of the reasoning process, making the learnt model more explainable.

Experimental results on the ROPES dataset demonstrate the effectiveness and explainability of our proposed approach. It surpasses the state-of-the-art model by a large margin (6% absolute difference) in the five-fold cross-validation setting. Furthermore, analyses on intermediate outputs show that each module in our learnt model performs well on its corresponding sub-task and well explains the reasoning process.

2 Related Work

Neural network modules have been studied by several works. Andreas et al. (2016) propose neural module networks with a semantic parser on visual question answering. Jiang and Bansal (2019) apply a self-assembling modular network with only three modules: Find, Relocate and Compare to Hotpot QA (Yang et al., 2018). Gupta et al. (2019) extend the neural module networks to answer compositional questions against a paragraphs of text as context, and perform symbolic reasoning on the self-pruned subset of DROPS (Dua et al., 2019b). Compared with them, we focus on a more challenging MRC task: reasoning over paragraph effects in situation, which has been rarely investigated and needs more complex reasoning. So far as we know, the only two works (i.e. (Lin et al., 2019) and (Khashabi et al., 2020)) on this topic uses a one-step "black box" model. Such an approach performs well on some questions at the expense of limited intepretability. Our work solves this task in a logical manner and exposes intermediate reasoning steps which improves performance and interpretability concurrently.

3 Methodology

As shown in Figure 1, our approach consists of three components which are contextual encoding, interpretable reasoning, and answer prediction.

3.1 Contextual Encoding

We use RoBERTa (Devlin et al., 2019; Liu et al., 2019) to encode background, situation and question together and generate contextualized embeddings. Specifically, given a background passage $B = \{b_i\}_{i=1}^{m}$, a situation passage $S = \{s_j\}_{j=1}^{n}$ and a question $Q = \{q_k\}_{k=1}^{l}$,

a) Model Achitecture

b) Interpretable Reasoning

Module	Input	Output
World Detection	H^s	$\mathbf{p}_w^s$
Effect and Cause Detection	H^s, H^b	$\mathbf{p}_e^b, \mathbf{p}_c^b$
Comparison	$\mathbf{p}_c^b, \mathbf{p}_w^s$, H^s,H^b	p_{com_w}
Relation Classification	$\mathbf{p}_e^b, \mathbf{p}_c^b$, H^b	p_{rel}
Reasoning	p_{com_w}, p_{rel}	p_{e_w}

c) Input and Output for Modules

Figure 1: The left part is the architecture of our model. The middle part is the interpretable reasoning component in our model. The right part is the summary for inputs and outputs flowing between each module. The encoded contextual representations, $\boldsymbol{H^q}, \boldsymbol{H^s}, \boldsymbol{H^b}$, serve as global variables for the interpretable reasoning component.

we concatenate them with special tokens as $\langle s \rangle\, q_1, \ldots, q_l\, \langle /s \rangle\, \langle /s \rangle\, s_1, \ldots, s_n; b_1, \ldots, b_m\, \langle /s \rangle$, which is then fed into a series of successive transformer blocks contained in RoBERTa,

$$\boldsymbol{H^q}, \boldsymbol{H^s}, \boldsymbol{H^b} = \text{Transformers}(Q, S, B), \quad (1)$$

where $\boldsymbol{H^b} \in \mathbb{R}^{m \times d}$, $\boldsymbol{H^s} \in \mathbb{R}^{n \times d}$, and $\boldsymbol{H^q} \in \mathbb{R}^{l \times d}$ are contextual embeddings for the background, situation, and question, respectively, d is the dimension for hidden states.

3.2 Interpretable Reasoning

World Detection

The module aims to identify concerned worlds from situation according to a question. Take Table 1 as an example, the question cares about two worlds, *Sand Village* and *Salt Village*. To achieve that, we apply a multilayer perceptron (MLP) over the situation representations $\boldsymbol{H^s}$ and normalize the projected logits (using a softmax function) to get attention over all situation tokens for each world,

$$\boldsymbol{p^s_{w_1}} = \text{softmax}(\text{MLP}(\boldsymbol{H^s}; \theta_{w_1})) \in \mathbb{R}^n, \quad (2)$$

$$\boldsymbol{p^s_{w_2}} = \text{softmax}(\text{MLP}(\boldsymbol{H^s}; \theta_{w_2})) \in \mathbb{R}^n, \quad (3)$$

where $\boldsymbol{p^s_{w_1}}$ and $\boldsymbol{p^s_{w_2}}$ are the attention vectors over situation for the first and second world, θ's are learnable parameters of MLP. Note that since most examples in the ROPES dataset are related to two concerned worlds, we identify two worlds in our model. However, we can handle multiple worlds by simply extending the module with more MLPs.

Effect and Cause Detection

This module aims to identify effect and cause properties described in the background. To achieve that, another MLP is used to identify the effect property,

$$\boldsymbol{p^b_e} = \text{softmax}(\text{MLP}(\boldsymbol{H^b}; \theta_e)) \in \mathbb{R}^m. \quad (4)$$

Here $\boldsymbol{p^b_e}$ is the attention vector over background tokens in terms of the effect property, which attends more to tokens of effect property. Take Table 1 as an example, $\boldsymbol{p^b_e}$ is the attention over background tokens, whose value is much larger for *developmental difficulties* than other tokens.

Next, we apply a *relocate* operation which reattends to the background based on the situation and is used to find the cause property in the background (e.g., shifting the attention from *developmental difficulties* to *iodized salt* in Table 1). This is achieved with the help of a situation-aware background-to-background attention matrix $\boldsymbol{R} \in \mathbb{R}^{m \times m}$,

$$\boldsymbol{R}_{ij} = \boldsymbol{w_{relo}}^T \left[(\boldsymbol{s} + \boldsymbol{H^b_i}); \boldsymbol{H^b_j}; (\boldsymbol{s} + \boldsymbol{H^b_i}) \odot \boldsymbol{H^b_j} \right], \quad (5)$$

$$\boldsymbol{s} = \frac{1}{n} \sum_i^n \boldsymbol{H^s_i} \in \mathbb{R}^d, \quad (6)$$

where [;] denotes the concatenation operation and $\odot$ is Hadamard product. $\boldsymbol{w_{relo}} \in \mathbb{R}^{3d}$ is a learnable parameter vector, $\boldsymbol{s}$ can be viewed as an embedding of the whole situation. Then each row of

$\boldsymbol{R}$ is normalized using the softmax operation. Finally we get the attention vector over background tokens in terms of the cause property $\boldsymbol{p_c^b}$,

$$\boldsymbol{p_c^b} = \boldsymbol{R}^T \boldsymbol{p_e^b} \in \mathbb{R}^m. \tag{7}$$

Here $\boldsymbol{p_c^b}$ should attend more to the tokens of effect property. For example, *iodized salt* will get larger attention value than other tokens in the background.

Relation Classification

This module aims to predict the qualitative relation between effect and cause property. Take Table 1 as an example, the cause property *iodized salt* and the effect property *developmental difficulty* is negatively correlated. To achieve that, we first derive and concatenate representations of cause and effect property by averaging background representation $\boldsymbol{H^b}$ weighted by according attention vector, $\boldsymbol{p_c^b}$ and $\boldsymbol{p_e^b}$. Next, we adopt another MLP stacked with softmax to get corresponding probabilities,

$$\boldsymbol{p_{rel}} = \text{softmax}(\text{MLP}((\boldsymbol{H^b}^T \boldsymbol{p_e^b}; \boldsymbol{H^b}^T \boldsymbol{p_c^b}); \theta_{rel})), \tag{8}$$

where $\boldsymbol{p_{rel}} = [p_{rel-}, p_{rel+}]$ denotes probability of negative and positive relation, θ_{rel} is a learnable parameter in the MLP. In the example shown in Table 1, p_{rel-} is supposed to be larger than p_{rel+}.

Comparison

This module aims to compare the worlds in terms of the cause property. For example, world 1 (*salt village*) is more relevant to *iodized salt* than world 2 (*sand village*) in Table 1 since people in *salt village* use *iodized salt* while people in *sand village* use *regular salt*.

This is achieved by three steps. First, we derive the attention of cause property over situation $\boldsymbol{p_c^s}$ from $\boldsymbol{p_c^b}$ with a similarity matrix $\boldsymbol{M} \in \mathbb{R}^{n \times m}$ between situation and background,

$$\boldsymbol{M}_{ij} = \boldsymbol{H_i^s} \boldsymbol{W}_{sb} \boldsymbol{H_j^b}^T, \tag{9}$$

$$\boldsymbol{p_c^s} = \boldsymbol{M} \boldsymbol{p_c^b} \in \mathbb{R}^n, \tag{10}$$

where $\boldsymbol{W}_{sb} \in \mathbb{R}^{d \times d}$ are learnable parameters.

Second, we use $\boldsymbol{p_w^s}$ to mask out irrelevant cause property for each world. This part ensures the alignment between each world and its cause property, which is critical when one situation contains multiple worlds.

$$\boldsymbol{p_{c_{w_1}}^s} = \text{softmax}(\boldsymbol{p_{w_1}^s} \odot \boldsymbol{p_c^s}), \tag{11}$$

$$\boldsymbol{p_{c_{w_2}}^s} = \text{softmax}(\boldsymbol{p_{w_2}^s} \odot \boldsymbol{p_c^s}). \tag{12}$$

Third, each world's cause property is evaluated by a bilinear function in terms of its relevance to the cause property in background, which is further normalized into a probability with softmax,

$$logit_{w_1} = (\boldsymbol{H^b}^T \boldsymbol{p_c^b})^T \boldsymbol{W}_{com} (\boldsymbol{H^s}^T \boldsymbol{p_{c_{w_1}}^s}), \tag{13}$$

$$logit_{w_2} = (\boldsymbol{H^b}^T \boldsymbol{p_c^b})^T \boldsymbol{W}_{com} (\boldsymbol{H^s}^T \boldsymbol{p_{c_{w_2}}^s}), \tag{14}$$

$$\boldsymbol{p_{com_w}} = \text{softmax}(logit_{w_1}, logit_{w_2}), \tag{15}$$

where $\boldsymbol{W_{com}} \in \mathbb{R}^{d \times d}$ is a learnable matrix, $\boldsymbol{H^b}^T \boldsymbol{p_c^b}$ represents expected embedding of cause property in background, $\boldsymbol{H^s}^T \boldsymbol{p_{c_{w_i}}^s}$ represents expected embedding of cause property for world i, $p_{com_{w_i}}$ denotes the probability that world i is relevant to cause property.

Reasoning

Given the relationship between effect property and cause property, p_{rel+} and p_{rel-}, and the comparison between worlds in terms of cause property $p_{com_{w_i}}$, this module infers comparison between identified worlds in terms of the effect property. Take Table 1 as an example, given the negative relationship between *developmental difficulties* and *iodized salt*, and *salt village* uses more *iodized salt* than *sand village*, we infer that people in *sand village* are more likely to have *developmental difficulties*.

To this end, we have

$$p_{e_{w_1}} = p_{com_{w_1}} \times p_{rel+} + p_{com_{w_2}} \times p_{rel-}, \tag{16}$$

$$p_{e_{w_2}} = p_{com_{w_1}} \times p_{rel-} + p_{com_{w_2}} \times p_{rel+}, \tag{17}$$

where $p_{e_{w_i}}$ is the probability that world i is more relevant to effect property.

3.3 Answer Prediction

Given intermediate outputs from the interpretable reasoning component, this module predicts the final answer for a question. Specifically, we first convert these intermediate outputs into text spans or 0/1 class as follow.

- We take two steps to convert an attention vector output by *World Detection* or *Effect and Cause Detection* into a text span. First, the token with the highest probability is selected. Then it is expanded with left and right neighbors which are continuous spans and the probability of each token is larger than threshold t. In our experiment we set $t = \frac{1}{l}$, where l is the length of the paragraph.

- For *Comparison, Relation Classification, and Reasoning*, we select the class with the highest probability.

Then we synthesize a sentence $\hat{s}$ in the format of `[World 1] has [larger/smaller] [Effect Property] than [World 2]`, where choosing "larger" or "smaller" depends on results from the *Reasoning* module. Take Table 1 as an example, the synthetic sentence is *Salt village has larger developmental difficulties than Sand village*. Such synthetic text explicitly expresses comparison between the identified worlds in terms of the effect property. Finally, we concatenate it with the situation s and question q as $\langle s\rangle\, q; s\,\langle/s\rangle\,\langle/s\rangle\,\hat{s}\,\langle/s\rangle$, and feed them into RoBERTa which directly predicts the starting and end position of the final answer.

3.4 Model Training

Two models (i.e. interpretable reasoning model; and answer prediction model) are learned in our approach.

Interpretable Reasoning The final loss function for interpretable reasoning is defined as

$$l_{intp} = -\sum_{\boldsymbol{x}\in \boldsymbol{X}} \alpha_{\boldsymbol{x}} \tilde{\boldsymbol{x}}^T log(\boldsymbol{x}). \tag{18}$$

Here $\boldsymbol{X} = \{\boldsymbol{p^s_{w_1}} \in \mathbb{R}^n, \boldsymbol{p^s_{w_2}} \in \mathbb{R}^n, \boldsymbol{p^b_e} \in \mathbb{R}^m, \boldsymbol{p^b_c} \in \mathbb{R}^m, \boldsymbol{p^s_{c_{w_1}}} \in \mathbb{R}^n, \boldsymbol{p^s_{c_{w_2}}} \in \mathbb{R}^n, \boldsymbol{p_{rel}} \in \mathbb{R}^2, \boldsymbol{p_{com_w}} \in \mathbb{R}^2, \boldsymbol{p_{e_w}} \in \mathbb{R}^2\}$ are predictions of different modules, $\tilde{\boldsymbol{x}}^T \in \{0,1\}^n$ or $\tilde{\boldsymbol{x}}^T \in \{0,1\}^m$ or $\tilde{\boldsymbol{x}}^T \in \{0,1\}^2$ are corresponding gold labels, and α_x is the weight for module x.

Answer Prediction The training objective of the answer prediction model is defined as

$$l_{ans} = -(\tilde{\boldsymbol{s}} \log(\boldsymbol{s}) + \tilde{\boldsymbol{e}} \log(\boldsymbol{e})), \tag{19}$$

where $\boldsymbol{s}, \boldsymbol{e} \in \mathbb{R}^{m+n+k}$ are predicted probabilities of the starting and end position, k is the length of the synthetic sentence $\hat{s}$, and $\tilde{\boldsymbol{s}}, \tilde{\boldsymbol{e}} \in \{0,1\}^{m+n+k}$ are corresponding gold labels.

4 Experimental Setup

4.1 Dataset

We evaluate our proposed approach on the ROPES (Lin et al., 2019) dataset[2]. So far as we know, it is the only dataset that requires reasoning over paragraph effects in situation. Given a background paragraph that contains knowledge about relations of causes and effects and a novel situation, questions about applying the knowledge to the novel situation need to be answered. Table 1 shows an example and Table 2 presents the statistics. To be noticed, different from other extractive MRC datasets, train/dev/test set in ROPES is split based on annotators instead of context (Geva et al., 2019; Lin et al., 2019). This might pose a large data bias in each set. For example, as can be seen in Table 2, dev and test sets have similar numbers of questions, while the vocabulary size of background and situation in test set is 2× and 2.7× larger than that in dev set. The same thing happens on the size of question vocabulary, which indicates the existence of the distribution gap between train/dev and test sets and it might lead to underestimate/overestimate the performance of a model.

Statistics	**Train**	**Dev**	**Test**
background vocabulary size	8,616	2,008	3,988
situation vocabulary size	6,949	1,077	2,736
question vocabulary size	1,457	1,411	1,885
avg. background length	121.6	90.7	123.1
avg. situation length	49.1	63.4	55.6
avg. question length	10.9	12.4	10.6
No. of questions	10,924	1,688	1,710
No. of annotators	7	2	2

Table 2: ROPES statistics

Cross Validation Because of the limited size of the official dev set and potential data bias between train/dev and test, we conduct 5-fold cross-validation to verify the effectiveness of the proposed approach. K-fold cross-validation assesses the predictive performance of the models and judges how they perform outside the sample to a new data set. Therefore it can assure unbiased results, avoid over-fitting, and testify the generalization capability of a model (Burman, 1989; Browne, 2000; Raschka, 2018). Specifically, we first exclude the labeled 1074 questions from the training data, and then split the remaining training plus dev data into five folds based on background, which ensures each subset has independent vocabulary space and they do not look through each other. For each split, we directly apply modules trained from auxiliary supervision data, and use the training data

---

[2] `https://leaderboard.allenai.org/ropes/submissions/get-started`

to train a model for answer prediction. Averaged results on the 5-fold cross-validation setting are reported.

Auxiliary Supervision We randomly sampled 10% (1,074 questions) of the original training data and labeled them for training the proposed modules. For each example, we label two concerned worlds, effect property in background and situation, values of cause property for two worlds in situation, comparison between two worlds in terms of cause property and effect property, and relationship between cause property and effect property. More detailed guidelines and labeled examples are in Appendix B. Note the neural network modules are trained only on the labeled 1,074 questions.

4.2 Implementation Details

Our model is evaluated based on the pretrained language model RoBERTa large in Pytorch version[3]. We train the five modules on one P100 16GB GPU and use four GPUs for predicting final answer. We tune the parameter α_x's according to the averaged performance of all modules, and set it to be 0.05 for span-based loss, 0.2 for the *Comparison* and *Relation* prediction, and 0.3 for the *Reasoning* prediction. Evaluation metrics are EM and F1 which are same as the ones used in SQuAD[4]. The detailed hyperparameters are described in the Appendix A.

4.3 Baseline

We re-implemented the best model (RoBERTa) in the leaderboard[5] and achieved similar performance (Our implemented baseline achieves EM 69.0 / F1 71.1 on dev and EM 55.2 / F1 61.0 on test while the official one achieves EM 59.7 / F1 70.2 on dev and EM 55.4 / F1 61.1 on test). The basic idea is to leverage the RoBERTa large model (Liu et al., 2019) to encode the concatenation of question, background and situation, and then apply a linear layer to predict the starting and end position of an answer directly.

Model	Dev		Test	
	EM	F1	EM	F1
RoBERTa$^*_{Large}$	61.4	68.4	64.0	71.1
Ours	**73.0**	**78.1**	**72.4**	**77.5**
RoBERTa$^*_{Large}$(10% $data$)	-	-	43.1	53.9
Ours(10% $data$)	-	-	60.9	71.8
Ours (rule-based)	-	-	54.3	65.5

Table 3: Performance of different models on the ROPES dataset under cross-validation setting.

5 Experimental Results

5.1 Question Answering Performance

Table 3 shows question answering performance of different models, where our approach outperforms the RoBERTa large model by 8.4% and 6.4% in terms of EM and F1 scores respectively. These results show that compared to one-step "black box" model, our interpretable approach which mimics the human reasoning process has a better capability of conducting such complex reasoning.

Furthermore, we also list the performance of our approach and the baseline model when using only randomly sampled 10% of training data in Table 3. That is, both the neural network modules and answer prediction model in our approach are trained with only 1074 questions. As seen in the table, our model learned from 10% of training examples achieves competitive performance to the baseline model learned from full data (71.8% v.s. 71.1% in terms of F1 score). In contrast, the performance of the baseline model drops dramatically by 32%. This indicates that traditional black-box approach requires much more training data while our approach has better generalization ability and can learn the reasoning capability with much fewer examples.

We also implement a rule-based answer prediction approach (detailed descriptions in the Appendix E), which are generated based on the same 10% of training examples as in interpretable reasoning components. As shown in Table 3 the rule-based approach performs worse than the RoBERTa model, indicating better generalization ability of pre-trained models.

5.2 Case Study of Interpretability

The most remarkable difference between our model and the one-step "black box" model is that our

[5] `https://leaderboard.allenai.org/ropes/submissions/public`

Background

Storing large volumes of data - When storing XML to either file or database, the volume of data a system produces can often exceed reasonable limits, with a number of detriments: the access times go up as more data is read, CPU load goes up as XML data takes more power to process, and storage costs go up....

Situation

Tory had a busy day storing XML. At 7 AM, he stored 201 Gigabytes to the database. At 8 AM, he stored 301 Gigabytes to the database. At 9 AM,... At 10 AM, ... At 11 AM, ... At 12 PM, ... At 1 PM, he went to sleep to finish storing XML later on that day.

Q&A

Q: What time did CPU load go up: 8 AM or 1 PM? A: 8 AM

Predictions

Worlds:	*[8 AM,1 PM]*
Effect:	*CPU load goes up*
Cause^B:	*Storing large volumes of data*
Cause$^S_{\text{World1}}$:	*301 Gigabytes*
Cause$^S_{\text{World2}}$:	*sleep*
Cause Cmp:	*World 1*
Relation:	*positively related*
Effect Cmp:	*World 1*
Final Answer:	8 AM

Table 4: A running example with visualized intermediate outputs of our approach.

model outputs multiple intermediate predictions which well explains the reasoning process. Note all modules in our model output probabilities or attention on input text, which are further fed into downstream ones for end-to-end learning. In order to explicitly visualize the output of each module, we take a similar approach to §3.3 to convert these probabilities into a text span or a 0/1 classification.

We demonstrate the reasoning process of our model with a running example shown in Table 4. Please see more examples in Appendix D. Here the background states the relationship between *CPU load* and *data volume*, i.e. *CPU load goes up when processing larger volume of data*. The situation describes that Tory stored different sizes of data at a different time. For example, he stored *301 Gigabytes* at *8 AM* and went to *sleep* at *1 PM*. Finally, the question asks to compare CPU loads between 8 AM and 1 PM. As shown in Table 4, our model outputs several intermediate results. First, it identifies two concerned worlds, *8 AM* and *1 PM* from the situation. Then it predicts the effect property, *CPU load goes up*, given which the cause property in the background (i.e. *storing large volumes of data*) and according values for the two worlds (i.e. *301 Gigabytes* and *sleep*) are predicted. Next, it compares the two worlds in terms of cause property and predicts that world 1 is larger than world 2. Also it predicts that the cause property and effect property is positively related, i.e. the relation is classified as 1. Finally, it reasons that world 1 takes higher CPU loads than world 2. This example demonstrates that our approach not only predicts the final answer for the question, but also provides detailed explanations for the reasoning process.

	F1	Fuzzy F1		Accuracy
World 1	83.5	86.8	Comparison	83.8%
World 2	84.4	86.1	Relation	84.5%
Effect	67.8	83.6	Reasoning	74.0%
Cause^B	57.6	70.1		
Cause$^S_{\text{World1}}$	69.4	81.3		
Cause$^S_{\text{World2}}$	58.2	71.9		

Table 5: Performance of Each Module

5.3 Neural Network Module Performance

Taking the same approach as in §5.2, we convert the output of each module into a text span or a predicted class. We manually sampled another 5% of the training data, labeled them with outputs for each module, and evaluate the visualized results of all modules. Table 5 summarizes the performance for each module, where the predicted text span is measured by F1 score and classification prediction is measured by accuracy.

World Detection This module implements a similar capability as traditional extractive MRC, since both require to detect concerned text spans from a passage according to a question. Consequently, it achieves similar performance to top models of the popular SQuAD dataset[6], where our *World Detection* module reaches about 83% F1 score and single RoBERTa large model on SQuAD gets about 89%. The gap might come from different modeling styles. Our model predicts the probability of each token being concerned, while SQuAD models directly predict the starting and end position of an answer,

---

[6] `https://rajpurkar.github.io/SQuAD-explorer/`

which performs better on boundary detection.

Effect and Cause Detection Compared with *World Detection*, the F1 score for this module decreases but actually still acceptable (F1=67.6 for Effect^B, 57.6 for Cause^B). The most possible reason is that, effects and causes are usually longer than world names. For example, the average length of world name is 1.2, while those of effect and cause are 2.7 and 2.2 respectively. Longer text span increases the difficulty of prediction.

For above two span-related modules, we argue that since our model leverages the attention score in a soft way, it is less sensitive to accuracy of boundary changes. Therefore, we added another fuzzy F1 score for them. The fuzzy F1 of each question is set to 1 as long as its original F1 is larger than 0. As shown in Table 5, the fuzzy F1 scores of these two modules increase to 70%∼86%, indicating good reasoning capability of them.

Comparison, Relation Classification These two modules essentially requires the capability of classification. The high accuracy (83.8% and 84.5%) indicates that our modeling approach can effectively leverages the prediction of upstream modules and does a good job on them.

Reasoning Given the high accuracy of the *Comparison* and *Relation Classification* modules, the *Reasoning* model achieves 74% of accuracy, which provides high-quality input for final answer prediction.

5.4 Error Analysis

We randomly sampled 200 wrongly predicted questions to do error analysis and find that they fall into two major types, which are described below (Please see complete description of questions, backgrounds and situations in the Appendix C).

5.4.1 Type One Error

Type one errors are caused by wrong model predictions, most of which occur in below three modules.

Wrong Predicted Worlds Such errors are mainly caused by length imbalance between question and situation. Since situation is usually much longer than question, the *World Detection* module might make the same predictions for different questions of same situation.

Wrong Predicted Cause Property in Situation Such errors are mainly caused by imbalanced descriptions for different worlds, where a situation describes details for one world but mentions another world with very few words. In such cases, the *Comparison* module might assign the same cause property for different worlds in situation.

Wrong Predicted Comparison Results Such errors often occur when two worlds are described with similar words, e.g. “high” v.s. “higher”, or “smoking” vs. “not smoking”, in which case the *Comparison* module might be confused by similar expressions of two worlds and fail to compare them.

5.4.2 Type Two Error

Type two errors occur when the proposed framework is not suitable to solve the questions. Here we list some example cases.

Missing Knowledge Background paragraph does not provide sufficient knowledge for reasoning. For example, a background paragraph only describes information about fish while the questions asks fertilization take place inside or outside of mother’s body for a mammal creature.

Implicit Worlds Concerned worlds in a question are not explicitly described in the situation. For example, a situation paragraph says that Mattew does intensive worksouts while the question asks that his strengths will increase or decrease when he stops working out. In such a case, the *world* that Mattew stop working out is not explicitly described in the situation.

Additional Math Computation Answering such questions requires additional math computation. For example, a background states the speed of sound waves in air/water/iron and the question asks how much faster a channel (with water) would be than another channel (with air). Answering such questions requires additional math computation (i.e. subtraction, addition etc.)

6 Conclusion and Future Work

In this paper, we aim to answer ROPES questions in an interpretable way by leveraging five neural network modules. These modules are trained in an end-to-end manner and each module provides transparent intermediate outputs. Experimental results demonstrate the effectiveness of each module, and analysis on intermediate outputs presents good interpretability for the inference process in contrasted with “black box” models. Moreover, we find that with explicitly designed compositional modeling of inference process, our approach with a few training examples achieves similar accuracy to strong baselines with full-size training data which indicates a better generalization capability. Meanwhile, extending these models to a larger scope of question types or more complex scenarios is still a challenge, and we will further investigate the trade-off between explainability and scalability.

Background

As a cell grows, its volume increases more quickly than its surface area. If a cell was to get very large, the small surface area would not allow enough nutrients to enter the cell quickly enough for the cell's needs...Such cell types are found lining your small intestine, where they absorb nutrients from your food through protrusions called microvilli .

Situation

There are two cells inside a Petri dish in a laboratory, cell X and cell Z. These cells are from the same organism, but are not the same age. Cell X was created two weeks ago, and cell Z was created one month ago. Therefore, cell Z has had two extra weeks of growth compared to cell X.

Q&A

Q: Which cell has a larger volume?

A: cell Z

Labels

World1:	*Cell X*	[142,148]
World2:	*cell Z*	[180,186]
Effect:	*volume*	[21,27]
Cause^{B}:	*cell grows*	[5,15]
$\text{Cause}^{S}_{\text{World1}}$:	*two weeks ago*	[161,174]
$\text{Cause}^{S}_{\text{World2}}$:	*one month ago*	[199,212]
Cause Cmp:	*cell Z*	1
Relation:	*positively related*	1
Effect Cmp:	*World 2*	1

Table 8: An example with auxiliary supervision labels.

2. Generate machine-readable labels automatically: Then we use scripts to automatically transform the annotations to the machine-

readable form, i.e. we record the start and end character index for all spans and keep the results for comparison, relation and reasoning modules as binary form.

C Error Cases for Modules

Table 9 lists out several type 1 error cases mentioned in the Error Analysis part, while Table 10 lists out type 2 error cases which beyonds the scope of our model.

D More Examples

We present more examples that correctly answered by our model in Table 11.

E Heuristic Rules for Answer Prediction

We also conduct a rule-based approached to predict the final answer which contains the following steps:

1. Categorize questions based on the type of answer: By looking at the labeled train dataset, we can summarize that the types of answer can be divided into two types:1) World Type, answer is one of the compared worlds; 2) Comparative Word Type, like ”more” or ”less”.

2. For World Type, we filter out such type of questions by searching question keywords, for example, questions started with { *What, Which, Who, Where, When*} usually have world type of answers. Then we determine the results based on the prediction obtained in Reasoning Module.

3. For Comparative Word Type, we further filter out this type of questions from the rest questions by defining a list of comparative word pair like {*’more’:’less’,’higher’:’lower’...* }. Then we identify the primary world that being compared in the question and associate it with our identified worlds from Group Detection module, then determine the comparative word for the primary compared world by using the results from Reasoning module.

4. For the remaining questions, we simply return the world with higher effect property probability from Reasoning module as the final answer.

Examples	**Prediction**
ID:1867731649 & 350571026 Background: Fish mortality is a parameter used in fisheries population dynamics to account for the loss of fish in a fish stock through death. The mortality can be divided into two types:Natural mortality: the removal of fish from the stock due to causes not associated with fishing. Such causes can include disease, competition, cannibalism, old age, predation, pollution or any other natural factor that causes the death of fish. In fisheries models natural mortality is denoted by (M).[1]Fishing mortality: the removal of fish from the stock due to fishing activities using any fishing gear It is denoted by (F) in fisheries models. Situation: Tony is about to go on two fishing trips in the up coming week. On Friday, he is going to Bear Lake, which is located near a factory that has been known to dump waste into the lake. On Saturday, he is going to Fox Lake, which is in a secluded valley. Q&A:Which day will Tony visit a lake that more likely has more fish? **Saturday** Q&A:Which lake probably has more fish in it? **Fox Lake**	**Wrong Predicted Worlds** Worlds: *[Bear Lake, Fox Lake]* Effect: *fishing* Cause^{B}: *Natural mortality* $\text{Cause}^{S}_{\text{World1}}$: *dump waste* $\text{Cause}^{S}_{\text{World2}}$: *secluded valley* Cause Cmp: *World 1* Relation: *negatively related* Effect Cmp: *World 2* *Final Answer*: Fox Lake
ID:4215374242 Background: Making these healthy lifestyle choices can also help prevent some types of cancer. In addition, you can lower the risk of cancer by avoiding carcinogens , which are substances that cause cancer. For example, you can reduce your risk of lung cancer by not smoking. You can reduce your risk of skin cancer by using sunscreen. How to choose a sunscreen that offers the most protection is explained below (Figure below). Some people think that tanning beds are a safe way to get a tan. This is a myth. Tanning beds expose the skin to UV radiation. Any exposure to UV radiation increases the risk of skin cancer. It doesn't matter whether the radiation comes from tanning lamps or the sun. Situation: Steve and Bill are really good friends with each other. The other day they were talking about some habits they have. Steve likes to work out and stay in shape, eats healthy and does not smoke. Bill said he wants to be more like Steve. Bill currently smokes, and loves to go out tanning in the sun without out sunscreen. Q&A:Who has a more likely chance to get lung cancer in the future? **Bill**	**Wrong Predicted Comparison Results** Worlds: *[Steve, Bill]* Effect: *risk of lung cancer* Cause^{B}: *not smoking.* $\text{Cause}^{S}_{\text{World1}}$: *does not smoke* $\text{Cause}^{S}_{\text{World2}}$: *smokes* Cause Cmp: *World 2* Relation: *negatively related* Effect Cmp: *World 1* *Final Answer*: Steve
ID: 4035582237 Background: Sometimes muscles and tendons get injured when a person starts doing an activity before they have warmed up properly. A warm up is a slow increase in the intensity of a physical activity that prepares muscles for an activity. Warming up increases the blood flow to the muscles and increases the heart rate. Warmed-up muscles and tendons are less likely to get injured. For example, before running or playing soccer, a person might jog slowly to warm muscles and increase their heart rate. Even elite athletes need to warm up (Figure below). Situation: Greg and Carl and about to do a marathon. Greg sees Carl doing some warm ups and laughs to himself and thinks it is silly. They both want to get a good time, and are both avid runners. Q&A:Who is more likely to **get an injury** during the race? **Greg**	**Wrong Predicted Cause Property in Situation** Worlds: *[Greg,Carl]* Effect: *get injured.* Cause^{B}: *Warmed-up* $\text{Cause}^{S}_{\text{World1}}$: *warm ups* $\text{Cause}^{S}_{\text{World2}}$: *warm ups* Cause Cmp: *World 1* Relation: *negatively related* Effect Cmp: *World 2* *Final Answer*: Carl

Table 9: Type 1 error cases made by our model

Examples	Prediction
ID:710693196 Background: Fish reproduce sexually. They lay eggs that can be fertilized either inside or outside of the body. In most fish, the eggs develop outside of the mother's body. In the majority of these species, fertilization also takes place outside the mother's body. The male and female fish release their gametes into the surrounding water, where fertilization occurs. Female fish release very high numbers of eggs to increase the chances of fertilization. Situation: All marine creatures are not fish. There are some mammals, for example, whales, also live in the water. Rob wants to know more about differences between fish and other non fish creatures in the water. He divided them into two groups, group A and group B. Group A consists of fish, and group B consists of non fish creatures in the water. He started to see the differences between these two groups Q&A:In group B, would fertilization most likely take place inside or outside of mother's body? **inside**	**Missing Knowledge** Worlds: *[Group A, group B]* Effect: *fish* Cause^B: *fertilization* $\text{Cause}^S_{\text{World1}}$: *fish* $\text{Cause}^S_{\text{World2}}$: *non fish creatures* Cause Cmp: *World 1* Relation: *positively related* Effect Cmp: *World 1* *Final Answer*: Group A
ID:3339143431 Background: In exercises such as weight lifting, skeletal muscle contracts against a resisting force (see Figure below). Using skeletal muscle in this way increases its size and strength. In exercises such as running, the cardiac muscle contracts faster and the heart pumps more blood. Using cardiac muscle in this way increases its strength and efficiency. Continued exercise is necessary to maintain bigger, stronger muscles. If you don't use a muscle, it will get smaller and weaker–so use it or lose it. Situation: A study was done in the town of Greenwich comparing muscle strength to the amount a person exercises. Mathew goes to the gym 5 times a week and does very intensive workouts. Damen on the other hand does not go to the gym at all and lives a mostly sedentary lifestyle. Q&A:Given Mathew suffers an injury while working out and cannot go to the gym for 3 months, will Mathews strength increase or decrease? **decrease**	**Implicit Worlds** Worlds: *[Mathew, Damen]* Effect: *strength and efficiency* Cause^B: *exercises such as running* $\text{Cause}^S_{\text{World1}}$: *goes to the gym* $\text{Cause}^S_{\text{World2}}$: *does not go to the gym* Cause Cmp: *World 1* Relation: *positively related* Effect Cmp: *World 1* *Final Answer*: Mathew
ID: 2918297602 Background: In common everyday speech, speed of sound refers to the speed of sound waves in air. However, the speed of sound varies from substance to substance: sound travels most slowly in gases; it travels faster in liquids; and faster still in solids. For example, (as noted above), sound travels at 343 m/s in air; it travels at 1,480 m/s in water (4.3 times as fast as in air); and at 5,120 m/s in iron (about 15 times as fast as in air). In an exceptionally stiff material such as diamond, sound travels at 12,000 metres per second (27,000 mph);[1] (about 35 times as fast as in air) which is around the maximum speed that sound will travel under normal conditions. Situation: John and Keith are neighbors. They have been pondering about how to communicate with each other in a doomsday scenario when all the electronic devices would be useless. They connected their houses with three ducts. One of the ducts is filled with air; they called it channel A. Another duct is filled with water; they called it channel B. And the last duct is filled with iron; they called it channel C. They can now transmit sound with these channels of communication; in case, disaster strikes Q&A:How much faster would be channel B than channel A in m/s, 1130 m/s or 1137 m/s?**1137 m/s**	**Additional Math Computation** Worlds: *[channel A,channel B]* Effect: *5,120 m/s* Cause^B: *water* $\text{Cause}^S_{\text{World1}}$: *air* $\text{Cause}^S_{\text{World2}}$: *water* Cause Cmp: *World 1* Relation: *positively related* Effect Cmp: *World 1* *Final Answer*: channel A

ID:2133492859 Background:Turner et al (2006) derived crash prediction models for this report's predecessor and found a pronounced '2018safety in numbers' effect in the models. Using the crash prediction model for mid-block locations, generic motorist and cyclist volumes can be used to demonstrate the impacts on the expected crash rate of varying motor vehicle and cycle volumes. As shown in figure 2.20, an increase in the proportion of cyclists to the overall traffic volume causes an increase in expected crashes at mid-block locations, but the crash rate increases at a decreasing rate. That is to say, the **crash rate per cyclist** goes down as the cycle volume increases. Situation: There were a lot of motorcycles on Interstate 17 last week. On Monday, there were 1355 motorcyclists. On Tuesday, there were 2355 motorcyclists. On Wednesday, there were 3351 motorcyclists. On Thursday, there were 4351 motorcyclists. On Friday, there were 5351 motorcyclists. On Saturday, there were 6351 motorcyclists. On Sunday, there were 7351 motorcyclists. Q&A: What day had a lower **crash rate per cyclist**: Thursday or Sunday? **Sunday**	Module Output: Worlds: *[Thursday,Sunday]* Effect: *crash rate per cyclist* Cause^{B}: *the cycle volume* Cause$^{S}_{\text{World1}}$: *4351 motorcyclists* Cause$^{S}_{\text{World2}}$: *7351 motorcyclists* Cause Cmp: *World 2* Relation: *negatively related* Effect Cmp: *World 1* *Final Answer*: Thursday
ID:3099625752 Background:The example of someone having a positive experience with a drug is easy to see how drug dependence and the law of effect works. The **tolerance** for a drug goes up as one continues to use it after having a positive experience with a certain amount the first time. It will take more and more to get that same feeling. This is when the controlled substance in an experiment would have to be modified and the experiment would really begin. The law of work for psychologist B. F. Skinner almost half a century later on the principles of operant conditioning, ä learning process by which the effect, or consequence, of a response influences the future rate of production of that response. Situation: The Speed Squad met to discuss their experiences. They all said they always had a great experience using speed and used the same amount each time. They told how many times they used speed. Todd used it 36 times, Jesse used it 40 times, Craig used it 44 times, Alan used it 56 times, Shawn used it 69 times, Clarence used it 78 times, and Sean used it 86 times. Q&A: Who has a higher **tolerance** for speed: Alan or Clarence? **Clarence**	Module Output: Worlds: *[Alan,Clarence]* Effect: *tolerance* Cause^{B}: *positive experience with* Cause$^{S}_{\text{World1}}$: *used it 56 times* Cause$^{S}_{\text{World2}}$: *used it 78 times* Cause Cmp: *World 2* Relation: *positively related* Effect Cmp: *World 2* *Final Answer*: Clarence

Abstract

Numerical reasoning over texts, such as addition, subtraction, sorting and counting, is a challenging machine reading comprehension task, since it requires both natural language understanding and arithmetic computation. To address this challenge, we propose a heterogeneous graph representation for the context of the passage and question needed for such reasoning, and design a question directed graph attention network to drive multi-step numerical reasoning over this context graph. Our model, which combines deep learning and graph reasoning, achieves remarkable results in benchmark datasets such as DROP [1].

1 Introduction

Machine reading comprehension (MRC) aims to develop AI models that can answer questions for text documents. Recently, the performance of MRC in public datasets has been improved dramatically due to the advanced pre-trained models, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2019).

However, pre-trained models are not explicitly aware of the concepts of numerical reasoning since numeracy supervision signals are rarely available during pre-training. The representations from these pre-trained models fall short in their ability to support downstream numerical reasoning. Yet such ability is critical for the comprehension of financial news and scientific articles, since basic numerical operations, such as addition, subtraction, sorting and counting, need to be conducted to extract the essential information (Dua et al., 2019).

Recently, Dua et al. (2019) proposed a numerically-aware QANet (NAQANet), which treats the span extractions, counting, and numerical addition/subtraction separately. However, this work is preliminary in the sense that the model neglects the relative magnitude between numbers. To improve this method, Ran et al. (2019) proposed NumNet, which constructs a number comparison graph that encodes the relative magnitude information between numbers on directed edges. Although NumNet achieves superior performance than other numerically-aware models (Hu et al., 2019a; Andor et al., 2019; Geva et al., 2020; Chen et al., 2020), we argue that NumNet is insufficient for sophisticated numerical reasoning, since it lacks two critical ingredients for numerical reasoning:

1. **Number Type and Entity Mention.** The number comparison graph in NumNet is not able to identify different number types, and lacks the information of entities mentioned in the document that connect the number nodes.
2. **Direct Interaction with Question.** The graph reasoning module in NumNet leaves out the direct question representation, which may encounter difficulties in locating important numbers directed by the question as the pivot for numerical reasoning.

The number type and entity information play essential roles in numerical comprehension and reasoning. As per the study in the cognitive system - "this abstract, notation-independent appreciation of numbers develops gradually over the first several years of life ... human infants appreciate numerical quantities at a non-symbolic level: They know approximately how many objects they see before them even though they do not understand number words or Arabic numerals.", the concept of discrete number is gradually developed through the real-life experience (Cantlon et al., 2009). The association among the numbers and entities is a strong regularization for learning the numerical reasoning model: the comparison and addition/subtraction between numbers are typically applied to those with the same type or referring to the same entity. To illustrate it, we show two concrete examples of numerical reasoning over texts in Table 1. In the first example, a question related to the "population" is being asked. There are 5 "*people counting*" numbers and 3 "*date*" numbers. When the type of number is given, the reasoning difficulty is largely reduced if the model learns to extract the "*people counting*" numbers conditioned on this "population" question. In addition, the entities in the graph provide explicit information on the correlation between the passage and

Table 1: Two MRC cases requiring numerical reasoning are illustrated. There are entities and numbers of different types. Both are emphasized by different colors: entity, number, percentage, date, ordinal. We explicitly encode the type information into our model and leverage the question representation to conduct the reasoning process.

Question	Passage	Answer
At the battle of Caiboaté how many Spanish and Portuguese were injured or killed?	... In 1754 Spanish and Portuguese military forces were dispatched to force the Guarani to leave the area ... Hostilities resumed in 1756 when an army of 3,000 Spanish, Portuguese, and native auxiliary soldiers under José de Andonaegui and Freire de Andrade was sent to subdue the Guarani rebels. On February 7, 1756 the leader of the Guarani rebels, Sepé Tiaraju, was killed in a skirmish with Spanish and Portuguese troops. ... 1,511 Guarani were killed and 152 taken prisoner, while 4 Spanish and Portuguese were killed and about 30 were wounded...	34
In which quarter did Stephen Gostkowski kick his shortest field goal of the game?	The Cardinals' east coast struggles continued in the second quarter as quarterback Matt Cassel completed a 15-yard touchdown pass to running back Kevin Faulk and an 11-yard touchdown pass to wide receiver Wes Welker, followed by kicker Stephen Gostkowski's 38-yard field goal. In the third quarter, Arizona's deficit continued to climb as Cassel completed a 76-yard touchdown pass to wide receiver Randy Moss, followed by Gostkowski's 35- and 24-yard field goal. In the fourth quarter, New England concluded its domination with Gostkowski's 30-yard	third

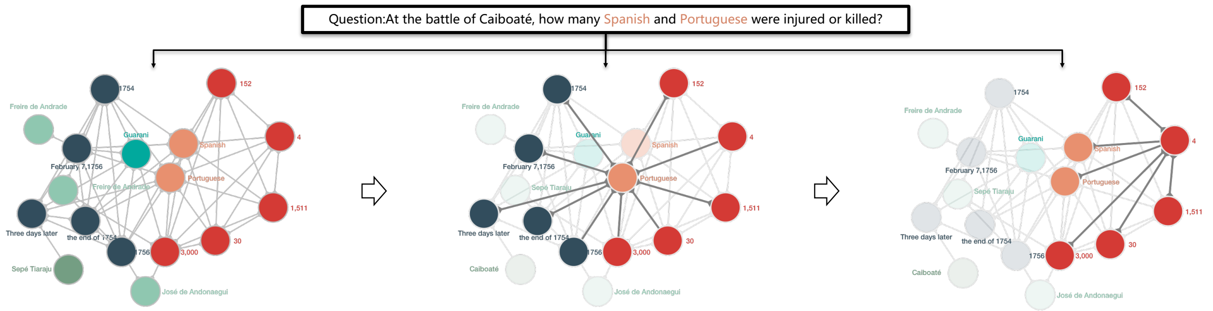

Figure 1: The constructed heterogeneous typed graph of the example in Table 1 is illustrated on the left. The red (dark blue) nodes are the numbers (dates) and the others are entities. The edges encode the relations among the numbers and entities: (1) The numbers with the same number type, e.g., date, are wired together. (2) The graph connects the numbers and the entities that are in the same sentence to indicate their co-occurrence. In the first round, the model pays attention to a sub-graph that contains the *Spanish* and *Portuguese* entities since they are mentioned in the question. In the update, the model learns to distinguish between the numbers and the dates and extracts the numbers related to the question. In the second round, the representations of the numbers are updated by the messages from the entities as well as the question to conduct the reasoning.

the question. The entities in the question may occur in several sentences in the passage, indicating how each number is related to each other through these bridging entities, which helps the QA model better collect and aggregate the information for numerical reasoning. We also observe that when the question entities co-occur in a single sentence (the last sentence in this example), this could be a hint that the answer can be derived from that sentence. The second example illustrates the case in span extraction. Similarly, the model is benefited when the correlations between the numbers and "Stephen Gostkowski" are explicitly provided.

To explicitly integrate the type and entity information into the model, we construct a heterogeneous directed graph where the nodes consist of entities and different types of numbers, and the edges can encode different types of relations. The corresponding graph of the example in Table 1 is illustrated in Figure 1. The graph nodes are composed of entities and numbers from both the question and the passage. The numbers of the same type are densely connected with each other. The co-occurred numbers and entities within a sentence are also connected with each other.

Based on this heterogeneous graph, we propose a question directed graph attention network (QDGAT) for the task of numerical MRC. As the answer-related numbers can be directed by the question, QDGAT incorporates the contextual encoding of the question in the graph reasoning process. More specifically, QDGAT employs a contextual encoder, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), to extract the representations of the numbers and entities in both the question and the passage, serving as the initial embeddings of each node in the graph. With the heterogeneous graph, QDGAT learns to collect information from the graph conditioned on the question for numerical reasoning. Each node is also described by a context-aware representation conditioned on the question, and the representations are updated through a message-passing iteration. After multiple iterations of message passing with graph neural networks, QDGAT gradually aggregates the node information to answer the question. In this sense, QDGAT abstracts the representation of passage and question in a way more consistent with human perception and reasoning, making the model produces a more interpretable reasoning pattern.

We evaluate QDGAT on two benchmark datasets: the DROP dataset (Dua et al., 2019) which requires Discrete Reasoning Over the content of Paragraph, and a subset of the RACE dataset (Lai et al., 2017) that contains the number-related questions. Experimental results indicate that QDGAT achieves remarkable performance on the DROP dataset, currently ranked as top 1 for all released models. And also rank first compared with other models that use the identical pre-training model.

2 Related Work

Machine Reading Comprehension. Benefit from recent improvements of pre-trained deep language models like BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), a considerable progress of MRC have been made on the annotated datasets such as SQuAD (Rajpurkar et al., 2016), RACE (Lai et al., 2017), TriviaQA (Joshi et al., 2017) and so on. To answer complex questions of MRC, a number of neural architectures have been proposed such as Attentive Reader (Hermann et al., 2015), BiDAF (Seo et al., 2017), Gated Attention Reader (Dhingra et al., 2017), R-NET (Wang et al., 2017), QANet (Yu et al., 2018), which achieved excellent results on existing datasets. Some recent works (LCGN (Hu et al., 2019b), NMNs (Gupta et al., 2020), NumNet (Ran et al., 2019)) attaching reasoning capabilities to models shows a promising direction. LCGN uses graph neural networks (GNN) conditioned on the input questions to support rational reasoning. NMNs parse the questions into one of several programs, each of which is responsible for specific reasoning ability.

Numerical Reasoning in MRC. Numerical reasoning has been studied when solving arithmetic word problems (AWP). However, existing AWP models only worked on small datasets, and the arithmetic expression must be clearly given. Numerical reasoning in MRC is more challenging since the numbers and reasoning rules are extracted from raw text, which requires a more sophisticated model. NAQANet improved the output layer of QANet to predict the answers from the arithmetic computation over numbers. In addition to NAQANet, GenBERT (Geva et al., 2020) injects numerical skills into BERT by generating numerical data. (Chen et al., 2020) provides a semantic parser that points to locations in the text that can be used in further numerical operations. BERT-Calculator (Andor et al., 2019) defines a set of executable programs and learns to choose one to derive numerical answers. NumNet (Ran et al., 2019) uses a numerically-aware graph neural network to encode numbers, which made further progress on the DROP dataset. However, the graph in NumNet contains only numbers and ignores their types and context information which play a key point in numerical reasoning. Our model differs from NumNet in two aspects: (1) We use a heterogeneous graph containing entities and different types of numbers to encode the relations among the entities and numbers, rather than the relations from numerical comparison; (2) We use the question embedding to modulate the attention over graph neighbors and update the representation to achieve reasoning.

3 Method

In this section, we first introduce the machine reading comprehension task requiring numerical reasoning. Then the framework of our model is provided, followed by detailed descriptions about its components.

3.1 Problem Definition

In the MRC task, each data sample consists of a passage P and a related question Q. The goal of an MRC model is to answer the question according to P. Besides predicting the text spans as in the standard MRC tasks, the answer A in the case of numerical reasoning can also be a number derived from arithmetic computations, such as sorting, counting, addition and subtraction.

3.2 Overall Framework

The framework of the proposed model is briefly depicted in Figure 2. The model is composed of three main components, i.e., a representation extractor module, a reasoning module, and a prediction module. The representation extractor is responsible for semantic comprehension. Upon the extractor, a heterogeneous graph with typed numbers and related entities is constructed. To aggregate the information between the numbers and entities, we propose a question directed graph attention network (QDGAT) to make sophisticated reasoning. This graph attention network directly employs the question Q to manage the message passing over the typed graph.

Word Representation Extractor. We employ RoBERTa (Liu et al., 2019) as the base architecture for the representation of textual inputs. The module takes the passage P and the question Q as input and outputs representation vectors for each token:

$$\hat{\mathbf{Q}}, \hat{\mathbf{P}} = \texttt{RoBERTa}(Q, P)\,, \tag{1}$$

where `RoBERTa` denotes the transformer encoder initialized with RoBERTa parameters, $\hat{\mathbf{P}}$ ($\hat{\mathbf{Q}}$) denotes the list of the token vectors of size d_h in the passage (question). It takes the concatenation of `[CLS]`, Q, `[SEP]`, P and `[SEP]` as input, and outputs representations of $\mathbf{Q}$ and $\mathbf{P}$ as $\hat{\mathbf{Q}}$ and $\hat{\mathbf{P}}$.

Graph Construction. This module builds the heterogeneously typed graph from text data. The graph $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ contains numbers $\mathbf{N}$ and entities $\mathbf{T}$ as the nodes $\mathbf{V} = \{\mathbf{N}, \mathbf{T}\}$, and its edges $\mathbf{E}$ encode the information of the number type and the relationship between the numbers and the entities. The details will be clarified in Section 3.3.

Numerical Reasoning Module. The numerical reasoning module, i.e., QDGAT, is built upon the representation and graph extractor. Based on the graph $\mathcal{G} = (\mathbf{V}, \mathbf{E})$, the QDGAT network can be formulated as

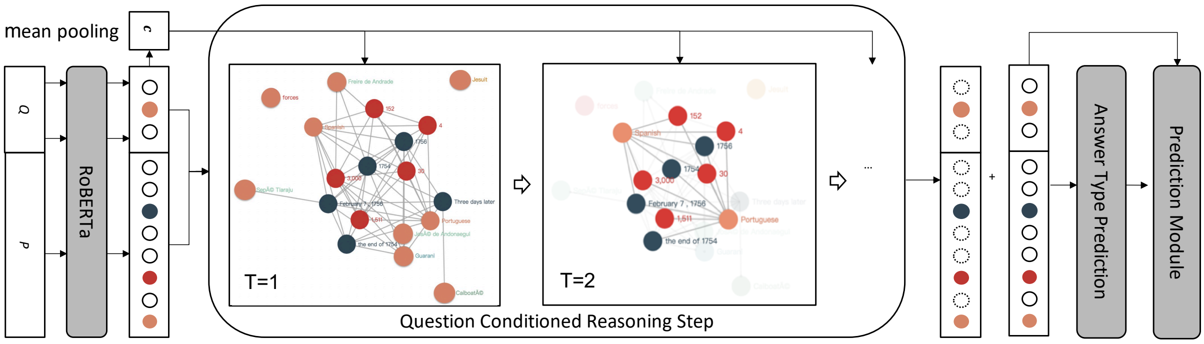

Figure 2: The framework of our model. It consists of a representation extractor (left), a reasoning module (middle) and a prediction module (right). The reasoning module reasons over a heterogeneous directed graph whose nodes are the numbers and the entities. Two kinds of relations are encoded: (1) the numbers of the same type are connected with each other by the type-specific edges, (2) the entities and the numbers are connected when they co-occur in a sentence. The reasoning is conditioned on the question explicitly to guide the message propagation over the graph. In each iteration, each node selectively receives the messages from the neighboring nodes with the question representation to update its representation. The derived representations of these nodes are then combined with the RoBERTa output for the final prediction module. The dashed circle means zero vector.

follows:

$$\mathbf{M}^Q = \mathbf{W}^M \hat{\mathbf{Q}}\,, \tag{2}$$

$$\mathbf{M}^P = \mathbf{W}^M \hat{\mathbf{P}}\,, \tag{3}$$

$$\mathbf{c} = \mathbf{W}^c \texttt{MEAN}(\hat{\mathbf{Q}})\,, \tag{4}$$

$$\mathbf{U} = \texttt{QDGAT}(\mathcal{G}; \mathbf{M}^P, \mathbf{M}^Q, \mathbf{c})\,, \tag{5}$$

where $\mathbf{W}^M \in \mathbb{R}^{d_h \times d_h}$ is a shared projection matrix to obtain the input of QDGAT, `MEAN` denotes the mean pooling, $\mathbf{W}^c \in \mathbb{R}^{d_h \times d_h}$ projects the averaged vector of the representations in the question to derive **c**. **c** is the question language embedding used to direct the reasoning in `QDGAT`. QDGAT then reasons over the representations ($\mathbf{M}^P$, $\mathbf{M}^Q$) and the graph $\mathcal{G}$ conditioned on the question command **c**.

Prediction Module The prediction module takes the output of graph reasoning network **U** for final prediction. At present, the types of answers are generally divided into three categories in NAQANet and NumNet+: (a) span extraction, (b) count, (c) arithmetic expression. We implemented separate modules for these answer types and all of them take the output of graph network **U** and question embedding **c** as input. They are specified as follows:

- Span extraction: There are three span extraction tasks, i.e., single passage span, multiple passage spans, single question span. The probability for single span extraction is derived by the product of the probabilities of the start and end positions in either question or passage. For multiple spans extraction, the probability is constructed referring to (Efrat et al., 2019).
- Count: This problem is regarded as a 10-class classification problem (0-9), which covers about 97% counting problems in the DROP dataset.
- Arithmetic expression: The answer is derived by an arithmetic computation. In the DROP dataset, only addition and subtraction operations are involved. We achieved this by classifying each number into one of $(-1, 0, +1)$, which is then used as the coefficient of the number in the numerical expression to arrive at the final answer.

We used a unique classification network to classify the data sample into one of five fine-grained types (T). And each type solver employs a unique output layer to calculate the conditional answer probability $p(A|T)$.

3.3 Graph Construction with Typed Number and Entities

Here, we illustrate how to construct the heterogeneous graph $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ in our model. NumNet solely concerns the numerical comparisons between numbers by using the directed edges. The graph used in our model differs from NumNet significantly: Rather than modeling the numerical comparison, our graph instead exploits two sources of information, i.e., the type of numbers and the related entities. As illustrated in Figure 2, the nodes of graph **V** consists of both entities **T** and numbers **N**, both of which are recognized by an external name entity recognition (NER) system [2].

Specifically, the NER software labels each token in the text into one of 21 pre-defined categories. The tokens labeled as `NUMBER`, `PERCENT`, `MONEY`, `TIME`, `DATE`, `DURATION`, `ORDINAL` are regarded as the numbers. Since DROP dataset contains a lot of samples related to American football games, we also used heuristic rules to extract the numbers of `YARD` type in the data samples. Besides, we leveraged a number extractor, i.e., word2num [3], to extract the remaining

---

[2] We used Standford CoreNLP toolkit (Manning et al., 2014).

[3] https://pypi.org/project/word2number/

numbers, which are labeled as `NUMBER`. All these tokens construct the number set $\mathbf{N}$ with 8 number types ($\mathcal{V}_N = (\texttt{NUMBER}, \texttt{PERCENT}, \texttt{MONEY}, \texttt{TIME}, \texttt{DATE}, \texttt{DURATION}, \texttt{ORDINAL}, \texttt{YARD})$). As for other recognized tokens, we map them into the label `ENTITY` to build the entity set $\mathbf{T}$ whose type set $\mathcal{V}_T$ is `ENTITY`. In the following, we use $t(v) \in \mathcal{V}_N \cup \mathcal{V}_T$ to indicate the type of the node. The type information can directly inform the model to find the numbers related to the question and thus reduces the reasoning difficulty.

The edges $\mathbf{E}$ encode the relationship among the numbers and the entities, which correspond to two situations.

- *The edge between the numbers*: An edge $e_{i,j}$ exists between two numbers v_i and v_j if and only if these two numbers are of the same type in $\mathcal{V}_N$. And its relation $r_{i,j} = r_{j,i}$ corresponds to the number type.
- *The edge between the entity and the number*: An edge $e_{i,j}$ exists between an entity v_i and a number v_j if and only if v_i and v_j co-occur in the same sentence. In this situation, the relation $r_{i,j} = r_{j,i}$ is `ENT+DIGIT`.

The edges in the first situation cluster the same typed numbers together, which provides an evident clue to help to reason over the numbers. In the second situation, we assume that an entity is relevant to a number when they appear closely. This kind of edges roughly indicates the correlations between the numbers and the entities in most cases. On the other hand, the relative magnitude relations in Numnet+ are not considered in our graph since early experiments with these relations did not improve results. Overall, the graph has 9 relations $\mathcal{R}$, i.e., 8 relations for number types and 1 relation for `ENT+DIGIT`.

3.4 Question Directed Graph Attention Network

Here, we present the details of the `QDGAT` function. Based on the heterogeneous graph $\mathcal{G}$, our QDGAT makes context-aware numerical reasoning conditioned on the question, which collects the relational information through multiple iterations of message passing between the numbers and the entities. It dynamically determines which objects to interact with through the edges in the graph, and sends messages through the graph to propagate the relational information. To achieve this, we augment the reasoning module with the contextualized question representation. For instance in the example in Table 1, the task is to find how many *Spanish* and *Portuguese* were injured or killed. The entities and the numbers are explicitly marked and are modeled in a heterogeneous graph, as shown in Figure 1. Our model is able to extract the related entities, i.e., the *Spanish* and *Portuguese*, conditioned on $\mathbf{c}$. Among the numbers related to these two entities, a number of them are of date type, while the others are about people. However, only the numbers related to people should be concerned as requested by the question. Then the model reasons over these numbers to derive the expression for the answer calculation.

Module Input. The graph neural network takes the representations from the extractor as the input. Each node is represented by the corresponding vector in $\mathbf{M}^P$ and $\mathbf{M}^Q$. Formally, when v_i is in the passage, the input of node v_i is the $\mathbf{v}_i = \mathbf{M}^P[\mathbf{I}^P(v_i)]$, where $\mathbf{I}^P$ returns the index of v_i in $\mathbf{M}^P$ [4]. The collected vectors from the question and the passage construct the input of reasoning module $\mathbf{v}^0$.

Question Directed Node Embedding Update. At each iteration $t \in \{1, ...T\}$, a question directed layer integrates the question information with the current node embedding representations. This step is to mimic the reasoning step of detecting relevant nodes. More specifically, the question, represented by $\mathbf{c}$, is used to direct the information propagation between the nodes (i.e., the numbers and the entities). Each node collects the information from the neighbors with the question command. The role of numbers and entities is not only dependent on the input itself, but also the neighbors and the relations between them. Therefore, we adopt the self-attention layer (Vaswani et al., 2017) to dynamically aggregate the information. The representation is first converted into three spaces denoting the query, key and value, conditioned on $\mathbf{c}$:

$$\mathbf{m}^t = \mathbf{W}^t_{dc} g(\mathbf{W}_{fc}\mathbf{c}) \,, \tag{6}$$

$$\mathbf{x}^t_q = \mathbf{W}_{qv}[\mathbf{v}^t : \mathbf{v}^0] \odot \mathbf{W}_{qc}\mathbf{m}^t \,, \tag{7}$$

$$\mathbf{x}^t_k = \mathbf{W}_{kv}[\mathbf{v}^t : \mathbf{v}^0] \odot \mathbf{W}_{kc}\mathbf{m}^t \,, \tag{8}$$

$$\mathbf{x}^t_v = \mathbf{W}_{vv}[\mathbf{v}^t : \mathbf{v}^0] \odot \mathbf{W}_{vc}\mathbf{m}^t \,, \tag{9}$$

where $\mathbf{m}^t$ denotes the command vector extracted dynamically from the $\mathbf{c}$ with $\mathbf{W}^t_{dc}$ and $\mathbf{W}_{fc} \in \mathrm{R}^{d_h \times 2d_h}$, g denotes the ELU activation function (Clevert et al., 2016), $\mathbf{W}_{qv}$, $\mathbf{W}_{kv}$ and $\mathbf{W}_{vv}$ are of size $d_h \times 2d_h$, $\mathbf{W}_{qc}$, $\mathbf{W}_{kc}$ and $\mathbf{W}_{vc}$ are of size $d_h \times d_h$, $[a : b]$ means the concatenation of a and b, and $\odot$ means the element-wise multiplication. These equations include the input $\mathbf{v}^0$ to maintain the original information.

Directed Graph Attention. At each iteration, this graph attention layer for each node aggregates information from the neighbors of the node. This step is to mimic the reasoning step of selecting the relevant relations to operate on. More specifically, we compute the relatedness between the node i and j, which is measured by summarizing all relations:

$$a^t_{i,j} = f\Big(\sum_{r \in \mathcal{R}_{i,j}} \mathbf{W}^r_a [\mathbf{x}^t_{q,i} : \mathbf{x}^t_{k,j}]\Big) \,, \tag{10}$$

where $\mathcal{R}_{i,j}$ means the relations between the two nodes, $a_{i,j}$ denotes the attention score of the node i for the node j, $\mathbf{W}^k_a$ is the vector to map the representations into a scalar for the relation r and f denotes the leakyReLU activation function (Xu et al., 2015).

This attention score is used in the message propagation to collect the right amount of information from each neighboring node. In the propagation function, the

---

[4] When v_i corresponds to several tokens, the average of these vectors is used.

calculation of the node interaction is as follows:

$$\alpha_{i,j}^t = \frac{\exp(a_{i,j}^t)}{\sum_{j' \in \mathcal{N}_i} \exp(a_{i,j'}^t)} \,, \tag{11}$$

$$\hat{\mathbf{x}}_i^t = \sum_{j \in \mathcal{N}_i} \alpha_{i,j} \mathbf{x}_{v,j} \,, \tag{12}$$

$$\mathbf{v}_i^{t+1} = \mathbf{W}_u [\mathbf{v}_i^t ; \hat{\mathbf{x}}_i^t] \,, \tag{13}$$

where $\mathcal{N}_i$ contains the adjacent nodes of the node i in the $\mathcal{G}$ and $\mathbf{W}_u$ is in $\mathbb{R}^{d_h \times 2d_h}$. With the weight $\alpha_{i,j}$ obtained, the values of neighboring nodes are summarized to derive a new representation $\hat{\mathbf{x}}$. Finally, the new representation of $\mathbf{v}$ is computed by mapping the concatenation of $\mathbf{v}^0$ and $\hat{\mathbf{x}}$.

We denote the node embedding update and the graph attention layers as a function:

$$\mathbf{v}^{t+1} = \texttt{QDGAT-single}(\mathcal{G}, \mathbf{v}^t, \mathbf{c}) \,. \tag{14}$$

From the process of this reasoning step, we can see that the module receives the information from the question, which directly manages the message propagation among the numbers and the entities.

Module Output We perform T iterations of the reasoning step of `QDGAT-single` to perform `QDGAT` in Equation 5. The output of the last layer $\mathbf{v}^T$ is obtained for the numbers and entities in $\mathbf{U}$. For other tokens, the representation vectors from the extractor are used. Formally, the calculation of the output $\mathbf{U}$ is implemented as follows:

$$\mathbf{U}_i = \begin{cases} \mathbf{M}_i + \mathbf{v}_{\mathbf{J}(i)}^T, & \text{if } i\text{-th token} \in \mathbf{V} \\ \mathbf{M}_i, & \text{otherwise} \end{cases} \tag{15}$$

where $\mathbf{J}(i)$ denotes the index of token i in the graph nodes, $\mathbf{M}$ denotes the combination of $\mathbf{M}^P$ and $\mathbf{M}^Q$ for simplicity. $\mathbf{U}$ is then used in the prediction module for the five answer types mentioned above.

4 Experiments

4.1 Dataset and Evaluation Metrics

We performed experiments on the DROP dataset (Dua et al., 2019), which was recently released for research on numerical machine reading comprehension (MRC). DROP is constructed by crowd-sourcing question-answer pairs on passages from Wikipedia, which contains 77,409 / 9,536 / 9,622 samples in the original training / development / testing split. Following the previous work (Dua et al., 2019), we used Exact Match (EM) and F1 score as the evaluation metrics.

4.2 Baselines

We choose publicly available methods (including non-published ones on the dataset leaderboard) as our baselines:

- **Semantic parsing models:** Syn Dep, OpenIE and SRL (Dua et al., 2019). All these models are enhanced versions of KDG (Krishnamurthy et al., 2017) with different sentence representations.
- **Traditional MRC models:** (1) BiDAF, a model that uses a bi-directional attention flow network to obtain a query-aware context representation; (2) QANet, a model that combines convolution and self-attention models to answer the questions; (3) BERT (Devlin et al., 2019), a pre-trained deep Transformer (Vaswani et al., 2017) model that has improved results on many NLP tasks.
- **MRC models with numerical reasoning module:** (1) NAQANet (Dua et al., 2019), a model that adapts the output layer of QANet to numeric reasoning; (2) ALBERT-Calculator (Andor et al., 2019), a model based on ALBERT-xxlarge (Lan et al., 2020) that picks one of executable programs from a predefined set to derive numerical answers. (3) NumNet, a model that embeds numerical properties into the distributed representation by using a GNN on the number graph; (4) NumNet+ [5], an enhanced version of NumNet, which uses a pre-trained RoBERTa model and supports multi-span answers.

4.3 Experiment Settings

We use the large RoBERTa model as the contextual encoder, with 24 layers, 16 attention heads, and 1024 embedding dimensions. This indicates that the hidden size d_h is 1024. The model was trained end-to-end for 5 epochs using Adam optimizer (Kingma and Ba, 2015) with a batch size of 16. For the hyperparameters of RoBERTa, the learning rate is 5e-5 and the L2 weight decay is 1e-6. For the other parts, the learning rate is 1e-4 and the L2 weight decay is 5e-5. We perform $T = 4$ iterations of the graph reasoning step, which performs best in our experiments. We adopt the standard data preprocessing following previous work (Ran et al., 2019).

4.4 Main Results

The overall experimental results are reported in Table 2, where the performance of baseline methods is obtained from previous work (Dua et al., 2019; Seo et al., 2017; Ran et al., 2019; Andor et al., 2019) and the public leaderboard.[6]

The first three methods in Table 2 are based on either semantic parsing or information extraction, and perform poorly on the numerical MRC task. Traditional MRC methods BiDAF and QANet, which has no numerical reasoning modules, achieve slightly better performance but still far from satisfying. Methods that are customized for numerical reasoning, including NAQANet and NumNet, have achieved significantly better performance in terms of EM and F1 score. Compared to traditional MRC methods, these methods can handle different answer types, e.g., span extraction, counting, and addition/subtraction of numbers.

Our method QDGAT outperforms all the existing methods, achieving 86.38 F1 score and 83.23 EM on

Human			94.09	96.42

the test set, which narrows the human performance gap to less than 11 points. NumNet+ is the most relevant one to our method, which also leverages a graph neural network as well as the RoBERTa contextual encoder. Compared to NumNet+, QDGAT incorporates the number types and entity mentions into the graph attention network, and directs the graph reasoning process with the question. In this way, our method can better capture the relations between numbers and entities, and also reduce the learning difficulty due to the interaction with the question during the graph reasoning. Experimental results demonstrate the effectiveness of QDGAT, which outperforms NumNet+ by 1.23 in terms of EM and 1.37 in terms of F1 score. Ensembling three of our models with different random seeds and learning rates further improves the performance.

4.5 Ablation Analysis

To examine the impact of different components of QDGAT, we conduct ablation studies and compare the performance in Table 3. QDGAT$_{\mathrm{NH}}$ removes the number type and entity from the graph, and QDGAT$_{\mathrm{NQ}}$ removes question direction from QDGAT and instead uses a normal graph convolution message passing mechanism. NumNet+ serves as a baseline for reference, since it has no question attention, no entities and no number types in the graph. We observe that QDGAT$_{\mathrm{NQ}}$, which has no question directed attention, performs worse. This justifies that the reasoning with graph neural network is more effective when conditioned on the input question. We also observe that QDGAT$_{\mathrm{NH}}$ performs significantly worse, which demonstrates the importance of incorporating the information of number types and entity mentions in the reasoning graph. This is consistent with our intuition that numbers with the same type or connected to the same entity are more relevant to each other.

Table 3: Ablation study results on the development set of DROP. QDGAT$_{\mathrm{NH}}$ removes the number type and entity from the graph, and QDGAT$_{\mathrm{NQ}}$ removes question direction from QDGAT. Better results are in bold.

Method	EM	F1
NumNet+	81.07	84.42
QDGAT$_{\mathrm{NH}}$	81.98	84.94
QDGAT$_{\mathrm{NQ}}$	82.04	85.01
QDGAT	**82.74**	**85.85**

Table 4: Decomposed performance on different answer types in the development set of DROP. Better results are in bold.

Method	Number		Date		Span	
	EM	F1	EM	F1	EM	F1
NumNet+	82.89	83.13	56.67	63.91	82.00	86.84
QDGAT	**86.00**	**86.23**	**60.27**	**67.48**	**84.05**	**88.53**

Table 4 decomposes the QA performance on different answer types in the development set of DROP. As reported in the table, QDGAT works better on the questions relating to numbers and dates, which requires more specific numerical reasoning compared with the span extraction. The remarkable improvement indicates that the proposed method effectively benefits the reasoning module to comprehend the numerical problems. Notably, the performance in span extraction can still be improved by our method. The span extraction in DROP heavily relies on the ability to comprehend the relation between the number and the entity (c.f. the second example in Table 1).

4.6 Performance on RACENum

To investigate the generalization capability of QDGAT in numerical reasoning, we examine whether the pretrained model on DROP is transferable. We compare QDGAT with NumNet+ on RACE (Lai et al., 2017), a dataset collected from the English exams for middle and high school Chinese students. We extracted a special part of examples from RACE, where the questions start with "how many", referred to as RACENum. RACENum is then divided into middle school exam (RACENum-M) and high school exam (RACENum-H) categories. The RACENum-M and RACENum-H datasets contain 633 and 611 questions accordingly. Since the original RACE dataset is in the multiple-choice form, we converted them into the DROP data format. The accuracy of NumNet+, QDGAT and its ablation variants on RACENum are summarized in Table 6, which is consistent with the performance comparison on the DROP dataset.

The overall low scores are attributed to the lack of training on the in-domain data. QDGAT achieves

Table 5: The cases from the DROP dataset. The predictions from the QDGAT and NumNet+ are illustrated. The differences between the output of these two models demonstrate the properties of the proposed model. The last two columns indicate the arithmetic expression, obtained by assigning a sign (plus, minus or zero) for each extracted numbers (we omitted the zero sign numbers). Then the answer was derived by summing up the signed numbers.

Question & Answer	Passage	NumNet+	QDGAT
Q: How many less in age percentage in teenagers than adult? **A:** 1.3	The age distribution, in Aigle is; 933 children or 10.7% of the population are between 0 and 9 years old and 1,137 teenagers or 13.0% are between 10 and 19. Of the adult population, 1,255 people or 14.3% of the population are between 20 and 29 years old...	19-13.0-10=-4	14.3-13.0 =1.3
Q: How many yards did Kasay kick? **A:** 94	... Carolina scored first in the second quarter with kicker John Kasay hitting a 45-yard field goal . The Falcons took the lead with QB Joey Harrington completing a 69-yard TD pass to WR Roddy White . The Panthers followed up with QB Jake Delhomme completing a 13-yard TD pass to RB DeShaun Foster ... In the fourth quarter , the Panthers scored again , with Kasay kicking a 49-yard field goal . The Falcons ' Andersen nailed a 25-yard field goal to end the scoring ...	+45=45	45+49 =94
Q: How many months after Mengistu Haile Mariam was made head of state did Ethiopia close the U.S. military mission and the communications centre? **A:** 2	... A sign that order had been restored among the Derg was the announcement of Mengistu Haile Mariam as head of state on 02/1977. However, the country remained in chaos as the military attempted to suppress its civilian opponents in a period known as the Red Terror ... Ethiopia closed the U.S. military mission and the communications centre in 04/1977. In 06/1977, Mengistu accused Somalia of infiltrating SNA soldiers into the Somali area to fight alongside the WSLF. Despite considerable evidence to the contrary...	Count: 3	+4-2=2

Table 6: The accuracy on the unsupervised RACENum dataset.

Method	RACE-M	RACE-H	Avg.
NumNet+	46.98	31.59	39.29
QDGAT$_{\mathrm{NH}}$	50.88	35.30	43.09
QDGAT$_{\mathrm{NQ}}$	49.67	**35.84**	42.76
QDGAT	**52.53**	34.86	**43.70**

43.7 points on RACENum on average, which is approximately 4.5 points higher than NumNet+. Both QDGAT$_{\mathrm{NQ}}$ and QDGAT$_{\mathrm{NH}}$ still outperform NumNet+ by a 2–3 points margin. We further confirmed that ablating either the entity information or question attention from the heterogeneous graph weakens the power of QDGAT to learn numeracy and the capability of understanding numbers in either digits or word form. Compared with QDGAT, ablating the question directed attention, i.e., QDGAT$_{\mathrm{NQ}}$, leads to about a 1 point drop. For QDGAT$_{\mathrm{NH}}$ that removes the number type and entity mentions from the graph, it performs consistently worse than QDGAT, demonstrating the impact of the heterogeneous graph for numerical reasoning.

4.7 Case Study

We show several examples to provide insights into how our model works. Table 5 compares the different model prediction results from NumNet+ and QDGAT:

- The first example shows the importance of number types. NumNet+ treats all numbers as the same type, which fails to capture that the question only cares about percentage and incorrectly predicts "*19*" (type age) as part of the result. In contrast, QDGAT extracts the relevant numbers and derives the correct answer.
- The second example highlights the importance of entity mentions. NumNet+ fails to extract "*49-yard*", but QDGAT easily captures this number since "*49-yard*" and "*45-yard*" are connected to the same entity "*Kassy*" on the heterogeneous graph which is generated from the passage.
- The third example shows the importance of question conditioning. Solving this example requires to extract the two dates related to two events mentioned in the question. Without direct interaction between the question, the model tends to recognize this example as a counting problem since the question starts with "how many". However, when combined with question directed attention, correct numbers can be filtered out.

5 Conclusion

In this work, we propose a novel method named QDGAT for numerical reasoning in the machine reading comprehension task. Our method not only builds a more compact graph containing different types of numbers, entities, and relations, which can be a general method for other sophisticated reasoning tasks but also conditions the reasoning directly on the question language embedding, which modulates the attention over graph neighbors and change messages being passed iteratively to achieve reasoning. The experimental results verify the effectiveness of our method. In the future, we plan to extend our model to learn the heterogeneous graph automatically, which assures more flexibility for numerical reasoning. We would also explore to learn the types of numbers and entities together the reasoning modules using variational autoencoder techniques (Kingma and Welling, 2014), which may help the NER system better adapt to the numerical reasoning task.

Abstract

Open-domain question answering relies on efficient passage retrieval to select candidate contexts, where traditional sparse vector space models, such as TF-IDF or BM25, are the de facto method. In this work, we show that retrieval can be practically implemented using *dense* representations alone, where embeddings are learned from a small number of questions and passages by a simple dual-encoder framework. When evaluated on a wide range of open-domain QA datasets, our dense retriever outperforms a strong Lucene-BM25 system greatly by 9%-19% absolute in terms of top-20 passage retrieval accuracy, and helps our end-to-end QA system establish new state-of-the-art on multiple open-domain QA benchmarks.[1]

1 Introduction

Open-domain question answering (QA) (Voorhees, 1999) is a task that answers factoid questions using a large collection of documents. While early QA systems are often complicated and consist of multiple components (Ferrucci (2012); Moldovan et al. (2003), *inter alia*), the advances of reading comprehension models suggest a much simplified two-stage framework: (1) a context *retriever* first selects a small subset of passages where some of them contain the answer to the question, and then (2) a machine *reader* can thoroughly examine the retrieved contexts and identify the correct answer (Chen et al., 2017). Although reducing open-domain QA to machine reading is a very reasonable strategy, a huge performance degradation is often observed in practice[2], indicating the needs of improving retrieval.

Retrieval in open-domain QA is usually implemented using TF-IDF or BM25 (Robertson and Zaragoza, 2009), which matches keywords efficiently with an inverted index and can be seen as representing the question and context in high-dimensional, sparse vectors (with weighting). Conversely, the *dense*, latent semantic encoding is *complementary* to sparse representations by design. For example, synonyms or paraphrases that consist of completely different tokens may still be mapped to vectors close to each other. Consider the question *"Who is the bad guy in lord of the rings?"*, which can be answered from the context *"Sala Baker is best known for portraying the villain Sauron in the Lord of the Rings trilogy."* A term-based system would have difficulty retrieving such a context, while a dense retrieval system would be able to better match *"bad guy"* with *"villain"* and fetch the correct context. Dense encodings are also *learnable* by adjusting the embedding functions, which provides additional flexibility to have a task-specific representation. With special in-memory data structures and indexing schemes, retrieval can be done efficiently using maximum inner product search (MIPS) algorithms (e.g., Shrivastava and Li (2014); Guo et al. (2016)).

However, it is generally believed that learning a good dense vector representation needs a large number of labeled pairs of question and contexts. Dense retrieval methods have thus never be shown to outperform TF-IDF/BM25 for open-domain QA before ORQA (Lee et al., 2019), which proposes a sophisticated inverse cloze task (ICT) objective, predicting the blocks that contain the masked sentence, for additional pretraining. The question encoder and the reader model are then fine-tuned using pairs of questions and answers jointly. Although ORQA successfully demonstrates that dense retrieval can outperform BM25, setting new state-of-the-art results on multiple open-domain

---

[*] Equal contribution

[1] The code and trained models have been released at https://github.com/facebookresearch/DPR.

[2] For instance, the exact match score on SQuAD v1.1 drops from above 80% to less than 40% (Yang et al., 2019a).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6769–6781,
November 16–20, 2020.

QA datasets, it also suffers from two weaknesses. First, ICT pretraining is computationally intensive and it is not completely clear that regular sentences are good surrogates of questions in the objective function. Second, because the context encoder is not fine-tuned using pairs of questions and answers, the corresponding representations could be suboptimal.

In this paper, we address the question: can we train a better dense embedding model using only pairs of questions and passages (or answers), *without* additional pretraining? By leveraging the now standard BERT pretrained model (Devlin et al., 2019) and a dual-encoder architecture (Bromley et al., 1994), we focus on developing the right training scheme using a relatively small number of question and passage pairs. Through a series of careful ablation studies, our final solution is surprisingly simple: the embedding is optimized for maximizing inner products of the question and relevant passage vectors, with an objective comparing all pairs of questions and passages in a batch. Our *Dense Passage Retriever* (DPR) is exceptionally strong. It not only outperforms BM25 by a large margin (65.2% vs. 42.9% in Top-5 accuracy), but also results in a substantial improvement on the end-to-end QA accuracy compared to ORQA (41.5% vs. 33.3%) in the open Natural Questions setting (Lee et al., 2019; Kwiatkowski et al., 2019).

Our contributions are twofold. First, we demonstrate that with the proper training setup, simply fine-tuning the question and passage encoders on existing question-passage pairs is sufficient to greatly outperform BM25. Our empirical results also suggest that additional pretraining may not be needed. Second, we verify that, in the context of open-domain question answering, a higher retrieval precision indeed translates to a higher end-to-end QA accuracy. By applying a modern reader model to the top retrieved passages, we achieve comparable or better results on multiple QA datasets in the open-retrieval setting, compared to several, much complicated systems.

2 Background

The problem of open-domain QA studied in this paper can be described as follows. Given a factoid question, such as "*Who first voiced Meg on Family Guy?*" or "*Where was the 8th Dalai Lama born?*", a system is required to answer it using a large corpus of diversified topics. More specifically, we assume the extractive QA setting, in which the answer is restricted to a span appearing in one or more passages in the corpus. Assume that our collection contains D documents, $d_1, d_2, \cdots, d_D$. We first split each of the documents into text passages of equal lengths as the basic retrieval units[3] and get M total passages in our corpus $\mathcal{C} = \{p_1, p_2, \ldots, p_M\}$, where each passage p_i can be viewed as a sequence of tokens $w_1^{(i)}, w_2^{(i)}, \cdots, w_{|p_i|}^{(i)}$. Given a question q, the task is to find a span $w_s^{(i)}, w_{s+1}^{(i)}, \cdots, w_e^{(i)}$ from one of the passages p_i that can answer the question. Notice that to cover a wide variety of domains, the corpus size can easily range from millions of documents (e.g., Wikipedia) to billions (e.g., the Web). As a result, any open-domain QA system needs to include an efficient *retriever* component that can select a small set of relevant texts, before applying the reader to extract the answer (Chen et al., 2017).[4] Formally speaking, a retriever $R : (q, \mathcal{C}) \rightarrow \mathcal{C}_{\mathcal{F}}$ is a function that takes as input a question q and a corpus $\mathcal{C}$ and returns a much smaller *filter set* of texts $\mathcal{C}_{\mathcal{F}} \subset \mathcal{C}$, where $|\mathcal{C}_{\mathcal{F}}| = k \ll |\mathcal{C}|$. For a fixed k, a *retriever* can be evaluated in isolation on *top-k retrieval accuracy*, which is the fraction of questions for which $\mathcal{C}_{\mathcal{F}}$ contains a span that answers the question.

3 Dense Passage Retriever (DPR)

We focus our research in this work on improving the *retrieval* component in open-domain QA. Given a collection of M text passages, the goal of our dense passage retriever (DPR) is to index all the passages in a low-dimensional and continuous space, such that it can retrieve efficiently the top k passages relevant to the input question for the reader at run-time. Note that M can be very large (e.g., 21 million passages in our experiments, described in Section 4.1) and k is usually small, such as 20–100.

3.1 Overview

Our dense passage retriever (DPR) uses a dense encoder $E_P(\cdot)$ which maps any text passage to a d-dimensional real-valued vectors and builds an index for all the M passages that we will use for retrieval.

---

[3] The ideal size and boundary of a text passage are functions of both the retriever and reader. We also experimented with natural paragraphs in our preliminary trials and found that using fixed-length passages performs better in both retrieval and final QA accuracy, as observed by Wang et al. (2019).

[4] Exceptions include (Seo et al., 2019) and (Roberts et al., 2020), which *retrieves* and *generates* the answers, respectively.

At run-time, DPR applies a different encoder $E_Q(\cdot)$ that maps the input question to a d-dimensional vector, and retrieves k passages of which vectors are the closest to the question vector. We define the similarity between the question and the passage using the dot product of their vectors:

$$\mathrm{sim}(q, p) = E_Q(q)^\intercal E_P(p). \tag{1}$$

Although more expressive model forms for measuring the similarity between a question and a passage do exist, such as networks consisting of multiple layers of cross attentions, the similarity function needs to be decomposable so that the representations of the collection of passages can be pre-computed. Most decomposable similarity functions are some transformations of Euclidean distance (L2). For instance, cosine is equivalent to inner product for unit vectors and the Mahalanobis distance is equivalent to L2 distance in a transformed space. Inner product search has been widely used and studied, as well as its connection to cosine similarity and L2 distance (Mussmann and Ermon, 2016; Ram and Gray, 2012). As our ablation study finds other similarity functions perform comparably (Section 5.2; Appendix B), we thus choose the simpler inner product function and improve the dense passage retriever by learning better encoders.

Encoders Although in principle the question and passage encoders can be implemented by any neural networks, in this work we use two independent BERT (Devlin et al., 2019) networks (base, uncased) and take the representation at the `[CLS]` token as the output, so $d = 768$.

Inference During inference time, we apply the passage encoder E_P to all the passages and index them using FAISS (Johnson et al., 2017) offline. FAISS is an extremely efficient, open-source library for similarity search and clustering of dense vectors, which can easily be applied to billions of vectors. Given a question q at run-time, we derive its embedding $v_q = E_Q(q)$ and retrieve the top k passages with embeddings closest to v_q.

3.2 Training

Training the encoders so that the dot-product similarity (Eq. (1)) becomes a good ranking function for retrieval is essentially a *metric learning* problem (Kulis, 2013). The goal is to create a vector space such that relevant pairs of questions and passages will have smaller distance (i.e., higher similarity) than the irrelevant ones, by learning a better embedding function.

Let $\mathcal{D} = \{\langle q_i, p_i^+, p_{i,1}^-, \cdots, p_{i,n}^- \rangle\}_{i=1}^m$ be the training data that consists of m instances. Each instance contains one question q_i and one relevant (positive) passage p_i^+, along with n irrelevant (negative) passages $p_{i,j}^-$. We optimize the loss function as the negative log likelihood of the positive passage:

$$\begin{aligned} & L(q_i, p_i^+, p_{i,1}^-, \cdots, p_{i,n}^-) \qquad (2) \\ = & -\log \frac{e^{\mathrm{sim}(q_i, p_i^+)}}{e^{\mathrm{sim}(q_i, p_i^+)} + \sum_{j=1}^n e^{\mathrm{sim}(q_i, p_{i,j}^-)}}. \end{aligned}$$

Positive and negative passages For retrieval problems, it is often the case that positive examples are available explicitly, while negative examples need to be selected from an extremely large pool. For instance, passages relevant to a question may be given in a QA dataset, or can be found using the answer. All other passages in the collection, while not specified explicitly, can be viewed as irrelevant by default. In practice, how to select negative examples is often overlooked but could be decisive for learning a high-quality encoder. We consider three different types of negatives: (1) Random: any random passage from the corpus; (2) BM25: top passages returned by BM25 which don't contain the answer but match most question tokens; (3) Gold: positive passages paired with other questions which appear in the training set. We will discuss the impact of different types of negative passages and training schemes in Section 5.2. Our best model uses gold passages from the same mini-batch and one BM25 negative passage. In particular, re-using gold passages from the same batch as negatives can make the computation efficient while achieving great performance. We discuss this approach below.

In-batch negatives Assume that we have B questions in a mini-batch and each one is associated with a relevant passage. Let $\mathbf{Q}$ and $\mathbf{P}$ be the $(B \times d)$ matrix of question and passage embeddings in a batch of size B. $\mathbf{S} = \mathbf{Q}\mathbf{P}^T$ is a $(B \times B)$ matrix of similarity scores, where each row of which corresponds to a question, paired with B passages. In this way, we reuse computation and effectively train on B^2 (q_i, p_j) question/passage pairs in each batch. Any (q_i, p_j) pair is a positive example when $i = j$, and negative otherwise. This creates B training instances in each batch, where there are $B - 1$

negative passages for each question.

The trick of in-batch negatives has been used in the full batch setting (Yih et al., 2011) and more recently for mini-batch (Henderson et al., 2017; Gillick et al., 2019). It has been shown to be an effective strategy for learning a dual-encoder model that boosts the number of training examples.

4 Experimental Setup

In this section, we describe the data we used for experiments and the basic setup.

4.1 Wikipedia Data Pre-processing

Following (Lee et al., 2019), we use the English Wikipedia dump from Dec. 20, 2018 as the source documents for answering questions. We first apply the pre-processing code released in DrQA (Chen et al., 2017) to extract the clean, text-portion of articles from the Wikipedia dump. This step removes semi-structured data, such as tables, infoboxes, lists, as well as the disambiguation pages. We then split each article into multiple, disjoint text blocks of 100 words as *passages*, serving as our basic retrieval units, following (Wang et al., 2019), which results in 21,015,324 passages in the end.[5] Each passage is also prepended with the title of the Wikipedia article where the passage is from, along with an `[SEP]` token.

4.2 Question Answering Datasets

We use the same five QA datasets and training/dev/testing splitting method as in previous work (Lee et al., 2019). Below we briefly describe each dataset and refer readers to their paper for the details of data preparation.

Natural Questions (NQ) (Kwiatkowski et al., 2019) was designed for end-to-end question answering. The questions were mined from real Google search queries and the answers were spans in Wikipedia articles identified by annotators.

TriviaQA (Joshi et al., 2017) contains a set of trivia questions with answers that were originally scraped from the Web.

WebQuestions (WQ) (Berant et al., 2013) consists of questions selected using Google Suggest API, where the answers are entities in Freebase.

CuratedTREC (TREC) (Baudiš and Šedivỳ, 2015) sources questions from TREC QA tracks as well as various Web sources and is intended for open-domain QA from unstructured corpora.

Dataset	**Train**		**Dev**	**Test**
Natural Questions	79,168	58,880	8,757	3,610
TriviaQA	78,785	60,413	8,837	11,313
WebQuestions	3,417	2,474	361	2,032
CuratedTREC	1,353	1,125	133	694
SQuAD	78,713	70,096	8,886	10,570

Table 1: Number of questions in each QA dataset. The two columns of **Train** denote the original training examples in the dataset and the actual questions used for training DPR after filtering. See text for more details.

SQuAD v1.1 (Rajpurkar et al., 2016) is a popular benchmark dataset for reading comprehension. Annotators were presented with a Wikipedia paragraph, and asked to write questions that could be answered from the given text. Although SQuAD has been used previously for open-domain QA research, it is not ideal because many questions lack context in absence of the provided paragraph. We still include it in our experiments for providing a fair comparison to previous work and we will discuss more in Section 5.1.

Selection of positive passages Because only pairs of questions and answers are provided in TREC, WebQuestions and TriviaQA[6], we use the highest-ranked passage from BM25 that contains the answer as the positive passage. If none of the top 100 retrieved passages has the answer, the question will be discarded. For SQuAD and Natural Questions, since the original passages have been split and processed differently than our pool of candidate passages, we match and replace each gold passage with the corresponding passage in the candidate pool.[7] We discard the questions when the matching is failed due to different Wikipedia versions or pre-processing. Table 1 shows the number of questions in training/dev/test sets for all the datasets and the actual questions used for training the retriever.

5 Experiments: Passage Retrieval

In this section, we evaluate the retrieval performance of our Dense Passage Retriever (DPR), along with analysis on how its output differs from

---

[5] However, Wang et al. (2019) also propose splitting documents into overlapping passages, which we do not find advantageous compared to the non-overlapping version.

[6] We use the unfiltered TriviaQA version and discard the noisy evidence documents mined from Bing.

[7] The improvement of using gold contexts over passages that contain answers is small. See Section 5.2 and Appendix A.

Training	Retriever	Top-20					Top-100				
		NQ	TriviaQA	WQ	TREC	SQuAD	NQ	TriviaQA	WQ	TREC	SQuAD
None	BM25	59.1	66.9	55.0	70.9	68.8	73.7	76.7	71.1	84.1	80.0
Single	DPR	78.4	79.4	73.2	79.8	63.2	85.4	**85.0**	81.4	89.1	77.2
	BM25 + DPR	76.6	79.8	71.0	85.2	**71.5**	83.8	84.5	80.5	92.7	**81.3**
Multi	DPR	**79.4**	78.8	**75.0**	**89.1**	51.6	**86.0**	84.7	**82.9**	93.9	67.6
	BM25 + DPR	78.0	**79.9**	74.7	88.5	66.2	83.9	84.4	82.3	**94.1**	78.6

Table 2: Top-20 & Top-100 retrieval accuracy on test sets, measured as the percentage of top 20/100 retrieved passages that contain the answer. *Single* and *Multi* denote that our Dense Passage Retriever (DPR) was trained using individial or combined training datasets (all the datasets excluding SQuAD). See text for more details.

traditional retrieval methods, the effects of different training schemes and the run-time efficiency.

The DPR model used in our main experiments is trained using the in-batch negative setting (Section 3.2) with a batch size of 128 and one additional BM25 negative passage per question. We trained the question and passage encoders for up to 40 epochs for large datasets (NQ, TriviaQA, SQuAD) and 100 epochs for small datasets (TREC, WQ), with a learning rate of 10^{-5} using Adam, linear scheduling with warm-up and dropout rate 0.1.

While it is good to have the flexibility to adapt the retriever to each dataset, it would also be desirable to obtain a single retriever that works well across the board. To this end, we train a *multi*-dataset encoder by combining training data from all datasets excluding SQuAD.[8] In addition to DPR, we also present the results of BM25, the traditional retrieval method[9] and BM25+DPR, using a linear combination of their scores as the new ranking function. Specifically, we obtain two initial sets of top-2000 passages based on BM25 and DPR, respectively, and rerank the union of them using BM25(q,p) + $\lambda \cdot \text{sim}(q, p)$ as the ranking function. We used $\lambda = 1.1$ based on the retrieval accuracy in the development set.

5.1 Main Results

Table 2 compares different passage retrieval systems on five QA datasets, using the top-k accuracy ($k \in \{20, 100\}$). With the exception of SQuAD, DPR performs consistently better than BM25 on all datasets. The gap is especially large when k is small (e.g., 78.4% vs. 59.1% for top-20 accuracy on Natural Questions). When training with multiple datasets, TREC, the smallest dataset of the five, benefits greatly from more training examples. In contrast, Natural Questions and WebQuestions improve modestly and TriviaQA degrades slightly. Results can be improved further in some cases by combining DPR with BM25 in both single- and multi-dataset settings.

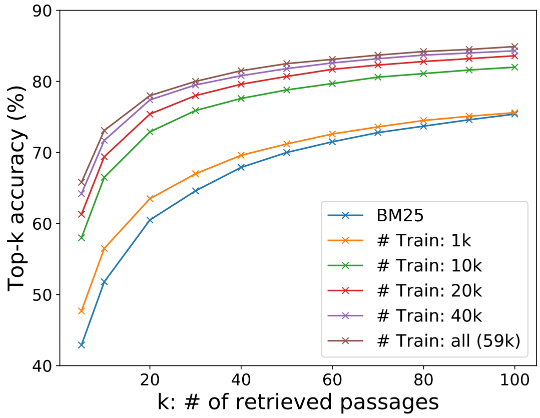

Figure 1: Retriever top-k accuracy with different numbers of training examples used in our dense passage retriever vs BM25. The results are measured on the development set of Natural Questions. Our DPR trained using 1,000 examples already outperforms BM25.

We conjecture that the lower performance on SQuAD is due to two reasons. First, the annotators wrote questions after seeing the passage. As a result, there is a high lexical overlap between passages and questions, which gives BM25 a clear advantage. Second, the data was collected from only 500+ Wikipedia articles and thus the distribution of training examples is extremely biased, as argued previously by Lee et al. (2019).

5.2 Ablation Study on Model Training

To understand further how different model training options affect the results, we conduct several additional experiments and discuss our findings below.

---

[8] SQuAD is limited to a small set of Wikipedia documents and thus introduces unwanted bias. We will discuss this issue more in Section 5.1.

[9] Lucene implementation. BM25 parameters $b = 0.4$ (document length normalization) and $k_1 = 0.9$ (term frequency scaling) are tuned using development sets.

Sample efficiency We explore how many training examples are needed to achieve good passage retrieval performance. Figure 1 illustrates the top-k retrieval accuracy with respect to different numbers of training examples, measured on the development set of Natural Questions. As is shown, a dense passage retriever trained using only 1,000 examples already outperforms BM25. This suggests that with a general pretrained language model, it is possible to train a high-quality dense retriever with a small number of question–passage pairs. Adding more training examples (from 1k to 59k) further improves the retrieval accuracy consistently.

In-batch negative training We test different training schemes on the development set of Natural Questions and summarize the results in Table 3. The top block is the standard 1-of-N training setting, where each question in the batch is paired with a positive passage and its own set of n negative passages (Eq. (2)). We find that the choice of negatives — random, BM25 or gold passages (positive passages from other questions) — does not impact the top-k accuracy much in this setting when $k \geq 20$.

The middle bock is the in-batch negative training (Section 3.2) setting. We find that using a similar configuration (7 gold negative passages), in-batch negative training improves the results substantially. The key difference between the two is whether the gold negative passages come from the same batch or from the whole training set. Effectively, in-batch negative training is an easy and memory-efficient way to reuse the negative examples already in the batch rather than creating new ones. It produces more pairs and thus increases the number of training examples, which might contribute to the good model performance. As a result, accuracy consistently improves as the batch size grows.

Finally, we explore in-batch negative training with additional "hard" negative passages that have high BM25 scores given the question, but do not contain the answer string (the bottom block). These additional passages are used as negative passages for all questions in the same batch. We find that adding a single BM25 negative passage improves the result substantially while adding two does not help further.

Impact of gold passages We use passages that match the gold contexts in the original datasets (when available) as positive examples (Section 4.2). Our experiments on Natural Questions show that switching to distantly-supervised passages (using the highest-ranked BM25 passage that contains the answer), has only a small impact: 1 point lower top-k accuracy for retrieval. Appendix A contains more details.

Type	**#N**	**IB**	**Top-5**	**Top-20**	**Top-100**
Random	7	✗	47.0	64.3	77.8
BM25	7	✗	50.0	63.3	74.8
Gold	7	✗	42.6	63.1	78.3
Gold	7	✓	51.1	69.1	80.8
Gold	31	✓	52.1	70.8	82.1
Gold	127	✓	55.8	73.0	83.1
G.+BM25$^{(1)}$	31+32	✓	65.0	77.3	84.4
G.+BM25$^{(2)}$	31+64	✓	64.5	76.4	84.0
G.+BM25$^{(1)}$	127+128	✓	**65.8**	**78.0**	**84.9**

Table 3: Comparison of different training schemes, measured as top-k retrieval accuracy on Natural Questions (development set). #N: number of negative examples, IB: in-batch training. G.+BM25$^{(1)}$ and G.+BM25$^{(2)}$ denote in-batch training with 1 or 2 additional BM25 negatives, which serve as negative passages for all questions in the batch.

Similarity and loss Besides dot product, cosine and Euclidean L2 distance are also commonly used as decomposable similarity functions. We test these alternatives and find that L2 performs comparable to dot product, and both of them are superior to cosine. Similarly, in addition to negative log-likelihood, a popular option for ranking is triplet loss, which compares a positive passage and a negative one directly with respect to a question (Burges et al., 2005). Our experiments show that using triplet loss does not affect the results much. More details can be found in Appendix B.

Cross-dataset generalization One interesting question regarding DPR's discriminative training is how much performance degradation it may suffer from a non-iid setting. In other words, can it still generalize well when directly applied to a different dataset without additional fine-tuning? To test the cross-dataset generalization, we train DPR on Natural Questions only and test it directly on the smaller WebQuestions and CuratedTREC datasets. We find that DPR generalizes well, with 3-5 points loss from the best performing fine-tuned model in top-20 retrieval accuracy (69.9/86.3 vs. 75.0/89.1 for WebQuestions and TREC, respectively), while still greatly outperforming the BM25 baseline (55.0/70.9).

5.3 Qualitative Analysis

Although DPR performs better than BM25 in general, passages retrieved by these two methods differ qualitatively. Term-matching methods like BM25 are sensitive to highly selective keywords and phrases, while DPR captures lexical variations or semantic relationships better. See Appendix C for examples and more discussion.

5.4 Run-time Efficiency

The main reason that we require a retrieval component for open-domain QA is to reduce the number of candidate passages that the reader needs to consider, which is crucial for answering user's questions in real-time. We profiled the passage retrieval speed on a server with Intel Xeon CPU E5-2698 v4 @ 2.20GHz and 512GB memory. With the help of FAISS in-memory index for real-valued vectors[10], DPR can be made incredibly efficient, processing 995.0 questions per second, returning top 100 passages per question. In contrast, BM25/Lucene (implemented in Java, using file index) processes 23.7 questions per second per CPU thread.

On the other hand, the time required for building an index for dense vectors is much longer. Computing dense embeddings on 21-million passages is resource intensive, but can be easily parallelized, taking roughly 8.8 hours on 8 GPUs. However, building the FAISS index on 21-million vectors on a single server takes 8.5 hours. In comparison, building an inverted index using Lucene is much cheaper and takes only about 30 minutes in total.

6 Experiments: Question Answering

In this section, we experiment with how different passage retrievers affect the final QA accuracy.

6.1 End-to-end QA System

We implement an end-to-end question answering system in which we can plug different retriever systems directly. Besides the retriever, our QA system consists of a neural *reader* that outputs the answer to the question. Given the top k retrieved passages (up to 100 in our experiments), the reader assigns a passage selection score to each passage. In addition, it extracts an answer span from each passage and assigns a span score. The best span from the passage with the highest passage selection score is chosen as the final answer. The passage selection model serves as a reranker through cross-attention between the question and the passage. Although cross-attention is not feasible for retrieving relevant passages in a large corpus due to its non-decomposable nature, it has more capacity than the dual-encoder model $\mathrm{sim}(q, p)$ as in Eq. (1). Applying it to selecting the passage from a small number of retrieved candidates has been shown to work well (Wang et al., 2019, 2018; Lin et al., 2018).

Specifically, let $\mathbf{P}_i \in \mathbb{R}^{L\times h}$ $(1 \leq i \leq k)$ be a BERT (base, uncased in our experiments) representation for the i-th passage, where L is the maximum length of the passage and h the hidden dimension. The probabilities of a token being the starting/ending positions of an answer span and a passage being selected are defined as:

$$P_{\text{start},i}(s) = \mathrm{softmax}\big(\mathbf{P}_i \mathbf{w}_{\text{start}}\big)_s, \quad (3)$$

$$P_{\text{end},i}(t) = \mathrm{softmax}\big(\mathbf{P}_i \mathbf{w}_{\text{end}}\big)_t, \quad (4)$$

$$P_{\text{selected}}(i) = \mathrm{softmax}\big(\hat{\mathbf{P}}^{\intercal} \mathbf{w}_{\text{selected}}\big)_i, \quad (5)$$

where $\hat{\mathbf{P}} = [\mathbf{P}_1^{[\text{CLS}]}, \ldots, \mathbf{P}_k^{[\text{CLS}]}] \in \mathbb{R}^{h\times k}$ and $\mathbf{w}_{\text{start}}, \mathbf{w}_{\text{end}}, \mathbf{w}_{\text{selected}} \in \mathbb{R}^h$ are learnable vectors. We compute a span score of the s-th to t-th words from the i-th passage as $P_{\text{start},i}(s) \times P_{\text{end},i}(t)$, and a passage selection score of the i-th passage as $P_{\text{selected}}(i)$.

During training, we sample one positive and $\tilde{m} - 1$ negative passages from the top 100 passages returned by the retrieval system (BM25 or DPR) for each question. $\tilde{m}$ is a hyper-parameter and we use $\tilde{m} = 24$ in all the experiments. The training objective is to maximize the marginal log-likelihood of all the correct answer spans in the positive passage (the answer string may appear multiple times in one passage), combined with the log-likelihood of the positive passage being selected. We use the batch size of 16 for large (NQ, TriviaQA, SQuAD) and 4 for small (TREC, WQ) datasets, and tune k on the development set. For experiments on small datasets under the *Multi* setting, in which using other datasets is allowed, we fine-tune the reader trained on Natural Questions to the target dataset. All experiments were done on eight 32GB GPUs.

6.2 Results

Table 4 summarizes our final end-to-end QA results, measured by *exact match* with the reference answer after minor normalization as in (Chen et al., 2017; Lee et al., 2019). From the table, we can

---

[10] FAISS configuration: we used HNSW index type on CPU, neighbors to store per node = 512, construction time search depth = 200, search depth = 128.

Training	Model	NQ	TriviaQA	WQ	TREC	SQuAD
Single	BM25+BERT (Lee et al., 2019)	26.5	47.1	17.7	21.3	33.2
Single	ORQA (Lee et al., 2019)	33.3	45.0	36.4	30.1	20.2
Single	HardEM (Min et al., 2019a)	28.1	50.9	-	-	-
Single	GraphRetriever (Min et al., 2019b)	34.5	56.0	36.4	-	-
Single	PathRetriever (Asai et al., 2020)	32.6	-	-	-	**56.5**
Single	REALM$_{\text{Wiki}}$ (Guu et al., 2020)	39.2	-	40.2	46.8	-
Single	REALM$_{\text{News}}$ (Guu et al., 2020)	40.4	-	40.7	42.9	-
Single	BM25	32.6	52.4	29.9	24.9	38.1
	DPR	**41.5**	56.8	34.6	25.9	29.8
	BM25+DPR	39.0	57.0	35.2	28.0	36.7
Multi	DPR	**41.5**	56.8	**42.4**	49.4	24.1
	BM25+DPR	38.8	**57.9**	41.1	**50.6**	35.8

Table 4: End-to-end QA (Exact Match) Accuracy. The first block of results are copied from their cited papers. REALM$_{\text{Wiki}}$ and REALM$_{\text{News}}$ are the same model but pretrained on Wikipedia and CC-News, respectively. *Single* and *Multi* denote that our Dense Passage Retriever (DPR) is trained using individual or combined training datasets (all except SQuAD). For WQ and TREC in the *Multi* setting, we fine-tune the reader trained on NQ.

see that higher retriever accuracy typically leads to better final QA results: in all cases except SQuAD, answers extracted from the passages retrieved by DPR are more likely to be correct, compared to those from BM25. For large datasets like NQ and TriviaQA, models trained using multiple datasets (Multi) perform comparably to those trained using the individual training set (Single). Conversely, on smaller datasets like WQ and TREC, the multi-dataset setting has a clear advantage. Overall, our DPR-based models outperform the previous state-of-the-art results on four out of the five datasets, with 1% to 12% absolute differences in exact match accuracy. It is interesting to contrast our results to those of ORQA (Lee et al., 2019) and also the concurrently developed approach, REALM (Guu et al., 2020). While both methods include additional pretraining tasks and employ an expensive end-to-end training regime, DPR manages to outperform them on both NQ and TriviaQA, simply by focusing on learning a strong passage retrieval model using pairs of questions and answers. The additional pretraining tasks are likely more useful only when the target training sets are small. Although the results of DPR on WQ and TREC in the single-dataset setting are less competitive, adding more question–answer pairs helps boost the performance, achieving the new state of the art.

To compare our pipeline training approach with joint learning, we run an ablation on Natural Questions where the retriever and reader are jointly trained, following Lee et al. (2019). This approach obtains a score of 39.8 EM, which suggests that our strategy of training a strong retriever and reader in isolation can leverage effectively available supervision, while outperforming a comparable joint training approach with a simpler design (Appendix D).

One thing worth noticing is that our reader does consider more passages compared to ORQA, although it is not completely clear how much more time it takes for inference. While DPR processes up to 100 passages for each question, the reader is able to fit all of them into one batch on a single 32GB GPU, thus the latency remains almost identical to the single passage case (around 20ms). The exact impact on throughput is harder to measure: ORQA uses 2-3x longer passages compared to DPR (288 word pieces compared to our 100 tokens) and the computational complexity is superlinear in passage length. We also note that we found $k = 50$ to be optimal for NQ, and $k = 10$ leads to only marginal loss in exact match accuracy (40.8 vs. 41.5 EM on NQ), which should be roughly comparable to ORQA's 5-passage setup.

7 Related Work

Passage retrieval has been an important component for open-domain QA (Voorhees, 1999). It not only effectively reduces the search space for answer extraction, but also identifies the support context for users to verify the answer. Strong sparse vector space models like TF-IDF or BM25 have been used as the standard method applied broadly to various QA tasks (e.g., Chen et al., 2017; Yang et al., 2019a,b; Nie et al., 2019; Min et al., 2019a; Wolfson et al., 2020). Augmenting text-based retrieval with external structured information, such as knowledge graph and Wikipedia hyperlinks, has also been explored recently (Min et al., 2019b; Asai et al., 2020).

The use of dense vector representations for retrieval has a long history since Latent Semantic Analysis (Deerwester et al., 1990). Using labeled pairs of queries and documents, discriminatively trained dense encoders have become popular recently (Yih et al., 2011; Huang et al., 2013; Gillick et al., 2019), with applications to cross-lingual document retrieval, ad relevance prediction, Web search and entity retrieval. Such approaches complement the sparse vector methods as they can potentially give high similarity scores to semantically relevant text pairs, even without exact token matching. The dense representation alone, however, is typically inferior to the sparse one. While not the focus of this work, dense representations from pretrained models, along with cross-attention mechanisms, have also been shown effective in passage or dialogue re-ranking tasks (Nogueira and Cho, 2019; Humeau et al., 2020). Finally, a concurrent work (Khattab and Zaharia, 2020) demonstrates the feasibility of full dense retrieval in IR tasks. Instead of employing the dual-encoder framework, they introduced a late-interaction operator on top of the BERT encoders.

Dense retrieval for open-domain QA has been explored by Das et al. (2019), who propose to retrieve relevant passages iteratively using reformulated question vectors. As an alternative approach that skips passage retrieval, Seo et al. (2019) propose to encode candidate answer phrases as vectors and directly retrieve the answers to the input questions efficiently. Using additional pretraining with the objective that matches surrogates of questions and relevant passages, Lee et al. (2019) jointly train the question encoder and reader. Their approach outperforms the BM25 plus reader paradigm on multiple open-domain QA datasets in QA accuracy, and is further extended by REALM (Guu et al., 2020), which includes tuning the passage encoder asynchronously by re-indexing the passages during training. The pretraining objective has also recently been improved by Xiong et al. (2020b). In contrast, our model provides a simple and yet effective solution that shows stronger empirical performance, without relying on additional pretraining or complex joint training schemes.

DPR has also been used as an important module in very recent work. For instance, extending the idea of leveraging hard negatives, Xiong et al. (2020a) use the retrieval model trained in the previous iteration to discover new negatives and construct a different set of examples in each training iteration. Starting from our trained DPR model, they show that the retrieval performance can be further improved. Recent work (Izacard and Grave, 2020; Lewis et al., 2020b) have also shown that DPR can be combined with generation models such as BART (Lewis et al., 2020a) and T5 (Raffel et al., 2019), achieving good performance on open-domain QA and other knowledge-intensive tasks.

8 Conclusion

In this work, we demonstrated that dense retrieval can outperform and potentially replace the traditional sparse retrieval component in open-domain question answering. While a simple dual-encoder approach can be made to work surprisingly well, we showed that there are some critical ingredients to training a dense retriever successfully. Moreover, our empirical analysis and ablation studies indicate that more complex model frameworks or similarity functions do not necessarily provide additional values. As a result of improved retrieval performance, we obtained new state-of-the-art results on multiple open-domain question answering benchmarks.

A Distant Supervision

When training our final DPR model using Natural Questions, we use the passages in our collection that best match the gold context as the positive passages. As some QA datasets contain only the question and answer pairs, it is thus interesting to see when using the passages that contain the answers as positives (i.e., the distant supervision setting), whether there is a significant performance degradation. Using the question and answer together as the query, we run Lucene-BM25 and pick the top passage that contains the answer as the positive passage. Table 5 shows the performance of DPR when trained using the original setting and the distant supervision setting.

B Alternative Similarity Functions & Triplet Loss

In addition to dot product (DP) and negative log-likelihood based on softmax (NLL), we also experiment with Euclidean distance (L2) and the triplet loss. We negate L2 similarity scores before applying softmax and change signs of question-to-positive and question-to-negative similarities when applying the triplet loss on dot product scores. The margin value of the triplet loss is set to 1. Table 6 summarizes the results. All these additional experiments are conducted using the same hyper-parameters tuned for the baseline (DP, NLL).

Note that the retrieval accuracy for our "baseline" settings reported in Table 5 (Gold) and Table 6 (DP, NLL) is slightly better than those reported in Table 3. This is due to a better hyper-parameter setting used in these analysis experiments, which is documented in our code release.

C Qualitative Analysis

Although DPR performs better than BM25 in general, the retrieved passages of these two retrievers actually differ qualitatively. Methods like BM25 are sensitive to highly selective keywords and phrases, but cannot capture lexical variations or semantic relationships well. In contrast, DPR excels at semantic representation, but might lack sufficient capacity to represent salient phrases which appear rarely. Table 7 illustrates this phenomenon with two examples. In the first example, the top scoring passage from BM25 is irrelevant, even though keywords such as *England* and *Ireland* appear multiple times. In comparison, DPR is able to return the correct answer, presumably by matching *"body of water"* with semantic neighbors such as *sea* and *channel*, even though no lexical overlap exists. The second example is one where BM25 does better. The salient phrase *"Thoros of Myr"* is critical, and DPR is unable to capture it.

	Top-1	**Top-5**	**Top-20**	**Top-100**
Gold	44.9	66.8	78.1	85.0
Dist. Sup.	43.9	65.3	77.1	84.4

Table 5: Retrieval accuracy on the development set of Natural Questions, trained on passages that match the gold context (Gold) or the top BM25 passage that contains the answer (Dist. Sup.).

Sim	**Loss**	**Retrieval Accuracy**			
		Top-1	Top-5	Top-20	Top-100
DP	NLL	**44.9**	**66.8**	**78.1**	**85.0**
	Triplet	41.6	65.0	77.2	84.5
L2	NLL	43.5	64.7	76.1	83.1
	Triplet	42.2	66.0	**78.1**	84.9

Table 6: Retrieval Top-k accuracy on the development set of Natural Questions using different similarity and loss functions.

D Joint Training of Retriever and Reader

We fix the passage encoder in our joint-training scheme while allowing only the question encoder to receive backpropagation signal from the combined (retriever + reader) loss function. This allows us to leverage the HNSW-based FAISS index for efficient low-latency retrieving, without reindexing the passages during model updates. Our loss function largely follows ORQA's approach, which uses log probabilities of positive passages selected from the retriever model, and correct spans and passages selected from the reader model. Since the passage encoder is fixed, we could use larger amount of retrieved passages when calculating the retriever loss. Specifically, we get top 100 passages for each question in a mini-batch and use the method similar to in-batch negative training: all retrieved passages' vectors participate in the loss calculation for *all* questions in a batch. Our training batch size is set to 16, which effectively gives 1,600 passages per question to calculate retriever loss. The reader still uses 24 passages per question, which are selected

Question	**Passage received by BM25**	**Passage retrieved by DPR**
What is the body of water between England and Ireland?	Title:British Cycling . . . **England** is not recognised as a region by the UCI, and there is no English cycling team outside the Commonwealth Games. For those occasions, British Cycling selects and supports the **England** team. Cycling is represented on the Isle of Man by the Isle of Man Cycling Association. Cycling in Northern **Ireland** is organised under Cycling Ulster, part of the all-Ireland governing **body** Cycling **Ireland**. Until 2006, a rival governing **body** existed, . . .	Title: Irish Sea . . . Annual traffic between Great Britain and **Ireland** amounts to over 12 million passengers and of traded goods. **The Irish Sea** is connected to the North Atlantic at both its northern and southern ends. To the north, the connection is through the North Channel between Scotland and Northern **Ireland** and the Malin Sea. The southern end is linked to the Atlantic through the St George's Channel between Ireland and Pembrokeshire, and the Celtic Sea. . . .
Who plays Thoros of Myr in Game of Thrones?	Title: No One (Game of Thrones) . . . He may be ”no one,” but there's still enough of a person left in him to respect, and admire who this girl is and what she's become. Arya finally tells us something that we've kind of known all along, that she's not no one, she's Arya Stark of Winterfell.” ”No One” saw the reintroduction of Richard Dormer and **Paul Kaye**, who portrayed Beric Dondarrion and **Thoros** of **Myr**, respectively, in the third season, . . .	Title: Pål Sverre Hagen Pål Sverre Valheim Hagen (born 6 November 1980) is a Norwegian stage and screen actor. He appeared in the Norwegian film ”Max Manus” and played Thor Heyerdahl in the Oscar-nominated 2012 film ”Kon-Tiki”. Pl Hagen was born in Stavanger, Norway, the son of Roar Hagen, a Norwegian cartoonist who has long been associated with Norwayś largest daily, ”VG”. He lived in Jtten, a neighborhood in the city of Stavanger in south-western Norway. . . .

Table 7: Examples of passages returned from BM25 and DPR. Correct answers are written in **blue** and the content words in the question are written in bold.

from the top 5 positive and top 30 negative passages (from the set of top 100 passages retrieved from the same question). The question encoder's initial state is taken from a DPR model previously trained on the NQ dataset. The reader's initial state is a BERT-base model. In terms of the end-to-end QA results, our joint-training scheme does not provide better results compared to the usual retriever/reader training pipeline, resulting in the same 39.8 exact match score on NQ dev as in our regular reader model training.

Distilling Structured Knowledge for Text-Based Relational Reasoning

Abstract

There is an increasing interest in developing text-based relational reasoning systems, which are capable of systematically reasoning about the relationships between entities mentioned in a text. However, there remains a substantial performance gap between NLP models for relational reasoning and models based on graph neural networks (GNNs), which have access to an underlying symbolic representation of the text. In this work, we investigate how the structured knowledge of a GNN can be distilled into various NLP models in order to improve their performance. We first pre-train a GNN on a reasoning task using structured inputs and then incorporate its knowledge into an NLP model (e.g., an LSTM) via *knowledge distillation*. To overcome the difficulty of cross-modal knowledge transfer, we also employ a *contrastive learning* based module to align the latent representations of NLP models and the GNN. We test our approach with two state-of-the-art NLP models on 12 different inductive reasoning datasets from the CLUTRR benchmark and obtain significant improvements.

1 Introduction

The task of text-based relational reasoning—where an agent must infer and compose relations between entities based on a passage of text—has received increasing attention in natural language processing (NLP) (Andreas, 2019). This task has been especially prominent in the context of systematic generalization in NLP, with synthetic datasets, such as CLUTTR and SCAN, being used to probe the ability of NLP models to reason in a systematic and logical way (Lake and Baroni, 2018; Sinha et al., 2019). More generally, these investigations dovetail with the rising prominence of relational reasoning throughout machine learning and cognitive science (Alexander et al., 2016; Battaglia et al., 2018; Hamilton et al., 2017).

However, despite the increased attention and research on text-based relational reasoning, serious challenges remain. Perhaps one of the biggest challenges is the persistent gap between the performance that can be achieved using NLP models and the performance of structured models—such as graph neural networks (GNNs)—which perform relational reasoning based on structured or symbolic inputs. This gap was made particularly evident in the the CLUTRR benchmark. CLUTRR includes relational reasoning problems that can be posed both in textual or symbolic form, and preliminary investigations using CLUTRR show that GNN-based models—which leverage the structured symbolic input—are able to achieve higher accuracy, better generalization, and are more robust than purely text-based systems (Sinha et al., 2019).

In this work, we investigate one potential avenue to close this gap. We design an approach to *distill* the structured knowledge learned by a GNN—which has access to the underlying symbolic representation of a reasoning problem—into an NLP model. Our goal is to do this knowledge distillation (Hinton et al., 2015) only during training so that the NLP model can achieve higher performance at test time, when only unstructured textual inputs are available. Due to the challenges inherent in cross-model knowledge distillation (Tian et al., 2020), we design an approach that combines both a KL-based distillation objective (Hinton et al., 2015) and a contrastive estimation loss (Hjelm et al., 2019), which aims to maximize the mutual information between the latent states of text-based NLP and graph-based GNN models.

Empirical results on 12 different datasets from the CLUTRR benchmark suite highlight the potential utility of this approach. We find that extending two state-of-the-art NLP models using our structured distillation approach significantly improves performance and that the gains are espe-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6782–6791,
November 16–20, 2020.

cially prominent in the context of noisy input data, on which we obtain an 13.6% relative improvement on accuracy.[1]

2 Related Work

Our work is closely related to recent research on machine reading comprehension (MRC), question answering (QA), and relational reasoning in NLP.

Prominent examples of large-scale QA benchmarks include datasets such as SQuAD (Rajpurkar et al., 2016) and TriviaQA (Joshi et al., 2017). However, these traditional datasets do not consider the reasoning aspect of MRC and only target extractive QA tasks. Usually, these tasks only require extracting a single fact (or span of text) and do not necessitate complex relational reasoning.

To address this shortcoming, there has been a surge of work tackling the relational reasoning and systematic generalization. Johnson et al. (2017) first proposed the CLEVR dataset that focuses on the relational reasoning aspect of visual question answering (VQA). Similarly, Sinha et al. (2019) released CLUTRR involving both text and graphs. These relational reasoning datasets also share inspirations with *multi-hop* QA, such as HotPotQA (Yang et al., 2018). Generally, the key distinction in the multi-hop setting is that an agent must reason about the relationship between multiple entities in order to answer a query.

Finally, the development of these relational reasoning datasets has also dovetailed with an increasing interest in combining NLP models with graph neural networks (GNNs) (Hamilton et al., 2017). This includes the use of GNNs for processing syntax trees (Marcheggiani and Titov, 2017), as well as the use of GNNs for reasoning over entity graphs extracted from text (Fang et al., 2019).

3 Task and Dataset

We use the CLUTRR benchmark suite as a testbed for our investigations (Sinha et al., 2019). CLUTRR is a relational reasoning dataset that requires an agent to infer family relationships between different characters in a passage of text. Importantly, the dataset was constructed in a *semi-synthetic* fashion, which facilitates a principled investigation of text-based relational reasoning. Every question-answer pair in CLUTRR was generated based on underlying family graph structure, where crowd workers were instructed to paraphrase natural language stories from a given set of family relations. To answer a question in the CLUTRR dataset, the model must infer the family relationship between a pair of entities, whose relationship is not explicitly mentioned. Doing so requires extracting the family relationships mentioned in the text and deducing the relationship between the query entities through inductive reasoning (e.g., learning that *a parent of a parent is a grandparent*.

A key element of CLUTRR is that it provides both text representations and the underlying family graphs used to generate the questions. This allowed Sinha et al. (2019) to compare the performance of NLP models, which use only text, with GNN-based models, which reason upon the underlying graph structure, and their analysis revealed a substantial gap in performance between the NLP and GNN models—a gap which we seek to address here.

Moreover, following Sinha et al. (2019), the semi-synthetic nature of CLUTRR allows us to evaluate performance in different settings based on the structure of the underlying family graph and the difficulty of the query, including evaluating performance on queries that require a varying number of steps of reasoning and family graphs that include different types of noisy facts (i.e., distractors).

4 Methodology

We now describe our approach for *structured distillation*, which involves improving the performance of an NLP model by distilling structured knowledge from a GNN (Fig. 1).

Graph encoder and text encoder. Our base model architectures follow Sinha et al. (2019), with minor improvements. As shown in Fig. 1, we implement both a *graph encoder*, which generates a vector embedding $\mathbf{p}_{\text{graph}}$ based on the input family graph, as well as a *text encoder*, which generates a vector embedding $\mathbf{p}_{\text{text}}$ of the input text. We use a variant of the graph isomorphism network (GIN) architecture Xu et al. (2019) as our graph encoder, since we found this model to outperform the GNN from Sinha et al. (2019). For our text encoders, we experiment with the two top-performing NLP models from Sinha et al. (2019): (1) a variation of an LSTM model with attention (Bahdanau et al., 2015) and (2) an adapted version of the MAC architecture (Hudson and Manning, 2018). See Appendix A for details on the model architectures.

---

[1] Code and data can be found at `https://github.com/djdongjin/gnnlogic`.

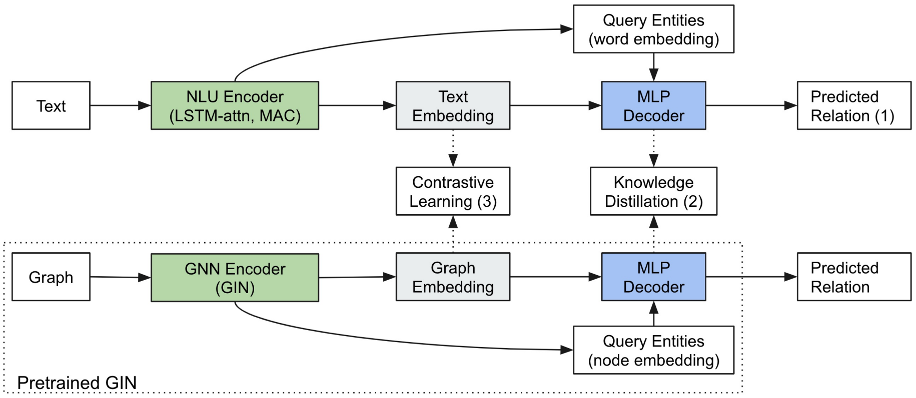

Figure 1: Model architecture with both knowledge distillation and contrastive learning. The supervised signal is produced in (1) with cross-entropy loss. We first pretrain a GIN model which is used later for knowledge distillation and contrastive learning. Knowledge distillation module (2) aligns the predictions made by a GIN model and an NLP model, via KL-divergence loss (Eq. 1). The contrastive learning module (3) aligns the latent space of these two models via a MI-based contrastive loss (Eq. 2).

Integration with knowledge distillation. We utilize knowledge distillation as a surrogate for the structured knowledge transfer from GNNs to NLP models. We take the text encoder as the student and a pretrained GNN as the teacher. After generating the representations of the paragraph $\mathbf{p}_{\text{text}}$ and the question entities $(\mathbf{h}^{(m)}, \mathbf{h}^{(n)})$, the text encoder sends the concatenation of these embeddings to an MLP decoder to obtain the logits $\mathbf{z}_{\text{text}}$. Similarly, a pretrained GNN can produce logits $\mathbf{z}_{\text{graph}}$ from a given underlying graph. We feed the two logits into a KL-based distillation term:

$$\mathcal{L}_{\text{KD}} = T^2 \cdot \text{KL}\left(\sigma\left(\frac{\mathbf{z}_{\text{text}}}{T}\right) \middle| \sigma\left(\frac{\mathbf{z}_{\text{graph}}}{T}\right)\right), \quad (1)$$

where σ is the softmax function and T is the temperature hyperparameter of softmax.

Integration with contrastive estimation. Although knowledge distillation enables NLP models to learn directly from the prediction of GNNs, there is no regularization between their latent representations. We mitigate this by using a mutual information (MI) based contrastive learning method to maximize the MI between graph representations from GNNs and paragraph representations from NLP models. Under our setting, we pair the text representation $\mathbf{p}_{\text{text}}$ and the graph representation $\mathbf{p}_{\text{graph}}$ of the same example as *positive pairs*, and take other graph representations in the same batch as *negative pairs*. Then, following Hjelm et al. (2019), we use a Jensen-Shannon estimator to compute the MI, resulting in the contrastive objective:

$$\begin{aligned}\mathcal{L}_{\text{MI}} = -\widehat{\mathcal{I}}(\mathbf{p}_{\text{text}}, \mathbf{p}_{\text{graph}}) = \\ -\mathbb{E}_{\mathbb{P}(p,g|c=1)}\left[-\text{sp}(-T(\mathbf{p}_{\text{text}}, \mathbf{p}_{\text{graph}}))\right] \\ +\mathbb{E}_{\mathbb{P}(p,g|c=0)}\left[\text{sp}(T(\mathbf{p}_{\text{text}}, \mathbf{p}_{\text{graph}}))\right], \quad (2)\end{aligned}$$

where $\mathbb{P}(p, g|c = 1)$ and $\mathbb{P}(p, g|c = 0)$ indicate the conditional probability of whether the given paragraph p and graph g correspond to the same question-answering example ($c = 1$) or not ($c = 0$). We use sp to denote the softplus function, and we use T to denote MLP that is trained to discriminate between positive and negative pairs.

Note that the contrastive loss in Eq. 2 is also composable with both the supervised cross-entropy loss (from the original CLUTRR task) and knowledge distillation loss (Eq. 1).

5 Experiments

Our key experimental question is whether an NLP model can be improved by distilling structured knowledge from a GNN. We investigate this question using the GNN and NLP models defined in the previous section, and we follow the experimental protocol from Sinha et al. (2019). We investigate if and how structured distillation can improve generalization and robustness. In all experiments, the NLP models only have access to information from the GNN during training. Appendix A contains detailed hyperparameter information.

Impact on generalization. We first test on the CLUTRR benchmark tasks where the model must generalize to reasoning problems that require more steps of reasoning than those seen during training.

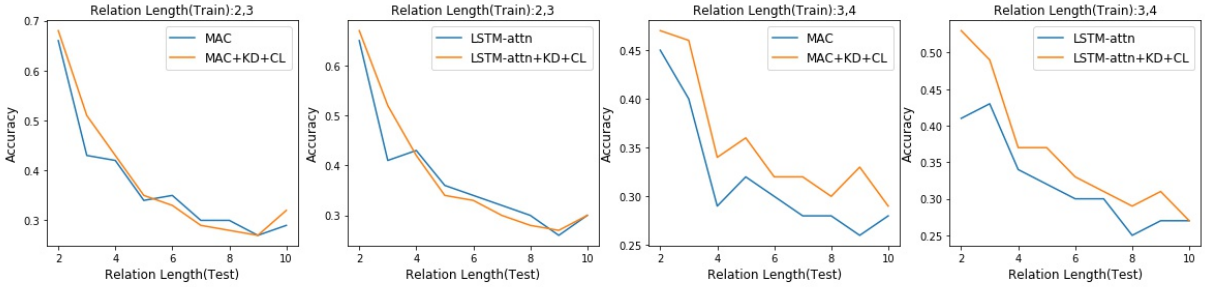

Figure 2: Accuracy on test sets with relation length of 2-10. KD denotes knowledge distillation; CL denotes the MI-based contrastive learning. All results are averaged over 5 runs with different random seeds. The maximum standard deviation is less than 0.05. Detailed accuracy values can be found in Appendix B.

Dataset		Model			
Relation length	Distractor	MAC	MAC+KD+CL	LSTM-attn	LSTM-attn+KD+CL
2,3	Clean	0.54	0.59	0.54	**0.60**
2,3	Supporting	0.54	0.57	0.45	**0.59**
2,3	Irrelevant	0.47	**0.52**	0.40	**0.52**
2,3	Disconnected	0.40	**0.45**	0.41	0.42

Table 1: Accuracy on test sets with different distractors. All results are averaged over 5 runs with different random seeds. The maximum standard deviation is less than 0.05.

Fig. 2 shows the results when we set the number of training reasoning steps to be $(2, 3)$ and $3, 4$, and where the test examples require between 2 and 10 reasoning steps. Both of the two NLP model obtain higher average performance on test sets with our proposed method. Interestingly, however, the positive impact of structured distillation is most apparent when training on examples with longer reasoning paths. Appendix B contains results from training on other reasoning path lengths, which are consistent with the trends in Fig. 2.

Impact on robustness. We next investigated the impact of structured generalization on how robust the NLP models are with respect to noise. Following Sinha et al. (2019), we examined settings where different types of noise facts are added into the CLUTRR reasoning problems. Tab. 1 shows the results where we train and test on reasoning problems with different types of noise. Here, we see that structured distillation consistently and substantially improves performance of both NLP models, providing an average 13.6% relative improvement on accuracy. The results also shows the distillation and contrastive estimation based on GNNs help NLP models ignore noise. However, their fundamental architecture difference limits the extent to which NLP models can learn from GNNs. Appendix C contains additional results, where the train and test sets do not have the same noise added and which further support this trend.

Ablation analysis. We found that both knowledge distillation and contrastive estimation (Eq. 1-2) losses are necessary in tandem to obtain the benefits of structured generalization. We found no significant gains when adding one loss alone. Appendix D contains detailed results on these ablations.

6 Discussion and Conclusion

Our structured distillation approach achieves promising results. Most prominently, the structured distillation approach significantly improved the performance of the NLP models in settings where noisy facts were added to the CLUTRR reasoning problems. The GNN-based models are particularly strong in this setting (see Appendix C), and this suggests that transferring knowledge about the relevancy of facts from structured to unstructured models may be a promising direction.

However, at the same time, the improvements for generalization were less substantial, indicating that some reasoning capacities are difficult to distill in this manner. Moreover, despite the improvements we observed, the performance of the NLP models is still substantially below the performance of the GNN teacher used for distillation (see Appendices B & C), highlighting that significant work that remains to close the gap between the reasoning performance of text-based and GNN-based models.

Acknowledgments

This research was funded in part by an academic grant from Microsoft Research, as well as a Canada CIFAR AI Chair, held by Prof. Hamilton at the Mila - Quebec AI Institute. We also thank Compute Canada for providing computational resources.

A Hyperparameters

For all experiments in this section, we train the model for 50 epochs with a batch size of 100. We use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001.

In the encoder part, we use 100-dimensional word embeddings and train them from scratch for all NLP models. For LSTM-based models, we use a 2-layer bidirectional LSTM with 100 hidden units. For the MAC network, we use 6 MAC cell units (6 reasoning steps), and 0.2 dropout (Srivastava et al., 2014) on all updates in the three units to avoid overfitting. We use a two-layer MLP with 100 hidden units as the score function for all attention modules. For the GIN model, we use 2 GIN layers with 100-dimensional node embeddings and 20-dimensional edge embeddings. All node embeddings and edge embeddings are uniformly initialized.

In the decoder part, we use MLPs with the same architecture (2 layers, 200 hidden units) for all encoders. The inputs will be the concatenation of the graph representation and two question node representations if the encoder is GIN, or the concatenation of the paragraph representation and two word representations if the encoder is an NLP model.

All hyperparameters were tuned based on the validation accuracy. Full setups and hyperparameters can be found in the corresponding configuration files in our codebase after releasing.

For knowledge distillation, the temperature used to compute KL-divergence loss is 3.5. For contrastive learning, the negative sampling size is equal to the batch size (e.g. 100). The weighting hyperparameters for supervised cross-entropy loss, KL-divergence loss and MI maximization loss are chosen from $\{[0.1, 0.6, 0.3], [1, 1, 5]\}$.

B Full Results on Generalization

Tab. 2 shows all empirical results on datasets that have different relation lengths in training sets. we observe that our proposed method can improve the performance of vanilla NLP models in 7 out of 8 CLUTRR datasets. Another observation is that the NLP models still cannot learn the superb generalization ability of GNNs regardless of the difficulty of the tasks. The improvement of reasoning ability, measured by accuracy, is most significant when the training set and test set have the same reasoning length. This is not surprising as the generalization ability is a known issue in modern NLP models and is an ongoing research topic (Bahdanau et al., 2019; Andreas, 2019). However, the generalization is in parallel with our contribution that is to improve the reasoning ability of NLP models. We refer readers to (Bahdanau et al., 2019; Andreas, 2019) for a comprehensive understanding of current progress in generalization of NLP models.

C Full Result on Robustness

Tab. 3 shows results on the CLUTRR tasks with various. For each dataset, the training set contains a single type of noise, and we test on four test sets, each of which has one different type of distractor. Our augmented models via knowledge distillation (KD) and contrastive learning (CL) still outperform corresponding baselines by 3%-13%, depending on datasets and models. The MAC+KD+CL achieves the best accuracy on three out of four CLUTRR datasets, and LSTM-attn+KD+CL achieves the best on the left one. This shows that our method is able to improve the robustness of NLP models as well.

D Ablation Study on Contrastive Learning and Knowledge Distillation

We enable knowledge distillation and MI-based contrastive learning by weighing their corresponding losses as well as the supervised cross-entropy loss. The three of them can be treated as individual modules, each of which has different effectiveness. The cross-entropy loss enables a model to learn from supervised labels; the knowledge distillation loss enables a model to learn from soft targets produced by a teacher model (in our setting, a GIN); the contrastive learning loss enables a model to learn latent representations (embeddings) in an unsupervised manner.

Tab. 4 shows the ablation study among these three objectives. First we can observe that the best models trained with our method outperforms the vanilla MAC network by 3%-13%. Surprisingly, a MAC network trained with only soft signals produced by a GIN teacher can match the performance of a MAC network trained with supervised signals. If a MAC network is trained with both the supervised signal and soft signal, it outperforms the vanilla MAC network on 3 out of 4 CLUTRR datasets. When the MI-based contrastive learning loss is added, the MAC network performs the best on all the four datasets. These observations show that both knowledge distillation and contrastive learning are important for the model performance.

Model — Test relation length	2	3	4	5	6	7	8	9	10

MAC+KD+CL	0.48	0.50	0.52	0.46
Training set: disconnected distractor				
MAC	0.40	0.41	0.39	0.40
MAC+KD(w/o label)	0.36	0.45	0.41	0.42
MAC+KD(w/ label)	0.40	0.41	0.39	0.40
MAC+KD+CL	0.47	0.45	0.44	0.45

Table 4: Ablation study on different learning objectives. MAC means a MAC network trained with only supervised signals. MAC+KD is a MAC network with knowledge distillation, and we can choose to use labels together with KD (w/ label) or only use soft target produced by a teacher model (w/o label). MAC+KD+CL is a MAC network trained with all three objectives: supervised loss, knowledge distillation loss, and contrastive learning loss. We also tried a model trained with only contrastive learning objective. Its performance is too worse and thus we didn't include it in comparison. A possible reason is that a solo contrastive learning based model is usually trained in two separate periods in which we train an encoder first with contrastive learning, and then train a decoder with labels according to the evaluation task. In our setting, however, we train an encoder and a decoder all together in an end-to-end manner. All results are averaged over 5 runs with different random seeds. The maximum standard deviations is less than 0.05.

Asking without Telling: Exploring Latent Ontologies in Contextual Representations

Julian Michael[1]*, **Jan A. Botha**[2], **and Ian Tenney**[2]

Abstract

The success of pretrained contextual encoders, such as ELMo and BERT, has brought a great deal of interest in what these models learn: do they, without explicit supervision, learn to encode meaningful notions of linguistic structure? If so, how is this structure encoded? To investigate this, we introduce *latent subclass learning* (LSL): a modification to classifier-based probing that induces a latent categorization (or *ontology*) of the probe's inputs. Without access to fine-grained gold labels, LSL extracts *emergent* structure from input representations in an interpretable and quantifiable form. In experiments, we find strong evidence of familiar categories, such as a notion of personhood in ELMo, as well as novel ontological distinctions, such as a preference for fine-grained semantic roles on core arguments. Our results provide unique new evidence of emergent structure in pretrained encoders, including departures from existing annotations which are inaccessible to earlier methods.

1 Introduction

The success of self-supervised pretrained models in NLP (Devlin et al., 2019; Peters et al., 2018a; Radford et al., 2019; Lan et al., 2020) on many tasks (Wang et al., 2018, 2019b) has stimulated interest in how these models work, and what they learn about language. Recent work on model analysis (Belinkov and Glass, 2019) indicates that they may learn a lot about linguistic structure, including part of speech (Belinkov et al., 2017a), syntax (Blevins et al., 2018; Marvin and Linzen, 2018), word sense (Peters et al., 2018a; Reif et al., 2019), and more (Rogers et al., 2020).

Many of these results are based on *predictive methods*, such as probing, which measure how well a linguistic variable can be predicted from intermediate representations. However, the ability of supervised probes to fit weak features makes it difficult to produce unbiased answers about how those representations are structured (Saphra and Lopez, 2019; Voita et al., 2019). *Descriptive methods* like clustering and visualization explore this structure directly, but provide limited control and often regress to dominant categories such as lexical features (Singh et al., 2019) or word sense (Reif et al., 2019). This leaves open many questions: *how* are linguistic features like entity types, syntactic dependencies, or semantic roles represented by an encoder like ELMo (Peters et al., 2018a) or BERT (Devlin et al., 2019)? To what extent do familiar categories like PropBank roles or Universal Dependencies appear naturally? Do these unsupervised encoders learn their own categorization of language?

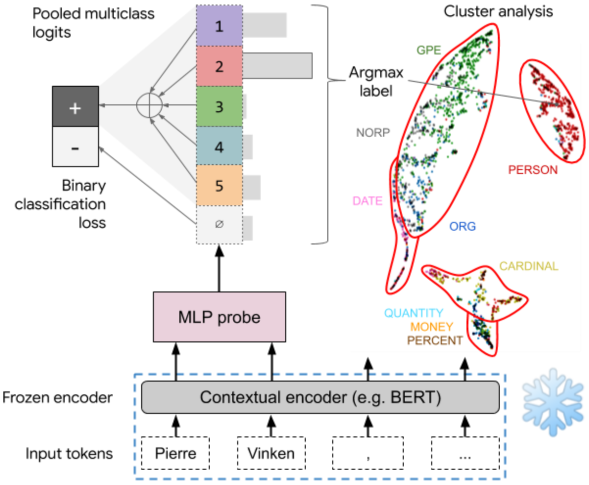

Figure 1: LSL overview. A probing classifier over contextual embeddings produces multi-class *latent logits*, which are marginalized into a single logit trained on binary classification. In this example, "Pierre Vinken" is identified as a named entity and assigned to latent class 2, which aligns well with the PERSON label. We treat the classes as clusters representing a latent ontology that describes the underlying representation space. Figure 2 visualizes latent logits in more detail.

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6792–6812,
November 16–20, 2020.

To tackle these questions, we propose a systematic way to extract *latent ontologies*, or discrete categorizations of a representation space, which we call *latent subclass learning* (LSL); see Figure 1 for an overview. In LSL, we use a binary classification task (such as detecting entity mentions or syntactic dependency arcs) as weak supervision to induce a set of latent clusters relevant to that task (*i.e.*, entity or dependency types). As with *predictive* methods, the choice of task allows us to explore varied phenomena, and induced clusters can be quantified and compared to gold annotations. But also, as with *descriptive* methods, our clusters can be inspected and qualified directly, and observations have high specificity: agreement with external (*e.g.*, gold) categories provides strong evidence that those categories are salient in the representation space.

We describe the LSL classifier in Section 3, and apply it to the edge probing paradigm (Tenney et al., 2019b) in Section 4. In Section 5 we evaluate LSL on multiple encoders, including ELMo and BERT. We find that LSL induces stable and consistent ontologies, which include both striking rediscoveries of gold categories—for example, ELMo discovers *personhood* of named entities and BERT has a notion of *dates*—and novel ontological distinctions—such as fine-grained core argument semantic roles—which are not easily observed by fully supervised probes. Overall, we find unique new evidence of emergent latent structure in our encoders, while also revealing new properties of their representations which are inaccessible to earlier methods.

2 Background

Predictive analysis A common form of model analysis is *predictive*: assessing how well a linguistic variable can be predicted from a model, whether in intrinsic behavioral tests (Goldberg, 2019; Marvin and Linzen, 2018; Petroni et al., 2019) or extrinsic *probing tasks*.

Probing involves training lightweight classifiers over features produced by a pretrained model, and assessing the model's knowledge by the probe's performance. Probing has been used for low-level properties such as word order and sentence length (Adi et al., 2017; Conneau et al., 2018), as well as phenomena at the level of syntax (Hewitt and Manning, 2019), semantics (Tenney et al., 2019b; Liu et al., 2019b; Clark et al., 2019), and discourse structure (Chen et al., 2019). Error analysis on probes has been used to argue that BERT may simulate sequential decision making across layers (Tenney et al., 2019a), or that it encodes its own, soft notion of syntactic distance (Reif et al., 2019).

Predictive methods such as probing are *flexible*: Any task with data can be assessed. However, they only track predictability of pre-defined categories, limiting their descriptive power. In addition, a powerful enough probe, given enough data, may be insensitive to differences between encoders, making it difficult to interpret results based on accuracy (Saphra and Lopez, 2019; Zhang and Bowman, 2018). So, many probing experiments appeal to the *ease of extraction* of a linguistic variable (Pimentel et al., 2020). Existing work has measured this by controlling for probing model capacity, either using relative claims between layers and encoders (Belinkov et al., 2017b; Blevins et al., 2018; Tenney et al., 2019b; Liu et al., 2019a) or using explicit measures to estimate and trade off capacity with accuracy (Hewitt and Liang, 2019; Voita and Titov, 2020). An alternative is to control *amount of supervision*, by restricting training set size (Zhang and Bowman, 2018), comparing learning curves (Talmor et al., 2019), or using description length with online coding (Voita and Titov, 2020).

We extend this further by removing the distinction between gold categories in the training data and reducing the supervision to binary classification, as explained in Section 3. This extreme measure makes our test *high specificity*, in the sense that positive results—*i.e.*, when comprehensible categories are recovered by our probe—are much stronger, since a category must be essentially *invented* without direct supervision.

Descriptive analysis In contrast to predictive methods, which assess an encoder with respect to particular data, *descriptive* methods analyze models on their own terms, and include clustering, visualization (Reif et al., 2019), and correlation analysis techniques (Voita et al., 2019; Saphra and Lopez, 2019; Abnar et al., 2019; Chrupała and Alishahi, 2019). Descriptive methods produce high-specificity tests of what structure is present in the model, and facilitate discovery of new patterns that were not hypothesized prior to testing. However, they lack the flexibility of predictive methods. Clustering results tend to be dominated by principal components of the embedding space, which correspond to only some salient aspects of linguistic knowledge, such as lexical features (Singh et al., 2019) and word sense (Reif et al., 2019). Alterna-

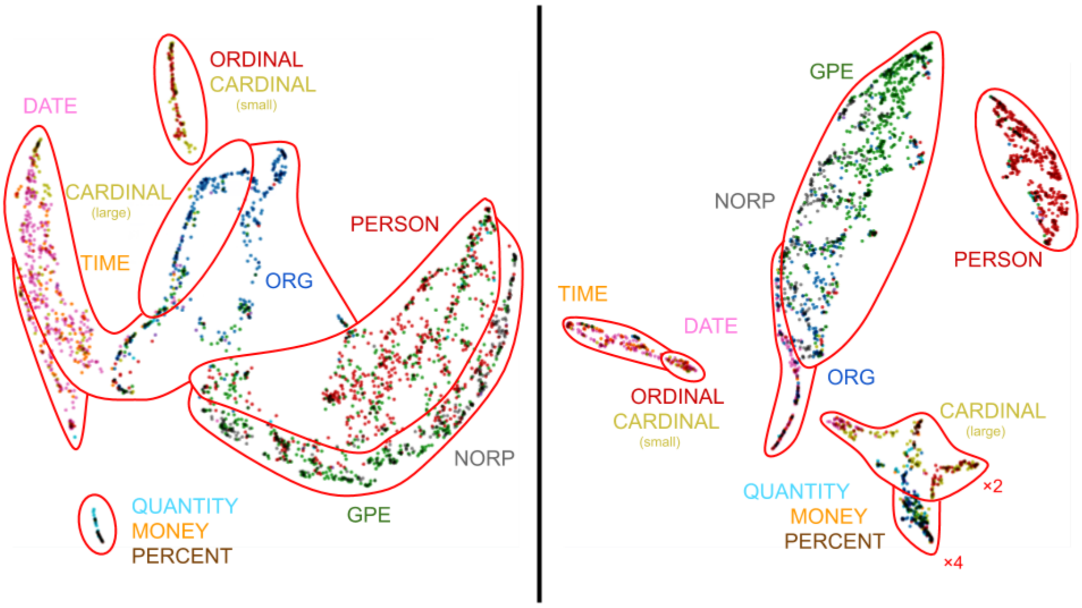

Figure 2: Latent logit vectors from BERT (left) and ELMo (right) for a sample from the Named Entities development set visualized in the Embedding Projector (Smilkov et al., 2016) using UMAP (McInnes et al., 2018), which is designed to preserve local clustering structure in a low dimensional visualization. Points are colored by gold label, and induced clusters are outlined in red. ELMo has a clear notion of personhood (PERSON), while BERT groups people with geopolitical entities (GPE) and nationalities (NORP). BERT strongly identifies dates (DATE) and organizations (ORG), and both models group numeric/quantitative entities together. Both models separate small CARDINAL numbers (roughly, seven or less) and group them with ORDINALs, separate from larger CARDINALs. The outlined areas in the bottom-right of the ELMo visualization include 2 and 4 induced clusters.

tively, more targeted analysis techniques generally have a restricted inventory of inputs, such as layer mixing weights (Peters et al., 2018b), transformer attention distributions (Clark et al., 2019), or pairwise influence between tokens (Wu et al., 2020). As a result of these issues, it is more difficult to discover the underlying structure corresponding to rich, layered ontologies. Our approach retains the advantages of descriptive methods, while admitting more control as the choice of binary classification targets can guide the LSL model to discover structure relevant to a particular linguistic task.

Linguistic ontologies Questions of what encoders learn about language require well-defined *linguistic ontologies*, or meaningful categorizations of inputs, to evaluate against. Most analysis work uses formalisms from the classical NLP pipeline, such as part-of-speech and syntax from the Penn Treebank (Marcus et al., 1993) or Universal Dependencies (Nivre et al., 2015), semantic roles from PropBank (Palmer et al., 2005) or Dowty (1991)'s Proto-Roles (Reisinger et al., 2015), and named entities, which have a variety of available ontologies (Pradhan et al., 2007; Ling and Weld, 2012; Choi et al., 2018). Work on ontology-free, or *open*, representations suggests that the linguistic structure captured by traditional ontologies may be encoded in a variety of possible ways (Banko et al., 2007; He et al., 2015; Michael et al., 2018) while being annotatable at large scale (FitzGerald et al., 2018). This raises the question: when looking for linguistic knowledge in pretrained encoders, what exactly should we expect to find? Predictive methods are useful for fitting an encoder to an existing ontology; but do our encoders latently hold their own ontologies as well? If so, what do they look like? That is the question we investigate in this work.

3 Approach

We propose a way to extract latent linguistic ontologies from pretrained encoders and systematically compare them to existing gold ontologies. We use a classifier based on *latent subclass learning* (Section 3.1), which is applicable in any binary classification setting.[1] We propose several quantitative metrics to evaluate the induced ontologies (Section 3.2), providing a starting point for qualitative analysis (Section 5) and future research.

---

[1] A similar classifier was concurrently developed and presented for use in model distillation by Müller et al. (2020).

3.1 Latent Subclass Learning

Consider a logistic regression classifier over inputs $\mathbf{x} \in \mathbb{R}^d$. It outputs probabilities according to the following formula:

$$\mathrm{P}(y \mid \mathbf{x}) = \sigma(\mathbf{w}^\top \mathbf{x}),$$

where $\mathbf{w} \in \mathbb{R}^d$ is a learned parameter. Instead, we propose the *latent subclass learning* classifier:

$$\mathrm{P}_{\mathrm{LSL}}(y \mid \mathbf{x}) = \sigma\left(\log \sum_i^N e^{\mathbf{W}_i \mathbf{x}}\right),$$

where $\mathbf{W} \in \mathbb{R}^{N \times d}$ is a parameter matrix, and N is a hyperparameter corresponding to the number of latent classes.

This corresponds to N+1-way multiclass logistic regression with a fixed 0 baseline for a null class, but trained on binary classification by marginalizing over the N non-null classes (Figure 1). The vector $\mathbf{W}\mathbf{x} \in \mathbb{R}^N$ may then be treated as a set of *latent logits* for a random variable $C(\mathbf{x}) \in \{1, \ldots, N\}$ defined by the softmax distribution. Taking the hard maximum of $\mathbf{W}\mathbf{x}$ assigns a latent class $\hat{C}(\mathbf{x})$ to each input, which may be viewed as a *weakly supervised clustering*, learned on the basis of external supervision but not explicitly optimized to match prior gold categories.

For the loss $\mathcal{L}_{\mathrm{LSL}}$, we use the cross-entropy loss on $\mathrm{P}_{\mathrm{LSL}}$. However, this does not necessarily encourage a diverse, coherent set of clusters; an LSL classifier may simply choose to collapse all examples into a single category, producing an uninteresting ontology. To mitigate this, we propose two *clustering regularizers*.

Adjusted batch-level negative entropy We wish for the model to induce a diverse ontology. One way to express this is that the expectation of C has high entropy, *i.e.*, we wish to maximize

$$\mathrm{H}(\mathbb{E}_{\mathbf{x}}\, C(\mathbf{x})).$$

In practice, we use the expectation over a batch. The maximum value this can take is the entropy of the uniform distribution over N items, or $\log N$. Therefore, we wish to minimize the *adjusted batch-level negative entropy loss*:

$$\mathcal{L}_{\text{be}} = \log N - \mathrm{H}(\mathbb{E}_{\mathbf{x}}\, C(\mathbf{x})),$$

which takes values in $[0, \log N]$.

Instance-level entropy In addition to using all latent classes in the expected case, we also wish for the model to assign a single coherent class label to each input example. This can be done by minimizing the *instance-level entropy loss*:

$$\mathcal{L}_{\text{ie}} = \mathbb{E}_{\mathbf{x}}\, \mathrm{H}(C(\mathbf{x})).$$

This also takes values in $[0, \log N]$, and we compute the expectation over a batch.

Loss We optimize the regularized LSL loss

$$\mathcal{L}_{\mathrm{LSL}} + \alpha \mathcal{L}_{\text{be}} + \beta \mathcal{L}_{\text{ie}},$$

where α and β are hyperparameters, via gradient descent. Together, the regularizers encourage a balanced solution where the model uses many clusters yet gives each input a distinct assignment. Note that if $\alpha = \beta$, the this objective maximizes the mutual information between $\mathbf{x}$ and C, encouraging the ontology to encode as much information as possible about the training data while still supporting the binary classification objective.

3.2 Metrics

Since our interest is in descriptively analyzing encoders' latent ontologies, there are no normatively 'correct' categories. However, we can leverage existing gold ontologies—such as PropBank role labels or Universal Dependencies—to quantify our results in terms of well-understood categories. For the following metrics, we consider only points in the gold positive class.

B^3 B-cubed (or B^3) is a standard clustering metric (Bagga and Baldwin, 1998; Amigó et al., 2009) which calculates the precision and recall of each point's predicted cluster against its gold cluster, averaging over points. It allows for label-wise scoring by restricting to points with specific gold labels, allowing for fine-grained analysis, *e.g.*, of whether a gold label is concentrated in few predicted clusters (high recall) or well-separated from other labels (high precision).

Normalized PMI Pointwise mutual information (PMI) is commonly used as an association measure reflecting how likely two items (such as tokens in a corpus) are to occur together relative to chance (Church and Hanks, 1989). *Normalized* PMI (nPMI; Bouma, 2009) is a way of factoring out the effect of item frequency on PMI. Formally, the nPMI of two items x and y is

$$\left(\log\frac{\mathrm{P}(x,y)}{\mathrm{P}(x)\,\mathrm{P}(y)}\right)\Big/ -\log(\mathrm{P}(x,y))\ ,$$

taking the limit value of -1 when they never occur together, 1 when they only occur together, and 0 when they occur independently. We use nPMI to analyze the co-occurrence of *gold labels* in *predicted clusters*: A pair of gold labels with high nPMI are preferentially grouped together by the induced ontology, whereas two labels with low nPMI are preferentially distinguished.

Plotting pairwise nPMI of gold labels allows us to see specific ways the induced clustering agrees or disagrees with a gold reference (Section 5, Figure 3). Since nPMI is information-theoretic and chance-corrected, it is a reliable indicator of the degree of information about gold labels contained in a set of predicted clusters. However, it is relatively insensitive to cluster granularity (*e.g.*, the total number of predicted categories, or whether a single gold category is split into many different predicted clusters), which is better understood through our other metrics.

Diversity We desire fine-grained ontologies with many meaningful classes. Number of attested classes may not be a good measure of this, since it could include classes with very few members and no broad meaning. So we propose *diversity*:

$$\exp(\mathrm{H}(\mathbb{E}_{\mathbf{x}}\,\hat{C}(\mathbf{x}))).$$

This increases as the clustering becomes more fine-grained and evenly distributed, with a maximum of N when $\mathrm{P}(\hat{C})$ is uniform. More generally, exponentiated entropy is sometimes referred to as the *perplexity* of a distribution, and corresponds (softly) to the number of classes required for a uniform distribution of the same entropy. In that sense, it may be regarded as the effective number of classes in an ontology. We use the predicted class $\hat{C}$ rather than its distribution C because we care about the diversity of the model's clustering, and not just uncertainty in the model.

Uncertainty In order for our learned classes to be meaningful, we desire distinct and coherent clusters. To measure this, we propose *uncertainty*:

$$\mathbb{E}_{\mathbf{x}}\exp(\mathrm{H}(C(\mathbf{x}))).$$

This is also related to perplexity, but unlike diversity, it takes the expectation over the input after calculating the perplexity of the distribution. This reflects how many classes, on average, the model is confused between when provided with an input. Low values correspond to coherent clusters, with a minimum of 1 when every latent class is assigned with full confidence. As with diversity, we take the expectation over the evaluation set.

4 Experimental Setup

We adopt a similar setup to Tenney et al. (2019b) and Liu et al. (2019a), training probing models over several contextualizing encoders on a variety of linguistic tasks.

4.1 Tasks

We cast several structure labeling tasks from Tenney et al. (2019b) as binary classification by adding negative examples, bringing the positive to negative ratio to 1:1 where possible.

Named entity labeling requires labeling noun phrases with entity types, such as person, location, date, or time. We randomly sample non-entity noun phrases as negatives.

Nonterminal labeling requires labeling phrase structure constituents with syntactic types, such as noun phrases and verb phrases. We randomly sample non-constituent spans as negatives.

Syntactic dependency labeling requires labeling token pairs with their syntactic relationship, such as a subject, direct object, or modifier. We randomly sample non-attached token pairs as negatives.

Semantic role labeling requires labeling predicates (usually verbs) and their arguments (usually syntactic constituents) with labels that abstract over syntactic relationships in favor of more semantic notions such as *agent*, *patient*, modifier roles involving, *e.g.*, time and place, or predicate-specific roles. We draw the closest non-attached predicate-argument pairs as negatives.

We use the English Web Treebank part of Universal Dependencies 2.2 (Silveira et al., 2014) for dependencies, and the English portion of Ontonotes 5.0 (Weischedel et al., 2013) for other tasks.

4.2 Encoders

We run experiments on the following encoders:

ELMo (Peters et al., 2018a) is the concatenation of representations from 2-layer LSTMs (Hochreiter and Schmidhuber, 1997) trained with forward and

	Named Entities				Universal Dependencies

backward language modeling objectives. We use the publicly available instance[2] trained on the One Billion Word Benchmark (Chelba et al., 2014).

BERT (Devlin et al., 2019) is a deep Transformer stack (Vaswani et al., 2017) trained on masked language modeling and next sentence prediction tasks. We use the 24-layer BERT-large instance[3] trained on about 2.3B tokens from English Wikipedia and BooksCorpus (Zhu et al., 2015).

BERT-lex is a lexical baseline, using only BERT's context-independent wordpiece embedding layer.

4.3 Probing Model

We reimplement the model of Tenney et al. (2019b),[4] which gives a unified architecture that works for a wide range of probing tasks. Specifically, it classifies single spans or pairs of spans in the following way: 1) construct token representations by pooling across encoder layers with a learned scalar mix (Peters et al., 2018a), 2) construct span representations from these token representations using self-attentive pooling (Lee et al., 2017), and 3) concatenate those span representations and feed the result through a fully-connected layer to produce input features for the classification layer. We follow Tenney et al. (2019b) in training a probing model over a frozen encoder, while using our LSL classifier (Section 3) as the final output layer in place of the usual softmax.

4.4 Model selection

We run initial studies to determine hidden layer sizes and regularization coefficients. For all LSL probes, we use $N = 32$ latent classes.[5]

Probe capacity To mitigate the influence of probe capacity on the results, we follow the best practice recommended by Hewitt and Liang (2019) and use a single hidden layer with the smallest size that does not sacrifice performance. For each task, we train binary logistic regression probes with a range of hidden sizes and select the smallest yielding at least 97% of the best model's performance. Details are in Appendix A.

Mitigating variance To decrease variance across random restarts, we use a consistency-based model selection criterion: train 5 models, compute their pairwise B^3 F1 scores, and choose the one with the highest average F1. (However, as we find in Section 5, the qualitative patterns that emerged were consistent between runs.)

Regularization coefficients We run preliminary experiments using BERT-large on Universal Dependencies and Named Entity Labeling with ablations on our clustering regularizers. For each ablation, we choose hyperparameters with the best F1 against gold.

Results Results are shown in Table 1. As expected, the batch-level entropy loss drives up both diversity and uncertainty, while the instance-level entropy loss drives them down. In combination,

Table 2: Results by task for three pretrained encoding methods. All probing models were trained with the LSL loss and cluster regularization coefficients $\alpha = \beta = 1.5$, and chosen by the best-of-5 consistency criterion and detailed in Section 4.4. Uncertainty for all models was close to 1 and is omitted for space.

however, they produce the right balance, with uncertainty near 1 while retaining diversity.

Notably, the Named Entity model with the batch-level loss has *higher* diversity when the instance-level loss is added. This happens because batch-level entropy can be increased by driving up instance-level entropy without changing the entropy of the expected distribution of predictions $\mathrm{H}(\mathbb{E}_{\mathbf{x}}\,\mathrm{P}(\hat{C}(\mathbf{x})))$. So by keeping the uncertainty down on each input, the instance-level entropy loss helps the batch-level entropy loss promote diversity in the induced ontology.

Based on these results, we set $\alpha = \beta = 1.5$ for $\mathcal{L}_{be}$ and $\mathcal{L}_{ie}$ for the main experiments.

5 Results and Analysis

Table 2 shows aggregate results for the tasks and encoders described in Section 4.[6] Taking all metrics into account, contextualized encodings produce richer ontologies that agree more with gold than the lexical baseline does. In fact, BERT-lex has normalized PMI scores very close to zero across the board (plots are provided in Appendix C), encoding virtually no information about gold categories. For this reason, we omit it from the rest of the analysis.

Named entities As shown in Table 3, neither BERT nor ELMo are sensitive to categories that are related to specialized world knowledge, such as languages, laws, and events. However, they are in tune with other types: ELMo discovers a clear PERSON category, whereas BERT has distinguished DATEs. Visualization of the clusters (Figure 2) corroborates this, furthermore showing that the models have a sense of scalar values and measurement; indeed, instead of the gold distinction between ORDINAL and CARDINAL numbers, both models distinguish between *small* and *large* (roughly, seven or greater) numbers. See Appendix C for detailed nPMI scores.

	DATE	PERCENT	ORG	PERSON	⋯	EVENT	LAW	LANG.
BERT	.70	.60	.54	.48	·	.03	.02	.01
ELMo	.38	.28	.35	.81	·	.02	.01	.01

Table 3: Label-wise B^3 F1 scores for Named Entities, sorted by decreasing BERT-large F1. Induced ontologies capture some labels surprisingly well, but are indifferent to more specialized categories which may require more world knowledge to distinguish.

Nonterminals Patterns in nPMI (Figure 3a) suggest basic syntactic notions: complete clauses (S, TOP, SINV) form a group, as do phrase types which take subjects (SBAR, VP, PP), and wh-phrases (WHADVP, WHPP, WHNP).

Dependencies Patterns in nPMI (Figure 3b) indicate several salient groups: verb arguments (nsubj, obj, obl, xcomp), left-heads (det, nmod:poss, compound, amod, case), right-heads (acl, acl:relcl, nmod[7]), and punct.

Semantic roles Patterns in nPMI (Figure 3c) roughly match intuition: primary core arguments (ARG0, ARG1) are distinguished, as well as modals (ARGM-MOD) and negation (ARGM-NEG), while trailing arguments (ARG2–5) and modifiers (ARGM-TMP, LOC, etc.) form a large group. On one hand, this reflects surface patterns: primary core arguments are usually close to the verb, with ARG0 on the left and ARG1 on the right; trailing arguments and modifiers tend to be prepositional phrases or subordinate clauses; and modals

[7] Often the object in a prepositional phrase modifying a noun.

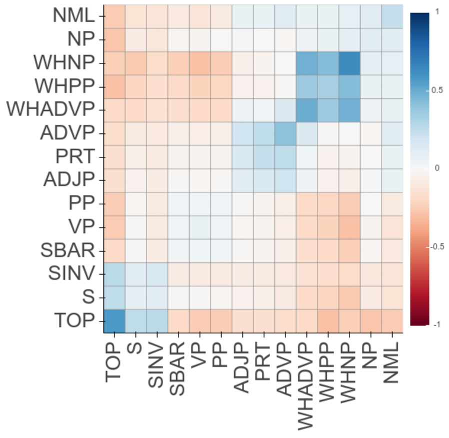
Gold Label	P / R / F1
ARGM-MOD	.62 / .41 / .49
ARG0	.52 / .17 / .26
ARG1	.50 / .09 / .15
ARGM-NEG	.36 / .60 / .45
ARG2	.28 / .13 / .18

Table 4: Top semantic role labels by BERT-large B^3 precision. Core arguments ARG0–2 are most preferentially split, with high precision but low recall.

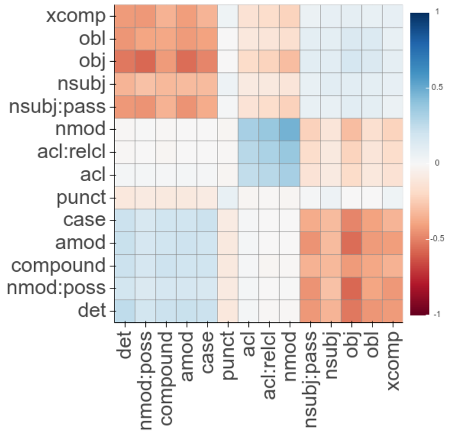
and negation are identified by lexical and positional cues. On the other hand, this also reflects error patterns in state-of-the-art systems, where label errors can sometimes be traced to ontological choices in PropBank, which distinguish between arguments and adjuncts that have very similar meaning (He et al., 2017; Kingsbury et al., 2002).

While the number of induced classes roughly matches gold for most tasks, induced ontologies for semantic roles are considerably more diverse, with a diversity measure close to 20 for ELMo and BERT (Table 2). Even though the alignment of predicted clusters with gold is dominated by a few patterns (Figure 3), the induced clustering contains more information than just these patterns. To locate this information, we examine the gold classes exhibiting the highest B^3 precision, shown in Table 4. Among these, core arguments ARG0, ARG1, and ARG2 have very low recall, indicating that the ontology splits them into finer-grained labels.

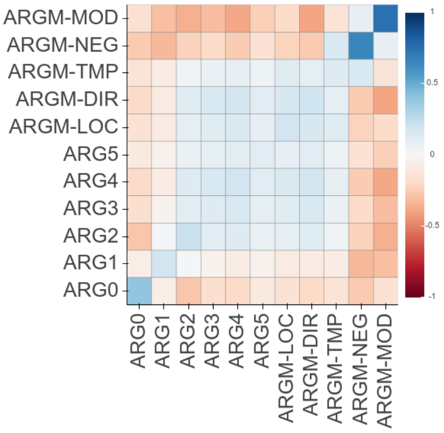
This follows intuition for PropBank core argument labels, which have predicate-specific meanings. Other approaches based on Frame Semantics (Baker et al., 1998; Fillmore et al., 2006), Proto-Roles (Dowty, 1991; Reisinger et al., 2015), or Levin classes (Levin, 1993; Schuler, 2005) have more explicit fine-grained roles. Concurrent work (Kuznetsov and Gurevych, 2020) shows that the choice of semantic role formalism meaningfully affects the behavior of supervised probes; further comparisons using LSL probing may help shed light on the origins of such differences.



(a) Nonterminals.



(b) Universal dependencies.



(c) Semantic roles.

Figure 3: Pairwise gold label nPMIs on selected categories for ontologies induced from BERT-large on selected tasks. Blue is positive nPMI, representing that gold labels are preferentially grouped together (*i.e.*, conflated by the model) relative to chance. Red is negative nPMI, representing that gold labels are well-separated. Perfectly matching ontologies would be 1 (blue) along the diagonal and -1 (red) in all off-diagonal cells. Counts are summed over all 5 runs to better reflect the underlying representations, though variance was low and our observed trends hold across all runs.

6 Discussion

Our exploration of latent ontologies has yielded some surprising results: ELMo knows people, BERT knows dates, and both sense scalar and measurable values, while distinguishing between small and large numbers. Both models preferentially split core semantic roles into many fine-grained categories, and seem to encode broad notions of syntactic and semantic structure. These findings contrast with those from fully-supervised probes, which produce strong agreement with existing annotations (Tenney et al., 2019b) but can also report false positives by fitting to weak patterns in large feature spaces (Zhang and Bowman, 2018; Voita and Titov, 2020). Instead, agreement of latent categories with known concepts can be taken as strong evidence that these concepts (or similar ones) are present as important, salient features in an encoder's representation space.

This issue is particularly important when looking for *deep, inherent understanding* of linguistic structure, which by nature must generalize. For supervised systems, generalization is often measured by out-of-distribution objectives like out-of-domain performance (Ganin et al., 2016), transferability (Wang et al., 2018), targeted forms of compositionality (Geiger et al., 2020), or robustness to adversarial inputs (Jia and Liang, 2017). Recent work also advocates for counterfactual learning and evaluation (Qin et al., 2019; Kaushik et al., 2020) to mitigate confounds, or contrastive evaluation sets (Gardner et al., 2020) to rigorously test local decision boundaries. Overall, these techniques target discrepancies between salient features in a model and causal relationships in a task. In this work, we extract such features directly and investigate them by comparing induced and gold ontologies. This identifies some very strong cases of transferability from the binary detection task to detection tasks over gold subcategories, such as ELMo's *people* and BERT's *dates* (Table 3). Future work may investigate *cross-task* ontology matching to identify other transferable features, the emergence of categories signifying pipelined reasoning (Tenney et al., 2019a), surface patterns, or new, perhaps unexpected distinctions which can appear when going beyond existing schemas (Michael et al., 2018).

Our results point to a paradigm of **probing with latent variables**, for which LSL is one potential technique. We have only scratched the surface of what may emerge with such methods: while our probing test is high specificity, it is low power; extant latent structure may still be missed. LSL probing may produce different ontologies due to many factors, such as tokenization (Singh et al., 2019), encoder architecture (Peters et al., 2018b), probe architecture (Hewitt and Manning, 2019), data distribution (Gururangan et al., 2018), pretraining task (Liu et al., 2019a; Wang et al., 2019a), or pretraining checkpoint. Any such factors may be at work in the differences we observe between ELMo and BERT: for example, BERT's tokenization method may not as readily induce *personhood* features due to splitting of rare words (like names) in byte-pair encoding. Furthermore, concurrent work (Chi et al., 2020) has already found qualitative evidence of syntactic dependency types emergent in the special case of multilingual structural probes (Hewitt and Manning, 2019). With LSL, we provide a method that can be adapted to a variety of probing settings to both quantify and qualify this kind of structure.

7 Conclusion

We introduced a new model analysis method based on *latent subclass learning*: by factoring a binary classifier through a forced choice of latent subclasses, latent ontologies can be coaxed out of input features. Using this approach, we showed that encoders such as BERT and ELMo can be found to hold stable, consistent latent ontologies on a variety of linguistic tasks. In these ontologies, we found clear connections to existing categories, such as *personhood* of named entities. We also found evidence of ontological distinctions beyond traditional gold categories, such as distinguishing large and small numbers, or preferring fine-grained semantic roles for core arguments. In latent subclass learning, we have shown a general technique to uncover some of these features discretely, providing a starting point for descriptive analysis of our models' latent ontologies. The high specificity of our method opens doors to more insights from future work, which may include investigating how LSL results vary with probe architecture, developing intrinsic quality measures on latent ontologies, or applying the technique to discover new patterns in settings where gold annotations are not present.

Acknowledgments

We would like to thank Tim Dozat, Kenton Lee, Emily Pitler, Kellie Webster, other members of Google Research, Sewon Min, and the anonymous reviewers, who all provided valuable feedback on this paper. We also thank Rafael Müller, Simon Kornblith, and Geoffrey Hinton for discussion on the LSL classifier, and Alessandro Sordoni for pointing out the connection between the clustering regularizers and mutual information.

A Probe capacity tuning

Results from hidden size tuning are shown in Figure 4. We use the accuracy of a binary classifier trained only on binary labels, choosing the smallest hidden size with at least 97% of the maximum performance over all trials. For comparison, we report the accuracy of a fully supervised multi-class model with the same hidden size. Our method sometimes chooses a hidden size where the accuracy of the fully supervised probe is much lower than max. While this suggests limits on the structure that can be produced, it makes our method independent of fine-grained gold labeling. Future work may investigate the role of probe expressiveness in determining induced ontologies.

B More Experimental Results

Results on larger set of encoders and tasks are shown in Tables 5–11. The extra tasks are undirected Universal Dependencies (Nivre et al., 2015), TAC relation classification (Zhang et al., 2017), and OntoNotes coreference (Pradhan et al., 2007). The extra encoders are BERT-base, multilingual BERT (mBERT)[8] and ALBERT (Lan et al., 2020).

C More Analysis Results

We show more comparative nPMI plots for BERT-large and ELMo in Figure 5 and Figure 6. These use co-occurrence counts summed over 5 runs, and exhibit the same overall trends as each run.

Relation classification nPMI plots for BERT-large and ELMo are shown for TAC relation classification in Figure 7. ELMo produces two diffuse groups of gold labels, while BERT seems to more clearly identify several categories of relations. Some of these may seem intuitive, *e.g.*, `org:founded_by` and `per:date_of_birth` relate to the creation of an entity, and are grouped together. However, the model distinguishes these from `per:origin` and `per:parents`, which may also intuitively seem similar. The broad distribution and highly specific semantics of TAC relations makes direct qualitative assessment difficult. Further analysis, perhaps comparing induced clusters more surface-level features (*e.g.*, dependency paths) may shed more light on these results.

Lexical baseline results Normalized PMI plots for the lexical baseline on several tasks are shown in Figure 8. In most cases, these show essentially no relation to gold categories. In the few cases where groups seem to emerge, they are coarser and more diffuse than what we observe with probes over contextual representations.

---

[8] `https://github.com/google-research/bert/blob/master/multilingual.md`

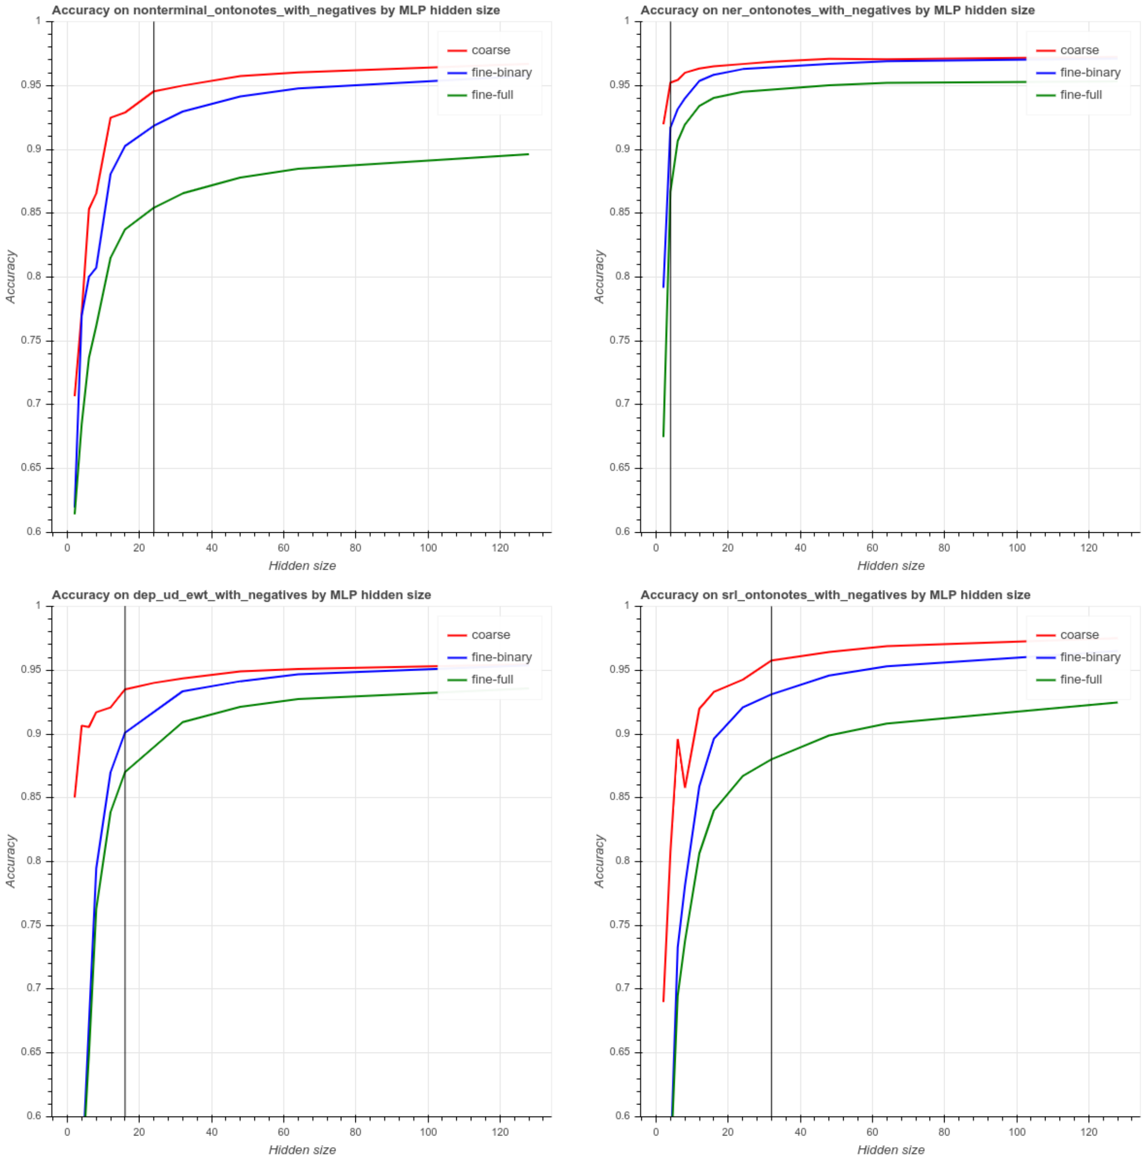

Figure 4: Performance on hidden size tuning experiments for different tasks. Clockwise from top-left, they are nonterminals, named entities, semantic roles, and syntactic dependencies. `coarse` (red) is binary accuracy of a binary classifier, `fine-binary` (blue) is binary accuracy of a full multiclass classifier, and `fine-full` (green) is the full multiclass accuracy of the multiclass classifier. The black vertical line is the smallest hidden size that passes the 97% performance threshold for `coarse`.

Abstract

While behaviors of pretrained language models (LMs) have been thoroughly examined, what happened during pretraining is rarely studied. We thus investigate the developmental process from a set of randomly initialized parameters to a totipotent[1] language model, which we refer to as the *embryology* of a pretrained language model. Our results show that ALBERT learns to reconstruct and predict tokens of different parts of speech (POS) in different learning speeds during pretraining. We also find that linguistic knowledge and world knowledge do not generally improve as pretraining proceeds, nor do downstream tasks' performance. These findings suggest that knowledge of a pretrained model varies during pretraining, and having more pretrain steps does not necessarily provide a model with more comprehensive knowledge. We provide source codes and pretrained models to reproduce our results at `https://github.com/d223302/albert-embryology`.

1 Introduction

The world of NLP has gone through some tremendous revolution since the proposal of contextualized word embeddings. Some big names are ELMo (Peters et al., 2018), GPT (Radford et al.), and BERT (Devlin et al., 2019), along with its variants (Sanh et al., 2019; Liu et al., 2019b; Lan et al., 2019). Performance boosts on miscellaneous downstream tasks have been reported by finetuning these totipotent pretrained language models. With a view to better grasping what has been learned by these contextualized word embedding models, probing is generally applied to the pretrained models and the models finetuned from them. Probing targets can range from linguistic knowledge, including semantic roles and syntactic structures (Liu et al., 2019a; Tenney et al., 2019, 2018; Hewitt and Manning, 2019), to world knowledge (Petroni et al., 2019).

While the previous work focuses on what knowledge has been learned after pretraining of transformer-based language models, few delve into their dynamics during pretraining. What happened during the training process of a deep neural network model has been widely studied, including Gur-Ari et al. (2018), Frankle et al. (2019), Raghu et al. (2017), Morcos et al. (2018). Some previous works also study the dynamics of the training process of an LSTM language model (Saphra and Lopez, 2018, 2019), but the training dynamics of a large scale pretrained language models are not well-studied. In this work, we probe ALBERT (Lan et al., 2019) during its pretraining phase every N parameter update steps and study what it has learned and what it can achieve so far. We perform a series of experiments, detailed in the following sections, to investigate the development of predicting and reconstructing tokens (Section 3), how linguistic and world knowledge evolve through time (Section 4, Section 6), and whether amassing those information serves as an assurance of good downstream task performances (Section 5).

We have the following findings based on ALBERT:

- The prediction and reconstruction of tokens with different POS tags have different learning speeds. (Section 3)
- Semantic and syntactic knowledge is developed simultaneously in ALBERT. (Section 4)
- Finetuning from model pretrained for 250k steps gives a decent GLUE score (80.23), and

---

[1] According to Wikipedia, totipotency is the ability of a single cell to divide and produce all of the differentiated cells in an organism. We use its adjective form here to refer to the ability of a pretrained model which can be finetuned for a variety of downstream tasks.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 6813–6828,
November 16–20, 2020. ©2020 Association for Computational Linguistics

further pretrain steps only make the GLUE score rise as high as 81.50.

- While ALBERT does generally gain more world knowledge as pretraining goes on, the model seems to be dynamically renewing its knowledge about the world. (Section 6)

While we only include the detailed results of ALBERT in the main text, we find that the results also generalize to the other two transformer-based language models, ELECTRA (Clark et al., 2019) and BERT, which are quite different from ALBERT in the sense of pretext task and model architecture. We put the detailed results of ELECTRA and BERT in the appendix.

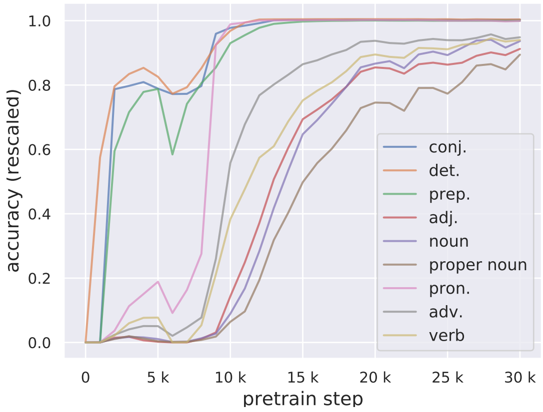
2 Pretraining ALBERT

ALBERT is a variant of BERT with cross-layer parameters sharing and factorized embedding parameterization. The reason why we initially chose ALBERT as our subject lies in its parameter efficiency, which becomes a significant issue when we need to store 1000 checkpoints during the pretraining process.

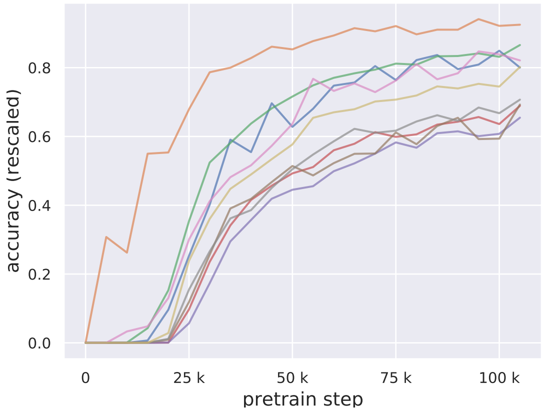
To investigate what happened during the pretraining process of ALBERT, we pretrained an ALBERT-base model ourselves. To maximally reproduce the results in Lan et al. (2019), we follow most of the training hyperparameters in the original work, only modifying some hyperparameters to fit in our limited computation resources[2]. We also follow Lan et al. (2019), using English Wikipedia as our pretraining data, and we use the Project Guttenberg Dataset (Lahiri, 2014) instead of BookCorpus. The total size of the corpus used in pretraining is 16GB. The pretraining was done on a single Cloud TPU V3 and took eight days to finish 1M pretrain steps, costing around 700 USD. More details on pretraining are specified in appendix B.1.

3 Learning to Predict the Masked Tokens and Reconstruct the Input Tokens

During the pretraining stage of a masked LM (MLM), it learns to predict masked tokens based on the remaining unmasked part of the sentence, and it also learns to reconstruct token identities of unmasked tokens from their output representations of the model. Better prediction and reconstruction results indicate the model being able to utilize contextual information. To maximally reconstruct the input tokens, the output representations must keep sufficient information regarding token identities.



(a) Token reconstruction



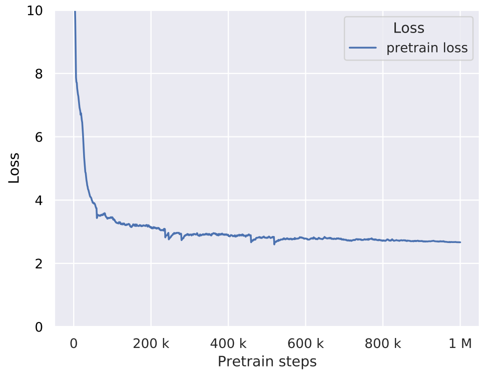
(b) Mask prediction

Figure 1: Rescaled accuracy of token reconstruction and mask prediction during pretraining. We rescale the accuracy of each line by the accuracy when the model is fully pretrained, i.e., the accuracy after pretraining 1M steps. Token reconstruction are evaluated every 1K pretrain steps, and mask prediction evaluated every 5K steps.

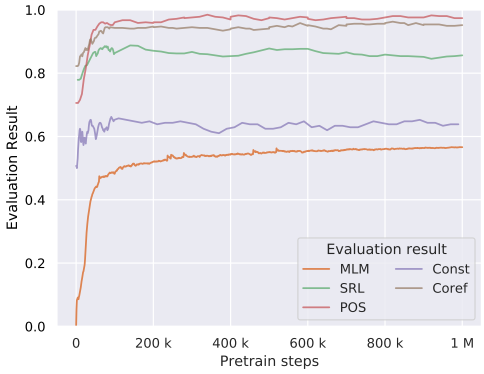
We investigate the behavior of mask prediction and token reconstruction for tokens of different POS during the early stage of pretraining. We use the POS tagging in OntoNotes 5.0 (Weischedel et al., 2013) in this experiment. For the mask prediction part, we mask a whole word (which may contain multiple tokens) of an input sentence, feed the masked sentence into ALBERT, and predict the masked token(s). We evaluate the prediction performance by calculating the prediction's accuracy based on POS of the word; the predicted token(s) should exactly match the original token(s) to be deemed an accurate prediction. As for the token reconstruction part, the input to the model is simply

---

[2] We use the official implementation of ALBERT at `https://github.com/google-research/albert`.



(a) Total loss during pretraining



(b) Masked LM accuracy and F1 scores of different probing tasks over the course of pretraining

Figure 2: The probing results of hidden representation from layer 8; all four tasks are evaluated with test set of OntoNotes 5.0 and F1 scores are reported. MLM accuracy is also shown. We smoothed the lines by averaging 3 consecutive data points for better illustration. The unsmoothed result is in Appendix D.3.

the original sentence.

The results of reconstruction are shown in Figure 1(a). ALBERT first learns to reconstruct function words, e.g., determiners, prepositions, and then gradually learns to reconstruct content words in the order of verb, adverb, adjective, noun, and proper noun. We also found that different forms and tenses of a verb do not share the same learning schedule, with third-person singular present being the easiest to reconstruct and present participle being the hardest (shown in Appendix C.2). The prediction results in Figure 1(b) reveal that learning mask prediction is generally more challenging than token reconstruction. ALBERT learns to predict masked tokens with an order similar to token reconstruction, though much slower and less accurate. We find that BERT also learns to perform mask prediction and token reconstruction in a similar fashion, with the results provided in Appendix C.4.

4 Probing Linguistic Knowledge Development During Pretraining

Probing is widely used to understand what kind of information is encoded in embeddings of a language model. In short, probing experiments train a task-specific classifier to examine if token embeddings contain the knowledge required for the probing task. Different language models may give different results on different probing tasks, and representations from different layers of a language model may also contain different linguistic information (Liu et al., 2019a; Tenney et al., 2018).

Our probing experiments are modified from the "edge probing" framework in Tenney et al. (2018). Hewitt and Liang (2019) previously showed that probing models should be *selective*, so we use linear classifiers for probing. We select four probing tasks for our experiments: part of speech (POS) tagging, constituent (const) tagging, coreference (coref) resolution, and semantic role labeling (SRL). The former two tasks probe syntactic knowledge hidden in token embeddings, and the last two tasks are designed to inspect the semantic knowledge provided by token embeddings. We use annotations provided in OntoNotes 5.0 (Weischedel et al., 2013) in our experiments.

The probing results are shown in Figure 2b. We observe that all four tasks show similar trends during pretraining, indicating that semantic knowledge and syntactic knowledge are developed simultaneously during pretraining. For syntactically related tasks, the performance of both POS tagging and constituent tagging boost very fast in the first 100k pretrain steps, and no further improvement can be seen throughout the remaining pretraining process, while performance fluctuates from time to time. We also observe an interesting phenomenon: the probed performances of SRL peak at around 150k steps and slightly decay over the remaining pretraining process, suggesting that some information in particular layers related to probing has been dwindling while the ALBERT model strives to advance its performance on the pretraining objective. The loss of the pretraining objective is also shown in Figure 2a.

Scrutinizing the probing results of different layers (Figure 3 and Appendix D.3), we find that the behaviors among different layers are slightly different. While the layers closer to output layer perform worse than layers closer to input layer at the beginning of pretraining, their performances rise

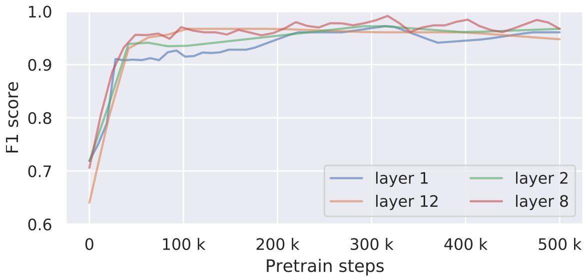


Figure 3: The probing results of POS during pretraining. Layers are indexed from the input layer to the output layer.

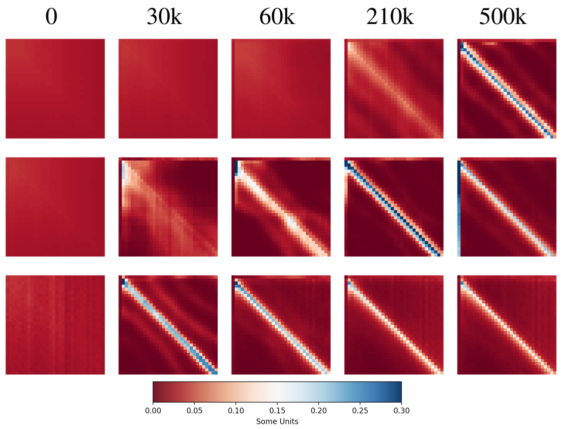

Figure 4: Attention patterns of head 11 across layer 1 (first row), 2 (second row), and 8 (third row) during pretraining. Pretrain steps labeled atop the attention map. We averaged the attention maps of different input sentences to get the attention pattern of a single head.

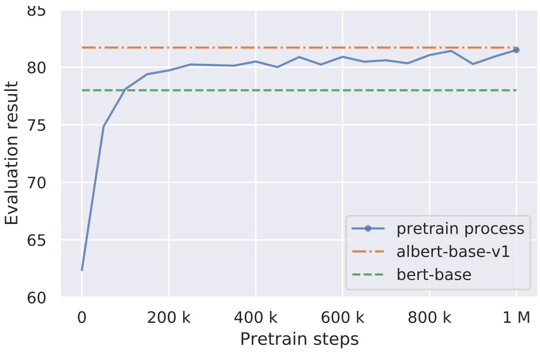
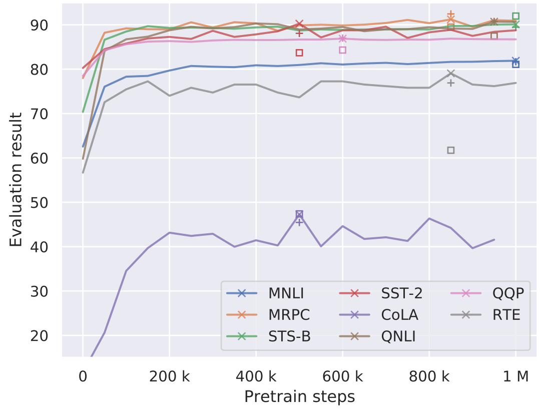


(a) GLUE scores over pretraining. GLUE scores of albert-base-v1 and bert-base are also shown by horizontal lines.[4].



(b) Performance of individual tasks in GLUE benchmark. Best result during pretraining marked with 'x'. Performances of albert-base-v1 and bert-base-uncased are marked with '+' and square respectively.

Figure 5: Downtream evaluation of ALBERT on develpoment set every 50k pretrain steps. GLUE score is averaged among all tasks except WNLI. Evaluation metrics: MRPC and QQP: F1, STS-B: Spearman corr., others: accuracy. The result of MNLI is the average of matched and mismatched.

drastically and eventually surpass the top few layers; however, they start to decay after they reach best performances. This implies the last few layers of ALBERT learn faster than the top few layers. This phenomenon is also revealed by observing the attention patterns across different layers during pretraining. Figure 4 shows that the diagonal attention pattern (Kovaleva et al., 2019) of layer 8 emerges earlier than layer 2, with the pattern of layer 1 looms the last[3].

5 Does Expensive and Lengthy Pretraining Guarantee Exceptional Results on Downstream Tasks?

While Devlin et al. (2019) and Lan et al. (2019) have shown that more pretrain steps lead to better GLUE scores, whether the performance gain of downstream tasks is proportional to the resources spent on additional pretrain steps is unknown. This drives us to explore the downstream performance of the ALBERT model before fully pretrained. We choose GLUE benchmark (Wang et al., 2018) for downstream evaluation, while excluding WNLI, following Devlin et al. (2019).

We illustrate our results of the downstream performance of the ALBERT model during pretraining in Figure 5. While the GLUE score gradually increases as pretraining proceeds, the performance after 250k does not pale in comparison with a fully pretrained model (80.23 v.s. 81.50). From Figure 5b, we also observe that most GLUE tasks reach comparable results with their fully pretrained counterpart over 250k pretrain steps, except for

---

[4] GLUE score of albert-base-v1 and bert-base are obtained by finetuning ALBERT and BERT models from HuggingFace(Wolf et al., 2019)

MNLI and QNLI, indicating NLI tasks do benefit from more pretrain steps when the training set is large.

We also finetuned BERT and ELECTRA models as pretraining proceeds, and we observe similar trends. The GLUE scores of the BERT and ELECTRA model rise drastically in the first 100k pretrain steps, and then the performance increments less slowly afterward. We put the detailed result of these two models in Section E.4.

We conclude that it may not be necessary to train an ALBERT model until its pretraining loss converges to obtain exceptional downstream performance. The majority of its capability for downstream tasks has already been learned in the early stage of pretraining. Note that our results do not contradict previous findings in Devlin et al. (2019), Liu et al. (2019b), and Clark et al. (2019), all of which showing that downstream tasks do benefit from more pretrain steps; we show that the performance gain on downstream tasks in latter pretrain steps might be disproportional to the cost on more pretrain steps.

6 World Knowledge Development During Pretraining

Petroni et al. (2019) has reported that language models contain world knowledge. To examine the development of world knowledge of a pretrained language model, we conduct the same experiment as in Petroni et al. (2019). We use a subset of T-REx (Elsahar et al., 2018) from the dataset provided by Petroni et al. (2019) to evaluate ALBERT's world knowledge development.

The results are shown in Figure 6, in which we observe that world knowledge is indeed built up during pretraining, while performance fluctuates occasionally. From Figure 6, it is clear that while some types of knowledge stay static during pretraining, some vary drastically over time, and the result of a fully pretrained model (at 1M steps) may not contain the most amount of world knowledge. We infer that world knowledge of a model depends on the corpus it has seen recently, and it tends to forget some knowledge that it has seen long ago. These results imply that it may not be sufficient to draw a conclusion on ALBERT's potential as a knowledge base merely based on the final pretrained one's behavior. We also provide qualitative results in Appendix F.2.

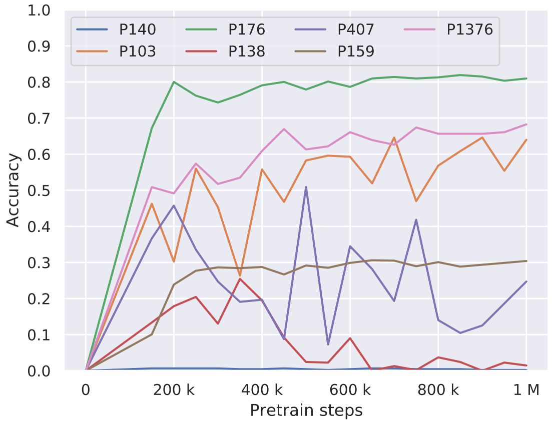

Figure 6: World knowledge development during pretraining evaluated every 50k pretrain steps. Types of relation, and template are shown in Table 1

Type	Query template
P140	[X] is affiliated with the [Y] religion .
P103	The native language of [X] is [Y] .
P176	[X] is produced by [Y] .
P138	[X] is named after [Y] .
P407	[X] was written in [Y] .
P159	The headquarter of [X] is in [Y] .
P1376	[X] is the capital of [Y] .

Table 1: Relations in Figure 6. We fill in [X] with the subject, [Y] with [MASK] and ask model to predict Y.

7 Conclusion

Although finetuning from pretrained language models puts in phenomenal downstream performance, the reason is not fully uncovered. This work aims to unveil the mystery of the pretrained language model by looking into how it evolves. Our findings show that the learning speeds for reconstructing and predicting tokens differ across POS. We find that the model acquires semantic and syntactic knowledge simultaneously at the early pretraining stage. We show that the model is already prepared for finetuning on downstream tasks at its early pretraining stage. Our results also reveal that the model's world knowledge does not stay static even when pretraining loss converges. We hope our work can bring more insights into what makes a pretrained language model a pretrained language model.

A Modifications from the Reviewed Version

We made some modifications in the camera-ready version, mostly based on the reviewers' recommendations and for better reproducibility.

- We add the result of BERT and ELECTRA in Section 3, Section 4, and Section 5.
- We reimplement the source code for Section 4 and renew the experiment results accordingly. While the exact values are slightly different, the general trends are the same and do not affect our observation.
- We add the results of coreference resolution in our probing experiments, following the reviewers' suggestion.
- We polish our wordings and presentations in text and figures.

B Pretraining

B.1 ALBERT

As mentioned in the main text, we only modified a few hyperparameters to fit in out limited computation resources, listed in Table 2. The Wikipedia corpus used in our pretraining can be download from `https://dumps.wikimedia.org/enwiki/latest/enwiki-latest-pages-articles.xml.bz2`, and the Gutenburg dataset can be download from `https://web.eecs.umich.edu/~lahiri/gutenberg_dataset.html`. The number of parameters in our ALBERT model is 12M.

Batch size	512
Learning rate	6.222539674E-4
Total steps	1M
Warmup steps	25k

Table 2: Pretraining hyperparemeters for ALBERT.

B.2 BERT

We use the same dataset as we trained ALBERT to pretrain BERT. We pretrained a BERT-base-uncased model using the official implementation of BERT at `https://github.com/google-research/bert`, and we follow all hyperparameters of the original implementation. Note that the Devlin et al. (2019) mentioned they trained BERT with a maximum sequence length of 128 for the first 900K steps, and then trained the model with a maximum sequence length 512 for the rest 100K steps; we follow this training procedure. The number of parameters in our BERT model is 110M.

B.3 ELECTRA

We use OpenWebTextCorpus (Gokaslan and Cohen, 2019) from `https://skylion007.github.io/OpenWebTextCorpus/` to pretrain an Electra-base model. We pretrained this model using the official implementation of ELECTRA at `https://github.com/google-research/electra`, and we follow all hyperparameters of the original implementation. The number of parameters in our ELECTRA model used for finetuning (the discriminator part) is 110M.

C Mask Predict and Token Reconstruction

C.1 Dataset

As mentioned in Section 3, we use the POS annotations in OntoNotes 5.0, and we only use the CoNLL-2012 test set for our experiments. While there are 48 POS labels, we only report the mask prediction and token reconstruction of a much smaller subset—those we are more familiar with. The statistics of these POS are in Table 3.

POS	Count
Conjunction	5109
Determiner	14763
Preposition	18059
Adjective	9710
Adverb	7992
Verb (all forms)	21405
Noun	29544
Proper noun	13144

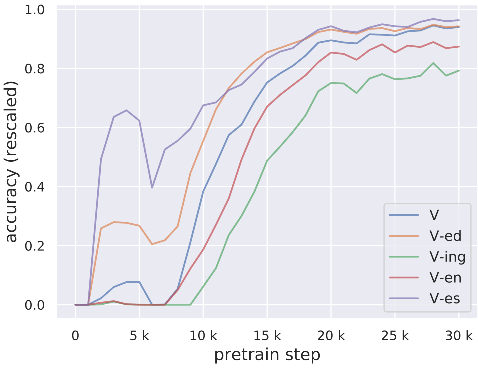
Table 3: Statistics of POS used in experiments.

Verb form	Count
Base form	5865
Past tense	5398
Gerund or present participle	2821
Past participle	3388
3rd person singular present	3933

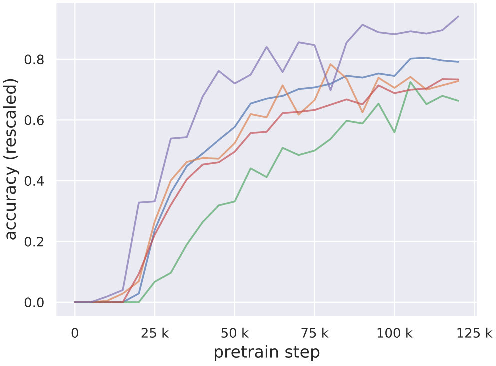
Table 4: Statistics of different verb forms used in experiments.

C.2 Mask Predict and Token Reconstruction of Different Verb Forms

We provide supplementary materials for Section 3. In Figure 7, we observe that ALBERT learns to reconstruct and predict verb of different forms at different times. The average occurrence rate of verb in different form from high to low is V-es, V-ed, V, V-en, V-ing, which coincides with the priority being leaned.



(a) Token reconstruction.



(b) Mask prediction.

Figure 7: Token reconstruction (7a) and mask prediction (7b) accuracy. We also rescale the accuracy as in Figure 1.

C.3 How Does Occurrence Frequency Affect Learning Speed of A Word?

In the main text, we observe that words of different POS are learned at different times of pretraining. We also pointed out that the learning speed of different POS roughly corresponds to their occurrence rate. However, it is not clear to what extent a word's occurrence frequency affects how soon it can be learned to reconstruct or mask-predict by the model. We provide a deeper analysis of the relationship between the learning speed of a word and its occurrence rate in Figure 8. We observe from Figure 8 that the top 50 to 99 occurring tokens are indeed learned faster than other words which occur lesser. However, as for the top 300 to 349 occurring tokens and the top 1550 to 1599 occurring tokens, it is unclear which ones are learned earlier. We can infer from Figure 8 and Figure 1b that the occurring rate and POS of a word both contribute to how soon the model can learn it to some extent.

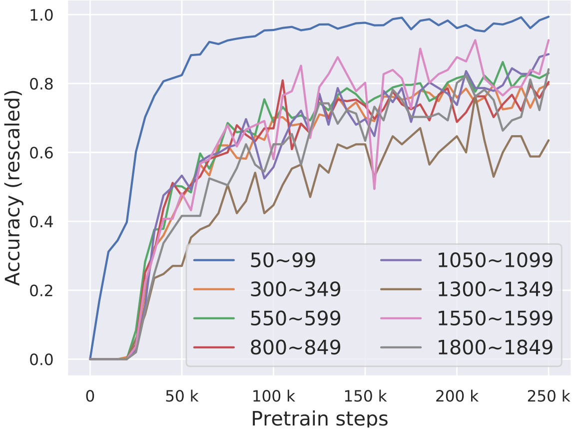


Figure 8: Rescaled mask prediction accuracy for different frequency. 50~99 means the top 50 to top 99 occurring tokens

C.4 Mask Predict and Token Reconstruction of BERT

We provide the results of BERT's token reconstruction and mask prediction in Figure 9. We observe content words are learned later than function words, while the learning speed is faster than ALBERT. To be more specific, we say a word type A is learned faster than another word type B if either the learning curve of A rises earlier than B from 0, or if the rescaled learning curve of A is steeper than that of B.

D Probing Experiments

D.1 Probing Model Details

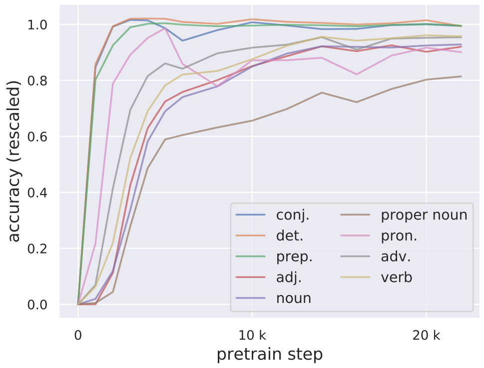
As mentioned in the main text, we modified and reimplemented the edge probing (Tenney et al., 2018) models in our experiments. The modifications are detailed as follow:

- We remove the projection layer that projects representation output from the language model to the probing model's input dimension.

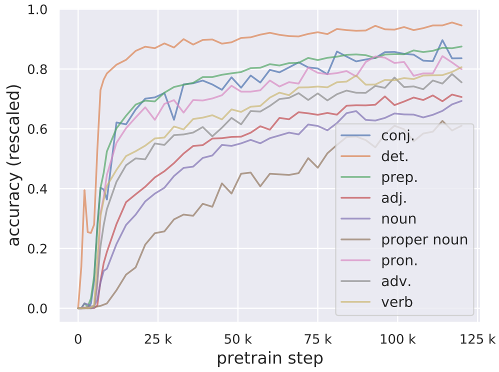
- We use average pooling to obtain span representation, instead of self-attention pooling.

Task	$\lvert\mathcal{L}\rvert$	Examples	Tokens	Total Targets
POS	48	116K / 16K / 12K	2.2M / 305K / 230K	2.1M / 290K / 212K
Constituent	30	116K / 16K / 12K	2.2M / 305K / 230K	1.9M / 255K / 191K
SRL	66	253K / 35K / 24K	6.6M / 934K / 640K	599K / 83K / 56K

Table 5: Statistics of the number of labels, examples, tokens and targets (split by train/dev/test) we used in probing experiments. $\lvert\mathcal{L}\rvert$ denotes number of target labels.



(a) Token reconstruction of BERT



(b) Mask prediction of BERT

Figure 9: We also rescale the accuracy as in Figure 1b.

- We use linear classifiers instead of 2-layer MLP classifiers.
- We probe the representation of a single layer, instead of concatenating or scalar-mixing representations across all layers.

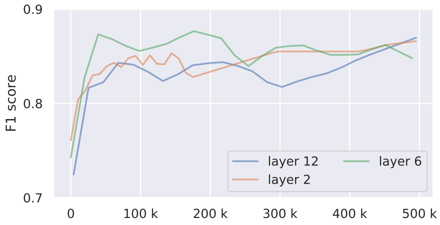
Since our probing models are much simpler than those in Tenney et al. (2018), probing results might be inferior to the original work. The number of model's parameters in our experiments is approximately 38K for POS tagging, 24K for constituent tagging, and 100K for SRL.

D.2 Dataset

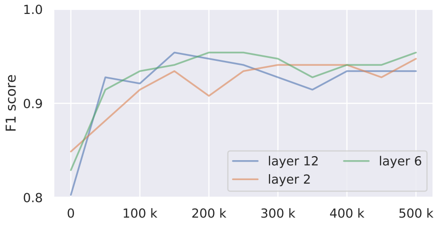
We use OntoNotes-5.0, which can be download from `https://catalog.ldc.upenn.edu/LDC2013T19`. The statistics of this dataset is in Table 5.

D.3 SRL, Coreference Resolution, and Constituent Labeling Results

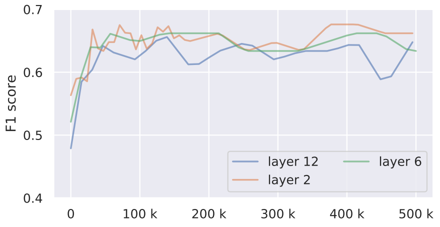
Here in Figure 10, we show supplementary figures for SRL, coreference resolution, and constituent tagging over 3 of 12 layers in ALBERT for the first 500K pretrain steps. Together with Figure 3, all four tasks show similar trends.



(a) Semantic role labeling



(b) Coreference resolution



(c) Constituent tagging

Figure 10: The probing results of SRL (10a, coreference resolution (10b) and constituency tagging (10c) during pretraining . Layers are indexed from the input layer to the output layer, so layer 2 is the output representation from layer 2 of ALBERT. Layers are indexed from 1 to 12.

Task	Examples

QQP	363K / 40.4K / 391.0K
CoLA	8.5K / 1.0K / 1.1K
MNLI	392.7K / 9.8K + 9.8K / 9.8K + 9.8K
SST-2	67.4K / 0.9K / 1.8K
SQuAD2.0	13.3K / 11.9K / 8.9K

Table 6: Statistics of (train / dev/ test) in GLUE tasks and SQuAD2.0. MNLI contains matched and mismatched in dev and test set. We didn't evaluate our models' performance on test set.

D.4 Probing Results of BERT and ELECTRA

We provide the probing results of BERT and ELECTRA in Figure 11. All the probing experiments of ALBERT, BERT, and ELECTRA share the same set of hyperparameters and model architectures. We observe a similar trend as ALBERT: the probing performance rises quite quickly and plateaus (or even slightly decay) afterward. We also found that performance drop of those layers closer to ELECTRA's output layers are highly observable, which may spring from its discriminative pretraining nature.

E Downstream Evaluation

E.1 Dataset Details

We provide detail statistics of downstream tasks' dataset in Table 6. We download GLUE dataset using `https://gist.github.com/W4ngatang/60c2bdb54d156a41194446737ce03e2e`, and download SQuAD2.0 dataset from `https://rajpurkar.github.io/SQuAD-explorer/`.

E.2 Finetune Details

We use the code in `https://github.com/huggingface/transformers/tree/master/examples/text-classification` to run GLUE and use `https://github.com/huggingface/transformers/tree/master/examples/question-answering` to run SQuAD2.0. We provide detailed hyperparameters when we run GLUE benchmark and SQuAD2.0 in Table 7. We follow Liu et al. (2019b) and Lan et al. (2019), finetuning RTE, STS-B, and MRPC using an MNLI checkpoint when finetuning ALBERT. The number of parameters of all downstream tasks is close to the original ALBERT model, which is 12M.

E.3 Downstream results of ALBERT (with SQuAD2.0)

Here we provide performance of individual tasks in GLUE benchmark on development set in Figure 12, along with performance of SQuAD2.0 (Rajpurkar et al., 2018).

E.4 Downstream performance of BERT and ELECTRA

We use the same hyperparamters in Table7 to finetune BERT and ELECTRA models. Except for the performance of BERT on SQuAD2.0, all the other results are comparable with those results finetuned from the official Google pretrained models. We can observe from Figure 13 and Figure 12 that all three models' performance on downstream tasks show similar trends: Performance skyrocketed during the initial pretraining stages, and the return gradually decays later. From Figure 13c, we also find that among the three models, ALBERT plateaus the earliest, which may result from its parameter-sharing nature.

F World Knowledge Development

F.1 Dataset Statistics

In our experiment of world knowledge, we only use 1-1 relations (P1376 and P36) and N-1 relations (the rest relations in Table 8). Among those relations, we only ask our model to predict object ([Y] in the template in Table 8) that has only one token, following Petroni et al. (2019). From those relations, we report world knowledge that behaves differently during pretraining in Figure 6: we select the knowledge that can be learned during pretraining (e.g., P176), the knowledge that cannot be learned during the whole pretraining process (e.g., P140), the knowledge that was once learned and then forgotten after pretraining (e.g., P138), and knowledge that kept oscillating during pretraining (e.g., P407). The statistics of all world knowledge evaluated are in listed in Table 8.

F.2 Qualitative Results and Complete World Knowledge Results

We provide qualitative examples for Section 6 in Table 9. We also provide the complete results of all world knowledge we use in Figure 14.

Learning Music Helps You Read: Using Transfer to Study Linguistic Structure in Language Models

Isabel Papadimitriou
Stanford University

Dan Jurafsky
Stanford University
`jurafsky@stanford.edu`

Abstract

We propose transfer learning as a method for analyzing the encoding of grammatical structure in neural language models. We train LSTMs on non-linguistic data and evaluate their performance on natural language to assess *which kinds of data induce generalizable structural features* that LSTMs can use for natural language. We find that training on non-linguistic data with latent structure (MIDI music or Java code) improves test performance on natural language, despite no overlap in surface form or vocabulary. To pinpoint the kinds of abstract structure that models may be encoding to lead to this improvement, we run similar experiments with two artificial parentheses languages: one which has a hierarchical recursive structure, and a control which has paired tokens but no recursion. Surprisingly, training a model on either of these artificial languages leads the same substantial gains when testing on natural language. Further experiments on transfer between natural languages controlling for vocabulary overlap show that zero-shot performance on a test language is highly correlated with typological syntactic similarity to the training language, suggesting that representations induced by pre-training correspond to the cross-linguistic syntactic properties. Our results provide insights into the ways that neural models represent abstract syntactic structure, and also about the kind of structural inductive biases which allow for natural language acquisition. [1]

1 Introduction

Understanding how neural language models learn and represent syntactic structure is an important analytic question for NLP. Recent work has directly probed the internal activations of models (Conneau et al., 2018a; Dalvi et al., 2019; Hewitt and Manning, 2019; Clark et al., 2019), or fed them curated inputs that depend on complex syntax (Linzen et al., 2016; Gulordava et al., 2018; Talmor et al., 2019; McCoy et al., 2020), in order to uncover latent syntactic awareness.

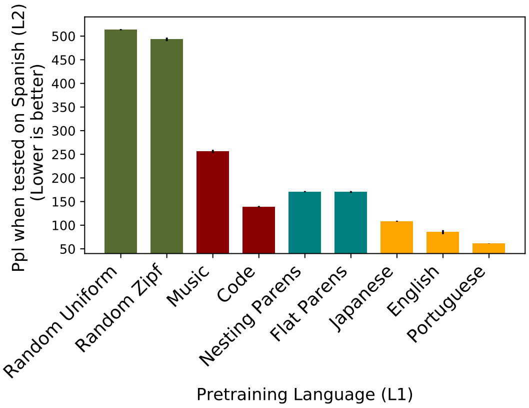

Figure 1: We find that LSTM LMs can utilize various types of non-linguistic structure to help learn to model human language, and that nested hierarchical structure does not lead to more expressive encodings than flat, head-dependency pair structure. We also find that LSTM LMs learn representations that correlate with typological syntactic feature distance, allowing them to transfer more effectively from languages which are grammatically similar.

We propose a different approach: we measure the structural awareness of a language model *by studying how much this structure acts as an inductive bias to improve learning when we transfer from one language or symbolic system to another.*

We train LSTM models on data with varying degrees of language-like structure (music, Java code, nested symbols), and then evaluate their performance on natural language. Before evaluation, we freeze the LSTM parameters and fine-tune the word embeddings on the evaluation language. This lets us see if the training data induces language-like

---

November 16–20, 2020. ©2020 Association for Computational Linguistics

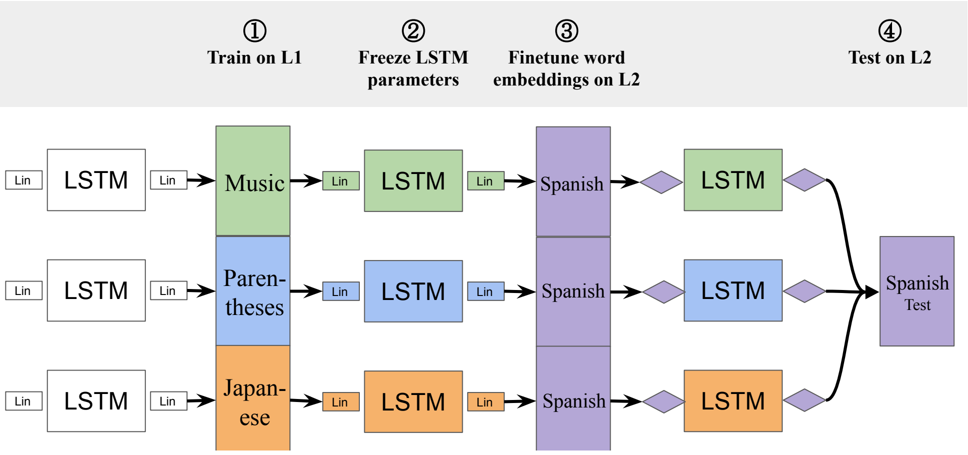

Figure 2: Diagram illustrating our training procedure: k models are trained on k L1 languages, and then their LSTM weights are frozen while their linear layers are finetuned on a common L2 language (in our case, we always use Spanish as the L2). We can then compare their performance on the common L2.

structure in the recurrent parameters of LSTMs—despite removing vocabulary-level confounders. By assessing if representations are useful *across* languages, we examine the generalizable representations of grammar that LSTMs encode. We call this new method the Test for Inductive Bias via Language Model Transfer (TILT).

Firstly, we examine the transfer of abstract structural features from languages that are very different on the surface from human language. We find that pretraining an LSTM on music data[2] or Java code greatly improves transfer to human language over pretraining on structureless random baseline data. To test if the gain in performance is due to the LSTM utilizing the recursive nature of music and code, we train models on an artificial language with recursion (hierarchically nested symbols) and observe that they also perform well when evaluated on human language. However, we also surprisingly find that recursion is a sufficient, but not necessary condition for generalizable, language-like grammar induction. We observe similar gains when pretraining on a language of matching pairs that do not nest hierarchically, showcasing the importance of non-hierarchical head-dependent-type relations in LSTM language processing.

Lastly, in transfer experiments between different human languages, we find that transfer is better between languages that are syntactically typologically similar, even with no vocabulary overlap. This suggests that models have the ability to form representations of typologically sensible properties rather than relying on ad-hoc or non-natural representations. For this result we draw on recent interlingual work such as Artetxe et al. (2020), Ponti et al. (2019), and Conneau et al. (2018b), extending it to use typological distance to turn these observations into quantitative probes.

The TILT method allows us to ask a complementary set of questions to those answered by current analysis methods. TILTs demonstrate the abstract structural notions that LSTMs can learn, rather than probing for the manifestation of a particular known structure, as in most current methods. By examining the pretraining structures that give LSTMs a better ability to model language, we also contribute to the more general cognitive question of what structural inductive biases a learner needs to be able to easily acquire human language.

2 Architecture and Training

Our methodology consists of training LSTM language models on k different first languages (L1s) which include natural languages, artificial languages, and non-linguistic symbol systems, and testing the performance of these models on a common second (L2) language. In our case, we used Spanish as the common L2. Before testing on the L2 test set, we fine-tune the linear embedding layer of the models on the L2 training set, while keeping the LSTM weights frozen. This aligns the vocabulary of each model to the new language, but does not let it learn any structural information about the L2 language. Though word embeddings do contain some grammatical information like part of

---

[2] We use the MAESTRO music dataset, which utilizes an exact symbolic representation of music (like a music score) that is sequentialized for sequence modelling

speech, they do not contain information about how to connect tokens to each other – that information is only captured in the LSTM. Figure 2 illustrates our training process. [3]

We vary the L1 languages and maintain a common L2 (instead of the other way around) in order to have a common basis for comparison: all of the models are tested on the same L2 test set, and therefore we can compare the perplexity scores. We run $n = 5$ trials of every experiment with different random seeds. Any high-resource human language would have provided a good common L2, and Spanish works well for our human languages experiments due to the fact that many higher-resource languages fall on a smooth gradation of typological distance from it (see Table 1).

We use the AWD-LM model (Merity et al., 2018) with the default parameters of 3 LSTM layers, 300-dimensional word embeddings, a hidden size of 1,150 per layer, dropout of 0.65 for the word embedding matrices and dropout of 0.3 for the LSTM parameters. We used SGD and trained to convergence, starting the learning rate at the default of 30 and reducing it at loss plateau 5 times.

Much of the work on multilingual transfer learning has speculated that successes in the field may be due to vocabulary overlap (see for example Wu and Dredze (2019)). Since our work focuses mostly on syntax, we wanted to remove this possibility. As such, we shuffle each word-to-index mapping to use disjoint vocabularies for all languages: the English word “Chile” and the Spanish word “Chile” would map to different integers. This addresses the confound of vocabulary overlap, as all language pairs have zero words in common from the point of view of the model.

Since the vocabularies are totally separated between languages, we align the vocabularies for all L1-L2 pairs by finetuning the word embeddings of all the pretrained models on the Spanish (L2) training data, keeping the LSTM weights frozen. By doing this, we remove the confound that would arise should one language’s vocabulary randomly happen to be more aligned with Spanish than another’s. These controls ensure that lexical features, whether they be shared vocabulary or alignment of randomly aligned indices, do not interfere with the experimental results which are meant to compare higher-level syntactic awareness.

3 Experiment 1: Random Baselines

We run our method on a random baseline L1: a corpus where words are sampled uniformly at random. This gives us a baseline for how much information we gain finetuning the word embeddings to the L2, when there has not been any structurally biasing input to the LSTM from the L1.

We also examine the importance of vocabulary distribution by training on a random corpus that is sampled from a Zipfian distribution. Human languages are surprisingly consistent in sharing a roughly Zipfian vocabulary distribution, and we test how pretraining on this distribution affects the ability to model human language. [4]

3.1 Data

Our random corpora are sampled from the Spanish vocabulary, since Spanish is the common L2 language across all experiments. Words are sampled uniformly for the Uniform Random corpus, and drawn from the empirical Spanish unigram distribution (as calculated from our Spanish training corpus) for the Zipfian Random corpus. Illustrative examples from all of our corpora can be found in Figure 3. The random corpora are controlled to 100 million tokens in length.

3.2 Results

When tested on Spanish, the average perplexity is 513.66 for models trained on the Random Uniform corpus and 493.15 for those trained on the Random Zipfian corpus, as shown in Figure 4. These perplexity values are both smaller than the vocabulary size, which indicates that the word embedding finetuning captures information about the test language even when the LSTM has not been trained on any useful data.

The models trained on the Zipfian Random corpus are significantly better than those trained on the Uniform corpus ($p << 0.05$, Welch’s t-test over $n = 5$ trials). However, even though training on a Zipfian corpus provides gains when compared to training on uniformly random data, in absolute terms performance is very low. This indicates that, without higher-level language-like features, there is very little that an LSTM can extract from properties of the vocabulary distribution alone.

---

[3] All pretraining jobs took less than 2 days to run on one GPU, all finetuning jobs took less than 1 day to run on one GPU.

[4] See Piantadosi (2014) for a review of cognitive, communication and memory-based theories seeking to explain the ubiquity of power law distributions in language.

Random

Uniform: `marroquín jemer pertenecer osasuna formaron citoesqueleto relativismo`

Zipf: `en con conocidas y en los victoriano como trabajar` ⟨unk⟩ `monte * en juegos días en el`

The random corpora are sampled randomly from the Spanish vocabulary. There is no underlying structure of any kind that links words with each other. All words are equally likely to be sampled in the Uniform corpus, while common words are more likely in the Zipfian corpus.

Music

The music data is encoded from classical piano performances according to the MAESTRO standard. Music is structured on many levels. The red arrow in the example illustrates how, on a small timescale, each note is linked to its corresponding note when a motif is repeated but modulated down a whole-step.

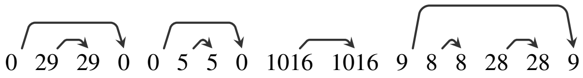
Code

```
    if (coordFactor == 1.0f)
        return sumExpl
    else {
        result = sum * coordFactor
    }
```

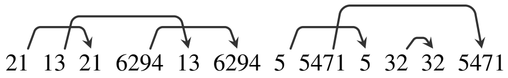
The code corpus is composed of Java code. The above snippet demonstrates some kinds of structure that are present in code: brackets are linked to their pairs, `else` statements are linked to an `if` statement, and coreference of variable names is unambiguous.

Parentheses

Nesting:



Flat:



Our artificial corpora consist of pairs of matching integers. In the Nesting Parentheses corpus, integer pairs nest hierarchically and so the arcs do not cross. In the Flat Parentheses corpus, each integer pair is placed independently of all the others, and so the arcs can cross multiple times.

(There is a one-to-one mapping between Spanish words and integers and so these integers are sampled from the same Spanish vocabulary distribution as the Random Zipfian corpus. We visualize these corpora here with integers and the Random corpora with words for simplicity).

Figure 3: Examples illustrating the content of our non-linguistic corpora for Experiments 1-3. All examples are taken from the corpora.

The Zipfian Random baseline is controlled for vocabulary distribution: if an experiment yields better results than the Zipfian Random baseline, we cannot attribute its success only to lexical-level similarity to the L2. Therefore, models that are more successful than the Zipfian baseline at transfer to human language would have useful, generalizable syntactic information about the structures that link tokens.

4 Experiment 2: Non-linguistic structure

In this experiment, we test the performance of LSTMs on Spanish when they have been trained on music and on code data. While music data especially is very different from human language on the surface level, we know that music and code both contain syntactic elements that are similar to human language.[5] By comparing performance to our random baselines, we ask: can LSTMs encode the abstract structural features that these corpora share with natural language in a generalizable way that's usable to model human language?

4.1 Data

For our music data we use the MAESTRO dataset of Hawthorne et al. (2018). The MAESTRO dataset embeds MIDI files of many parallel notes into a linear format suitable for sequence modelling, without losing musical information. The final corpus has a vocabulary of 310 tokens, and encodes over 172 hours of classical piano performances. [6]

For programming code data, we used the Habeas corpus released by Movshovitz-Attias and Cohen (2013), of tokenized and labelled Java code. We took out every token that was labelled as a comment so as to not contaminate the code corpus with natural language. [7]

---

[5] See for example Lerdahl and Jackendoff (1996) for grammatical structure in music.

[6] The MAESTRO dataset is available at https://magenta.tensorflow.org/datasets/maestro

[7] The Habeas corpus is available at https://github.com/habeascorpus/

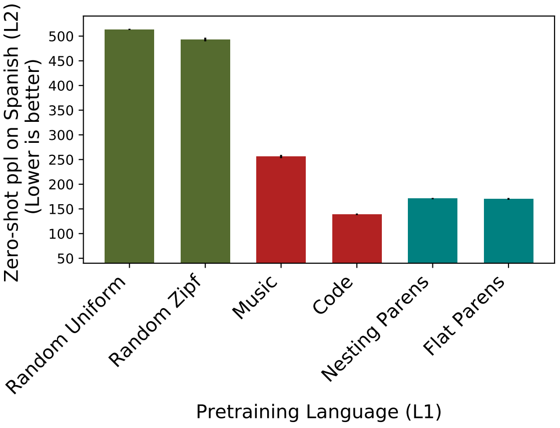


Figure 4: Results of Experiments 1 through 3, training on non-linguistic corpora. Error bars on all bars indicate a 95% t-test confidence interval over 5 restarts with different random seeds. All structured data is much better to train on than random data, including music which has a totally divergent vocabulary surface form from the rest. The two parentheses corpora result in equivalent perplexities, even though one has a hierarchical underlying structure and the other does not.

The music corpus is 23 million tokens in length and the code corpus is 9.5 million. We cannot effectively control the lengths of these corpora to be the same as all of the others, since there is no controlled notion of what one token means in terms of information. However, we only compare these results to the random baseline, which we have trained on 100 million tokens – if the LSTMs trained on these corpora are under-specified compared to the baseline, this would only strengthen our results.

4.2 Results

Our results show that language models pretrained on music are far better at modelling Spanish than those pretrained on random data. As shown in figure 4, LSTMs trained on music data have an average performance of 256.15 ppl on Spanish, compared with 493.15 when training on the Zipfian random corpus. This discrepancy suggests that the model, when training on music, creates representations of the relationships between tokens which are generalizable and can apply to Spanish.

The music corpus is markedly different from the Spanish corpus by most measures. Most saliently, MAESTRO uses a vocabulary of just 310 tokens to encode various aspects of music like volume and note co-occurrence.[8] This is in contrast to the Zipfian Random corpus, which has the same surface-level vocabulary and distribution as Spanish, yet models trained on it perform on average 237 ppl worse compared to those trained on the music corpus. Since the surface forms between music and language are so different, the difference in performance cannot be based on surface-level heuristics, and *our results suggest the presence of generalizable, structurally-informed representations in LSTM language models.*

We also show that models trained on Java code can transfer this knowledge to a human L2 better than the random baseline. Syntactic properties of code such as recursion are similar to natural language, though code is constructed to be unambiguously parsed and lacks a lot of the subtlety and ambiguity that characterizes natural language. Models trained on code have an average perplexity of 139.10 on the Spanish test set. The large discrepancy between this performance and the baseline indicates that LSTMs trained on code capture the syntactic commonalities between code and natural language in a manner that is usable for modelling natural language.

Our results on non-linguistic data suggest that LSTMs trained on structured data extract representations which can be used to model human languages. The non-linguistic nature of these data suggests that it is something structural about the music and Java code that is helping in the zero-shot task. However, there is a multitude of structural interpretations of music, and it is not clear what kinds of structure the LSTM encodes from music. In the next experiment, we create simple artificial corpora with known underlying structures in order to test how the LMs can represent and utilize these structures.

5 Experiment 3: Recursive Structure

In this experiment, we isolate and assess possible structural features of music and code that may explain the results of Experiment 2. The most widely-known structural hypothesis is the claim of Hauser et al. (2002) that the narrow language faculty in humans (the inductive bias in the mind/brain that allows humans to acquire and develop language) can be reduced to just recursion. Given the prominence of such theories, it is natural to ask: is it the

---

`habeascorpus-data-withComments`

[8] For consistency, the model still has a word embedding matrix of 50,000 rows, but during training only ever sees words 1-310, meaning that much of the word embedding space has never been seen by the LSTM part of the model.

underlying recursive nature of music and code data that causes the gains that we observe in Experiment 2?

To test this possibility, we create a simple recursive corpus: a *Nesting Parentheses corpus* of hierarchically nesting matching symbols, and run the same experimental setup as we did for Experiments 1 and 2 [9]. We find that plain recursion, even when the corpus has no other structural subtleties, is indeed a sufficient condition for inducing the kinds of structural transfer we observed in Experiment 2.

Recursion is a sufficient quality, but is it the only explanation for our results? We also create a control corpus: a *Flat Parentheses corpus*, which has similar pairs of matching parentheses, but which do not nest hierarchically and projectively (the difference between the two corpora is visually illustrated in Figure 3). We surprisingly find that this non-recursive corpus induces the same amount of structural transfer as the recursive nesting parentheses, which emphasizes the importance of pairing, head-dependency type structure in the linguistic structural embeddings of LSTMs.

5.1 Data

The vocabulary for these corpora are the integers 0-50,000, where each number is a parenthesis token, and that token "closes" when the same integer appears a second time. We draw the opening tokens from the empirical Spanish unigram distribution (mapping each Spanish word to an integer), meaning that these corpora have a similar vocabulary distribution, albeit a much simpler non-linguistic structure, to the L2. Both of the corpora are 100 million tokens long, like the random and the natural language corpora.

We create the Nesting Parentheses corpus by following a simple stack-based grammar. At timestep t, we flip a coin to decide whether to open a new parenthesis (with probability 0.4) or close the top parenthesis on the stack (with probability 0.6).[10] If we are opening a new parenthesis, we sample an integer x_{open} from the Spanish unigram distribution, write the integer x_{open} at the corpus position t, and push x_{open} onto the stack of open parentheses. If we are closing a parenthesis, we pop the top integer from the stack, x_{close}, and write x_{close} at corpus position t.
