summaries, we select three sentences as the summary for extractive models following the original papers, and let the algorithms self-stop for abstractive models, which also give three sentences as the decoding result in most cases. Table 3 presents the performances based on PolyTope and ROUGE. Cases supporting observations below are illustrated in Appendix C.

5.1 Preneural vs Neural Models

On ROUGE-1, Lead-3 ranks the 2nd among extractive models, and the 4th among all models. On PolyTope, it ranks the 3rd among extractive models and the 4th among all models. This shows that the simple method stands as a strong baseline even among neural methods. TextRank ranks the 9th and 7th among all methods on ROUGE and PolyTope, respectively, still competitive to some abstractive neural models. On the negative side, these two methods show the largest numbers of *Addition* errors, which demonstrates that unsupervised methods are relatively weaker in filtering out useless information compared to the supervised methods.

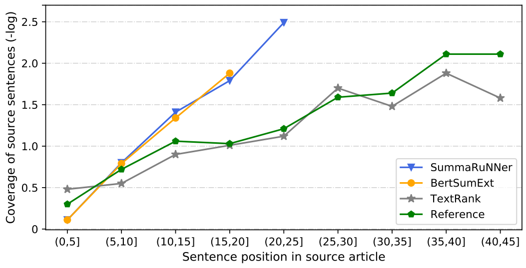
5.2 Extractive vs Abstractive Summarization

On ROUGE, there is no strong gap between extractive and abstractive methods, with BART and BertSumExt being the top abstractive and extractive models, respectively. On PolyTope, as a representative of abstractive models, BART overwhelmingly outperforms the others ($p < 0.01$ using t-test). However, excluding BART, extractive models take the following top three places. Under similar settings, extractive methods are better ($p < 0.01$ using t-test) compared with abstractive counterparts (e.g. BertSumExt vs BertSumExtAbs, SummaRuNNer vs Point-Generator, Point-Generator-with-Coverage).

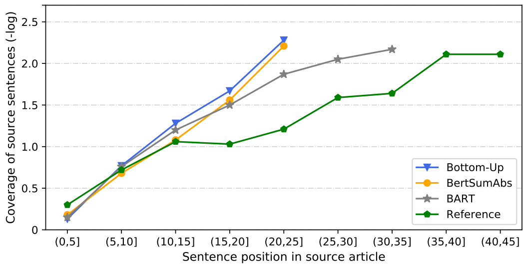
Extractive models tend to make only 3 types of errors, namely *Addition*, *Omission*, *Duplication*, while abstractive models make 4 to 7 types of errors. With respect to *Accuracy*, extractive methods are notably stronger in terms of *Inacc Intrinsic* and *Extrinsic*, which reflects that through directly copying snippets from the source, extractive methods are guaranteed to produce a summary with fair grammaticality, rationality and loyalty. However, extractive methods do not show stronger performances in *Addition* and *Omission*, which is because extracted sentences contain information not directly relevant to the main points. With regard to *Fluency*, two approaches are generally competitive with each other, showing that nowadays neural models are relatively effective in synthesizing coherent summaries.

5.3 Extractive Methods

We first compare neural methods BertSumExt and SummaRuNNer. BertSumExt gives better ROUGE-1/2 compared to SummaRuNNer, but the difference is not significant under ROUGE-L or PolyTope. Among detailed errors, BertSumExt demonstrates advantages only in *Duplication*, for the likely reason that the contextualized representations of the same phrases can be different by BERT encoding. It co-insides with previous findings (Kedzie et al., 2018) which demonstrate that more complicated architectures for producing sentence representations do not lead to better performance under the setting of extractive summarization. Given the fact that gold-standard extractive summaries are constructed according to ROUGE, the better ROUGE score of BertSumExt reflects the effectiveness of stronger representation on fitting training data.



(a) Extractive models.



(b) Abstractive models.

Figure 2: Distribution of source sentence used for content generation. X-axis: sentence position in source article. Y-axis: the negative log of coverage of sentence.

We then take statistical models into account. Figure 2a shows the distribution of source sentences used for content generation by each method. There is a high proportion in the first five sentences and a smooth tail over all positions for reference summaries. In contrast, BertSumExt and SummaRuNNer extract sentences mostly from the beginning, thereby missing useful information towards the end. TextRank improves the coverage slightly as it is graph-based and does not depend on sequence information. But as lack of supervision, the model has a large number of *Addition* and *Omission*.

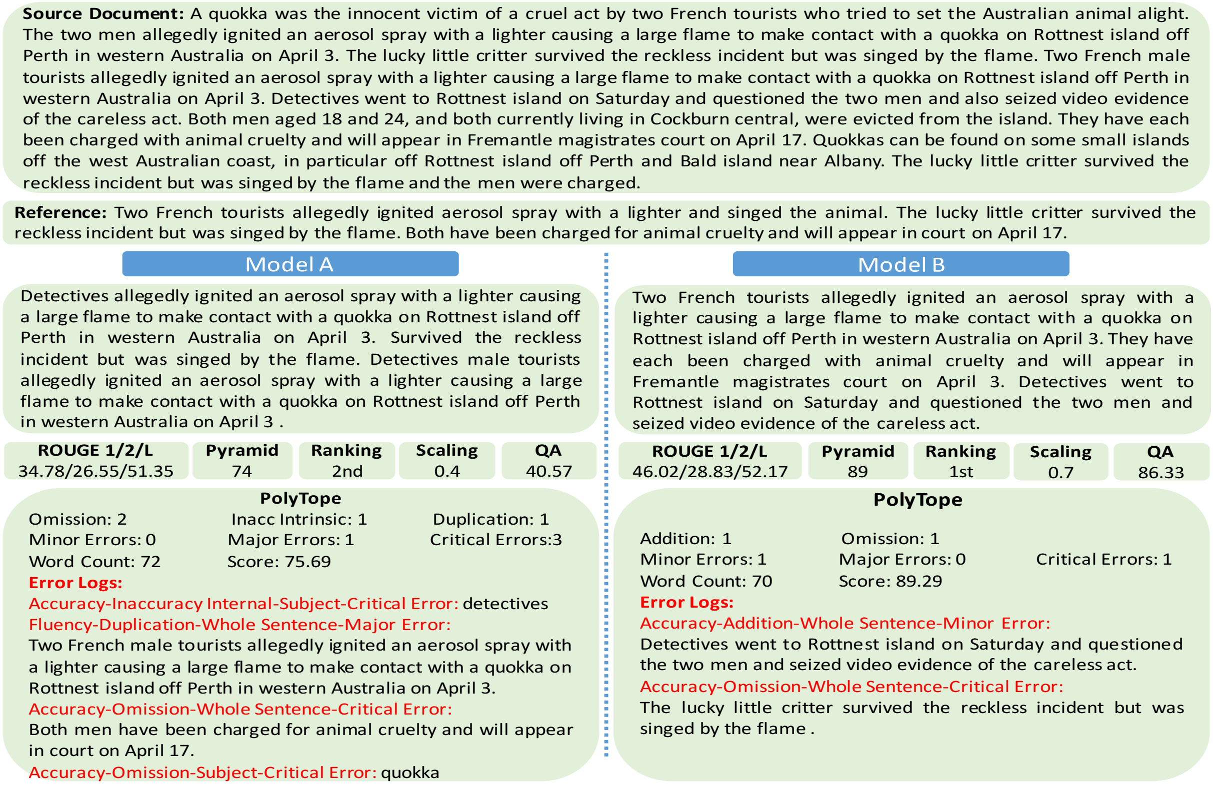
5.4 Abstractive Methods

Copy The naïve seq2seq model suffers an *Inacc-Intrinsic* count of 304, the worst among all models compared. In contrast, the Point-Generator model reduces the error count to 14, demonstrating the effectiveness of the copy mechanism in faithfully reproducing details. Another interesting finding is that *Duplication* errors are also sharply reduced from 139 to 68, although the copy mechanism is not explicitly designed to address this problem. Further investigation shows that the reduced duplication patterns are mostly on the word level, while the effect on sentence-level duplication reduction is nearly zero. One likely reason is that the seq2seq decoder relies heavily on short-term history when deciding the next output word, without effective use of long-term dependencies. The Point-Generator model solves this problem by interpolating vocabulary level probability with copy probability, reducing reliance on previous outputs. On the negative side, the copy mechanism introduces *Addition* errors, because the auto-regressive point generator network tends to copy long sequences in entirety from the source, failing to interrupt copying at desirable length. This is also observed by Gehrmann et al. (2018) and Balachandran et al. (2020).

Coverage Coverage (Tu et al., 2016) is introduced to neural summarization systems to solve repetition issues. Compared with Point-Generator, Point-Generator-with-Coverage reduces *Duplication* errors from 68 to 11 and *Omission* errors from 286 to 256, proving that coverage is useful for better content selection. However, Point-Generator-with-Coverage yields more *Addition* and *Inacc_Intrinsic* errors than Point-Generator. We further extract outputs of Point-Generator that do not have *Duplication* errors, finding that introducing the coverage mechanism reduces the average PolyTope scores from 77.54 to 74.07. It indicates that the coverage mechanism lacks inference capability and tends to generate summaries that incorrectly combine contents from the source into irrelevant information (see Figure10 and Figure11 in Appendix C as examples). This is likely because the coverage mechanism forces attention values from the decoder to the encoder to move monotonically to the right, and therefore can interfere with the original content selection process.

Hybrid Abstractive/Extractive Model Bottom-Up gives high ROUGE scores, but ranks the second worst on PolyTope. Compared with others, it suffers more from *Inaccuracy* errors. The inconsistency between ROUGE and PolyTope reflects the relative strengths and weaknesses of this method. On the positive side, it combines the advantages of extractive and abstractive models in selecting segments from the source and generating new contents in the summary, leading to a better recall. On the negative side, the abstractive generation model constrains copy attention only on the extracted snippets, thereby suffering from incomplete information sources for making inference and consequently lack of faithfulness and factual consistency.

Pre-training Both BertSumExtAbs and BART outperform the non-pretraining abstractive models by a large margin. They differ from the other methods in two aspects, namely the Transformer ar-



Source Document: A quokka was the innocent victim of a cruel act by two French tourists who tried to set the Australian animal alight. The two men allegedly ignited an aerosol spray with a lighter causing a large flame to make contact with a quokka on Rottnest island off Perth in western Australia on April 3. The lucky little critter survived the reckless incident but was singed by the flame. Two French male tourists allegedly ignited an aerosol spray with a lighter causing a large flame to make contact with a quokka on Rottnest island off Perth in western Australia on April 3. Detectives went to Rottnest island on Saturday and questioned the two men and also seized video evidence of the careless act. Both men aged 18 and 24, and both currently living in Cockburn central, were evicted from the island. They have each been charged with animal cruelty and will appear in Fremantle magistrates court on April 17. Quokkas can be found on some small islands off the west Australian coast, in particular off Rottnest island off Perth and Bald island near Albany. The lucky little critter survived the reckless incident but was singed by the flame and the men were charged.

chitecture and contextualized knowledge. Since it has been shown that Transformer does not bring improved ROUGE compared with LSTM (Gehrmann et al., 2018; Zhong et al., 2019), knowledge encoded by large-scale pre-training is likely the key for their better performance. Without the help of copy and coverage, BertSumExtAbs gives less number of *Inacc* and *Duplication* errors, and BART further gives the least number in almost all errors, showing the strength of pre-training technology.

It is worth noting that BART ranks the 1st on both ROUGE and PolyTope among the 10 models. Different from BertSumExtAbs which pretrains the encoder only, BART pre-trains the encoder and decoder jointly with seq2seq denoising auto-encoder tasks. It gives large improvements on *Addition*, *Omission* and *Inacc* errors, proving that unified pre-training for both understanding and generation is highly useful for content selection and combination. In particular, BART shows superior performance in handling the leading bias of CNN/DM dataset. Figure 2b shows the distribution of source sentences used for content generation by the abstractive methods. As can be seen, abstractive models tend to neglect sentences in the middle and at the end of source documents (e.g., Bottom-Up, BertSumExtAbs), indicating that performance of abstractive summarizers is strongly affected by the leading bias of dataset. In contrast, BART can attend to sentences all around the whole document, slightly closer to the distribution of golden reference. Intuitively, this improvement might result from the document rotation transformation of BART pre-training, which shuffles the sentences on the encoder side for the same decoder. We leave the verification to future work, which requires re-training of BART without document rotation transformation.

		R-1	R-2	R-L
Instance	PolyTope	0.40	0.32	0.32
	Accuracy	0.31	0.26	0.25

System	PolyTope	0.78	0.73	0.52

Table 4: Pearson correlation coefficients between ROUGE scores and human annotations from the perspective of instance and system level, respectively.

6 Analysis of Evaluation Methods

The main goal of this paper is to investigate the differences between summarization systems, rather than to promote a human evaluation metric. Nonetheless, our dataset gives us a testbed to calculate the correlation between automatic and human evaluation methods. In this section, we report a contrast between ROUGE and PolyTope quantitatively, and between PolyTope and other human evaluation metrics qualitatively to demonstrate why we used PolyTope for our research goal.

First, research has shown that ROUGE is inconsistent with human evaluation for summary quality (Liu and Liu, 2008; Zopf, 2018; Kryscinski et al., 2019; Maynez et al., 2020). We evaluate ROUGE using PolyTope from the perspective of both instance-level and system-level performances. On the instance level, the individual 1500 outputs from the 10 models are adopted to calculate the Pearson correlation coefficients between ROUGE and PolyTope. Additionally, we select test instances that only make *Accuracy* or *Fluency* errors to better understand the correlation between ROUGE and *Accuracy*/*Fluency* aspects. On the system level, the overall scores of each model are adopted to calculate the Pearson correlation coefficients between ROUGE and PolyTope.

The results are summarized in Table 4. For the instance-level comparison, we find a weak correlation between ROUGE and human judgement. In addition, with respect to *Accuracy* and *Fluency*, ROUGE can measure *Accuracy* to a certain extent, and ROUGE-2 is better than ROUGE-1/L in terms of evaluating *Fluency*. For the system-level comparison, the Pearson correlation coefficient is 0.78, 0.73, 0.52 for ROUGE-1, ROUGE-2, and ROUGE-L, respectively, much higher than 0.40, 0.32, 0.32 on the instance level. This confirms that ROUGE is useful for ranking systems after aggregation of samples but is relatively weak for assessing single summary quality, where the fine grained PolyTope could help (Peyrard et al., 2017).

Second, Figure 3 shows results of two models on one test document by ROUGE, Pyramid, ranking, scaling, QA and PolyTope evaluation metrics. As can be seen from the figure, PolyTope offers more fine-grained information in quality evaluation. Sun et al. (2019) warned that human evaluation prefers to give higher scores to longer and more informative summaries. Under the setting of PolyTope, there was relatively little influence from the sentence length. Taking BertSumExt and BertSumExtAbs models as examples, the Pearson correlation coefficients between length of their outputs and the corresponding scores is 0.25 and 0.27, respectively, suggesting that PolyTope is more objective and meaningful for current models that produce summaries without pre-specified length.

Finally, we also evaluate the reference summaries of our 150 test trials by means of PolyTope, obtaining a general score of 96.41, with 63 errors in the *Accuracy* aspect and 0 errors in the *Fluency* aspect. Gold summaries did not receive full marks in the PolyTope evaluation, mainly because of hallucinating content. For example, a news article describes an event as happening *"on Wednesday"* in a summary although the original document has *"on April 1"*. The human summary requires external knowledge beyond the document and thus suffers penalization. Another common hallucination involves rhetorical but irrelevant sentences, e.g., *"Click here for more news"*. In addition, there are a few grammatical issues that affect the accuracy. For example, in *"Piglet was born in China with only two front legs has learned to walk."*, there is a missing conjunction between two verb phrases.

7 Conclusion

We empirically compared 10 representative text summarizers using a fine-grained set of human evaluation metrics designed according to MQM for human writing, aiming to achieve a better understanding on neural text summarization systems and the effect of milestone techniques investigated recently. Our observations suggest that extractive summarizers generally outperform abstractive summarizers by human evaluation, and more details are also found about the unique advantages gained by copy, coverage, hybrid and especially pre-training technologies. The overall conclusions are largely in line with existing research, while we provide more details in an error diagnostics aspect.

A Details on PolyTope

A.1 Annotation Toolkit

We embed the evaluation rules in a Microsoft Excel workbook with Macros. The workbook contains 4 interrelated sheets, namely Score Card, Error Log, Scores per Segment, and Severity Matrix.

Score Card This sheet automatically calculates error numbers and scores (Figure 4), and demonstrates the whole performance of the tested model.

Error Log This sheet is the annotation interface designed for annotators (Figure 5). It is filled with source articles in column C and output summaries in column D in advance, and allows annotators to select segments that are deemed incorrect in column E to H. Upon one selection, annotators are asked to make a selection among 8 issue types (column F) and 8 syntactic labels (column G). A severity is then generated automatically in column J, and a quality score is calculated automatically in the Scores per Segment sheet individually and in the Score Card sheet overall.

Scores per Segment This sheet calculates word count, error count and score for each tested sample (Figure 6).

Severity Matrix This sheet is the predefined severity matrix (Table 2) embedded in the Excel workbook by Macros.

A.2 Issue Types

We give examples on *Inaccuracy_Intrinsic*, *Inaccuracy_Extrinsic* and *Positive-Negative Aspect* as follows, as other errors are easy to understand.

Inaccuracy_Intrinsic e.g., *"Pittsburgh Union Station is 10 kilometers from Exhibition Center and 3 kilometers from the University of Pittsburgh"* in the source but *"Pittsburgh Union Station is 3 kilometers from Exhibition Center"* in the output.

Inaccuracy_Extrinsic e.g., it is described as *"Pittsburgh Union Station, also known as Pittsburgh South Station"* in the output but *"Pittsburgh South Station"* is neither mentioned in the source text nor exists in the real world.

Figure 5: Error Log

Positive-Negative Aspect e.g., *"push a button"* summarized as *"don't push a button"*, *"non-slip"* summarized as *"slip"*. This category applies only to actions and modifiers and refers to omitted or added negative particles (Figure 13).

A.3 Syntactic Label

Subject The event body that is being discussed.

Predicate Acts and changes of state represented by verbs, verbal nouns, participles and gerunds. If a verb, verbal noun, participle or gerund acts as a modifier, it should be logged as "Attribute".

Object A noun or noun phrase that is affected by the action of a predicate.

Number&Time Number refers to digits, including cardinal and ordinal numerals, multiplicative and negative numbers, fractions and decimals, represented in numeric or word form. Time includes specific hours and minutes, part of the day (morning, evening, etc.), specific months and years, and words and phrases like tomorrow, in 3 days, during the next hours, etc.

Place&Name Place includes geographic name (e.g., *Europe*), administrative regions (e.g., *Texas*), specific addresses (e.g., *No 158, Fifth Ave*). Name includes names of real people, fictional characters, art, literature creations, companies, etc.

Attribute Attribute refers to a syntax unit, either a word, phrase or clause, that modifies a noun.

Function Word e.g., prepositions, auxiliary verbs, articles, determiners.

Whole Sentence A set of words that is complete in itself.

B Details on Human Evaluation

Through a professional language service company, three candidates with a linguistic background and high level of English proficiency are employed for manual evaluation. They are all qualified language workers with satisfactory levels in reading, and pass the training and testing before being hired. They go through two pilot studies to have a better understanding of PolyTope framework and the nature of text summary. Documents used in the pilot studies are not used in the final annotation. During annotation, they are all naive to the model names, ROUGE scores, architectures and techniques of tested samples. Each of them is requested to annotate 50 instance, where one instance includes the original document and 10 model generated summaries. And then cross check. Overall, we have 1500 examples in total. Each successful completion includes annotation and quality inspection. In this manner, we try to not only ensure fairness but also assure the quality of human evaluation.

For TextRank, SummaRuNNer and BART, we implement the model strictly following their corresponding papers and achieve their reported ROUGE scores. Then models are used to produce summaries on the 150 test trails. For other models, we obtain summaries directly from their publicly available sources.

C Case Study

Abstractive methods randomly splice fragments taken from the original text, leading to factual errors. See example of BertSumExtAbs (Figure 7), Pointer-Generator-with-Coverage (Figure 8) and Bottom-Up (Figure 9).

Comparing Pointer-Generator and Pointer-Generator-with-Coverage, among outputs of Pointer-Generator that do not suffer from *Duplication* errors, introducing the coverage mechanism may interfere with the original content selection process and cause new problems. See examples in Figure 10 and Figure 11.

The hybrid model gives high ROUGE scores overall, but does not necessarily combine strengths of extractive and abstractive methods. See example in Figure 12.

An example of *Positive-Negative Aspect* error is

in Figure 13.

D Details on Layout Bias Calculation

We compute the similarity score for each sentence in the output summary with each sentence in the source document by BERTSCORE (Zhang et al., 2019), and illustrate a distribution of source sentence used for summary generation in Figure 2a and Figure 2b. In the news domain, neural summarization methods are typically biased towards selecting and generating summaries based on the leading paragraph of the document (Kedzie et al., 2018; Zhong et al., 2019). This stems from the structure of news articles, which present the most salient information of an article in the first few sentences and expand in the subsequent ones.

E Pearson Correlation

ROUGE scores in Table 4 in the main text refer to the standard F1 scores. We also compute the Pearson correlation coefficients between ROUGE-P and PolyTope measurement, for the reason that ROUGE-P measures the precision which might be highly correlated to the proposed error-based PolyTope framework. We list the results in Table 5 for reference.

	R-1	R-2	R-L
PolyTope	0.15	0.22	0.06

Table 5: Pearson between ROUGE-P and PolyTope.

F Slips in Reference

The CNN/DM dataset is a commonly used summarization dataset which contains news articles and associated highlights as summaries. We choose to focus on this dataset for the following reasons: First, both extractive and abstractive works report results on this benchmark dataset. Second, the gold summary in the dataset is the highlight sentence prefacing each article, which in most cases contains three sentences. This length is relatively closer to real world applications and more comprehensive for analysis than shorter summaries such as single-sentence summary. Hence, it provides us with a better benchmark to assess summarization models.

However, as a nature of the CNN/DM dataset, some reference summaries are of poor quality. Figure 14 shows an exemplary document-summary pair whose summary contains grammatical errors. Figure 15 shows an exemplary document-summary pair whose summary has noise like “Click here for...”. Figure 16 shows an exemplary document-summary pair whose summary contains rhetorical sentences that interest readers but not crucial information to comprehend the document. In these cases, performance evaluation based on automatic evaluation is unreliable.

Source Document It used to be as much a part of a Sunday routine as eating a roast dinner or reading the papers. But new figures show that the art of washing your own car appears to be dying out in Britain with a third of men admitting they have never picked up a bucket or chamois leather to clean their own motor. The study also reveals that three-quarters of women never wash their own car with drivers more likely to take it to a car wash on a local forecourt. A new study has revealed that a third of men have never picked up a bucket or a chamois leather to wash their own car. The survey of 1,100 adults by vehicle leasing firm OSV, found that 31 percent of men have never washed their own car, with only 12 percent of those that do saying they do it regularly. Meanwhile only 5 percent of those surveyed said that had ever asked their children to wash the car, as a way for them to earn extra pocket money. Factors behind the decline vary from shops now opening on a Sunday and more live football on TV, meaning more people put off the chore at the weekend. The rise of hand car washes has been blamed for a decrease in drivers washing their own cars. Other reasons given for not washing cars include the rise of hand car washes and the fact that 4x4 and off-road vehicles are too large to clean. Brits are more likely to wash their own car during the holidays as the recent Easter break saw an estimated 15 million cars cleaned by their owners. However, one in four said they only did it as an excuse to get out of the house. Cars are most likely to be washed by their owners every week in Birmingham, Chelmsford and Sheffield and least likely in Oxford, Bath and Edinburgh. Audis, Toyotas and Bmws are most likely to be washed by their owners and Range Rovers, Peugeots and Mercedes least often. OSV spokesman Andrew Kirkley said: “A lot of us remember seeing our streets full of men cleaning their cars every Sunday. It was a national tradition. But let’s face it, we don’t have as much time any more, the cars are bigger and even the kids don’t seem to want to earn a bit of extra money doing it for us either.” On top of that, there is now plenty of choice out there if you want to put the car through an automated machine or get a gang of enthusiastic guys to do it fairly cheaply.
Reference 31 percent of British men say they have never washed their own car. Only 12 percent that have cleaned their own car say they do it regularly.
Model Output Three-quarters of women never wash their own car with drivers more likely to take it to a car wash on a forecourt. Survey of 1,100 adults by vehicle leasing firm OSV found 31% of men have never washed their own vehicle. Only 12% of those surveyed said that had ever asked their children to wash the car, as a way for them to earn extra pocket money.

Figure 7: Factual errors made by the BertSumExtAbs model.

Source Document She might be approaching her 89th birthday but nothing was going to stop the queen from enjoying a ride in the spring sunshine this morning. The monarch, 88, was spotted trotting through Windsor great park aboard her faithful black fell pony, Carltonlima Emma. Joined by a groom on another of her fell ponies, the queen cut a relaxed figure as she enjoyed her ride but, as is her wont, eschewed a helmet in favor of one of her silk scarves. Enjoying the sunshine: the queen enjoys a ride on her fell pony Carltonlima Emma. The queen, who has never worn riding helmets, has been encouraged to wear the safety hats in the past but is reportedly reluctant to wear one because of her hair. Speaking in an interview last year, her racing trainer Ian balding recalled the moment he asked why the monarch never wears a riding hat. The queen is said to have replied: "I never have and you don't have to have your hair done like I do." Her majesty is famous for her love of horses and first found herself in the saddle at the age of four after being presented with a Shetland pony, named Peggy, aged four. Since then, the royal stables have been home to a succession of steeds, among them Betsy, a black farm-bred horse who was her mount of choice in the 50's, and surprise, a grey gelding whom the queen famously galloped down the course at ascot in 1961. Equine enthusiast: her majesty adores the ponies and breeds them at Hampton court. No helmet: the queen never wears a riding helmet, preferring instead to ride in a silk headscarf. Cutting back: she has ridden less in recent years as a result of a niggling knee injury. Long term love: the queen has ridden all her life and continues to breed several breeds of horse and pony. Recent years have seen her cut down on the amount of time she spends in the saddle - the result of a niggling knee injury that also forced her to give up presiding over trooping the color on horseback. Nevertheless, the queen remains an enthusiastic equestrienne and, according to sources, is a familiar sight at her Windsor stables. She is also said to take a keen interest in all her horses and ponies, some of whom are now ridden by her grandchildren, notably Prince Edward's children, Lady Louise and James, Viscount Severn. Along with her thoroughbred race horses, the queen also breeds fell ponies and has a stud specialising in highland ponies at balmoral. First love: the queen's first pony was a tiny Shetland named Peggy who was given to her at the age of four. Familiar sight: the queen riding her much-loved horse Burmese during trooping the color. Seal of approval: a fell pony foal similar to those being bred by the queen at Hampton court. One of the oldest equine breeds on the planet, fell ponies like the queen's mount Carltonlima Emma, have roamed the moors of Cumbria since the Neolithic period. Docile, hardy and thick-set, the majority of fell ponies are black, grey or bay and measure between 13 and 14hh. Highly prized by the Carvetii, the iron age tribe who occupied the region more than two millennia ago, the ponies later caught the eye of the invading Romans and were used as trade goods all over the empire. The Romans also helped develop the breed into the relatively large animal it is today. Originally thought to have stood around 12hh tall (similar to Dartmoor and Exmoor ponies), by the end of the roman period, the average fell was more than a hand higher. Another invader to fall in love with the fell pony was the vikings, who used the animals as pack ponies; a use continued by the Normans. By the 13th century, the fell's usefulness as a pack animal was well-established and the pony played an important role in British trade until the end of the 18th century. Following the industrial revolution, fells were used to transport iron ore and coal from mine to town, as well as underground when the height of the shaft allowed. Although previously used in trotting races, the fell pony really came into its as a riding horse in the 1950s, when its gentle nature and pretty looks made it the pony of choice for families. Today, the pony remains a popular choice for riders of all ages, among them the queen who breeds fell ponies at her Hampton court stud. Source: the fell pony society.
Reference The queen was spotted enjoying a ride in Windsor great park today. Rode her favorite fell pony, named Carltonlima Emma. Left hard hats at home and opted for one of her favorite scarves instead.
Model Output The monarch, 88, was spotted trotting through Windsor great park aboard her faithful black fell pony, Carltonlima Emma. The queen, who has never worn riding helmets, has been encouraged to wear one because of her hair.

Figure 8: Factual errors made by the Point-Generator-with-Coverage model.

Source Document An argument between two Brisbane neighbors over noise levels has ended in tragedy with one man dead and another charged with manslaughter. Leon Yeaman, 55, was allegedly killed by a single punch in the head from 28-year-old shift worker Phillip Pama, 28, during a row in front of their north Brisbane homes. Mr.Yeaman was reportedly in his yard on muller road making a lot of noise at around 9 pm Thursday night. Phillip Pama covered his face as he left Brisbane magistrate courts where he was granted conditional bail on Friday. Pama, a married father of three, works a 3 am shift at a nearby warehouse and was sleeping at the time Mr.Yeaman was making a commotion. Pama's defence lawyer Bruce peters said Mr.Yeaman was known for getting drunk, playing loud music and yelling at "the world at large". Pama then confronted Mr.Yeaman and it was at that point the situation escalated. Mr.Peters said his client grabbed his neighbor by the hand and hit out "blindly". "He was being pushed at the same time he was throwing the punch," Mr.Peters revealed during a bail application for Pama. "he didn't see it connect but he felt it connect." The father of three allegedly killed his 55-year-old neighbor with one punch after he refused to turn his music down. Paramedics were unable to revive Mr.Yeaman who was pronounced dead at the scene at around 11 pm on Thursday night. Neighbors described Mr.Yeaman as king and generous while his friend John Fisher told ABC radio he was a schizophrenic pensioner who enjoyed playing loud music. Pama shielded his face from reporters outside Brisbane magistrate courts when he was granted bail on Friday. The Samoan man was ordered to surrender his passport, aherre to a curfew from 6 pm to 2 am and will have to report to the local police station twice a week. Pama, who has no history of violence, was reportedly "beside himself" with grief. The case is due to return to court on May 18.

Reference Two men got in an argument about noise levels on Thursday night. A scuffle broke out and Phillip Pama struck Leon Yeaman once in the head. Mr.Yeaman could not be revived and was announced dead at the scene. Pama has no history of violence and is reportedly "beside himself". His defence lawyer said he hit out "blindly" and didn't see his punch connect. Pama was granted conditional bail and is set to return to court May 18.

Model Output Leon Yeaman, 55, was allegedly killed by a single punch in the head from 28-year-old shift worker Phillip Pama, 28, during a row in front of their north Brisbane homes. Mr.Yeaman was granted conditional bail on Friday. He was ordered to return to court on May 18.

Figure 9: Factual errors made by the Bottom-Up model.

Source Document An obsessive arsenal fan made his girlfriend sit a test quizzing her about his favourite football club. Marking her answers with red pen, she scored an impressive 43.5 out of 50, to which he commented, “Well done Saskia! As a result, I will not be dumping you! (lucky you)”. Saskia posted snaps of the test to her twitter account, @saskiaisabxlla, commenting “boyfriend made me take an @arsenal exam!” with emoticons showing she didn’t know whether to laugh or cry. We don’t blame her. Saskia’s football fan boyfriend made her take an arsenal test and didn’t dump her thanks to her A grade. The test took the form of a school exam, with multiple choice questions, tables to complete, and ’in your own words...’ section. There were even “helpful” instructions including “read every question at least twice” and “check your answers if you have time at the end”. Oh, and “calculators may be used”. Saskia scored an impressive 87 percent, but according to her unnamed boyfriend’s feedback she could have performed better on q17, needs to learn all player positions and should understand that tottenham are scum. She scored some decent points for her more creative answers. Saskia clearly knows how to keep her boyfriend happy, as she humoured his question of “why are arsenal the best team to ever grace english football?” with the answer of “they’ve won many fa cups” and “Thierry Henry is a legend”. However, when she got an answer wrong, her examiner wrote the correct answer in capitals and drew an angry face. Saskia struggled to name all 11 players of the starting squad and got confused on the player positions. He was impressed with the end result, though, grading her an “A” and rewarding her by not ending their relationship. Comments generally hailed the man as a “legend” and fellow football fans were impressed with Saskia’s knowledge. Some twitter users hailed the unnamed boyfriend who tested Saskia on her arsenal knowledge as a legend. scoring 87%, football fans were impressed with Saskia, claiming her as “proper girlfriend material”.

Reference Arsenal fan’s girlfriend avoids getting dumped after passing football test. Saskia got an “A”, but apparently needs to work on her player positions. The bemused woman posted pictures of boyfriend’s test on twitter.

Model Output (PG) Saskia posted snaps of the test to her twitter account, @saskiaisabxlla. She posted snaps of the test to her twitter account, commenting “Well done Saskia! As a result, I will not be dumping you! (lucky you)”.

Model Output (PG Coverage) Arsenal fan made his girlfriend sit a test quizzing her about his favourite football club. She posted snaps of the test to her twitter account, @saskiaisabxlla, commenting “boyfriend made me take an @arsenal exam!” with emoticons showing she didn’t know whether to laugh or cry. Oh, and “calculators may be used”.

Figure 10: The Pointer-Generator-with-Coverage model tends to make *Addition* errors when Pointer-Generator does not have repetitions.

Source Document A teenager set herself on fire after allegedly being raped by five men from her village in India – and her family reportedly told her to keep quiet about the attack. The 14-year-old is now fighting for her life in Delhi's Safdarjung hospital with 70 percent burns. She was allegedly gang-raped on Sunday when she went outside her house in Kosi Kalan, in Uttar Pradesh's Mathura district, to relieve herself. A teenager set herself on fire after allegedly being raped by five men from her village in India. She is now recovering in Delhi's Safdarjung hospital. She was allegedly gang-raped on Sunday when she went outside her house in Kosi Kalan, in Uttar Pradesh's Mathura district, to relieve herself. On Tuesday she set herself on fire using kerosene, according to NDTV, to the shock of her brother, who doused her with water. He told the broadcaster: "when I woke up, I saw her in flames ... I poured water on her to put out the flames." The girl was screaming for help, according to a neighbour. The accused men have been arrested. There is a heightened sensitivity to the issue of sexual assault in India at the moment after officials last month banned India's daughter, a documentary about the gang rape and murder of an Indian student in Delhi. Recent attacks in India have resulted in street protests with many calling for more protection for women. Officials said the documentary would cause further disorder if it was shown, following a number of protests and incidents of vigilante justice in the country. The documentary explained the brutal rape and murder of 23-year-old student Jyoti Singh, who was attacked on a bus when she returned home from the cinema. One of the six men convicted of the attack, bus driver Mukesh Singh, was interviewed in prison and told researchers that had Jyoti not fought back she would not have been killed. Her death led to protests throughout India and outraged the world. Last month an angry mob was seen on video footage beating a man to death in the street who was accused of raping and murdering an 11-year-old girl. Video footage has emerged of the brutal prolonged attack on the 18-year-old, which was watched by a jeering 1,000-strong crowd in Nagaland in eastern India. Ibo Cha was said to have been beaten for an hour before he died of his injuries. The footage was shot in September last year after the girl's body was found in woodland, enraging locals. But it only came to light after earlier this year alleged rapist Syed Sarif Khan was kidnapped from prison and dragged through the streets of the same area. He was then stripped naked and beaten to death. He was accused but not convicted of raping a 19-year-old female student multiple times. Later Nagaland government said he was innocent. Jyoti Singh Pandey, a physiotherapy student, was gang raped as she travelled on a bus. The 23-year-old suffered in hospital for 13 days from her injuries before she died. Vinay Sharma, 20, Akshay Thakur, 28, Pawan Gupta, 19, and Mukesh Singh, 26, were all sentenced to death for her rape. Ram Singh, co-accused and widely considered the leader of the group, was found dead in his cell. A minor also found guilty was sentenced to three years in a reformatory institution. Her death sparked angry protests in India and internationally about misogyny in the country. The attention forced judges to prioritise the case and the lawyer's association in Saket reportedly refused to defend the perpetrators.

Reference She was allegedly attacked after leaving her house to relieve herself. The attack is said to have taken place in India's Uttar Pradesh region. Victim suffered 70 percent burns after dousing herself in kerosene. Her brother apparently saw her covered in flames and threw water on her.

Model Output (PG) The 14-year-old is now fighting for her life in Delhi's Safdarjung hospital. She was allegedly gang-raped on Sunday when she went outside her house. She was allegedly gang-raped on Sunday when she went outside her house. She set herself on fire using kerosene, according to NDTV.

Model Output (PG Coverage) Teenager set herself on fire after allegedly being raped by five men. She was allegedly gang-raped on Sunday when she went outside her house in Kosi Kalan, Uttar Pradesh's Mathura district, to relieve herself. On Tuesday she set herself on fire using kerosene, according to a neighbor.

Figure 11: The Pointer-Generator-with-Coverage model tends to incorrectly combine information from the document, thus leading to *Inacc_Intrinsic* errors.

Source Document A trend we are just starting to get our heads around is the wide leg trouser. Be it denim, cropped, printed or striped, the wide leg trouser is at the forefront of ss15 trends. There's something effortless about a wide leg trouser that really appeals. And if like us you are growing tired of the skinny jean and want to try out a new look this could be your answer. Louise redknapp says that a wide-leg trouser can come as a welcome relief from the skinny jean. Skinny jeans have held court for quite a few years now and while they will never go out of style the wide leg will give you an alternative look. It's not the first time this look has made a comeback since the seventies. Lou tried the out the trend seven years ago with a stella mccartney flared jean - luckily she kept hold of them! The wide leg can be intimidating, especially if you're on the shorter side. But the key is all in the shoe. Huge amounts of fabric is hard to look flattering but if you keep your heels high and your top half simple you can pull it off with confidence. A high heeled shoe with an exposed top of foot will elongate the leg, a must when wearing a cropped voluminous trouser. Louise and Emma say to avoid being drowned by too much fabric try a high heeled shoe. Louise recommends pairing a wide-leg with a simple knit to keep the outfit in proportion if going for a longer length go high-waisted and very long to give extra leg length. Proportion is everything, team with a simple knit, shirt or tee to keep the look current and cool, not costume. Denim is the easiest way to nail the trend - Gucci revisited the seventies with a collection filled with flared jeans in vintage washes. The stylish pair agree that denim is the easiest way to achieve the trend. The wide-leg trouser made an appearance on several catwalks including on the runway of Gucci ss15 who showcased a denim take on the trend, for a high street take try the topshop miller jean (right). Celine showcased colourful billowing bottoms on their ss15 runway topshop meanwhile have been quick to follow suit with their version - the miller - a 1970s-style wide leg flare. Celine and Stella Mccartney kept it classy with a dressier-style pant, perfect for an evening look. Try new online label finery London for a similar style with a lower price tag. A wide billowing trouser silhouette will update your wardrobe this season and the bonus is it's one spring trend you don't need nice weather for. To shop our looks and for more wide-leg trouser inspiration head to astylealbum.com. Poppy Delevingne channeled the trend at the aw15 chloe show in Paris.

Reference Louise Redknapp and stylist Emma Thatcher try the wide-leg trouser. They say it makes a good replacement for ever-popular skinny jeans.

Model Output (Bottom up) Louise redknapp says trouser can come as the wide leg trouser jean. Lou jeans will not go out of the leg trouser. The trouser is a wide leg trouser.

Model Output (SUMMA) Louise Redknapp says that a wide-leg trouser can come as a welcome relief from the skinny jean. Louise and Emma say to avoid being drowned by too much fabric try a high heeled shoe. Poppy Delevingne channeled the trend at the aw15 chloe show in Paris.

Source Document (CNN) Bobbi Kristina Brown, the daughter of Bobby Brown and Whitney Houston, has “global and irreversible brain damage”, according to her grandmother. Though the 22-year-old is no longer in a medically induced coma, she remains unresponsive, Cissy Houston said in a statement Monday after visiting her granddaughter. “meeting with the doctors and understanding that she can live in this condition for a lifetime truly saddens me,” Houston said. “we can only trust in god for a miracle at this time.” Houston’s statement matched that from a source with knowledge of brown’s condition, who told CNN on Monday that she remained in the same neurological state she has been in for nearly three months. She does not respond to visitors or familiar voices, and her eyes do not follow a person around the room, the source told CNN. She also has a tracheostomy in her throat, the source said. The reports come two days after Brown’s father, Bobby Brown, said his daughter’s condition had improved. “i can say today, Bobbi is awake. She’s watching me,” Brown told the audience at Dallas’ Verizon Theatre. The audience cheered. In a statement Monday, an attorney for the Brown family said that Bobbi Kristina Brown’s condition has improved but that the kind of life she will lead remains to be seen. “doctors have indicated that she will have a long life,” attorney Christopher Brown said. “however, Bobbi Kristina is presently embarking on a rehabilitation process, and the quality of her life will not be known for years to come.” Who’s who in the Bobbi Kristina Brown case? Bobby Brown was in an “emotional state” on stage when he made the remarks about his daughter being awake, according to the statement. “she has made it out of ICU, opened her eyes and started a rehabilitation that will be long and hard,” said Bobby Brown’s wife, Alicia Etheredge Brown.
Model Output Bobbi Kristina Brown is in a medically induced coma, her grandmother says. Bobbi Kristina Brown’s condition has improved but that the kind of life will be seen. Brown’s mother says Bobbi Kristina Brown’s condition has improved.

Source Document This little piggy has become an Internet sensation after learning how to walk on just two feet. The piglet was born with its back legs missing and has mastered the art of balancing on its front trotters. The heartwarming clip featured on the people’s daily online shows the young animal taking unsteady steps, wobbling about with its snout to the ground, foraging for food. Heartwarming: the two-legged pig has become an Internet sensation because of a cute video showing it learning to walk. There are several occasions it looked close to tipping over but remarkably the piglet always manages to regain its balance. It happily mixes with the rest of the litter, which have all been born with a full complement of legs. The piglet belongs to a farmer, Ms. Duan, from Qionglai city in Sichuan province, south western China. Since its birth, villagers have flocked to take a peek at the curious animal. Tricky: the piglet has to use extraordinary balance to stand on its front trotters while all its siblings were born with all four legs. Athletic: the piglet, nicknamed “super pig” can balance on its two front trotters and has captured the hearts of thousands since a video went online. Siblings: one of the other piglets looks to copy the two-legged creature as it takes a quick rest from trotting about. Ms. Duan said: “When the piglets were feeding I noticed something strange with one of them. When I picked it up I could see it had no hind legs.” It is not the first animal with two legs instead of four to win plaudits in China. A rabbit at Liuzhou zoo became a star attraction after learning to walk on its front paws. Many tourists in China’s Guangxi province have been taking a detour to see the furry star hop on its front paws. Looking for grub: the piglet balances on two legs while keeping its snout to the ground in the hunt for food.
Reference Piglet was born in China with only two front legs has learned to walk. Villagers have flocked to see the two-legged animal in Qionglai. A video released online and has captured the hearts of thousands.

Source Document Manchester United manager Louis Van Gaal says he has been dreaming of beating rivals City in Sunday's Derby at old Trafford but will have to do so without Robin Van Persie. Van Persie said he was fit to feature in the game against City on Sunday after ankle trouble but Van Gaal has ruled him out. "Most of the players are fit but being fit for me is different." Van Gaal said. Robin Van Persie will not return to the fray for Manchester United against Manchester City on Sunday. Louis Van Gaal explained at his press conference on Friday that Van Persie is not yet fit enough to play. United players train in the sunshine ahead of their game against local rivals City on Sunday. "Robin is not fit enough to play." With city rocking after defeat at crystal palace on Monday, Van Gaal and his players have an opportunity to finish as high as second or third and avoid a champions league qualifying fixture later in the summer. The United boss wants his side to move towards that target by taking all three points against City. Van Gaal said: "I dream of it. Every player should dream of the victory. Of course I want to win because it's a big step up the table also. If we win then third place is available." Van Gaal watches on as he prepares his side for his first Manchester Derby at Old Trafford. Manager Van Gaal oversees the training while captain Wayne Rooney runs with the ball. Goal keeper David De Gea, Winger Angel Di Maria and Radamel Falcao were in training action. Rooney leads the way in training as he runs through some cones in the sunshine on Friday in Manchester. Di Maria, Juan Mata, Falcao, Marcos Rojo and Ander Herrera prepare to take on City. "A few months ago, nobody would have thought about that, apart from me. If we win then the position in the table is good as we would then almost certainly be qualified for the top four. And if we are third it's better than the goal we set in preseason." Van Gaal acknowledged that City will provide a stern challenge to his team and played down the idea he will be motivated by revenge, after losing the away fixture earlier in the campaign. "We have lost 1-0, that is my history, the last game," Van Gaal said. "I say always in such games, always, you have to control your aggression." We did not do that at that time. So I hope we have learned from that moment. I can not say because we lost that game that we have to win this game. "In my opinion, you can lose to Man City two times. That is possible." The united boss also ruled out a potential return for Luke Shaw. Like Van Persie, Van Gaal does not yet consider him fit enough to feature. "I don't think Shaw is fit enough to play," Van Gaal said. "but I can not say they are not fit, but in my opinion they are not fit to play. That is a different question." Luke Shaw is another player yet to be at the standard of match fitness required by Van Gaal. Rooney, Ashley Young, Goalkeeper Anders Lindegaard and Michael Carrick have a breather. Falcao and Antonio Valencia look in high spirits as they prepare for the Derby. Herrera will be hoping to continue the fine form that has seen him become one of United's key players recently. Van Gaal admitted he is looking forward to sampling the Derby atmosphere at Old Trafford, as he takes on City with home advantage for the first time since arriving at the club. "When I see the fans of Man UTD, they are supporting us in a marvellous way, I think," Van Gaal said. "after matches, I give our fans a big compliment, not because I have to, because then I wouldn't say it. I say it because I feel it."

Reference Manchester United face Manchester City in the premier league on Sunday. Robin Van Persie said he was fit for united after nearly two months out. But Louis Van Gaal has since revealed he will be without the striker. Van Persie declares himself fit, but do Manchester United need him? Click here for all the latest Manchester United news.

Abstract

Unsupervised methods are promising for abstractive textsummarization in that the parallel corpora is not required. However, their performance is still far from being satisfied, therefore research on promising solutions is on-going. In this paper, we propose a new approach based on Q-learning with an edit-based summarization. The method combines two key modules to form an Editorial Agent and Language Model converter (EALM). The agent predicts edit actions (e.t., delete, keep, and replace), and then the LM converter deterministically generates a summary on the basis of the action signals. Q-learning is leveraged to train the agent to produce proper edit actions. Experimental results show that EALM delivered competitive performance compared with the previous encoder-decoder-based methods, even with truly zero paired data (i.e., no validation set). Defining the task as Q-learning enables us not only to develop a competitive method but also to make the latest techniques in reinforcement learning available for unsupervised summarization. We also conduct qualitative analysis, providing insights into future study on unsupervised summarizers.[1]

1 Introduction

Automatic text summarization[2] is an attractive technique for helping humans to grasp the content of documents effortlessly. While supervised neural methods have shown good performances (See et al., 2017; Zhang et al., 2019), the unsupervised approach is starting to attract interest due to its advantage of not requiring costly parallel corpora. However, the empirical performance of unsupervised methods is currently behind that of state-of-the-art supervised models (Zhao et al., 2018; Baziotis et al., 2019). Unsupervised text summarization is still developing and is now at the stage where various solutions should be actively explored.

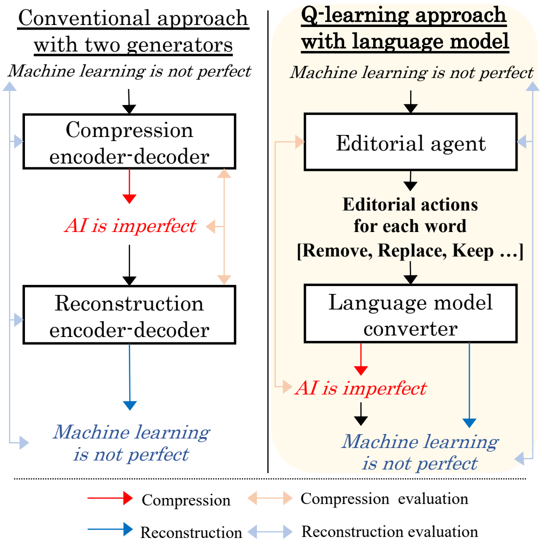

Figure 1: Overview of previous (left) and proposed (right) approaches on CR learning paradigm.

One previous unsupervised approach extends neural encoder-decoder modeling to the zero paired data scenario, where a model is trained with a paradigm called compression-reconstruction (CR) learning (Miao and Blunsom, 2016; Fevry and Phang, 2018; Zhao et al., 2018). The mechanism is similar to that of the back-translation (Sennrich et al., 2016): the model consists of a compressor (i.e., summarizer) and a reconstructor, and they are co-trained so that the reconstructor can recover the original sentence from the summary generated by the compressor (Miao and Blunsom, 2016; the left side of Figure 1). Experimental results showed that such an unsupervised encoder-decoder-based summarizer is able to learn the mapping from a sentence to a summary without paired data (Baziotis et al., 2019; Yang et al., 2020).

Reinforcement learning (RL) is also a potential

solution for the no paired data situation. In related fields, for example, there are unsupervised methods for text simplification and text compression with policy-gradient learning (Zhang and Lapata, 2017; Zhao et al., 2018). Recent RL techniques take a value-based approach (e.g., Q-learning) such as DQN (Mnih et al., 2015) or the combination of policy and value-based approaches such as Asynchronous Advantage Actor-Critic (Mnih et al., 2016). A critical requirement to leverage a value-based method is a value function that represents the goodness of an action on a given state (Sutton et al., 1998). We can naturally define the value function by utilizing the CR-learning paradigm, and it makes the latest value-based approaches available for unsupervised text summarization.

In this paper, we propose a new method based on Q-learning and an edit-based summarization (Gu et al. 2019; Malmi et al. 2019; right side of Figure 1). The edit-based summarization generates a summary by operating an edit action (e.g., keep, remove, or replace) for each word in the input sentence. Our method implements the editing process with two modules: 1) an **E**ditorial **A**gent that predicts edit actions, and 2) a **L**anguage **M**model (LM) converter that deterministically decodes a sentence on the basis of action signals, which we call EALM. The CR learning is defined on the Q-learning framework to train the agent to predict edit actions that instruct the LM converter to produce a good summary. Although a vast action space causing sparsity in reward, such as the word generation of an encoder-decoder model, is generally difficult to be learned in RL, our method mitigates this issue thanks to its fewer edit actions and the deterministic decoding of a language model. Moreover, the formulation by Q-learning enables us to incorporate the latest techniques in RL.

The main contribution of this paper is that we provide a new solution in the form of an unsupervised edit-based summarization leveraging Q-learning and a language model. Experimental results show that our method achieved a competitive performance with encoder-decoder-based methods even with truly no paired data (i.e., no validation set), and qualitative analysis brings insights as to what current unsupervised models are missing. Also, the problem formulation on Q-learning enables us to import the latest techniques in RL, which leads to potential improvements in future research.

2 Task Definition

We begin by formally defining the problem of unsupervised summarization with the CR learning. The goal of the task is to produce an informative summary $\boldsymbol{y}$ consisting of M words $y_1, y_2, ..., y_M$ for a given input sentence $\boldsymbol{x}$ consisting of N words $x_1, x_2, ..., x_N$ where $M < N$. The challenge in this task is to learn the transformation from $\boldsymbol{x}$ to $\boldsymbol{y}$ with only the input sentence $\boldsymbol{x}$.

To tackle this, the CR learning introduces an additional transformation called reconstruction. The reconstruction requests to reproduce the input sentence $\hat{\boldsymbol{x}}$ from the generated summary $\boldsymbol{y}$ where $\hat{\boldsymbol{x}}$ is the reproduced sentence consisting of N words $\hat{x}_1, \hat{x}_2, ..., \hat{x}_N$. In terms of the generated sentences $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$, let C be the compression function and R be the reconstruction function:

$$\boldsymbol{y} = C(\boldsymbol{x}, \theta_C)\,, \hat{\boldsymbol{x}} = R(\boldsymbol{y}, \theta_R)\,,$$

where θ_C and θ_R are their respective parameters. Thus, the task can be written as the following optimization problem:

$$\theta_C^*, \theta_R^* = \underset{\theta_C, \theta_R}{\arg\max}\{f(\boldsymbol{x}, \boldsymbol{y}) + g(\boldsymbol{x}, \hat{\boldsymbol{x}})\}\,,$$

where $f(\boldsymbol{x}, \boldsymbol{y})$ and $g(\boldsymbol{x}, \hat{\boldsymbol{x}})$ are functions to return a higher value for favorable $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$ in regard to the input sentence $\boldsymbol{x}$. According to the CR learning's hypothesis that the summary should contain enough information to guess the original contents, $\boldsymbol{y}$ becomes favorable when the difference between $\boldsymbol{x}$ and $\hat{\boldsymbol{x}}$ is smaller while $\boldsymbol{y}$ maintains the essential aspects of a summary (e.g., shortness, fluency).

3 Previous Method

The previous approaches use a generative encoder-decoder model (Sutskever et al. 2014), for the compression and reconstruction functions (Miao and Blunsom, 2016; Fevry and Phang, 2018; Wang and Lee, 2018; Baziotis et al., 2019). Although the objective functions and implementation details differ depending on the study, the underlying motivation entails the same hypothesis as the CR learning. For example, Baziotis et al. (2019) introduced four objective functions — discrepancy of $\boldsymbol{y}$ from a pretrained language model, topical distance of $\boldsymbol{x}$ and $\boldsymbol{y}$, and the length of $\boldsymbol{y}$ and probability difference of x_i and $\hat{x}_i$ — where the former threes can be regarded as $f(\boldsymbol{x}, \boldsymbol{y})$ and the final one as $g(\boldsymbol{x}, \hat{\boldsymbol{x}})$.

While such an encoder-decoder model has performed well on many generation tasks, it suffers from inherent difficulties related to repetition (See et al., 2017), length control (Kikuchi et al., 2016), and exposure bias (Ranzato et al., 2016). It also runs into convergence problems when co-training multiple generators (Salimans et al., 2016).

4 Proposed Method

Our proposed method, which we call EALM, consists of two essential modules: the editorial agent and the LM converter. The agent sends action signals (keep, remove, or replace each word in a sentence) to the conveter, which then deterministically transforms the input sentence according to the signals. We train the agent to find action signals so that the LM converter produces sentences demanded by the CR learning. In the following sections, we first share the background of Q-learning (§4.1) and then present how to put the task and our approach on the Q-learning framework (§4.2). We next explain the core algorithmic details (§4.3) and finish with explanations about training and inference (§4.4).

4.1 Preliminaries

Q-learning is a popular approach in RL as represented by Deep Q-Networks (DQN, Mnih et al. 2015). Q-learning leverages an action-value function to estimate the *value* of a pair of state and action with respect to a policy π. The action-value function (i.e., Q-function) is represented as the expected reward for the state-action pair:

$$Q^{\pi}(s,a) = \mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t r(s_t, a_t) \mid s_0 = s, a_0 = a\right],$$

where s is a state, a is an action, r is a reward function for the state-action pair, and γ is the discount factor. Hence, to solve a text summarization task via Q-learning, we first need to appropriately define the state, action, and reward function.

4.2 Unsupervised Edit-based Summarization with Q-learning

In our approach, given an input sentence $\boldsymbol{x}$, we define a state s_i in regard to each word x_i. An action a_i for the state s_i is chosen from among the three options, $\mathcal{A} = \{\texttt{Remove}, \texttt{Keep}, \texttt{Replace}\}$. The goal of the editorial agent is to provide the optimal action sequence, $\boldsymbol{a} = \{a_0, a_1, \ldots, a_N\}$, by iteratively making action decisions on each word (§4.3.1). To obtain $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$, we propose a deterministic transformation algorithm based on $\boldsymbol{a}$ and the LM converter (§4.3.2). Finally, we define the reward function r to evaluate the action and action sequence in terms of the produced sentences $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$ (§4.3.3). The reward function is designed to align with the CR learning paradigm and leads the agent into bringing the action sequence that generates an appropriate $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$.

4.3 Algorithms

In this section, we describe three principle algorithms: 1) how to create s_i and to predict a_i, 2) how to generate $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$ by means of $\boldsymbol{a}$ and the LM converter, and 3) how to compute the reward.

4.3.1 Iterative Action Prediction

The overall flow of iteratively predicting an action for each word is shown in Figure 2. The agent predicts an action for a state (i.e., a word) one by one, so we call one prediction a *step* and express it with a subscription (t). For example, $s_{i(t)}$ and $a_{i(t)}$ respectively denote the state and action for x_i at the t-th step. Note that $a_{i(t)}$ has a predicted action if the agent has already done the prediction on x_i by the t-th step, otherwise $a_{i(t)}$ is `Keep`. Also, we prepare a Boolean vector $\boldsymbol{u}_{(t)}$ of length N representing the prediction statuses at the t-th step; $u_{i(t)}$ is 1 if the prediction on the i-th word has been finished, otherwise, 0. The order to predict an action is determined by Q-values. Let s^* and a^* be a state-action pair to be operated next, which comes from the maximum Q-values over unoperated states:

$$s^*, a^* = \arg\max_{s \in \mathcal{S}', a \in \mathcal{A}} Q(s,a),$$

where $\mathcal{S}'$ is defined as $\mathcal{S}' = (\forall_i)\{s_{i(t)} \mid u_{i(t)} = 0\}$. The agent then reiterates the predictions until it finishes determining an action on all words. By defining the state in regard to a single word instead of a whole sentence and asking the agent to determine the prediction order, we can handle variable sentence lengths in natural language. Note that this is not a left-to-right process; the agent conducts the prediction in the order of “confidence”.

Next we explain how to encode $s_{i(t)}$. To send the agent contextual information, such as the previous decisions, the prediction statuses, and the whole sentence, we dynamically create a state $s_{i(t)}$ with a concatenation of two encodings; *local encoding* $\boldsymbol{l}_{i(t)}$ and *global encoding* $\boldsymbol{g}_{i(t)}$

$$s_{i(t)} = [\boldsymbol{l}_{i(t)}; \boldsymbol{g}_{i(t)}].$$

To create the two encodings, first, we map x_i to a fixed-sized vector $\boldsymbol{e}_i$ with an arbitrary encoder (we

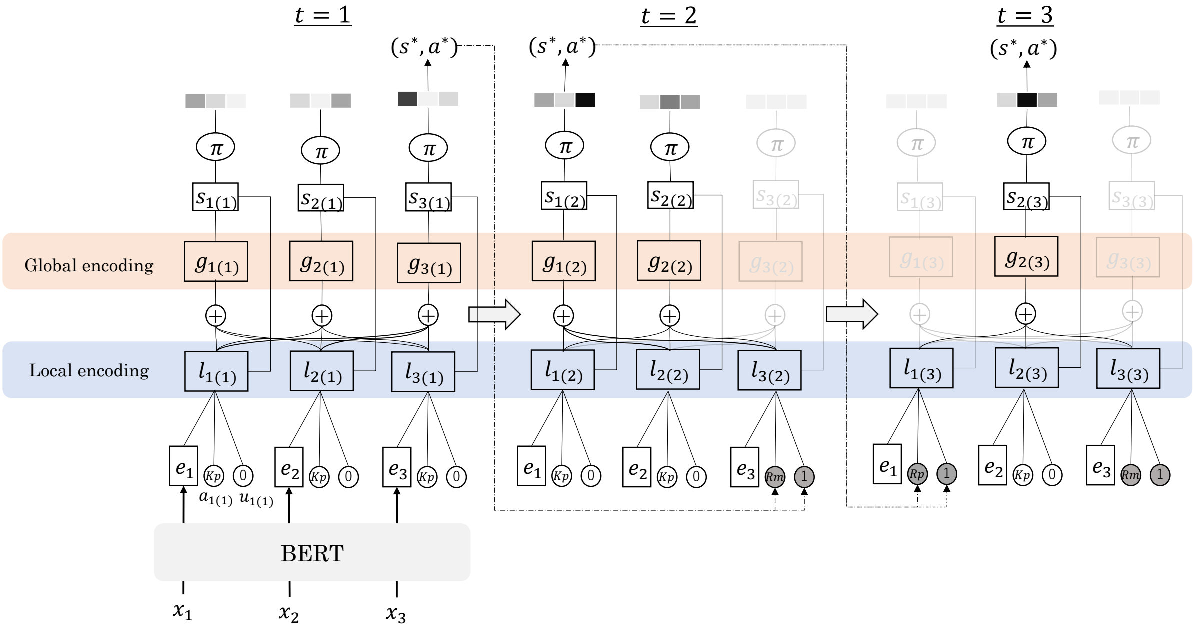

Figure 2: Algorithmic visualization of iterative action prediction

use BERT; Devlin et al. 2019), and $\boldsymbol{e}_i$ is repeatedly used throughout the process regardless of the steps. Then, we define the local encoding as

$$\boldsymbol{l}_{i(t)} = \boldsymbol{e}_i + \boldsymbol{b}^{a_{i(t)}} + \boldsymbol{b}^{u_{i(t)}},$$

where $\boldsymbol{b}^{a_{i(t)}}$ and $\boldsymbol{b}^{u_{i(t)}}$ are learnable bias vectors for the action and prediction status of the i-th word, respectively. Next, we create the global encoding in a self-attention fashion as

$$\boldsymbol{g}_{i(t)} = \sum_j w_{j(t)} \boldsymbol{l}_{j(t)},$$

where $w_{j(t)}$ is computed with ReLU:[3]

$$w_{j(t)} = \frac{\mathrm{ReLU}(\boldsymbol{l}_{i(t)} \cdot \boldsymbol{l}_{j(t)})}{\sum_k \mathrm{ReLU}(\boldsymbol{l}_{i(t)} \cdot \boldsymbol{l}_{k(t)})}.$$

Thanks to the bias terms in $\boldsymbol{l}_{i(t)}$ and the self-attention in $\boldsymbol{g}_{i(t)}$, $s_{i(t)}$ is aware of the previous decisions for each word and the interactions between those decisions. In addition, BERT encoding $\boldsymbol{e}_i$ enables us to take a whole sentence into account.

4.3.2 Deterministic Decoding by Language Model with Action Signals

In this section, we explain how to compress and reconstruct sentences in a deterministic manner with the LM converter. For the LM converter, we use BERT (Devlin et al., 2019) which is a masked language model (MLM) trained to predict "masked" portions in a sentence. MLM can estimate the probability distribution of i-th word x_i in a sentence as $p(x \mid \boldsymbol{x}_{\setminus i})$ where $\boldsymbol{x}_{\setminus i}$ is the same as $\boldsymbol{x}$ except that it has a mask at the i-th position ($\langle ..., x_{i-1}, \texttt{[MASK]}, x_{i+1}, ...\rangle$; Wang and Cho 2019). $L(\boldsymbol{x}_{\setminus i})$ denotes a function to return a word with the highest probability for the i-th position.

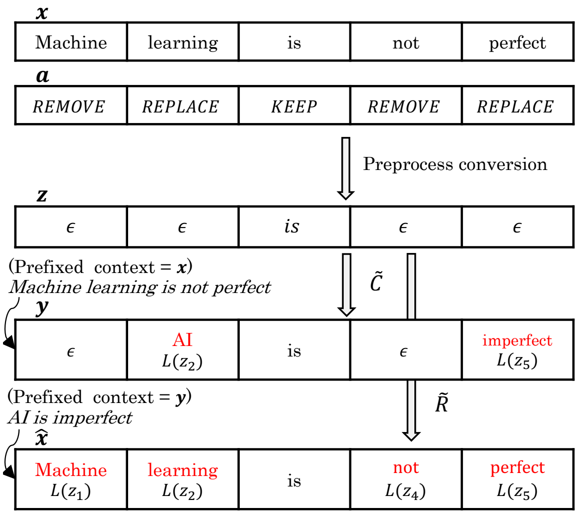

Figure 3: Deterministic compression and reconstruction with masked language model

The procedure to obtain $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$ by using $\boldsymbol{a}$

---

[3] We used ReLU(·) instead of the conventional exp(·) because exp(·) caused the exploding gradient in our case.

and MLM is shown in Figure 3. First, we convert $\boldsymbol{x}$ to a skeleton sequence $\boldsymbol{z}$ consisting of N tokens $z_1, z_2, ..., z_N$ where z_i is x_i if a_i is `Keep`, otherwise a null token ϵ. We then define our compression and reconstruction functions $\tilde{C}$ and $\tilde{R}$ as

$$\begin{aligned} y_i &= \tilde{C}(\boldsymbol{z}, a_i, L) \\ &= \begin{cases} L(\boldsymbol{z}_{\setminus i}) & (a_i = \texttt{Replace}) \\ z_i & (\text{otherwise}), \end{cases} \\ \hat{x}_i &= \tilde{R}(\boldsymbol{z}, a_i, L) \\ &= \begin{cases} L(\boldsymbol{z}_{\setminus i}) & (a_i \in \{\texttt{Remove}, \texttt{Replace}\}) \\ z_i & (\text{otherwise}). \end{cases} \end{aligned}$$

A word is predicted only for ϵ given by `Replace` in compression, but it does so for all ϵ in reconstruction. Also, we set the original sentence as a prefixed context, which comes from $\boldsymbol{x}$ in compression and $\boldsymbol{y}$ in reconstruction, to make MLM aware of a former meaning. An example is shown in Figure 3, where MLM receives "*Machine learning is not perfect .* [MASK] *is* [MASK] ." as the compression input and predicts words for the [MASK]s. If there are multiple masks, we conduct the prediction in an autoregressive fashion (see Appendix A.1). Note that while any language model can be used for the LM converter, MLM is advantageous because it utilizes before and after contexts, and there is no restriction on looking ahead at upcoming words.

4.3.3 Stepwise Reward Computation

In this section, we explain the reward computation of the chosen action by referring to $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$.

As stated in §4.3.1, we have an action sequence $\boldsymbol{a}_{(t)}$ for every step t. When we apply $\tilde{C}$ and $\tilde{R}$ to all the $\boldsymbol{a}_{(t)}$, we can obtain a list of tuples $(s, a, r, \boldsymbol{x}, \boldsymbol{y}, \hat{\boldsymbol{x}})_{(t)}$. A tuple — let us say, *experience* — enables us to evaluate a state-action pair with respect to a single transition. In this section, we propose three techniques — **step reward**, **violation penalty**, and **summary assessment** — to evaluate the agent's behavior with the stepwise experiences. Refer to Table 1 to see how these work in reward computation with an actual example.

Before moving on to the details, let us define two important notions throughout this section, compression rate (cr) and reconstruction rate (rr):

$$cr_{(t)} = 1 - \frac{|\boldsymbol{y}_{(t)}|}{|\boldsymbol{x}|}, rr_{(t)} = \frac{|\{i \mid x_i = \hat{x}_{i(t)}\}|}{|\boldsymbol{x}|}.$$

The CR learning assumes that the higher values of cr and rr are better. We use these for calculating rewards and pruning experiences.

Step Reward. The task of the agent is to produce an action sequence with which the LM converter generates an appropriately compressed sentence while keeping the reconstruction successful. As such, we define the reward function r as

$$r(s, a, \boldsymbol{x}, \boldsymbol{y}, \hat{\boldsymbol{x}}) = r_{SR} + r_{SA},$$

where r_{SR} is the step reward that are designed to encourage the agent to improve the compression and reconstruction rate, respectively. r_{SA} is an additional score from the qualitative assessment of $\boldsymbol{y}$, which we explain later. Returning to the step reward r_{SR}, it is a multiplication of r_C and r_R defined as

$$r_{SR} = r_C \times r_R,$$
$$r_C = 1 - \frac{|\boldsymbol{y}_{(t)}|}{|\boldsymbol{y}_{(t-1)}|}, r_R = \begin{cases} 1 & (rr_{(t)} > \tau_{(t)}) \\ -1 & (\text{otherwise}) \end{cases},$$

where $\tau_{(t)}$ is a minimum requirement for the reconstruction rate at the t-th step and is defined as $\tau_{(t)} = 1 - t\frac{1-\tau}{N}$ with the hyperparameter $\tau \in [0, 1]$. If we set $\tau = 1$ that requests perfect reconstruction, then $\tau_{(t)} = 1$ regardless of t. However, we need to forgive reconstruction failure to some extent because of the information loss in compression, and τ adjusts the allowed number of failures. For example, $\tau = 0.5$ requests the model to recover at least half of the original sentence correctly.

Let us describe the behavior of the step reward r_{SR}. First, the reward is 0 when the agent chooses `Keep` or `Replace` because $r_C = 0$ due to there being no change in the length of $\boldsymbol{y}$. Second, the reward gets a positive value when the agent chooses `Remove` and satisfies the requirement for the reconstruction rate ($rr_{(t)} > \tau_{(t)}$). Third, the reward gets a negative value when the agent chooses `Remove`, but the reconstruction rate is less than the requirement. In short, the step reward recommends `Remove` as long as the agent can recover the original word, and otherwise, `Keep` or `Replace`.

Violation Penalty. Sequential modeling, including that performed by our agent, essentially suffers from error propagation caused by incorrect predictions at an earlier stage (Collins and Roark, 2004). The violation penalty mitigates this issue by giving a negative reward to the latest problematic action and excluding experiences after the mistake.

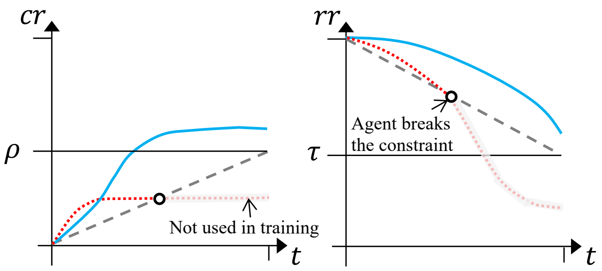

Figure 4: Violation penalty for compression (left) and reconstruction (right). The x-axis is step and the y-axis is each ratio. The horizontal lines in the middle are ρ and τ, and the dashed lines represent $\rho_{(t)}$ and $\tau_{(t)}$. The circles represent a step where the agent breaks the constraints.

Here, in addition to τ, we introduce the hyperparameter ρ, which represents a minimum requirement for the compression rate. $\rho_{(t)}$ denotes its threshold at the t-step defined as $\rho_{(t)} = t\frac{\rho}{N}$, and the agent must satisfy the condition $cr_{(t)} > \rho_{(t)}$. As the penalty, we forcibly assign -1 reward for the state-action pair at the T-th step when the agent breaks either constraint of $\tau_{(T)}$ or $\rho_{(T)}$. In addition, we ignore experiences from step $(T + 1)$ and onward. If the agent keeps predicting until the end, we define $T = N$. Figure 4 shows how these constraints work for the experience sequence.

Summary Assessment. Although the step reward considers the compression and reconstruction ratios, it ignores the critical aspects of the generated summary such as replacement with a shorter synonym and fluency as a sentence. Here, we explain the r_{SA} mentioned in the previous paragraph and describe how to reflect such qualitative assessments to the reward given to the agent.

As the essential properties for $\boldsymbol{y}$, we take three perspectives into account: informativeness, shortness, and fluency. The informativeness refers to how much $\boldsymbol{y}$ retains the original meaning of $\boldsymbol{x}$, and the shortness and fluency are self-explanatory. To reflect these perspectives onto the agent's decision, we define r_{SA} as

$$r_{SA} = \frac{T}{N} \cdot [cr_{(T)} \times rr_{(T)} + \alpha \cdot sim(\boldsymbol{x}, \boldsymbol{y}_{(T)}) + \beta \cdot llh(\boldsymbol{y}_{(T)})],$$

where sim computes a similarity score of $\boldsymbol{x}$ and $\boldsymbol{y}$, and llh computes a log-likelihood of $\boldsymbol{y}$. α and β are hyperparameters to adjust the importance of sim and llh. In addition to r_{SR}, we give r_{SA} to the experiences from the beginning to T-th steps as defined in the step reward paragraph.

Let us explain the terms inside the square brackets first. The first term, which is the multiplication of $cr_{(T)}$ and $rr_{(T)}$, aims for shortness and informativeness. It gets a higher value when the agent achieves the right balance of compression and reconstruction. The second term sim aims to evaluate informativeness brought about by `Replace`. Concretely, sim returns a semantic similarity score in the range of $[0, 1]$ through the sentence vectors of $\boldsymbol{x}$ and $\boldsymbol{y}_{(T)}$ rather than just checking exact matches of words. The last term llh represents fluency via the log-likelihood of $\boldsymbol{y}_{(T)}$ given by a pre-trained language model (Zhao et al., 2018). We use BERT for the computation of sim and llh (Devlin et al. 2019; Wang and Cho 2019; see Appendix A.3). Finally, T/N is the ratio of the number of operated words. It becomes closer to 1 when the agent is reaching a termination, i.e., finishing the prediction on all words by avoiding the violation penalty, which makes r_{SA} larger. In contrast, the agent who fails at an earlier stage gets a small value of r_{SA}.

4.4 Training and Inference

Training. Leveraging the experiences $(s, a, r, \boldsymbol{x}, \boldsymbol{y}, \hat{\boldsymbol{x}})$ in the replay buffer (Lin, 1992), the agent learns the policy for summarizing a sentence $\boldsymbol{x}$ within the Q-learning framework. Specifically, we utilize DQN (Mnih et al., 2015) to learn the Q-function Q^* corresponding to the optimal policy by minimizing the loss,

$$\mathcal{L}(\theta) = \mathbb{E}_{s,a,r,s'}[(Q^*(s, a) - \psi)^2],$$

where $\psi = r + \gamma \max_{a'} \bar{Q}^*(s', a')$ and $\bar{Q}$ is a target Q-function whose parameters are periodically updated in accordance with the latest network parameters. During the collection of experiences, RL requires the agent to explore an action on a given state for finding a better policy. As a unique point in this work, the agent must explore not only the action but also the order to predict. For both explorations, we use the ϵ-greedy algorithm (Watkins, 1989) that stochastically forces the agent to ignore Q-values and to behave randomly (see Appendix A.2).

Inference. Our modeling that provides $\boldsymbol{y}$ and $\hat{\boldsymbol{x}}$ for each step has another advantage in terms of the inference. For the final output, we use $\boldsymbol{y}$ at the t^*-th step that achieves the best balance of the compression and reconstruction ratios, where $t^* =$

t	Action	Type	1	2	3	4	5	6	$cr/\rho_{(t)}$	$rr/\tau_{(t)}$	$\frac{T}{N}/crrr/sim/llh$	r_{SR} / r_{SA}	r
1	`Remove` (May)	$\boldsymbol{y}_{(1)}$		the	force	be	with	you	.17/.05	1.0/.91	-	1.0 / .20	1.2
		$\hat{\boldsymbol{x}}_{(1)}$	May	the	force	be	with	you					
2	`Remove` (the)	$\boldsymbol{y}_{(2)}$			force	be	with	you	.33/.10	1.0/.83	-	1.0 / .20	1.2
		$\hat{\boldsymbol{x}}_{(2)}$	May	the	force	be	with	you					
3	`Remove` (force)	$\boldsymbol{y}_{(3)}$				be	with	you	.50/.15	.50/.75	.50/.25/.50 /1.0	**-1.0** / .20	-.80
		$\hat{\boldsymbol{x}}_{(3)}$	I	will	always	be	with	you					
4 5 6	No experiences due to the violation occurred at the step 3.												

Table 1: An example of stepwise reward computation. It breaks the reconstruction constraint at the step 3 when removing *force*, so $r_{SR} = -1$. r_{SA} is computed at the step 3 by $0.5 \times (0.25 + 0.5 \times 0.1 + 1.0 \times 0.1) = 0.20$, and it is used for the step 1 and 2 as well. The settings of hyperparameters are $\tau = 0.5$, $\rho = 0.3$, $\alpha = 0.1$, and $\beta = 0.1$.

$\arg\max_t\{cr_{(t)} + rr_{(t)}\}$. This is based on the trade-off relationship of compression and reconstruction as seen in the precision-recall curve.

5 Experiment

Baselines. We compare our proposed approach with three baselines: Lead-N, which simply takes the beginning N words as the summary, SEQ3, a recent encoder-decoder model (Baziotis et al., 2019), and CMatch, a new approach without explicit reconstruction learning (Zhou and Rush, 2019). To conduct qualitative analysis on generated summaries, we ran the baselines ourselves with a replicated model for SEQ3[4] and the provided model for CMatch.[5] Also, we test two types of SEQ3 models: one tuned with a validation set (SEQ3$^+$) and the other with parameters at the last iteration in the training (SEQ3$^-$). This is because EALM and CMatch do not need paired data even for validation.

Proposed method. We implemented EALM as follows. The Q-network of the agent consists of a two-layered MLP with 200 units per layer and ReLU. We used the Adam optimizer with the learning rate of 0.001 and apply gradient clipping by 1. For the epsilon-greedy strategy, we first set the exploring probability to 0.9 and decay it by multiplying by 0.995 every 100 updates until it reaches the minimum exploration rate of 0.03. We set the discount factor γ to 0.995. The size of the replay buffer is 2000, and we sample 128 experiences as a batch for one update. As the final model, we use parameters at a time when the averaged score of reward in the replay buffer is maximum, i.e., our model does not need a validation set. The hyperparameters of step reward (τ, ρ; §4.3.3) are set to 0.5 and 0.3, respectively. The hyperparameters of summary assessment (α, β; §4.3.3) are both set to 0.1. We train three models with the same configuration and report their averaged score, as Q-learning inherently contains randomness in training.

Dataset. The same as Baziotis et al. (2019), we train our model on the Gigaword corpus (GIGA, Rush et al., 2015). However, we used only $30K$ sentences randomly picked from sentences with less than 50 words for the training of EALM. This is because the whole data, $3.8M$ sentences, is too large to expose the agent to different experiences from the same sentence.[6] Note that we used the entirety of sentences for the training of the SEQ3 models.

We followed Baziotis et al. (2019) in the evaluation as well, using the test set consisting of the GIGA (1897 sentences) and DUC datasets (DUC3 with 624 sentences, DUC4 with 500 sentences; Over et al. 2007).

All models follow the same tokenization policy: the default tokenization in GIGA, DUC3, and DUC4. Although BERT (which EALM uses) has its own vocabulary based on subwords, we do not apply subwording to go along with a single tokenization policy. Therefore, words not in the BERT vocabulary are interpreted as unknown words, and the ratio of unknown words was around 10% in GIGA.

---

[4] `https://github.com/cbaziotis/seq3`. We ran the training script with the same configuration as the original paper except for decreasing the batch size from 128 to 32 due to our GPU limitation. We trained three models and obtained slightly lower scores than the ones reported in the original paper. We report the averaged score among the three models.

[5] `https://github.com/jzhou316/Unsupervised-Sentence-Summarization`

[6] EALM can be trained with the large dataset, but it takes long time due to the exploitation and exploration learning strategy of Q-learning. 30K was better in the balance of the required time and the model performance.

Table 2: ROUGE scores, averaged lengths (LEN), and averaged occurrences of new words (NW). L8 and L15 are Lead-N. $S3^{[+-]}$ represent SEQ3 models. CM is CMatch and EL is EALM. ROUGE scores are computed with summaries capped at the first 75 bytes.

Evaluation. In our quantitative analysis, we examine the ROUGE scores.[7] To mitigate the bias to longer sentences in ROUGE calculation, we capped all summaries at the first 75 bytes. Note that the averaged sentence length of gold summaries after the capping were 8.58, 9.59, and 10.25 for GIGA , DUC3, and DUC4, respectively. Also, we examine sentence length (LEN) and count of new words (NW; number of words that are used in a generated summary but do not appear in the input sentence). Additionally, we show qualitative comparisons with a manual check of generated summaries. Although a questionnaire survey is often conducted to assess the deeper quality of summaries such as informativeness and readability, this still hides the exact points of model's strengths and weaknesses. We consider that specific indications provide insights on future work for the current unsupervised summarizers. We manually checked more than 200 summaries for each model and each dataset and include a few samples in Appendix (A.6).

Results. Table 2 lists the results of ROUGE scores, averaged lengths, and averaged counts of new words. EALM showed a better performance in DUC3 and DUC4 with respect to R-1 and R-L. In GIGA, it performed competitively with the baselines. However, the original length of the generated summaries tended to be longer, and the occurrence of new words was the lowest.

$S3^+$	✔	Grammatical
	✔	Informative
	✘	Copy words from the top as it is
	✘	Meaningless rephrasing
CM	✔	Grammatical
	✔	Fluent in successful cases (in GIGA)
	✘	Lack of information (in DUC3 and DUC4)
	✘	Too much short (in DUC3 and DUC4)
EL	✔	Select words from the whole input
	✔	Contain keywords
	✘	Less grammatical
	✘	Lack of rephrasing

Table 3: Pros (✔) and cons (✘) found in the generated summaries of SEQ3, CMatch, and EALM.

CMatch achieved the highest scores of ROUGE and meaningful length in GIGA. The scores of R-2 and R-L were superior to others by about two points, which means CMatch captured not only salient words but also word co-occurrences. However, for generating summaries, CMatch uses a language model trained with gold summaries in GIGA. In other words, it may just internally store the probable word distributions in summary sentences on GIGA. Actually, the results on DUC3 and DUC4 were not better than those on GIGA. Even though CMatch does not require paired data, it is not practical to collect enough summaries to train a language model for each domain.

SEQ3 showed a competitive performance with other models, but its scores dropped when no validation set was available. The requirement of a validation set is a keen disadvantage because creating input-summary pairs comes at a significant human labor cost.

While almost all of the best scores were given by the statistical models, Lead-15 also performed competitively. This result indicates that unsupervised summarization methods can not yet overcome the trivial baseline. One significant barrier preventing the progress of unsupervised methods is presumably the difficulty of rephrasing. For writing a good summary, condensing a longer expression into a shorter form is essential. As seen in the NW column in Table 2, the number of new words was less than one in $SEQ3^+$, CMatch, and EALM. The current models tend to operate just by copy-and-paste, which is consistent with the report by Baziotis et al. (2019).

Finally, we manually assess the summaries produced by each model and sum up their pros and cons in Table 3. Also, actual examples are shown in

Table 4: Summaries by Human (gold reference), SEQ3, CMatch and EALM from GIGA (top), DUC3 (center), and DUC4 (buttom).

Table 4. First, we found that a summary of SEQ3 was likely to be an exact copy of the input sentence from the top, but it kept sentences grammatical and informative. Rephrasing by SEQ3 did not meet our expectation in most cases, such as changing a week of the day (e.g., *Wednesday* to *Thursday*) or a common adjective to a pronoun adjective (e.g., *astronomical* to *her*). CMatch stably generated fluent summaries in GIGA, as seen in the ROUGE scores. It also generated grammatically correct sentences such as number agreement (e.g., *nec agrees* ...). In the DUC datasets, however, meaningless summaries increased, such as containing no important information (e.g., *nasa observes*). Relatedly, CMatch's summaries on DUC3 and DUC4 were too short, and we found that more than half of the summaries consisted of less than or qeual to 5 words. Finally, EALM's outputs tended to be longer due to containing non-informative portions (e.g., *nasa officials told* ...). It was also likely to be ungrammatical due to leaving only a functional word (e.g., *mechanical problems that threaten* ...) or deleting required prepositions (e.g., ... *agreed (to) join* ...). Those failures resulted in lower readability. However, EALM tried to keep keywords from the whole input even though they exist at latter positions in a sentence, which is also supported by the relatively higher score of R-1 and R-L. Although this *challenge* caused low readable and ungrammatical summaries, it is an interesting research direction to sophisticate such EALM's behavior.

6 Conclusion

We brought the Q-learning framework into unsupervised text summarization and proposed a new method EALM that is an edit-based unsupervised summarizer leveraging a Q-learning agent and a language model. The experments showed that EALM performed competitively with the previous encoder-decoder-based methods. However, in qualitative analysis, we found that the quality of the generated summaries of any unsupervised model was not sufficient, and there are individual limitations for each model. These issue must be overcome as the step forward to generating practically available summaries without paired data. In particular for EALM, there is room for improvement by importing the latest techniques in RL. Our work paves the way for further research on bridging Q-learning and unsupervised text summarization.

A.1 Autoregressive Prediction with MLM

Algorithm 1 describes the autoregressive prediction with MLM, which we used when an input contains multiple masks.

Algorithm 1 Autoregressive prediction with MLM

```
Input: a sentence $\boldsymbol{x}$ that includes [MASK]s
Outpit: a sentence $\boldsymbol{x}$ after replacing all [MASK]s with predicted words
$I \leftarrow (\forall i)\{i \mid x_i = \text{[MASK]}\}$
while $I \neq \phi$ do
    for $j \in I$ do
        $w_j \leftarrow L(\boldsymbol{x}_{\backslash j})$
    end for
    $j^* \leftarrow \arg\max_{j \in I} P(w_j | x_{\backslash j})$
    $x_{j^*} \leftarrow w_{j^*}$
    $I \leftarrow I_{\backslash j^*}$
end while
```

A.2 Exploration of Prediction Order

As explained in section 4.3 in the main paper, the editorial agent explores the order to predict. While the agent basically chooses a state with a maximum Q-value as the next state, we sometimes pick a most uncertain state instead. We define the uncertainty of a state by the entropy of action probabilities as $H(s) = -\sum_{a \in \mathcal{A}} Q(s,a) \log Q(s,a)$, and then s^* and a^* are selected as

$$s^* = \arg\max_{s \in s^t} H(s)\ ,\ a^* = \arg\max_{a \in \mathcal{A}} Q(s^*, a)\ .$$

A.3 Semantic Similarity and Log-likelihood Computation in Summary Assessment

Semantic Similarity. We use a pre-trained model to predict the semantic similarity of paired-sentences with their BERT encodings.[8] The model is trained in a supervised manner with a pair of sentences and their similarity score. The original library outputs a real-valued score in the range of $[0, 5]$, whereas we normalize it to $[0, 1]$.

Log-likelihood. We compute the log-likelihood of a compressed sentence by using BERT as follows (Wang and Cho, 2019):

$$\frac{1}{M} \sum_{i \in M} \log(P(y_i \mid \boldsymbol{y}_{\backslash i}))\ .$$

However, our llh function performs thresholding — namely, it returns 1 if the score is beyond a threshold, otherwise 0 — because the raw log-likelihood score is not scaled with the other rewards. We empirically set the threshold to 0.005.

A.4 Relaxations in $rr_{(t)}$ Calculation

The calculation of the reconstruction rate introduced in section 4.3.3 is based on an exact match of each word of $\boldsymbol{x}$ and $\hat{\boldsymbol{x}}$. Given the ambiguity of natural language, this is very strict, so the agent rarely acquires rewards. We relax this situation by 1) excluding stop words in the calculation and 2) comparing with top-k candidates. Therefore, the equation of rr can be formally re-written as

$$rr_{(t)} = \frac{|\{i \mid x_i \in L^k(\boldsymbol{z}_{\backslash \boldsymbol{i}}) \cap x_i \notin W\}|}{|\{i \mid x_i \notin W\}|}\ ,$$

where $L^k(\boldsymbol{z}_{\backslash \boldsymbol{i}})$ returns top-k probable words for the i-th position and W is a pre-defined set of words. We set $k = 10$. We used common stopwords (e.g., *him*, *the*) and infrequent words in GIGA for W.

A.5 Experimental Details

Computing Infrastructure. We run the models on a machine with the below specifications:

- Ubuntu 18.04
- Intel(R) Xeon(R) @ 2.60GHz
- RAM 120GB
- NVIDIA Tesla P100

Model Size. In EALM, the number of trainable parameters was 348208 in our experimental setting, which is all for the editorial agent. There are no trainable parameters for the language model.

Hypperparameter Search. We did not conduct a hyperparameter search. We empirically determined the values described in the main paper (the "Proposed method" paragraph in §5).

Runtime Speed. EALM processes a sentence in three seconds pm average on the above GPU.

A.6 Generated Summaries

Samples of the summaries generated by each model are listed in the tables on the following next pages. These examples are taken from the first sentences for GIGA and randomly picked for DUC3 and DUC4. We also include human-generated summaries (i.e., gold reference).

Abstract

Abstractive document summarization is a comprehensive task including document understanding and summary generation, in which area Transformer-based models have achieved the state-of-the-art performance. Compared with Transformers, topic models are better at learning explicit document semantics, and hence could be integrated into Transformers to further boost their performance. To this end, we rearrange and explore the semantics learned by a topic model, and then propose a topic assistant (TA) including three modules. TA is compatible with various Transformer-based models and user-friendly since i) TA is a plug-and-play model that does not break any structure of the original Transformer network, making users easily fine-tune Transformer+TA based on a well pre-trained model; ii) TA only introduces a small number of extra parameters. Experimental results on three datasets demonstrate that TA is able to improve the performance of several Transformer-based models.

1 Introduction

Automatic summarization, requiring both document understanding and text generation, is a comprehensive task in natural language processing (NLP). Extractive approaches (Wong et al., 2008; Liu, 2019; Zhang et al., 2019c) identify and then concatenate the most representative sentences as a summary. By contrast, abstractive summarization (See et al., 2017; Narayan et al., 2018) is more challenging, aiming to generate a summary via rephrasing and introducing new concepts/words. Our work focuses on abstractive summarization, for which sequence-to-sequence (S2S) models are widely studied.

Recently, equipped with the attention mechanism (Vaswani et al., 2017), some Transformer-based language models (Subramanian et al., 2019; Zhang et al., 2019b; Dong et al., 2019; Liu and Lapata, 2019; Lewis et al., 2019; Raffel et al., 2019) are built with an encoder-decoder structure. These models benefit from pre-training on large-scale corpus, and then are fine-tuned to adapt to the summarization task. As a result, the encoder with bidirectional self-attention (SA) extracts document-token features, the decoder with left-to-right SA generates the summary, and the cross attention (CA) bridges the document and summary tokens.

Though achieving appealing performances, these Transformer-based models are better at exploring the relationships among local tokens than the document global semantics. Further, due to the limited position index during pre-training, most Transformer-based models have a maximum capacity of input tokens. Thus, they often truncate the length of a document to satisfy the length limitation of the encoder, which may lose some important semantics, especially for long documents.

Global semantics are important to summarization (Narayan et al., 2018; Ailem et al., 2019; Liu et al., 2019), since one need to comprehend the entire content before generate summaries. Compared with language models, topic models tell global semantics more explicitly. Basically, topic models, such as LDA (Blei et al., 2003) and PFA (Zhou et al., 2012), represent each document as a bag-of-word (BOW) vector and then factor the count vector as a product of topics and topic proportions, as shown in Fig. 1. Topics are global variables, describing the distributions over all tokens in the vocabulary. Topic proportions are local (document-specific) features, describing the weights of corresponding topics in each document. Therefore, topic models explore the *word co-occurrence patterns*, *i.e.*, semantics. However, no Transformer-based

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 485–497,
November 16–20, 2020.

model considers these explicit semantics.

In this paper, we rearrange and further explore the semantics of the topic model and develop a friendly topic assistant (TA) for Transformer-based abstractive summarization models. By introducing only a small number of parameters into the fine-tuning stage, TA is a flexible plug-and-play model, consisting of three modules:

- **Semantic-informed attention (SIA):** It is often observed that the learned attentive patterns of many heads are not as reasonable as we expect (Clark et al., 2019; Michel et al., 2019). This motivates us to employ the semantic "*distribution over topics*" as a token representation to construct an explicit semantic-similarity matrix among tokens, which is further used as the attention weights of a newly added head.

- **Topic embedding with masked attention (TEMA):** Since a topic is a distribution over tokens in the vocabulary, we use the mixture of token embeddings to represent the corresponding topic embedding. Thus, topics with large proportions for a document can be considered as extra input tokens of the decoder. Further, a topic describes a co-occurrence pattern of tokens with similar semantics, that is more likely to help the decoder to generate new tokens or concepts not included in the current document. To prevent the topic features affected by the summary-token features via attention, we perform masked attention in the decoder.

- **Document-related modulation (DRM):** Conditional biasing is an efficient way to integrate conditions into the network with a small number of extra parameters (Dumoulin et al., 2018). The topic-proportion vector is a low-dimensional document representation, conditioned on which we infer a document-related bias to modulate some hidden layers of the decoder.

TA does not break any structure of the original Transformer network, and hence is able to be jointly learned with a pre-trained model during the fine-tuning stage. Besides, SIA, TEMA, and DRM are cooperated with some basic Transformer modules, such as embedding and multi-head attention. Therefore, we can plug an arbitrary combination of these three modules into various Transformer-based models.

2 Related work

2.1 Transformer-based models for document summarization

Pre-training and fine-tuning have attracted much attention in Transformer-based models for various NLP tasks. Equipped with pre-trained Bert encoder (Devlin et al., 2019), Liu (2019); Liu and Lapata (2019) propose the BertSUM for both extractive and abstractive tasks; Zhang et al. (2019c) propose a hierarchical Bert model for extractive summarization, where the low-level and high-level Berts are built for sentence and document understanding, respectively.

Although the above methods achieve better performance than LSTM-based models, their Bert encoder pre-trained for document understanding may not well match the decoder trained from scratch for the summary generation (Rothe et al., 2019; Yang et al., 2019). To consider document understanding and generation in a unified framework, some S2S pre-training models are proposed for general purpose, such as MASS (Song et al., 2019), UniLM (Dong et al., 2019), T5 (Raffel et al., 2019), and BART (Lewis et al., 2019), which are further fine-tuned for downstream tasks, summarization included. Aiming at designing a pre-training objective tailored for abstractive text summarization, Zhang et al. (2019b) propose the PEGASUS that achieves the state-of-the-art performance.

2.2 S2S models combined with Topic models

To complement global semantics for S2S models that often focus on sequential information, topic models (Blei et al., 2003; Zhou et al., 2012) are considered to be combined with S2S models. Zhang et al. (2016) represent each word as a distribution over topics, and construct a topic-informed RNN model for neural machine translation. Based on the RNN-based pointer-generator network (See et al., 2017), Ailem et al. (2019) develop a topic augmented decoder that generates a summary conditioned on both the input document and the latent topics of the document. They find that the latent topics reveal more global semantic information that can be used to bias the decoder to generate words. With similar considerations, Narayan et al. (2018) propose another topic-conditioned S2S model under the CNN framework.

Although these models have demonstrated the advantages of combining S2S learning with topic models, integrating topic information into

Transformer-based summarization models is still an underexplored research area.

3 Background

TA is a friendly plug-and-play model that is compatible with many transformer-based summarization models. To illustrate TA without loss of generality, we choose the BertSUM (Liu and Lapata, 2019) as an example Transformer-based model, and PFA (Zhou et al., 2012) as an example topic model.

3.1 BertSUM: a Transformer-based summarization model

Given a data pair $\{\boldsymbol{x}, \boldsymbol{y}\}$, where the document $\boldsymbol{x}$ has N_1 tokens and the summary $\boldsymbol{y}$ has N_2 tokens ($N_2 < N_1$), BertSUM maximizes the following likelihood

$$\prod\nolimits_{j=1}^{N_2} p(\boldsymbol{y}_j | \{\boldsymbol{x}_i\}_{i=1}^{N_1}, \boldsymbol{y}_{i<j}), \qquad (1)$$

where $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$ denote the i-th token in document and summary, respectively.

BertSUM adopts an encoder-decoder architecture, as shown in Fig. 1. The encoder is a pre-trained twelve-layer Bert (Devlin et al., 2019), each layer mainly including a bidirectional SA and a fully-connected network (FNN). The encoder outputs the document-token features $\mathbf{H} \in \mathbb{R}^{N_1 \times d_{\text{model}}}$ at the top layer, where d_{model} is the output dimension of each module (*e.g.*, embedding, SA, CA, and FNN) in Transformer. The decoder is a randomly-initialized six-layer Transformer decoder (Vaswani et al., 2017), each layer mainly including SA, CA, and FNN. Due to the auto-regressive nature of the summary generation in (1), the decoder performs left-to-right SA. The CA forces the summary-token features to attend over all features in $\mathbf{H}$.

3.2 Poisson factor analysis (PFA)

Topic models are good at capturing global semantics of texts (Zhang et al., 2019a; Wang et al., 2020). PFA (Zhou et al., 2012) is a typical topic model inferred by Gibbs sampling or variational autoencoder (Zhang et al., 2018). Specifically, representing document $\boldsymbol{x}$ as a BOW vector $\boldsymbol{b} \in \mathbb{Z}^V$, where $\mathbb{Z} = \{0, 1, \cdots\}$ and V is the vocabulary size, PFA models $\boldsymbol{b}$ under the Poisson likelihood as

$$\boldsymbol{b} \sim \text{Poisson}\left(\boldsymbol{\Phi}\boldsymbol{\theta}\right), \boldsymbol{\theta} \sim \text{Gamma}\left(\boldsymbol{r}, 1\right). \qquad (2)$$

In (2), the k-th column of $\boldsymbol{\Phi} \in \mathbb{R}_{+}^{V \times K}$, denoted as $\boldsymbol{\phi}_k \in \mathbb{R}_{+}^{V}$, represents the k-th topic, which is a distribution over all tokens in the vocabulary. For this purpose, PFA applies a Dirichlet prior on $\boldsymbol{\phi}_k$ as $\boldsymbol{\phi}_k \sim \text{Dirichlet}\left(\boldsymbol{\eta}_k\right)$. $\boldsymbol{\theta} \in \mathbb{R}^K$ is the document-specific topic proportion vector (document feature) that represents the strength of the document on each topic. Thus, using the law of total expectation on (2), we have $\mathbb{E}\left[\boldsymbol{b} \,|\, \boldsymbol{\Phi}, \boldsymbol{\theta}\right] = \boldsymbol{\Phi}\boldsymbol{\theta}$, which means that a document can be decomposed as a weighted summation of topics, as illustrated in Fig. 1.

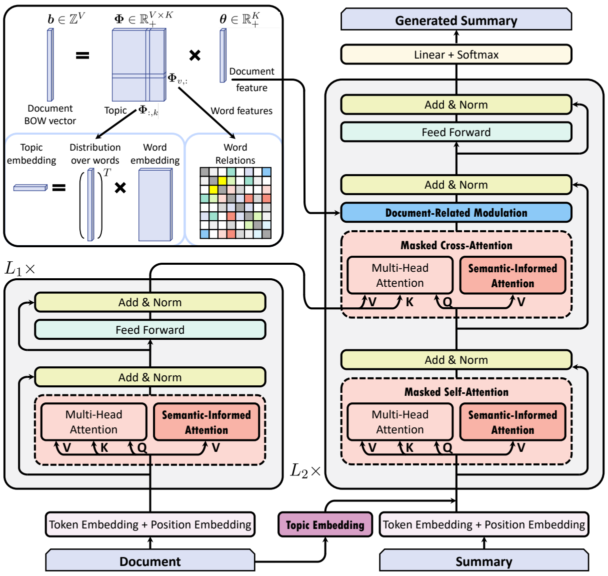

Figure 1: The structure of BertSUM with TA, where the names in bold are our proposed modules in TA.

4 Topic assistant for Transformer

Given a corpus, we train a PFA based on documents. Then, we use the extracted topics and topic proportions to build three plug-and-play modules to help the Transformer fine-tuning, including semantic-informed attention, topic embedding with masked attention, and document-related modulation.

4.1 Semantic-informed attention (SIA)

In Transformer-based models, the multi-head attention explores the relationships among tokens by calculating the token similarities in implicit feature spaces. Specifically, assume we have h heads, thus the attention function $\text{Att}(\cdot)$ in the i-th head is formulated as:

$$\text{head}_i = \text{Att}(\mathbf{Q}_i, \mathbf{K}_i, \mathbf{V}_i) = \mathbf{A}_i \mathbf{V}_i, \qquad (3)$$

$$\mathbf{A}_i = \text{softmax}\left(\frac{\mathbf{Q}_i {\mathbf{K}_i}^T}{\sqrt{d_k}}\right), i = 1, \cdots, h, \quad (4)$$

where, $\mathbf{A}_i$ is the attention matrix, $\mathbf{Q}_i$, $\mathbf{K}_i$, and $\mathbf{V}_i$ are learnable features, denoting queries, keys, and

Figure 2: Distribution of tokens represented by φ_v in SIA, learned on CNN/DM using PFA and (5).

values, respectively, d_k (d_v) is the dimension of the queries or keys (values).

However, recent works have illustrated that most attention heads learn simple, and often redundant, positional patterns (Clark et al., 2019; Michel et al., 2019). To improve the representation, some works incorporate external information, such as syntax, into the Transformer-based neural machine translation (Currey and Heafield, 2019; Deguchi et al., 2019). Inspired by their achievements and to focus on our summarization task, we attempts to inject the semantics learned from a topic model into the attention mechanism.

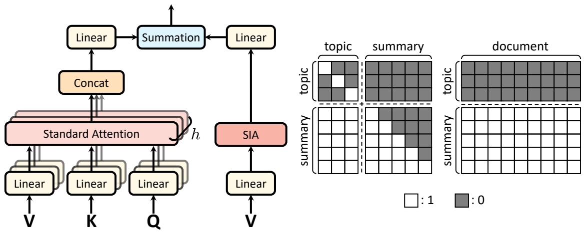
Besides, Raganato et al. (2020) tried to fix the attention matrices of many heads according to token positions, finding that the performance do not drop and is even better in some cases. Motivated by this phenomenon, we introduce an extra head (the $(h+1)$-th head) with a fixed attention matrix to express a semantic-informed attentive pattern.

Recapping $\mathbf{\Phi}$ in (2), each column, $\boldsymbol{\phi}_k$, is a distribution over all tokens, representing a topic. From another view, each row, $\mathbf{\Phi}_{v,:}$, is a token representation, as shown in Fig. 1. With normalization

$$\{\boldsymbol{\varphi}_v\}_{v=1}^{V} = \mathbf{\Phi}_{v,:}/||\mathbf{\Phi}_{v,:}||_1, \tag{5}$$

$\boldsymbol{\varphi}_v$ can be interpreted as a distribution over topics. Thus, we can measure the similarity between tokens using the cosine distance, *i.e.*, $\cos(\boldsymbol{\varphi}_{v_1}, \boldsymbol{\varphi}_{v_2})$, which is an explicit and fixed semantic relation.

In Fig. 2, based on XSum (Narayan et al., 2018), we use UMAP[1] to project $\{\boldsymbol{\varphi}_v\}_{v=1}^{V}$ in (5) into a 2-dimensional space to visualize their relations. We choose six regions, and randomly select 10 example tokens from each region. Clearly, *i)* words with similar meanings are often grouped together, describing a field; *ii)* if two fields are semantically related, their corresponding tokens are closely distributed, such as "*Economic-Government*" and "*Astronomy-Airplane*". These phenomena indicate that $\boldsymbol{\varphi}_v$ in SIA is able to describe the semantic relations among tokens.



(a) (b)

Figure 3: (a) TA for multi-head attention; (b) Mask matrices in decoder SA (left) and decoder CA (right).

To sum up, we consider SIA as an extra head (the $(h+1)$-th head) in every attention layer, as shown in Fig. 3(a), with its attention matrix formally stated as

$$\mathbf{A}_{h+1} = \text{softmax}\left(\frac{[\cos(\boldsymbol{\varphi}_{v_1}, \boldsymbol{\varphi}_{v_2})]}{\sqrt{d_k}}\right), \tag{6}$$

$$\begin{cases} v_1, v_2 : \text{document-token indexes, in encoder SA} \\ v_1, v_2 : \text{summary-token indexes, in decoder SA} \\ \left.\begin{array}{l} v_1 : \text{summary-token index} \\ v_2 : \text{document-token index} \end{array}\right\} \text{in decoder CA} \end{cases}$$

where, $[\cdot]$ denotes a matrix.

Then, the output of multi-head attention is obtained by:

$$\begin{aligned} &\text{Concat}(\text{head}_1, \cdots, \text{head}_h, \text{head}_{h+1})\mathbf{W}^a, \\ = &\text{Concat}(\text{head}_1, \cdots, \text{head}_h)\mathbf{W}^a_{\text{ori}} \\ &+ \text{head}_{h+1}\mathbf{W}^a_{\text{add}} \end{aligned} \tag{7}$$

where, $\mathbf{W}^a \in \mathbb{R}^{(h+1)d_v \times d_{\text{model}}}$ is rearranged as two parameter matrices $\mathbf{W}^a_{ori} \in \mathbb{R}^{hd_v \times d_{\text{model}}}$ and $\mathbf{W}^a_{add} \in \mathbb{R}^{d_v \times d_{\text{model}}}$. Clearly, $\mathbf{W}^a_{add}$ encapsulates the parameters brought by the SIA.

---

4.2 Topic embedding with masked attention (TEMA)

Given a corpus, the topic model is able to learn global topics $\boldsymbol{\Phi}$. For a specific document $\boldsymbol{x}$, the corresponding topic proportion vector $\boldsymbol{\theta}$ illustrates the importance degree of every topic. Therefore, those important topics represent the major or pertinent semantics of the document, which is expected to help the decoder to generate a summary.

For this purpose, we perform topic embedding so that the Transformer-based models can understand such topic representation. Recapping $\boldsymbol{\Phi}$ in (2), each column (topic), $\boldsymbol{\phi}_k$, is a distribution over all tokens in the vocabulary. Thus, we consider each topic embedding as a mixture of all token embeddings, as shown in Fig. 1, formally stated as:

$$\mathbf{E}_{\text{topic}} = \boldsymbol{\Phi}^T \mathbf{E}_{\text{token}} \tag{8}$$

where, $\mathbf{E}_{\text{topic}} \in \mathbb{R}^{K \times d_{\text{model}}}$ and $\mathbf{E}_{\text{token}} \in \mathbb{R}^{V \times d_{\text{model}}}$ are the topic and token embedding matrices, respectively. Clearly, topics and tokens lie in the same embedding space, making it possible to measure the relationships between document-topics and summary-tokens via attention.

Specifically, we choose the top-n topics according to $\boldsymbol{\theta}$, and consider these n topic embeddings as extra decoder inputs to guide the generation. We expect that the attention mechanism could fuse the topic information into the generation. Meanwhile, we should prevent the topic features polluted by the summary-token features via attention. Therefore, we build two kinds of masks for the SA and CA in decoder, as shown in Fig. 3(b).

As discussed before, a topic describes a co-occurrence pattern of all tokens. Moreover, recalling (8), each topic embedding vector can be interpreted as a semantic clustering center of all token embedding vectors, surrounded by tokens with similar semantics, as shown in Fig. 5(a) later. Using topics as inputs, the decoder is more likely to generate some recapitulative or new concepts that do not appear in the current document.

4.3 Document-related modulation (DRM)

Feature biasing is an efficient way to integrate conditions (Dumoulin et al., 2018). Subramani et al. (2019) introduced a sentence-specific bias into a pre-trained language model, showing superior performance on out-of-sample reconstruction.

As shown in (2), the topic proportion vector $\boldsymbol{\theta}$ is a latent representation of document $\boldsymbol{x}$, which can be considered as a conditioning information to fine-tune the Transformer-based models. To this end, we leverage $\boldsymbol{\theta}$ to infer a bias to modulate one hidden layer in every decoder layer. Specifically, in the l-th decoder layer, we infer a global feature bias via:

$$\boldsymbol{z}^{(l)} = \boldsymbol{\theta}^T \mathbf{W}_b^{(l)} \in \mathbb{R}^{d_{\text{model}}}. \tag{9}$$

where, $\mathbf{W}_b^{(l)} \in \mathbb{R}^{K \times d_{\text{model}}}$ is a parameter matrix in DRM. The bias vector $\boldsymbol{z}^{(l)}$ is then added to every position of the output of the CA block (before add and norm), as shown in Fig. 1.

4.4 Properties of TA

TA has three attractive properties, making it friendly to practical applications.

Small parameter footprint TA introduces three modules for the original Transformer encoder-decoder architecture: SIA, TEMA, and DRM. Among them, TEMA needs no extra parameters while SIA and DRM only introduce a small number of parameters compared with the original models, detailed illustrated in Table 8. Therefore, TA can be applied in many Transformer encoder-decoder structures without adding too much memory footprint or sacrificing the learning and test speed.

Plug-and-play The pipeline of pre-training and then fine-tuning has been widely accepted in NLP community, especially for transformer-based models. There are mainly two reasons. Firstly, many well pre-trained models provide checkpoints for users to fine-tune on their own tasks. Secondly, the Transformer models are getting bigger and bigger (Sanh et al., 2019), resulting in a fact that it is almost impossible to pre-train such a big model on a personal computer. Thus, models with plug-and-play property are attractive to Transformer-based models (Dathathri et al., 2019). Although we introduce TA based on a specific model, BertSUM, TA owns flexible plug-and-play property, since SIA, TEMA, and DRM do not break any structure of the original network. In experiments, shown in Table 5 later, we also demonstrate the effectiveness of TA on other Transformer-based summarization models, such as BART (Lewis et al., 2019), UNILM (Dong et al., 2019), and MASS (Song et al., 2019).

Efficient training The autoencoding variational inference (AVI) (Zhang et al., 2018) makes PFA scalable to big corpus and fast in out-of-sample prediction (calculating document-specific $\boldsymbol{\theta}$). In experiments, we find that the engineering-friendly pipeline training strategy[2] achieves attractive performance.

5 Experiments

5.1 Datasets

We evaluate the effectiveness and efficiency of TA on three benchmark datasets, including the CNN/DailyMail (CNN/DM) (Hermann et al., 2015), the New York Times Annotated Corpus (NYT) (Sandhaus, 2008) and the XSum (Narayan et al., 2018). The summary styles of these datasets varies from highlights, composed of several sentences, to very brief one sentence. Table 1 provides the statistics of these datasets. See more detailed descriptions in Appendix A. We perform data preprocessing following Liu and Lapata (2019).

5.2 Implementation details

Given a dataset, we first train the PFA based on the documents in the training set to obtain $\boldsymbol{\Phi}$, composed of 256 topics. More analysis on the number of topics can be found in Apendix B. For each document, we infer the corresponding $\boldsymbol{\theta}$ using the AVI in Zhang et al. (2018). According to the values in $\boldsymbol{\theta}$, we choose top-5 topics to perform topic embedding in TEMA. We adopts the settings in the original Transformer-based models. Following Liu and Lapata (2019), in the test stage, we use beam search with size 5, select the top-3 checkpoints based on their evaluation loss on the validation set, and report the averaged results on the test set. More detailed settings can be found in Appendix B. Our code is available at `https://github.com/BoChenGroup/TA`.

5.3 Quality evaluation on summarization

We evaluate the quality of the generated summaries using ROUGE scores (Lin, 2004). We report unigram and bigram overlap (ROUGE-1 and ROUGE-2) to assess informativeness, and the longest common subsequence (ROUGE-L) to assess fluency.

5.3.1 TA with BertSUM

We first combine TA with BertSUM on the abstractive summarization task. Given BertSUM checkpoints[3] on CNN/DM and XSum provided by Liu and Lapata (2019), we further fine-tune BertSUM with TA. Since Liu and Lapata (2019) did not provide checkpoints on NYT, we jointly fine-tune BertSUM and TA based on a pre-trained Bert.

Table 1: Statistics of summarization datasets.

Datasets	# docs (train/val/test)	avg. doc length		avg. summary length	
		words	sentences	words	sentences
CNN	90.266/1,220/1,093	760.50	33.98	45.70	3.59
DM	196,961/12,148/10,397	653.33	29.33	54.65	3.86
NYT	96,834/4,000/3,452	800.04	35.55	45.54	2.44
XSum	204,045/11,332/11,334	431.07	19.77	23.26	1.00

Transformer (Liu and Lapata, 2019)	29.41	9.77	23.01
BertSUM (Liu and Lapata, 2019)	38.81	16.50	31.27
BertSUM+TA	**39.77**	**17.39**	**32.39**

Table 4: ROUGE scores on NYT test set, where the results are cited from Liu and Lapata (2019).

Model	R1	R2	RL
PTGEN (See et al., 2017)	42.47	25.61	-
PTGEN+Cov (See et al., 2017)	43.71	26.40	-
DRM (Paulus et al., 2017)	42.94	26.02	-
Transformer (Liu and Lapata, 2019)	35.75	17.23	31.41
BertSUM (Liu and Lapata, 2019)	49.02	31.02	45.55
BertSUM+TA	**50.12**	**32.08**	**46.67**

ROUGE scores on CNN/DM, XSum and NYT are given in Tables 2, 3, and 4, respectively. Methods in the first group are LSTM-based or CNN-based models. Compared with them, the outperformance of BertSUM illustrates that the combination of a pre-trained Bert encoder and a Transformer decoder is a better S2S structure. Though having the same structure as the Transformer, the BertSUM employs a Bert encoder pre-trained on a very large corpus, showing higher scores. Equipped with TA, BertSUM+TA achieves superior performance than the BertSUM, with only a few extra parameters, which will be further illustrated in Table 8.

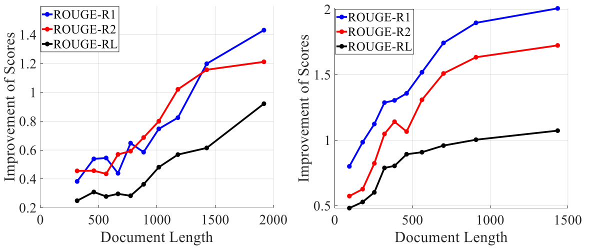
---

[2] 1) Pre-train a Transformer; 2) Train PFA to extract $\boldsymbol{\Phi}$ and $\boldsymbol{\theta}$; 3) Fine-tune the Transformer+TA.

[3] `https://github.com/nlpyang/PreSumm`

Table 5: ROUGE scores of TA applied in BART (Lewis et al., 2019), UNILM (Dong et al., 2019) and MASS (Song et al., 2019). Results of the UNILM on XSum are obtained by running the public code. Others are from Zhang et al. (2019b).

Model	**CNN/DM**			**XSum**		
	R1	**R2**	**RL**	**R1**	**R2**	**RL**
MASS	42.12	19.50	39.01	39.75	17.24	31.95
MASS+TA	**43.06**	**19.98**	**39.88**	**41.12**	**18.05**	**32.75**
UNILM	43.33	20.21	40.51	42.63	19.10	33.13
UNILM+TA	**43.87**	**20.78**	**40.65**	**43.70**	**20.01**	**34.56**
BART	44.16	21.28	40.90	45.14	22.27	37.25
BART+TA	**44.47**	**21.39**	**41.32**	**45.76**	**22.68**	**38.03**



(a) CNN/DM (b) XSum

Figure 4: The plot of the improvement of BertSUM+TA over BertSUM as a function of the document length for (a) CNN/DM and (b) Xsum, where the improvement is measured by the amount of increase in the ROUGE scores. The documents in each corpus are equally divided into 10 different groups based on their lengths. Each point of a curve indicates the average ROUGE score in its corresponding group.

5.3.2 TA with some advanced Transformers

As discussed above, TA is a plug-and-play model, that is friendly to many Transformer encoder-decoder architectures. To illustrate it, we plug TA into BART (Lewis et al., 2019), UNILM (Dong et al., 2019), and MASS (Song et al., 2019), which are some advanced language models for document understanding and generation.

Based on their pre-trained models, we jointly fine-tune the model with TA for CNN/DM and XSum, respectively, following their settings in public codes. The ROUGE comparisons[4] are shown in Table 5, while the numbers of new parameters brought by TA are listed in Table 8. It is observed that TA is able to improve different types of Transformer encoder-decoder models for abstractive summarization with a few extra parameters.

5.4 TA with different-length documents

To analyze the effectiveness of TA as the documents have different amounts of tokens, we calculate the improvement of BertSUM+TA over BertSUM in terms of the ROUGE scores, with the results shown in Fig. 4.

Note that, as the number of document-tokens exceeds 512 (the length limitation of the Bert encoder), both BertSUM and BertSUM+TA use the initial 512 document-tokens as the inputs of the encoder. Compared with BertSUM that ignores the subsequent document-tokens, BertSUM+TA is able to reserve these information in some degree, since the topic model extracts global semantics from all tokens in the document. As a result, with the increase of the document length, the improvement produced by TA gets more evident. In other words, the global semantics introduced by TA is indeed helpful to Transformer-based models on the summarization task, especially for long documents.

5.5 Semantic similarity

As mentioned before, TA aims to exploit the semantics provided by the topic model to boost the summariazation performance. To evaluate the semantic similarities between the generated summary and the document (or the gold summary), we propose a new criterion, *Semantic Similarity* (SS). Given a set of topics $\mathbf{\Phi}$ and two pieces of text, $\mathbf{D}_1$ and $\mathbf{D}_2$, we firstly infer the topic proportions of these two pieces of text, *i.e.*, $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$. Then, the simantic similarity (between $\mathbf{D}_1$ and $\mathbf{D}_2$) with respect to $\mathbf{\Phi}$ can be measured via the cosine similarity between $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$, as:

$$\mathrm{SS}(\mathbf{D}_1, \mathbf{D}_2; \mathbf{\Phi}) = \frac{\boldsymbol{\theta}_1^T \boldsymbol{\theta}_2}{\|\boldsymbol{\theta}_1\| \|\boldsymbol{\theta}_2\|}. \tag{10}$$

In our case, after learning the topics of the documents, we use them to further infer the topic proportions of the document $\boldsymbol{\theta}_d$, topic proportions of the gold summary (ground truth) $\boldsymbol{\theta}_g$, and the topic proportions of the generated summary $\boldsymbol{\theta}_s$. Then, we measure the cosine similarities between $\boldsymbol{\theta}_s$ and $\boldsymbol{\theta}_d$, $\boldsymbol{\theta}_s$ and $\boldsymbol{\theta}_g$. The averaged SS scores on CNN/DM and XSum are summarized in Table 6. It can be seen that, with the help of TA, the generated summaries are closer to (have higher similarities to) the document, and also closer to the ground truth in the semantic space.

---

[4] All these methods did not provide results on NYT.

Table 6: Averaged SS scores between the generated summary and the document (or the gold summary).

Dataset	Method	Sum.-Doc.	Sum.-Gold.
CNN/DM	BertSUM	0.622	0.775
CNN/DM	BerSUM+TA	**0.651**	**0.781**
XSum	BertSUM	0.313	0.727
XSum	BerSUM+TA	**0.336**	**0.757**

Table 7: Ablation studies based on BertSUM.

Model	CNN/DM			XSum		
	R1	**R2**	**RL**	**R1**	**R2**	**RL**
BertSUM	42.13	19.60	39.18	38.81	16.50	31.27
BertSUM+SIA	42.48	19.99	39.37	39.06	16.80	31.55
BertSUM+TEMA	42.77	20.12	39.46	39.35	17.01	31.98
BertSUM+DRM	42.66	20.33	39.56	39.33	17.16	32.22
BertSUM+TA	43.06	20.58	39.67	39.77	17.39	32.39

Table 8: The amount of newly added parameters (in millions) and the corresponding percentage relative to the model size of the base model[5].

Model	Newly added parameters
BertSUM+TEMA	0M
BertSUM+DRM	3.16M (1.7%)
BertSUM+SIA	7.09M (3.94%)
BertSUM+TA	10.25M (5.69%)
MASS+TA	14.26M (5.93%)
UNILM+TA	31.50M (9.26%)
BART+TA	38.91M (9.58%)

Table 9: Perplexities on the test summary set.

Model	CNN/DM	XSum	NYT
GPT2	19.72	4.21	26.35
GPT2+TEMA	**16.95**	**3.30**	**21.68**

5.6 Ablation study

TA includes three modules: SIA, TEMA, and DRM. In order to understand the effectiveness of each part, we perform ablation studies by combining each module with the BertSUM.

As shown in Table 7, all these modules are able to promote the summarization performance in different degrees. Specifically, SIA introduces explicit semantic relations between tokens. Though effective, SIA mainly focuses on the local relations as the standard Transformer attention does. Compared with SIA, TEMA and DRM are better at introducing global semantics (topics and topic proportions) into the Transformer-based models, achieving more evident improvements. This illustrates that the global semantics, a special "summary", is useful to the summarization task.

5.7 Model size

We plug SIA, TEMA, DRM, and TA into some base models[5]. The amount and ratio of the newly added parameters are listed in Table 8. Clearly, TA introduces a few parameters, less than 10%. Therefore, TA has a friendly memory footprint to the Transformer models.

5.8 Effectiveness of TEMA

As analyzed in Sections 5.6 and 5.7, TEMA is effective for the summarization and adds surprisingly no extra parameter for the Transformers, which excites our curiosity to further analyze TEMA.

TEMA utilizes topic embeddings as part of the decoder inputs. Assisted by the masked attention, TEMA helps the decoder to perform conditional generation, with topics acting as the conditions. Therefore, we plan to investigate the generative ability of TEMA in a pure decoder architecture. To this end, we plug TEMA into the GPT2 small[6] (Radford et al., 2019) and perform fine-tuning, where we consider each training summary as a training sample.

After fine-tuning, we perform summary generation based on the document-topics only[7]. Fig. 5(a) shows some example topics learned from the documents in CNN/DM and XSum. We consider two kinds of conditional topics: *i)* two randomly selected topics and *ii)* top-three topics of a document. Some generated sentences are provided in Fig. 5(b). Whether the topics are representative of a specific document or not, the decoder is able to generate fluent and meaningful samples, that well match the conditional topics. Moreover, compared with setting-*ii*, the style of the generated sentences under setting-*i* is not similar to that of the news in CNN/DM and XSum. This further illustrates that topics are able to provide new concepts for the generation. Table 9 provides the perplexities on the test set. Clearly, with TEMA, GPT2 achieves lower perplexities.

5.9 Generated summary examples

In Fig. 6, we show an example of the generated summaries of BertSUM and BertSUM+TA. It can be seen that BertSUM+TA generates some meaningful and recapitulative words that do not appear

---

[5] Model sizes of the base models: 180.22M for BertSUM, 240.48M for MASS, 340M for UNILM, and 406M for BART.

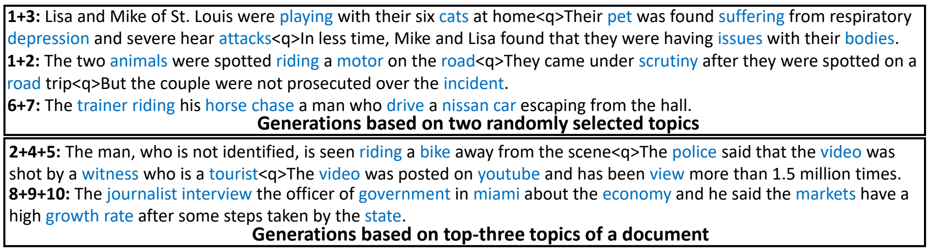
Five example topics of XSum

(a) Some example topics learned by PFA

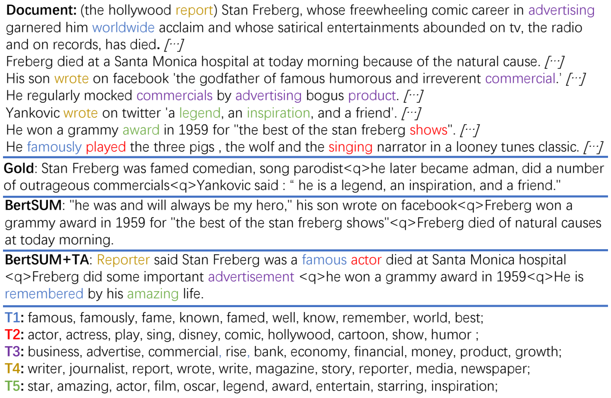


1+3: Lisa and Mike of St. Louis were playing with their six cats at home<q>Their pet was found suffering from respiratory depression and severe hear attacks<q>In less time, Mike and Lisa found that they were having issues with their bodies.
1+2: The two animals were spotted riding a motor on the road<q>They came under scrutiny after they were spotted on a road trip<q>But the couple were not prosecuted over the incident.
6+7: The trainer riding his horse chase a man who drive a nissan car escaping from the hall.
Generations based on two randomly selected topics

2+4+5: The man, who is not identified, is seen riding a bike away from the scene<q>The police said that the video was shot by a witness who is a tourist<q>The video was posted on youtube and has been view more than 1.5 million times.
8+9+10: The journalist interview the officer of government in miami about the economy and he said the markets have a high growth rate after some steps taken by the state.
Generations based on top-three topics of a document

(b) Sentence generation conditioned on topics in (a)

Figure 5: The conditional generation results by pluging TEMA into the GPT2 small.



Document: (the hollywood report) Stan Freberg, whose freewheeling comic career in advertising garnered him worldwide acclaim and whose satirical entertainments abounded on tv, the radio and on records, has died. *[···]*
Freberg died at a Santa Monica hospital at today morning because of the natural cause. *[···]*
His son wrote on facebook 'the godfather of famous humorous and irreverent commercial.' *[···]*
He regularly mocked commercials by advertising bogus product. *[···]*
Yankovic wrote on twitter 'a legend, an inspiration, and a friend'. *[···]*
He won a grammy award in 1959 for "the best of the stan freberg shows". *[···]*
He famously played the three pigs , the wolf and the singing narrator in a looney tunes classic. *[···]*

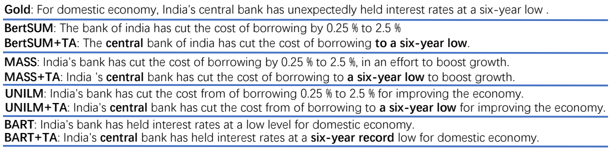
Gold: Stan Freberg was famed comedian, song parodist<q>he later became adman, did a number of outrageous commercials<q>Yankovic said : " he is a legend, an inspiration, and a friend."

BertSUM: "he was and will always be my hero," his son wrote on facebook<q>Freberg won a grammy award in 1959 for "the best of the stan freberg shows"<q>Freberg died of natural causes at today morning.

BertSUM+TA: Reporter said Stan Freberg was a famous actor died at Santa Monica hospital <q>Freberg did some important advertisement <q>he won a grammy award in 1959<q>He is remembered by his amazing life.

T1: famous, famously, fame, known, famed, well, know, remember, world, best;
T2: actor, actress, play, sing, disney, comic, hollywood, cartoon, show, humor ;
T3: business, advertise, commercial, rise, bank, economy, financial, money, product, growth;
T4: writer, journalist, report, wrote, write, magazine, story, reporter, media, newspaper;
T5: star, amazing, actor, film, oscar, legend, award, entertain, starring, inspiration;

Figure 6: Generated summaries of BertSUM and BertSUM+TA for a document in CNN/DM, where we also list the top-five topics of this document.



Gold: For domestic economy, India's central bank has unexpectedly held interest rates at a six-year low .

BertSUM: The bank of india has cut the cost of borrowing by 0.25 % to 2.5 %
BertSUM+TA: The **central** bank of india has cut the cost of borrowing **to a six-year low**.

MASS: India's bank has cut the cost of borrowing by 0.25 % to 2.5 %, in an effort to boost growth.
MASS+TA: India 's **central** bank has cut the cost of borrowing to **a six-year low** to boost growth.

UNILM: India's bank has cut the cost from of borrowing 0.25 % to 2.5 % for improving the economy.
UNILM+TA: India's **central** bank has cut the cost from of borrowing to **a six-year low** for improving the economy.

BART: India's bank has held interest rates at a low level for domestic economy.
BART+TA: India's **central** bank has held interest rates at a **six-year record** low for domestic economy.

Figure 7: Examples of generated summaries on Xsum.

in the document but conveyed by the topics. For example, BertSUM+TA summarizes *shows*, *played*, *singing* as *actor*, and summarizes *worldwide*, *famously* as *remembered* and *famous*. This is due to the fact that a topic describes a co-occurrence pattern of words with similar semantics.

Fig. 7 provides some generated examples as TA combined with different models. It can be seen that some neglected words, such as "central" and "six-year", are generated with the help of TA. More examples can be found in Appendix C.

6 Conclusion and future work

In this paper, we explore and rearrange semantics of a topic model and then propose a friendly plug-and-play TA for Transformer-based abstractive summarization models. By introducing a small number of parameters, TA is able to further improve the performance of these models, especially under a long-document scenario. In the future, we will study the effectiveness of TA on other NLP tasks, such as the document-level translation, and investigate whether TA is useful for Transformer pre-training.

Appendix

A Data descriptions

In experiments, we evaluate the models on three benchmark summarization datasets. They are the CNN/DailyMail news (CNN/DM) (Hermann et al., 2015), the New York Times Annotated Corpus (NYT) (Sandhaus, 2008) and XSum (Narayan et al., 2018).

CNN/DM CNN/DM consists of news and associated sentence highlights, that is a brief overview composed of a few sentences. Following the standard training/validation/testing splits in Hermann et al. (2015) without anonymizing entities, we perform our experiments. We splits sentences using the Stanford CoreNLP toolkit[8] and pre-process the dataset following Liu (2019).

NYT NYT contains $110,540$ articles with abstractive summaries. Following Liu (2019), we split the dataset into $100,834/9706$ training/test examples based on the date of publication (the test set contains all articles published from January 1, 2007 onward), and use $4,000$ examples from the training set as a validation set. We also follow their filtering procedure, removing documents whose summary has less than 50 tokens (not words), resulting in a filtered test set including $3,452$ examples. We also split the sentences using the Stanford CoreNLP toolkit and perform pre-processing following Liu (2019).

XSum XSum includes $226,711$ news articles, each of which is associated with a one-sentence summary. We use the standard training/validation/testing splits

Table 10: Comparions on the number of topics on the CNN/DM dataset.

Topic Num.	0	32	64	128	256	512
R1	42.13	42.52	42.77	42.91	43.06	43.08
R2	19.60	20.01	20.29	20.40	20.58	20.57
RL	39.18	39.46	39.57	39.62	39.67	39.69

$(204, 045/11, 332/11, 334)$ and follow the pre-processing in Narayan et al. (2018).

To satisfy the maximum capacity of the encoder in the base model, such as 512 for BertSUM, we use truncated document as the encoder input.

B Implementation Details

Topic model We remove stop words[9] to obtain the bag-of-word (BOW) vector for each document, and then use the BOW vectors to infer the topic model. For the PFA, we follow Zhang et al. (2018) to set model parameters.

As mentioned in Zhang et al. (2018), the number of topics is often set as 64, 128, or 256. Thus, we analyzed BertSUM (denoted as 0 topic) and BertSum+TA with different numbers of topics on the CNN/DM dataset, with the results shown in Table 10. It can be seen that a small number of topics are inadequate to express all the semantics, while too many topics are redundant and introduce more learnable parameters. Thus, we set 256 topics in all experiments.

We train PFA in one Nvidia GeForce RTX2080TI GPU. The experiments are performed with mini-batch size 200. We run 30 epochs to train the models on CNN/DM, NYT and Xsum. We use Adam optimizer with *learning-rate* $= 5^{-4}$, *weight-decay* $= 5^{-4}$ to optimize the topic model parameters. The hyper-parameters to update the topics with TLASGR-MCMC are the same with those in Zhang et al. (2018). According to the values of topic proportion in $\boldsymbol{\theta}$, in TEMA, we choose top-5 topics to obtain their corresponding topic embeddings.

Transformer+TA We do not change any setting of the original Transformer models. It should be noted that, to satisfy the maximum capacity of the encoder in the base model, such as 512 for BertSUM, one often use truncated documents as the encoder input. We set the hyper-parameters following the original papers and their public codes, where BertSUM[10] is referred to Liu and Lapata (2019), BART[11] referred to Lewis et al. (2019), UNILM[12] referred to Dong et al. (2019), and MASS[13] referred to Song et al. (2019). We fine-tune all models in four Nvidia GeForce RTX2080 TI GPUs. The experiments are performed with mini-batch size including 200 summary tokens with gradient accumulation every six iterations. Model checkpoints were saved and evaluated on the validation set every 1000 updates. Totally, we update the model $250,000$ times. Following Liu and Lapata (2019), we select the top-3 checkpoints based on their evaluation loss on the validation set, and report the averaged results on the test set. During decoding we used beam search with size 5, and tuned the α for the length penalty between 0.6 and 1 on validation set. It is worth noting that our decoder applies neither a copy nor a coverage mechanism, despite their popularity in abstractive summarization.

C More summary examples

Figs. 8 and 9 show some summary examples.

Contrastive Distillation on Intermediate Representations for Language Model Compression

Abstract

Existing language model compression methods mostly use a simple L_2 loss to distill knowledge in the intermediate representations of a large BERT model to a smaller one. Although widely used, this objective by design assumes that all the dimensions of hidden representations are independent, failing to capture important *structural* knowledge in the intermediate layers of the teacher network. To achieve better distillation efficacy, we propose Contrastive Distillation on Intermediate Representations (CODIR), a principled knowledge distillation framework where the student is trained to distill knowledge through intermediate layers of the teacher via a *contrastive objective*. By learning to distinguish positive sample from a large set of negative samples, CoDIR facilitates the student's exploitation of rich information in teacher's hidden layers. CoDIR can be readily applied to compress large-scale language models in both pre-training and finetuning stages, and achieves superb performance on the GLUE benchmark, outperforming state-of-the-art compression methods.[1]

1 Introduction

Large-scale pre-trained language models (LMs), such as BERT (Devlin et al., 2018), XLNet (Yang et al., 2019) and RoBERTa (Liu et al., 2019), have brought revolutionary advancement to the NLP field (Wang et al., 2018). However, as new-generation LMs grow more and more into behemoth size, it becomes increasingly challenging to deploy them in resource-deprived environment. Naturally, there has been a surge of research interest in developing model compression methods (Sun et al., 2019; Sanh et al., 2019; Shen et al., 2019) to reduce network size in pre-trained LMs, while retaining comparable performance and efficiency.

PKD (Sun et al., 2019) was the first known effort in this expedition, an elegant and effective method that uses knowledge distillation (KD) for BERT model compression at finetuning stage. Later on, DistilBERT (Sanh et al., 2019), TinyBERT (Jiao et al., 2019) and MobileBERT (Sun et al., 2020) carried on the torch and extended similar compression techniques to pre-training stage, allowing efficient training of task-agnostic compressed models. In addition to the conventional KL-divergence loss applied to the probabilistic output of the teacher and student networks, an L_2 loss measuring the difference between normalized hidden layers has proven to be highly effective in these methods. However, L_2 norm follows the assumption that all dimensions of the target representation are independent, which overlooks important structural information in the many hidden layers of BERT teacher.

Motivated by this, we propose **Co**ntrastive **D**istillation for **I**ntermediate **R**epresentations (CODIR), which uses a *contrastive objective* to capture higher-order output dependencies between intermediate representations of BERT teacher and the student. Contrastive learning (Gutmann and Hyvärinen, 2010) aims to learn representations by enforcing similar elements to be equal and dissimilar elements further apart. Formulated in either supervised or unsupervised way, it has been successfully applied to diverse applications (Hjelm et al., 2018; He et al., 2019; Tian et al., 2019; Khosla et al., 2020). To the best of our knowledge, utilizing contrastive learning to compress large Transformer models is still an unexplored territory, which is the main focus of this paper.

A teacher network's hidden layers usually contain rich semantic and syntactic knowledge that can be instrumental if successfully passed on to the student (Tenney et al., 2019; Kovaleva et al.,

---

[1] Code will be released at `https://github.com/intersun/CoDIR`.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 498–508,
November 16–20, 2020.

2019; Sun et al., 2019). Thus, instead of directly applying contrastive loss to the final output layer of the teacher, we apply contrastive learning to its intermediate layers, in addition to the use of KL-loss between the probabilistic outputs of the teacher and student. This casts a stronger regularization effect for student training by capturing more informative signals from intermediate representations. To maximize the exploitation of intermediate layers of the teacher, we also propose the use of mean-pooled representation as the distillation target, which is empirically more effective than commonly used special `[CLS]` token.

To realize constrastive distillation, we define a *congruent* pair $(\boldsymbol{h}_i^t, \boldsymbol{h}_i^s)$ as the pair of representations of the same data input from the teacher and student networks, as illustrated in Figure 1. *Incongruent* pair $(\boldsymbol{h}_i^t, \boldsymbol{h}_j^s)$ is defined as the pair of representations of two different data samples through the teacher and the student networks, respectively. The goal is to train the student network to distinguish the congruent pair from a large set of incongruent pairs, by minimizing the constrastive objective.

For efficient training, all data samples are stored in a memory bank (Wu et al., 2018; He et al., 2019). During finetuning, incongruent pairs can be selected by choosing sample pairs with different labels to maximize the distance. For pre-training, however, it is not straightforward to construct incongruent pairs this way as labels are unavailable. Thus, we randomly sample data points from the same mini-batch pair to form incongruent pairs, and construct a proxy congruent-incongruent sample pool to assimilate what is observed in the downstream tasks during finetuning stage. This and other designs in CoDIR make constrative learning possible for LM compression, and have demonstrated strong performance and high efficiency in experiments.

Our contributions are summarized as follows. (i) We propose CoDIR, a principled framework to distill knowledge in the intermediate representations of large-scale language models via a contrastive objective, instead of a conventional L_2 loss. (ii) We propose effective sampling strategies to enable CoDIR in both pre-training and finetuning stages. (iii) Experimental results demonstrate that CoDIR can successfully train a half-size Transformer model that achieves competing performance to BERT-base on the GLUE benchmark (Wang et al., 2018), with half training time and GPU demand. Our pre-trained model checkpoint will be released for public access.

2 Related Work

Language Model Compression To reduce computational cost of training large-scale language models, many model compression techniques have been developed, such as quantization (Shen et al., 2019; Zafrir et al., 2019), pruning (Guo et al., 2019; Gordon et al., 2020; Michel et al., 2019), knowledge distillation (Tang et al., 2019; Sun et al., 2019; Sanh et al., 2019; Jiao et al., 2019; Sun et al., 2020), and direct Transformer block modification (Kitaev et al., 2020; Wu et al., 2020).

Quantization refers to storing model parameters from 32- or 16-bit floating number to 8-bit or even lower. Directly truncating the parameter values will cause significant accuracy loss, hence quantization-aware training has been developed to maintain similar accuracy to the original model (Shen et al., 2019; Zafrir et al., 2019). Michel et al. (2019) found that even after most attention heads are removed, the model still retains similar accuracy, indicating there is high redundancy in the learned model weights. Later studies proposed different pruning-based methods. For example, Gordon et al. (2020) simply removed the model weights that are close to zero; while Guo et al. (2019) used re-weighted L_1 and proximal algorithm to prune weights to zero. Note that simple pruning does not improve inference speed, unless there is structure change such as removing the whole attention head.

There are also some efforts that try to improve the Transformer block directly. Typically, language models such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) can only handle a sequence of tokens in length up to 512. Kitaev et al. (2020) proposed to use reversible residual layers and locality-sensitive hashing to reduce memory usage to deal with extremely long sequences. Besides, Wu et al. (2020) proposed to use convolutional neural networks to capture short-range attention such that reducing the size of self-attention will not significantly hurt performance.

Another line of research on model compression is based on knowledge transfer, or knowledge distillation (KD) (Hinton et al., 2015), which is the main focus of this paper. Note that previously introduced model compression techniques are orthogonal to KD, and can be bundled for further speedup. Distilled BiLSTM (Tang et al., 2019) tried to dis-

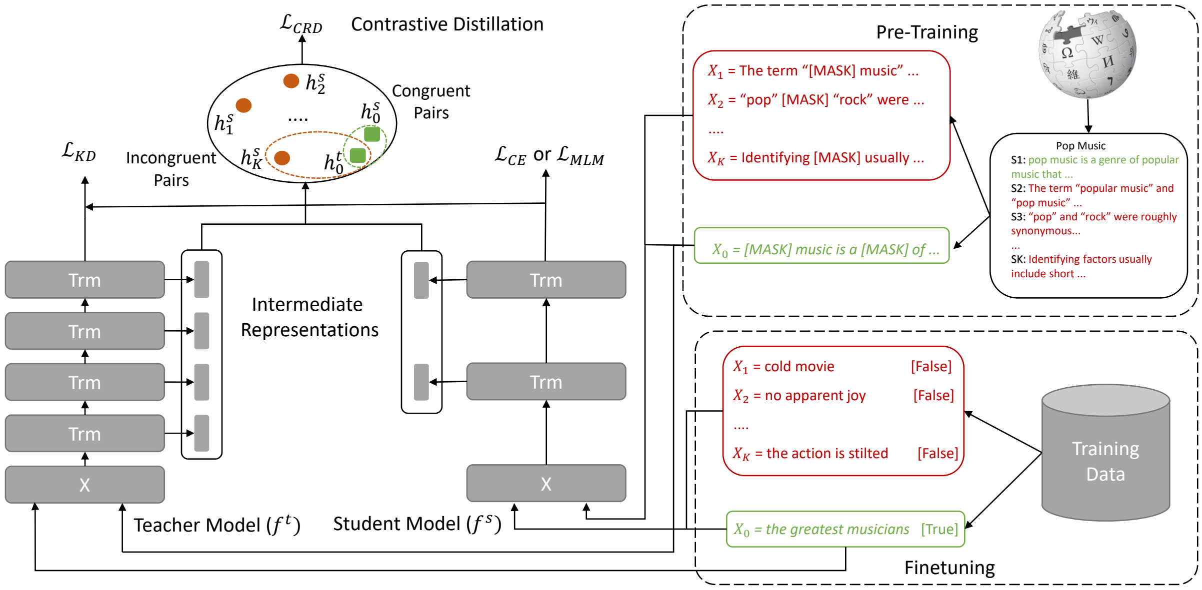

Figure 1: Overview of the proposed CoDIR framework for language model compression in both pre-training and finetuning stages. "Trm" represents a Transformer block, X are input tokens, f^t and f^s are teacher and student models, and $X_0, \{X_i\}_{i=1}^K$ represent one positive sample and a set of negative samples, respectively. The difference between CoDIR pre-training and finetuning mainly lies in the negative example sampling method.

till knowledge from BERT into a simple LSTM. Though achieving more than 400 times speedup compared to BERT-large, it suffers from significant performance loss due to the shallow network architecture. DistilBERT (Sanh et al., 2019) proposed to distill predicted logits from the teacher model into a student model with 6 Transformer blocks. BERT-PKD (Sun et al., 2019) proposed to not only distill the logits, but also the representation of `[CLS]` tokens from the intermediate layers of the teacher model. TinyBERT (Jiao et al., 2019), MobileBERT (Sun et al., 2020) and SID (Aguilar et al., 2019) further proposed to improve BERT-PKD by distilling more internal representations to the student, such as embedding layers and attention weights. These existing methods can be generally divided into two categories: (i) task-specific, and (ii) task-agnostic. Task-specific methods, such as Distilled BiLSTM, BERT-PKD and SID, require the training of individual teacher model for each downstream task; while task-agnostic methods such as DistilBERT, TinyBERT and MobileBERT use KD to pre-train a model that can be applied to all downstream tasks by standard finetuning.

Contrastive Representation Learning Contrastive learning (Gutmann and Hyvärinen, 2010; Arora et al., 2019) is a popular research area that has been successfully applied to density estimation and representation learning, especially in self-supervised setting (He et al., 2019; Chen et al., 2020). It has been shown that the contrastive objective can be interpreted as maximizing the lower bound of mutual information between different views of the data (Hjelm et al., 2018; Oord et al., 2018; Bachman et al., 2019; Hénaff et al., 2019). However, it is unclear whether the success is determined by mutual information or by the specific form of the contrastive loss (Tschannen et al., 2019). Recently, it has been extended to knowledge distillation and cross-modal transfer for image classification tasks (Tian et al., 2019). Different from prior work, we propose the use of contrastive objective for Transformer-based model compression and focus on language understanding tasks.

3 CoDIR for Model Compression

In this section, we first provide an overview of the proposed method in Sec. 3.1, then describe the details of contrastive distillation in Sec. 3.2. Its adaptation to pre-training and finetuning is further discussed in Sec. 3.3.

3.1 Framework Overview

We use RoBERTa-base (Liu et al., 2019) as the teacher network, denoted as f^t, which has 12 layers with 768-dimension hidden representations. We aim to transfer the knowledge of f^t into a student network f^s, where f^s is a 6-layer Transformer (Vaswani et al., 2017) to mimic the behavior of f^t (Hinton et al., 2015). Denote a training sample as (X, y), where $X = (x_0, \ldots, x_{L-1})$ is a sequence of tokens in length L, and y is the corresponding label (if available). The word embedding matrix of X is represented as $\mathbf{X} = (\boldsymbol{x}_0, \ldots, \boldsymbol{x}_{L-1})$, where $\boldsymbol{x}_i \in \mathbb{R}^d$ is a d-dimensional vector, and $\mathbf{X} \in \mathbb{R}^{L \times d}$. In addition, the intermediate representations at each layer for the teacher and student are denoted as $\mathbf{H}^t = (\mathbf{H}_1^t, \ldots, \mathbf{H}_{12}^t)$ and $\mathbf{H}^s = (\mathbf{H}_1^s, \ldots, \mathbf{H}_6^s)$, respectively, where $\mathbf{H}_i^t, \mathbf{H}_i^s \in \mathbb{R}^{L \times d}$ contains all the hidden states in one layer. And $\boldsymbol{z}^t, \boldsymbol{z}^s \in \mathbb{R}^k$ are the logit representations (before the softmax layer) of the teacher and student, respectively, where k is the number of classes.

As illustrated in Figure 1, our distillation objective consists of three components: (i) original *training loss* from the target task; (ii) conventional *KL-divergence-based loss* to distill the knowledge of $\boldsymbol{z}^t$ into $\boldsymbol{z}^s$; (iii) proposed *contrastive loss* to distill the knowledge of $\mathbf{H}^t$ into $\mathbf{H}^s$. The final training objective can be written as:

$$\begin{aligned}\mathcal{L}_{\text{CoDIR}}(\boldsymbol{\theta}) = \mathcal{L}_{\text{CE}}(\boldsymbol{z}^s, y; \boldsymbol{\theta}) + \alpha_1 \mathcal{L}_{\text{KD}}(\boldsymbol{z}^t, \boldsymbol{z}^s; \boldsymbol{\theta}) \\ + \alpha_2 \mathcal{L}_{\text{CRD}}(\mathbf{H}^t, \mathbf{H}^s; \boldsymbol{\theta}), \quad (1)\end{aligned}$$

where $\mathcal{L}_{\text{CE}}, \mathcal{L}_{\text{KD}}$ and $\mathcal{L}_{\text{CRD}}$ correspond to the original loss, KD loss and contrastive loss, respectively. $\boldsymbol{\theta}$ denotes all the learnable parameters in the student f^s, while the teacher network is pre-trained and kept fixed. α_1, α_2 are two hyper-parameters to balance the loss terms.

$\mathcal{L}_{\text{CE}}$ is typically implemented as a cross-entropy loss for classification problems, and $\mathcal{L}_{\text{KD}}$ can be written as

$$\mathcal{L}_{\text{KD}}(\boldsymbol{z}^t, \boldsymbol{z}^s; \boldsymbol{\theta}) = \text{KL}\left(g(\boldsymbol{z}^t/\rho) \| g(\boldsymbol{z}^s/\rho)\right), \quad (2)$$

where $g(\cdot)$ denotes the softmax function, and ρ is the temperature. $\mathcal{L}_{\text{KD}}$ encourages the student network to produce distributionally-similar outputs to the teacher network.

Only relying on the final logit output for distillation discards the rich information hidden in the intermediate layers of BERT. Recent work (Sun et al., 2019; Jiao et al., 2019) has found that distilling the knowledge from intermediate representations with L_2 loss can further enhance the performance. Following the same intuition, our proposed method also aims to achieve this goal, with a more principled contrastive objective as detailed below.

3.2 Contrastive Distillation

First, we describe how to summarize intermediate representations into a concise feature vector. Based on this, we detail how to perform contrastive distillation (Tian et al., 2019) for model compression.

Intermediate Representation Directly using $\mathbf{H}^t$ and $\mathbf{H}^s$ for distillation is infeasible, as the total feature dimension is $|\mathbf{H}^s| = 6 \times 512 \times 768 \approx 2.4$ million for a sentence in full length (*i.e.*, $L = 512$). Therefore, we propose to first perform mean-pooling over $\mathbf{H}^t$ and $\mathbf{H}^s$ to obtain a layer-wise sentence embedding. Note that the embedding of the `[CLS]` token can also be used directly for this purpose; however, in practice we found that mean-pooling performs better. Specifically, we conduct row-wise average over $\mathbf{H}_i^t$ and $\mathbf{H}_i^s$:

$$\bar{\boldsymbol{h}}_i^t = \text{Pool}(\mathbf{H}_i^t), \;\; \bar{\boldsymbol{h}}_i^s = \text{Pool}(\mathbf{H}_i^s), \quad (3)$$

where $\bar{\boldsymbol{h}}_i^t, \bar{\boldsymbol{h}}_i^s \in \mathbb{R}^d$ are the sentence embedding for layer i of the teacher and student model, respectively. Therefore, the student's intermediate representation can be summarized as $\bar{\boldsymbol{h}}^s = [\bar{\boldsymbol{h}}_1^s; \ldots; \bar{\boldsymbol{h}}_6^s] \in \mathbb{R}^{6d}$, where $[;]$ denotes vector concatenation. Similarly, the teacher's intermediate representation can be summarized as $\bar{\boldsymbol{h}}^t = [\bar{\boldsymbol{h}}_1^t; \ldots; \bar{\boldsymbol{h}}_{12}^t] \in \mathbb{R}^{12d}$. Two linear mappings $\phi^s : \mathbb{R}^{6d} \to \mathbb{R}^m$ and $\phi^t : \mathbb{R}^{12d} \to \mathbb{R}^m$ are further applied to project $\bar{\boldsymbol{h}}^t$ and $\bar{\boldsymbol{h}}^s$ into the same low-dimensional space, yielding $\boldsymbol{h}^t, \boldsymbol{h}^s \in \mathbb{R}^m$, which are used for calculating the contrastive loss.

Contrastive Objective Given a training sample (X_0, y_0), we first randomly select K negative samples with different labels, denoted as $\{(X_i, y_i)\}_{i=1}^K$. Following the above process, we can obtain a summarized intermediate representation $\boldsymbol{h}_0^t, \boldsymbol{h}_0^s \in \mathbb{R}^m$ by sending X_0 to both the teacher and student network. Similarly, for negative samples, we can obtain $\{\boldsymbol{h}_i^s\}_{i=1}^K$.

Contrastive learning aims to map the student's representation $\boldsymbol{h}_0^s$ close to the teacher's representation $\boldsymbol{h}_0^t$, while the negative samples' representations $\{\boldsymbol{h}_i^s\}_{i=1}^K$ far apart from $\boldsymbol{h}_0^t$. To achieve this, we use the following InfoNCE loss (Oord et al., 2018) for model training:

$$\mathcal{L}_{\text{CRD}}(\boldsymbol{\theta}) = -\log \frac{\exp\left(\langle \boldsymbol{h}_0^t, \boldsymbol{h}_0^s \rangle / \tau\right)}{\sum_{j=0}^K \exp\left(\langle \boldsymbol{h}_0^t, \boldsymbol{h}_j^s \rangle / \tau\right)}, \quad (4)$$

where $\langle \cdot, \cdot \rangle$ denotes the cosine similarity between two feature vectors, and τ is the temperature that controls the concentration level. As demonstrated, contrastive distillation is implemented as a $(K+1)$-way classification task, which is interpreted as maximizing the lower bound of mutual information between $\boldsymbol{h}_0^t$ and $\boldsymbol{h}_0^s$ (Oord et al., 2018; Tian et al., 2019).

3.3 Pre-training and Finetuning Adaptation

Memory Bank For a positive pair $(\boldsymbol{h}_0^t, \boldsymbol{h}_0^s)$, one needs to compute the intermediate representations for all the negative samples, *i.e.*, $\{\boldsymbol{h}_i^s\}_{i=1}^K$, which requires $K+1$ times computation compared to normal training. A large number of negative samples is required to ensure performance (Arora et al., 2019), which renders large-scale contrastive distillation infeasible for practical use. To address this issue, we follow Wu et al. (2018) and use a memory bank $\mathbf{M} \in \mathbb{R}^{N \times m}$ to store the intermediate representation of all N training examples, and the representation is only updated for positive samples in each forward propagation. Therefore, the training cost is roughly the same as in normal training. Specifically, assume the mini-batch size is 1, then at each training step, $\mathbf{M}$ is updated as:

$$\boldsymbol{m}_0 = \beta \cdot \boldsymbol{m}_0 + (1-\beta) \cdot \boldsymbol{h}_0^s \,, \tag{5}$$

where $\boldsymbol{m}_0$ is the retrieved representation from memory bank $\mathbf{M}$ that corresponds to $\boldsymbol{h}_0^s$, and $\beta \in (0,1)$ is a hyper-parameter that controls how aggressively the memory bank is updated.

Finetuning Since task-specific label supervision is available in finetuning stage, applying CoDIR to finetuning is relatively straightforward. When selecting negative samples from the memory bank, we make sure the selected samples have different labels from the positive sample.

Pre-training For pre-training, the target task becomes masked language modeling (MLM) (Devlin et al., 2018). Therefore, we replace the $\mathcal{L}_{\text{CE}}$ loss in Eqn. (1) with $\mathcal{L}_{\text{MLM}}$. Following Liu et al. (2019); Lan et al. (2019), we did not include the next-sentence-prediction task for pre-training, as it does not improve performance on downstream tasks. Since task-specific label supervision is unavailable during pre-training, we propose an effective method to select negative samples from the memory bank. Specifically, we sample negative examples randomly from the same mini-batch each time, as they have closer semantic meaning as some of them are from the same article, especially for Bookcorpus (Zhu et al., 2015). Then, we use the sampled negative examples to retrieve representations from the memory bank. Intuitively, negative examples sampled in this way serve as "hard" negatives, compared to randomly sampling from the whole training corpus; otherwise, the $\mathcal{L}_{\text{CRD}}$ loss could easily drop to zero if the task is too easy.

4 Experiments

In this section, we present comprehensive experiments on a wide range of downstream tasks and provide detailed ablation studies, to demonstrate the effectiveness of the proposed approach to large-scale LM compression.

4.1 Datasets

We evaluate the proposed approach on sentence classification tasks from the General Language Understanding Evaluate (GLUE) benchmark (Wang et al., 2018), as our finetuning framework is designed for classification, and we only exclude the STS-B dataset (Cer et al., 2017). Following other works (Sun et al., 2019; Jiao et al., 2019; Sun et al., 2020), we also do not run experiments on WNLI dataset (Levesque et al., 2012), as it is very difficult and even majority voting outperforms most benchmarks.[2]

CoLA Corpus of Linguistic Acceptability (Warstadt et al., 2019) contains a collection of 8.5k sentences drawn from books or journal articles. The goal is to predict if the given sequence of words is grammatically correct. Mattthews correlation coefficient is used as the evaluation metric.

SST-2 Stanford Sentiment Treebank (Socher et al., 2013) consists of 67k human-annotated movie reviews. The goal is to predict whether each review is positive or negative. Accuracy is used as the evaluation metric.

MRPC Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) consists of 3.7k sentence pairs extracted from online news, and the goal to predict if each pair of sentences is semantically equivalent. F1 score from GLUE server is reported as the metric.

QQP The Quora Question Pairs[3] task consists of 393k question pairs from Quora webiste. The

Table 1: Results on GLUE Benchmark. (*) indicates those numbers are unavailable in the original papers and were obtained by us through submission to the official leaderboard using their codebases. Other results are obtained from published papers. ($\star$) indicates those methods with fewer Transformer blocks, and may not be fair comparison.

task is to predict whether a pair of questions is semantically equivalent. Accuracy is used as the evaluation metric.

NLI Multi-Genre Natural Language Inference Corpus **(MNLI)** (Williams et al., 2017), Question-answering NLI **(QNLI)** (Rajpurkar et al., 2016) and Recognizing Textual Entailment **(RTE)**[4] are all natural language inference (NLI) tasks, which consist of 393k/108k/2.5k pairs of premise and hypothesis. The goal is to predict if the premise entails the hypothesis, or contradicts it, or neither. Accuracy is used as the evaluation metric. Besides, MNLI test set is further divided into two splits: matched (MNLI-m, in-domain) and mismatched (MNLI-mm, cross-domain), accuracy for both are reported.

4.2 Implementation Details

We mostly follow the pre-training setting from Liu et al. (2019), and use the fairseq implementation (Ott et al., 2019). Specifically, we truncate raw text into sentences with maximum length of 512 tokens, and randomly mask 15% of tokens as `[MASK]`. For model architecture, we use a randomly initialized 6-layer Transformer model as the student, and RoBERTa-base with 12-layer Transformer as the teacher. The student model was first trained by using Adam optimizer with learning rate 0.0007 and batch size 8192 for 35,000 steps. For computational efficiency, this model serves as the initialization for the second-stage pre-training with the teacher. Then, the student model is further trained for another 10,000 steps with KD and the proposed contrastive objective, with learning rate set to 0.0001. We denote this model as CoDIR-Pre. For ablation purposes, we also train two baseline models with only MLM loss or KD loss, using the same learning rate and number of steps. Similarly, these two models are denoted as MLM-Pre and KD-Pre, respectively. For other hyper-parameters, we use $\alpha_1 = \alpha_2 = 0.1$ for both $\mathcal{L}_{\text{KD}}$ and $\mathcal{L}_{\text{CRD}}$.

Due to high computational cost for pre-training, all the hyper-parameters are set empirically without tuning. As there exist many combinations of pre-training loss (MLM, KD, and CRD) and finetuning strategies (standard finetuning with cross-entropy loss, and finetuning with additional CRD loss), a grid search of all the hyper-parameters is infeasible. Thus, for standard finetuning, we search learning rate from {1e-5, 2e-5} and batch size from {16, 32}. The combination with the highest score on dev set is reported for ablation studies, and is kept *fixed* for future experiments. We then fix the hyper-parameters in KD as $\rho = 2, \alpha_1 = 0.7$, and search weight of the CRD loss α_2 from {0.1, 0.5, 1}, and the number of negative samples from {100, 500, 1000}. Results with the highest dev scores were submitted to the official GLUE server to obtain the final results. For fair comparison with other baseline methods, all the results are based on single-model performance.

4.3 Experimental Results

Results of different methods from the official GLUE server are summarized in Table 1. For sim-

CoDIR-Pre	6	82.7M	39.0M	1.25	2.08×

Table 3: Inference speed comparison between teacher and students. Inference time is measured on MNLI dev set. Speed up is measured against BERT-base, which is the teacher model for other baseline methods.

plicity, we denote our baseline approach without using any teacher supervision as "MLM-Pre + Fine": pre-trained by using MLM loss first, then finetuning using standard cross-entropy loss. Our baseline already achieves high average score across 8 tasks, and outperforms task-specific model compression methods (such as SID (Aguilar et al., 2019) and BERT-PKD (Sun et al., 2019)) as well as DistilBERT (Sanh et al., 2019) by a large margin.

After adding contrastive loss at the finetuning stage (denoted as CoDIR-Fine), the model outperforms the state-of-the-art compression method, TinyBERT with 6-layer Transformer, on average GLUE score. Especially on datasets with fewer data samples, such as CoLA and MRPC, the improved margin is large (+2.5% and +2.1%, respectively). Compared to our MLM-Pre + Fine baseline, CoDIR-Fine achieves significant performance gain on almost all tasks (+1.2% absolute improvement on average score), demonstrating the effectiveness of the proposed approach. The only exception is QQP (-0.1%) with more than 360k training examples. In such case, standard finetuning may already bring in enough performance boost with this large-scale labeled dataset, and the gap between the teacher and student networks is already small (89.6 vs 89.2).

We further test the effectiveness of CoDIR for pre-training (CoDIR-Pre), by applying standard finetuning on model pre-trained with additional contrastive loss. Again, compared to the MLM-Pre + Fine baseline, this improves the model performance on almost all the tasks (except QQP), with a significant lift on the average score (+1.4%). We notice that this model performs similarly to the contrastive-finetuning only approach (CoDIR-Fine) on almost all tasks. However, CoDIR-Pre is preferred because it utilizes the teacher's knowledge in the pre-training stage, thus no task-specific teacher is needed for finetuning downstream tasks. Finally, we experiment with the combination of CoDIR-Pre and CoDIR-Fine, and our observation is that adding constrastive loss for finetuning is not bringing in much improvement after already using constrastive loss in pre-training. Our hypothesis is that the model's ability to identify negative examples is already well learned during pre-training.

Inference Speed We compare the inference speed of the proposed CoDIR with the teacher network and other baselines. Statistics of Transformer layers and parameters are presented in Table 3. The statistics for BERT$_6$-PKD and TinyBERT$_6$ are omitted as they share the same model architecture as DistilBERT. To test the inference speed, we ran each algorithm on MNLI dev set for 3 times, with batch size 32 and maximum sequence length 128 under the same hardware configuration. The average running time with 3 different random seeds is reported as the final inference speed. Though our RoBERTa teacher has almost 16 million more parameters, it shares almost the same inference

Model	CoLA (8.5k)	SST-2 (67k)	MRPC (3.7k)	QQP (364k)	MNLI-m/-mm (393k)	QNLI (108k)	RTE (2.5k)	Ave.
CoDIR-Fine (`[CLS]`)	57.6	92.9	89.2	91.3	84.0/84.0	90.8	70.0	82.5

CoDIR-Fine (1000-neg)	59.3	92.7	90.0	91.3	84.2/84.2	90.7	70.4	**83.0**

Table 4: Ablation study on the use of `[CLS]` and Mean-Pooling as sentence embedding (upper part) and effect of number of negative examples (neg) for CoDIR-Fine (bottom part). The results are based on GLUE dev set.

Model	CoLA (8.5k)	SST-2 (67k)	MRPC (3.7k)	QQP (364k)	MNLI-m (393k)	QNLI (108k)	RTE (2.5k)
Median	56.4	92.4	87.9	91.2	83.9	90.7	66.3
Maximum	57.8	93.0	90.3	91.3	84.2	91.0	70.2
Standard Deviation	1.46	0.28	1.66	0.06	0.43	0.18	1.41

Table 5: Analysis of model variance on GLUE dev set. Statistical results (median, maximum, and standard deviation) are based on 8 runs with the same hyper-parameters.

speed as BERT-base, because its computational cost mainly comes from the embedding layer with 50k vocabulary size that does not affect inference speed. By reducing the number of Transformer layers to 6, our proposed student model achieves 2 times speed up compared to the teacher, and achieves state-of-the-art performance among all models with similar inference time.

4.4 Ablation Studies

Sentence Embedding We also conduct experiments to evaluate the effectiveness of using different sentence embedding strategies. More detailed, based on the same model pre-trained on $\mathcal{L}_{\text{MLM}}$ alone, we run finetuning experiments with contrastive loss on the GLUE dataset by using: (i) `[CLS]` as sentence embedding; and (ii) mean-pooling as sentence embedding. The results on GLUE dev set are presented in top rows of Table 4, showing that mean-pooling yields better results than `[CLS]` (83.0 vs. 82.5 on average). As a result, we use mean pooling as our chosen sentence embedding for all our experiments.

Negative Examples As we mentioned in Section 4.2, the experiments are conducted using 100, 500 and 1000 negative examples. We then evaluate the effect of number of negative examples by comparing their results on GLUE dev set, and the results are presented in the bottom part of Table 4. Obviously, for most dataset the accuracy increases as a larger number of negative examples are used during training. Similar observations were also reported in Tian et al. (2019), and a theoretical analysis is provided in Arora et al. (2019). The only two exceptions are QQP and RTE. As discussed in Section 4.3, our CoDIR method seems also not work well on QQP due to the small gap between teacher and student. As for RTE, due to the small number of training examples, the results are quite volatile, which may make the results inconsistent. Besides, the number of negative examples is close to the number of examples per class (1.25k) for RTE, which can also result in the contrastive loss close to 0.

Contrastive Loss We first evaluate the effectiveness of the proposed CRD loss for finetuning on a subset of GLUE dev set, using the following settings: (i) finetuning with cross-entropy loss only; (ii) finetuning with additional KD loss; and (iii) finetuning with additional KD loss and CRD loss. Results in Table 2 (upper part) show that using KD improves over standard finetuning by 0.9% on average, and using CRD loss further improves another 1.0%, demonstrating the advantage of using contrastive learning for finetuning.

To further validate performance improvement of using contrastive loss on pre-training, we apply standard finetuning to three different pre-trained models: (i) model pre-trained by $\mathcal{L}_{\text{MLM}}$ (MLM-Pre); (ii) model pre-trained by $\mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{KD}}$ (KD-Pre); and (iii) model pre-trained by $\mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{KD}} + \mathcal{L}_{\text{CRD}}$ (CoDIR-Pre). Results are summarized in Table 2 (bottom part). Similar trend can be observed that the model pre-trained with additional CRD loss performs the best, outperforming MLM-Pre and KD-Pre by 1.9% and 1.0% on average, respectively.

Model Variance Since different random seeds can exhibit different generalization behaviors, especially for tasks with a small training set (*e.g.,* CoLA), we examine the median, maximum and standard deviation of model performance on the dev set of each GLUE task, and present the results in Table 5. As expected, the models are more stable on larger datasets (SST-2, QQP, MNLI, and QNLI), where all standard deviations are lower than 0.5. However, the model is sensitive to the random seeds on smaller datasets (CoLA, MRPC, and RTE) with the standard deviation around 1.5. These analysis results provide potential references for future work on language model compression.

5 Conclusion

In this paper, we present CoDIR, a novel approach to large-scale language model compression via the use of contrastive loss. CoDIR utilizes information from both teacher's output layer and its intermediate layers for student model training. Extensive experiments demonstrate that CoDIR is highly effective in both finetuning and pre-training stages, and achieves state-of-the-art performance on GLUE benchmark compared to existing models with a similar size. All existing work either use BERT-base or RoBERTa-base as teacher. For future work, we plan to investigate the use of a more powerful language model, such as Megatron-LM (Shoeybi et al., 2019), as the teacher; and different strategies for choosing hard negatives to further boost the performance.

Abstract

Transformer-based pre-training models like BERT have achieved remarkable performance in many natural language processing tasks. However, these models are both computation and memory expensive, hindering their deployment to resource-constrained devices. In this work, we propose TernaryBERT, which ternarizes the weights in a fine-tuned BERT model. Specifically, we use both approximation-based and loss-aware ternarization methods and empirically investigate the ternarization granularity of different parts of BERT. Moreover, to reduce the accuracy degradation caused by the lower capacity of low bits, we leverage the knowledge distillation technique (Jiao et al., 2019) in the training process. Experiments on the GLUE benchmark and SQuAD show that our proposed TernaryBERT outperforms the other BERT quantization methods, and even achieves comparable performance as the full-precision model while being 14.9x smaller.

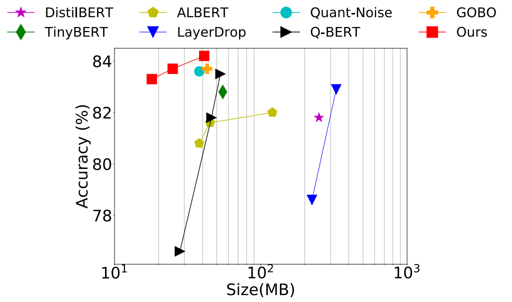

Figure 1: Model Size vs. MNLI-m Accuracy. Our proposed method (red squares) outperforms other BERT compression methods. Details are in Section 4.4.

1 Introduction

Transformer-based models have shown great power in various natural language processing (NLP) tasks. Pre-trained with gigabytes of unsupervised data, these models usually have hundreds of millions of parameters. For instance, the BERT-base model has 109M parameters, with the model size of 400+MB if represented in 32-bit floating-point format, which is both computation and memory expensive during inference. This poses great challenges for these models to run on resource-constrained devices like cellphones. To alleviate this problem, various methods are proposed to compress these models, like using low-rank approximation (Ma et al., 2019; Lan et al., 2020), weight-sharing (Dehghani et al., 2019; Lan et al., 2020), knowledge distillation (Sanh et al., 2019; Sun et al., 2019; Jiao et al., 2019), pruning (Michel et al., 2019; Voita et al., 2019; Fan et al., 2019), adaptive depth and/or width (Liu et al., 2020; Hou et al., 2020), and quantization (Zafrir et al., 2019; Shen et al., 2020; Fan et al., 2020).

Compared with other compression methods, quantization compresses a neural network by using lower bits for weight values without changing the model architecture, and is particularly useful for carefully-designed network architectures like Transformers. In addition to weight quantization, further quantizing activations can speed up inference with target hardware by turning floating-point operations into integer or bit operations. In (Prato et al., 2019; Zafrir et al., 2019), 8-bit quantization is successfully applied to Transformer-based models with comparable performance as the full-precision baseline. However, quantizing these models to ultra low bits (e.g., 1 or 2 bits) can be much more challenging due to significant reduction in model capacity. To avoid severe accuracy drop, more complex quantization methods, like mixed-precision quantization (Shen et al., 2020; Zadeh and Moshovos, 2020) and product quantization (PQ) (Fan et al., 2020), are used. However, mixed-precision quantization is unfriendly to some hardwares, and PQ requires extra clustering operations.

November 16–20, 2020.

Besides quantization, knowledge distillation (Hinton et al., 2015) which transfers knowledge learned in the prediction layer of a cumbersome teacher model to a smaller student model, is also widely used to compress BERT (Sanh et al., 2019; Sun et al., 2019; Jiao et al., 2019; Wang et al., 2020). Instead of directly being used to compress BERT, the distillation loss can also be used in combination with other compression methods (McCarley, 2019; Mao et al., 2020; Hou et al., 2020), to fully leverage the knowledge of teacher model.

In this work, we propose TernaryBERT, whose weights are restricted to $\{-1, 0, +1\}$. Instead of directly using knowledge distillation to compress a model, we use it to improve the performance of ternarized student model with the same size as the teacher model. In this way, we wish to transfer the knowledge from the highly-accurate teacher model to the ternarized student model with smaller capacity, and to fully explore the compactness by combining quantization and distillation. We investigate the ternarization granularity of different parts of the BERT model, and apply various distillation losses to improve the performance of TernaryBERT. Figure 1 summarizes the accuracy versus model size on MNLI, where our proposed method outperforms other BERT compression methods. More empirical results on the GLUE benchmark and SQuAD show that our proposed TernaryBERT outperforms other quantization methods, and even achieves comparable performance as the full-precision baseline, while being much smaller.

2 Related Work

2.1 Knowledge Distillation

Knowledge distillation is first proposed in (Hinton et al., 2015) to transfer knowledge in the logits from a large teacher model to a more compact student model without sacrificing too much performance. It has achieved remarkable performance in NLP (Kim and Rush, 2016; Jiao et al., 2019) recently. Besides the logits (Hinton et al., 2015), knowledge from the intermediate representations (Romero et al., 2014; Jiao et al., 2019) and attentions (Jiao et al., 2019; Wang et al., 2020) are also used to guide the training of a smaller BERT.

Instead of directly being used for compression, knowledge distillation can also be used in combination with other compression methods like pruning (McCarley, 2019; Mao et al., 2020), low-rank approximation (Mao et al., 2020) and dynamic networks (Hou et al., 2020), to fully leverage the knowledge of the teacher BERT model. Although combining quantization and distillation has been explored in convolutional neural networks (CNNs) (Polino et al., 2018; Stock et al., 2020; Kim et al., 2019), using knowledge distillation to train quantized BERT has not been studied. Compared with CNNs which simply perform convolution in each layer, the BERT model is more complicated with each Transformer layer containing both a Multi-Head Attention mechanism and a position-wise Feed-forward Network. Thus the knowledge that can be distilled in a BERT model is also much richer (Jiao et al., 2019; Wang et al., 2020).

2.2 Quantization

Quantization has been extensively studied for CNNs. Popular ultra-low bit weight quantization methods for CNNs can be divided into two categories: approximation-based and loss-aware based. Approximation-based quantization (Rastegari et al., 2016; Li et al., 2016) aims at keeping the quantized weights close to the full-precision weights, while loss-aware based quantization (Hou et al., 2017; Hou and Kwok, 2018; Leng et al., 2018) directly optimizes for the quantized weights that minimize the training loss.

On Transformer-based models, 8-bit fixed-point quantization is successfully applied in fully-quantized Transformer (Prato et al., 2019) and Q8BERT (Zafrir et al., 2019). The use of lower bits is also investigated in (Shen et al., 2020; Fan et al., 2020; Zadeh and Moshovos, 2020). Specifically, In Q-BERT (Shen et al., 2020) and GOBO (Zadeh and Moshovos, 2020), mixed-precision with 3 or more bits are used to avoid severe accuracy drop. However, mixed-precision quantization can be unfriendly to some hardwares. Fan et al. (2020) propose Quant-Noise which quantizes a subset of weights in each iteration to allow unbiased gradients to flow through the network. Despite the high compression rate achieved, the quantization noise rate needs to be tuned for good performance.

In this work, we extend both approximation-based and loss-aware ternarization methods to different granularities for different parts of the BERT model, i.e., word embedding and weights in Transformer layers. To avoid accuracy drop due to the reduced capacity caused by ternarization, various distillation losses are used to guide the training of the ternary model.

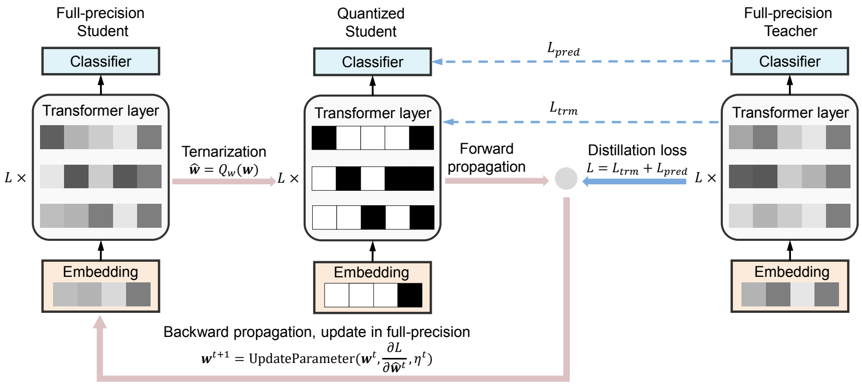

Figure 2: Depiction of the proposed distillation-aware ternarization of BERT model.

3 Approach

In this section, we elaborate on the method of using knowledge distillation to train TernaryBERT, the weights of which take values in $\{-1, 0, +1\}$.

Let the full-precision weight in the BERT model be $\mathbf{w}$, where $\mathbf{w} = \text{vec}(\mathbf{W})$ returns a vector by stacking all the columns of weight matrix $\mathbf{W}$. The corresponding ternarized weight is denoted as $\hat{\mathbf{w}} = Q_w(\mathbf{w})$ where Q_w is the weight ternarization function. The whole framework, which we call Distillation-aware ternarization, is shown in Figure 2. Specifically, at the t-th training iteration, we first ternarize the weights $\mathbf{w}^t$ in the student BERT model to $\hat{\mathbf{w}}^t$. Then we do the forward pass with the ternarized model. After that, the gradient of the distillation loss w.r.t. the quantized weights $\frac{\partial \mathcal{L}}{\partial \hat{\mathbf{w}}^t}$ is computed. As is shown in (Courbariaux et al., 2016; Hou and Kwok, 2018), it is important to keep the full-precision weight during training. Hence, we use the full-precision weight for parameter update: $\mathbf{w}^{t+1} = \text{UpdateParameter}(\mathbf{w}^t, \frac{\partial \mathcal{L}}{\partial \hat{\mathbf{w}}^t}, \eta^t)$, where η^t is the learning rate at the t-th iteration.

In the following, we will first introduce what and how to quantize in Section 3.1. Then in Section 3.2, we introduce the distillation loss used to improve the performance of the ternarized model.

3.1 Quantization

The BERT model (Devlin et al., 2019) is built with Transformer layers (Vaswani et al., 2017). A standard Transformer layer includes two main sub-layers: Multi-Head Attention (MHA) module and Feed-Forward Network (FFN).

For the l-th Transformer layer, suppose the input to it is $\mathbf{H}_l \in \mathbb{R}^{n \times d}$ where n and d are the sequence length and hidden state size, respectively. Suppose there are N_H attention heads in each layer, and head h is parameterized by $\mathbf{W}_h^Q, \mathbf{W}_h^K, \mathbf{W}_h^V \in \mathbb{R}^{d \times d_h}$ where $d_h = \frac{d}{N_H}$. After computing the attention scores by dot product of queries and keys

$$\mathbf{A}_h = \mathbf{Q}\mathbf{K}^\top = \mathbf{H}_l \mathbf{W}_h^Q \mathbf{W}_h^{K\top} \mathbf{H}_l^\top, \qquad (1)$$

the softmax function is applied on the normalized scores to get the output as $\text{head}_h = \text{Softmax}(\frac{1}{\sqrt{d}}\mathbf{A}_h)\mathbf{H}_l\mathbf{W}_h^V$. Denote $\mathbf{W}^* = [\mathbf{W}_1^*, \cdots, \mathbf{W}_{N_H}^*]$ where $*$ can be Q, K, V. The output of the multi-head attention is:

$$\begin{aligned} & \text{MHA}_{\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V, \mathbf{W}^O}(\mathbf{H}_l) \\ = \; & \text{Concat}(\text{head}_1, \cdots, \text{head}_{N_H})\mathbf{W}^O. \qquad (2) \end{aligned}$$

The FFN layer composes two linear layers parameterized by $\mathbf{W}^1 \in \mathbb{R}^{d \times d_{ff}}, \mathbf{b}^1 \in \mathbb{R}^{d_{ff}}$ and $\mathbf{W}^2 \in \mathbb{R}^{d_{ff} \times d}, \mathbf{b}^2 \in \mathbb{R}^d$ respectively, where d_{ff} is the number of neurons in the intermediate layer of FFN. Denote the input to FFN as $\mathbf{X}_l \in \mathbb{R}^{n \times d}$, the output is then computed as:

$$\text{FFN}(\mathbf{X}_l) = \text{GeLU}(\mathbf{X}_l\mathbf{W}^1 + \mathbf{b}^1)\mathbf{W}^2 + \mathbf{b}^2. \qquad (3)$$

Combining (2) and (3), the forward propagation for the l-th Transformer layer can be written as

$$\begin{aligned} \mathbf{X}_l &= \text{LN}(\mathbf{H}_l + \text{MHA}(\mathbf{H}_l)) \\ \mathbf{H}_{l+1} &= \text{LN}(\mathbf{X}_l + \text{FFN}(\mathbf{X}_l)), \end{aligned}$$

where LN is the layer normalization. The input to the first transformer layer

$$\mathbf{H}_1 = \text{EMB}_{\mathbf{W}^E, \mathbf{W}^S, \mathbf{W}^P}(\mathbf{z}) \qquad (4)$$

is the combination of the token embedding, segment embedding and position embedding. Here $\mathbf{z}$

is the input sequence, and $\mathbf{W}^E, \mathbf{W}^S, \mathbf{W}^P$ are the learnable word embedding, segment embedding and position embedding, respectively.

For weight quantization, following (Shen et al., 2020; Zafrir et al., 2019), we quantize the weights $\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V, \mathbf{W}^O, \mathbf{W}^1, \mathbf{W}^2$ in (2) and (3) from all Transformer layers, as well as the word embedding $\mathbf{W}^E$ in (4). Besides these weights, we also quantize the inputs of all linear layers and matrix multiplication operations in the forward propagation. We do not quantize $\mathbf{W}^S, \mathbf{W}^P$, and the bias in linear layers because the parameters involved are negligible. Following (Zafrir et al., 2019), we also do not quantize the softmax operation, layer normalization and the last task-specific layer because the parameters contained in these operations are negligible and quantizing them can bring significant accuracy degradation.

Weight Ternarization. In the following, we discuss the choice of the weight ternarization function Q_w in Figure 2.

Weight ternarization is pioneered in ternary-connect (Lin et al., 2016) where the ternarized values can take $\{-1, 0, 1\}$ represented by 2 bits. By ternarization, most of the floating-point multiplications in the forward pass are turned into floating-point additions, which greatly reduces computation and memory. Later, by adding a scaling parameter, better results are obtained in (Li et al., 2016). Thus in this work, to ternarize the weights of BERT, we use both approximation-based ternarization method TWN (Li et al., 2016) and loss-aware ternarization LAT (Hou and Kwok, 2018), where the ternary weight $\hat{\mathbf{w}}$ can be represented by the multiplication of a scaling parameter $\alpha > 0$ and a ternary vector $\mathbf{b} \in \{-1, 0, +1\}^n$ as $\hat{\mathbf{w}} = \alpha \mathbf{b}$. Here n is the number of elements in $\hat{\mathbf{w}}$.

In the t-th training iteration, TWN ternarizes the weights by minimizing the distance between the full-precision weight $\mathbf{w}^t$ and ternarized weight $\hat{\mathbf{w}}^t = \alpha^t \mathbf{b}^t$ with following optimization problem (Li et al., 2016)

$$\begin{aligned} \min_{\alpha^t, \mathbf{b}^t} \quad & \|\mathbf{w}^t - \alpha^t \mathbf{b}^t\|_2^2 \\ \text{s.t.} \quad & \alpha^t > 0, \mathbf{b}^t \in \{-1, 0, 1\}^n. \end{aligned} \tag{5}$$

Let $\mathbf{I}_\Delta(\mathbf{x})$ be a thresholding function that $[\mathbf{I}_\Delta(\mathbf{x})]_i = 1$ if $x_i > \Delta$, -1 if $x_i < -\Delta$, and 0 otherwise, where Δ is a positive threshold. Let $\odot$ be element-wise multiplication, the optimal solution of (5) satisfies (Hou and Kwok, 2018): $\mathbf{b}^t = \mathbf{I}_{\Delta^t}(\mathbf{w}^t)$ and $\alpha^t = \frac{\|\mathbf{b}^t \odot \mathbf{w}^t\|_1}{\|\mathbf{b}^t\|_1}$, where

$$\Delta^t = \arg\max_{\Delta > 0} \frac{1}{\|\mathbf{I}_\Delta(\mathbf{w}^t)\|_1} \left(\sum_{i:|[\mathbf{w}^t]_i| > \Delta} |[\mathbf{w}^t]_i| \right)^2.$$

The exact solution of Δ^t requires an expensive sorting operation (Hou et al., 2017). Thus in (Li et al., 2016), TWN approximates the threshold with $\Delta^t = \frac{0.7\|\mathbf{w}^t\|_1}{n}$.

Unlike TWN, LAT directly searches for the ternary weights that minimize the training loss $\mathcal{L}$. The ternary weights are obtained by solving the optimization problem:

$$\begin{aligned} \min_{\alpha, \mathbf{b}} \quad & \mathcal{L}(\alpha \mathbf{b}) \\ \text{s.t.} \quad & \alpha > 0, \mathbf{b} \in \{-1, 0, 1\}^n. \end{aligned} \tag{6}$$

For a vector $\mathbf{x}$, let $\sqrt{\mathbf{x}}$ be the element-wise square root, $\text{Diag}(\mathbf{x})$ returns a diagonal matrix with $\mathbf{x}$ on the diagonal, and $\|\mathbf{x}\|_Q^2 = \mathbf{x}^\top Q \mathbf{x}$. Problem (6) can be reformulated as solving the following sub-problem at the t-th iteration (Hou and Kwok, 2018)

$$\begin{aligned} \min_{\alpha^t, \mathbf{b}^t} \quad & \|\mathbf{w}^t - \alpha^t \mathbf{b}^t\|_{\text{Diag}(\sqrt{\mathbf{v}^t})}^2 \\ \text{s.t.} \quad & \alpha^t > 0, \mathbf{b}^t \in \{-1, 0, 1\}^n, \end{aligned} \tag{7}$$

where $\mathbf{v}^t$ is a diagonal approximation of the Hessian of $\mathcal{L}$ readily available as the second moment of gradient in adaptive learning rate optimizers like Adam (Kingma and Ba, 2015). Empirically, we use the second moment in BertAdam[1], which is a variant of Adam by fixing the weight decay (Loshchilov and Hutter, 2019) and removing the bias compensation (Kingma and Ba, 2015). For (7), both an expensive exact solution based on sorting operation, and an efficient approximate solution based on alternative optimization are provided in (Hou and Kwok, 2018). In this paper, we use the more efficient approximate solution.

In the original paper of TWN and LAT, one scaling parameter is used for each convolutional or fully-connected layer. In this work, we extend them to the following two granularities: (i) **layer-wise ternarization** which uses one scaling parameter for all elements in each weight matrix; and (ii) **row-wise ternarization** which uses one scaling parameter for each row in a weight matrix. With more scaling parameters, row-wise ternarization has finer granularity and smaller quantization error.

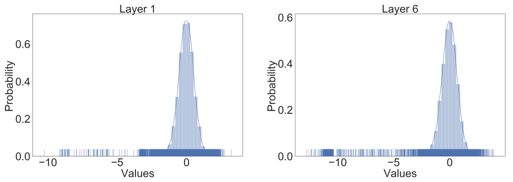

Figure 3: Distribution of the 1st and 6th Transformer layer's hidden representation of the full-precision BERT trained on SQuAD v1.1.

Activation Quantization. To make the most expensive matrix multiplication operation faster, following (Shen et al., 2020; Zafrir et al., 2019), we also quantize the activations (i.e., inputs of all linear layers and matrix multiplication) to 8 bits. There are two kinds of commonly used 8-bit quantization methods: symmetric and min-max 8-bit quantization. The quantized values of the symmetric 8-bit quantization distribute symmetrically in both sides of 0, while those of min-max 8-bit quantization distribute uniformly in a range determined by the minimum and maximum values.

We find that the distribution of hidden representations of the Transformer layers in BERT is skewed towards the negative values (Figure 3). This bias is more obvious for early layers (Appendix A). Thus we use min-max 8-bit quantization for activations as it gives finer resolution for non-symmetric distributions. Empirically, we also find that min-max 8-bit quantization outperforms symmetric quantization (Details are in Section 4.3).

Specifically, for one element x in the activation $\mathbf{x}$, denote $x_{max} = \max(\mathbf{x})$ and $x_{min} = \min(\mathbf{x})$, the min-max 8-bit quantization function is

$$Q_a(x) = \text{round}((x - x_{min})/s) \times s + x_{min},$$

where $s = (x_{max} - x_{min})/255$, is the scaling parameter. We use the straight-through estimator in (Courbariaux et al., 2016) to back propagate the gradients through the quantized activations.

3.2 Distillation-aware Ternarization

The quantized BERT uses low bits to represent the model parameters and activations. Therefore it results in relatively low capacity and worse performance compared with the full-precision counterpart. To alleviate this problem, we incorporate the technique of knowledge distillation to improve performance of the quantized BERT. In this teacher-student knowledge distillation framework, the quantized BERT acts as the student model, and learns to recover the behaviours of the full-precision teacher model over the Transformer layers and prediction layer.

Specifically, inspired by Jiao et al. (2019), the distillation objective for the Transformer layers $\mathcal{L}_{trm}$ consists of two parts. The first part is the distillation loss which distills knowledge in the embedding layer and the outputs of all Transformer layers of the full-precision teacher model to the quantized student model, by the mean squared error (MSE) loss: $\sum_{l=1}^{L+1} \text{MSE}(\mathbf{H}_l^S, \mathbf{H}_l^T)$. The second part is the distillation loss that distills knowledge from the teacher model's attention scores from all heads $\mathbf{A}_l^T$ in each Transformer layer to the student model's attention scores $\mathbf{A}_l^S$ as $\sum_{l=1}^{L} \text{MSE}(\mathbf{A}_l^S, \mathbf{A}_l^T)$. Thus the distillation for the Transformer layers $\mathcal{L}_{trm}$ is formulated as:

$$\mathcal{L}_{trm} = \sum_{l=1}^{L+1} \text{MSE}(\mathbf{H}_l^S, \mathbf{H}_l^T) + \sum_{l=1}^{L} \text{MSE}(\mathbf{A}_l^S, \mathbf{A}_l^T).$$

Besides the Transformer layers, we also distill knowledge in the prediction layer which makes the student model's logits $\mathbf{P}^S$ learn to fit $\mathbf{P}^T$ from the teacher model by the soft cross-entropy (SCE) loss:

$$\mathcal{L}_{pred} = \text{SCE}(\mathbf{P}^S, \mathbf{P}^T).$$

The overall objective of knowledge distillation in the training process of TernaryBERT is thus

$$\mathcal{L} = \mathcal{L}_{trm} + \mathcal{L}_{pred}. \tag{8}$$

We use the full-precision BERT fine-tuned on the downstream task to initialize our quantized model, and the data augmentation method in (Jiao et al., 2019) to boost the performance. The whole procedure, which will be called Distillation-aware ternarization, is shown in Algorithm 1.

4 Experiments

In this section, we evaluate the efficacy of the proposed TernaryBERT on both the GLUE benchmark (Wang et al., 2018) and SQuAD (Rajpurkar et al., 2016, 2018). The experimental code is modified from the huggingface transformer library.[2] We use both TWN and LAT to ternarize the weights. We use layer-wise ternarization for weights in Transformer layers while row-wise ternarization

---

[2] Given the superior performance of Huawei Ascend AI Processor and MindSpore computing framework, we are going to open source the code based on MindSpore (`https://www.mindspore.cn/en`) soon.

Algorithm 1 Distillation-aware ternarization.

```
initialize: A fixed teacher model and a trainable student model using a fine-tuned BERT model.
input: (Augmented) training data set.
output: TernaryBERT $\hat{\mathbf{w}}$.
for $t = 1, ..., T_{train}$ do
    Get next mini-batch of data;
    Ternarize $\mathbf{w}^t$ in student model to $\hat{\mathbf{w}}^t$;
    Compute distillation loss $\mathcal{L}$ in (8);
    Backward propagation of the student model and compute the gradients $\frac{\partial \mathcal{L}}{\partial \hat{\mathbf{w}}^t}$;
    $\mathbf{w}^{t+1}$ = UpdateParameter($\mathbf{w}^t, \frac{\partial \mathcal{L}}{\partial \hat{\mathbf{w}}^t}, \eta^t$);
    $\eta^{t+1}$ = UpdateLearningRate($\eta^t, t$).
end for
```

for the word embedding, because empirically finer granularity to word embedding improves performance (Details are in Section 4.3).

We compare our proposed method with Q-BERT (Shen et al., 2020) and Q8BERT (Zafrir et al., 2019) using their reported results. We also compare with a weight-ternarized BERT baseline Q2BERT by modifying the min-max 8-bit quantization to min-max ternarization using the released code of Q8BERT.[3] For more direct comparison, we also evaluate the proposed method under the same 8-bit quantization settings as Q-BERT and Q8BERT. When the weights are quantized to 8-bit, we use layer-wise scaling for both the weights in Transformer layers and the word embedding as 8-bit quantization already has high resolution.

4.1 GLUE benchmark

Setup. The GLUE benchmark is a collection of diverse natural language understanding tasks, including textual entailment (RTE), natural language inference (MNLI, QNLI), similarity and paraphrase (MRPC, QQP, STS-B), sentiment analysis (SST-2) and linguistic acceptability (CoLA). For MNLI, we experiment on both the matched (MNLI-m) and mismatched (MNLI-mm) sections. The performance metrics are Matthews correlation for CoLA, F1/accuracy for MRPC and QQP, Spearman correlation for STS-B, and accuracy for the other tasks.

The batch size is 16 for CoLA and 32 for the other tasks. The learning rate starts from 2×10^{-5} and decays linearly to 0 during 1 epoch if trained with the augmented data while 3 epochs if trained with the original data. The maximum sequence length is 64 for single-sentence tasks CoLA and SST-2, and 128 for the rest sentence-pair tasks. The dropout rate for hidden representations and the attention probabilities is 0.1. Since data augmentation does not improve the performance of STS-B, MNLI, and QQP, it is not used on these three tasks.

Results on BERT and TinyBERT. Table 1 shows the development set results on the GLUE

---

[3] `https://github.com/NervanaSystems/nlp-architect.git`

benchmark. From Table 1, we find that: 1) For ultra-low 2-bit weight, there is a big gap between the Q-BERT (or Q2BERT) and full-precision BERT due to the dramatic reduction in model capacity. TernaryBERT significantly outperforms Q-BERT and Q2BERT, even with fewer number of bits for word embedding. Meanwhile, TernaryBERT achieves comparable performance with the full-precision baseline with $14.9\times$ smaller size. 2) When the number of bits for weight increases to 8, the performance of all quantized models is greatly improved and is even comparable as the full-precision baseline, which indicates that the setting '8-8-8' is not challenging for BERT. Our proposed method outperforms Q-BERT on both MNLI and SST-2 and outperforms Q8BERT in 7 out of 8 tasks. 3) TWN and LAT achieve similar results on all tasks, showing that both ternarization methods are competitive.

In Table 1, we also apply our proposed quantization method on a 6-layer TinyBERT (Jiao et al., 2019) with hidden size of 768, which is trained using distillation. As can be seen, the quantized 8-bit TinyBERT and TernaryTinyBERT achieve comparable performance as the full-precision baseline.

Test set results are summarized in Table 2. The proposed TernaryBERT or TernaryTinyBERT achieves comparable scores as the full-precision baseline. Specially, the TernaryTinyBERT has only 1.6 point accuracy drop while being 23.2x smaller.

4.2 SQuAD

Setup. SQuAD v1.1 is a machine reading comprehension task. Given a question-passage pair, the task is to extract the answer span from the passage. SQuAD v2.0 is an updated version where the question might be unanswerable. The performance metrics are EM (exact match) and F1.

The learning rate decays from 2×10^{-5} linearly to 0 during 3 epochs. The batch size is 16, and the maximum sequence length is 384. The dropout rate for the hidden representations and attention probabilities is 0.1. Since $\mathcal{L}_{trm}$ is several magnitudes larger than $\mathcal{L}_{pred}$ in this task, we separate the distillation-aware quantization into two stages, i.e., first using $\mathcal{L}_{trm}$ as the objective and then $\mathcal{L}$ in (8).

Results. Table 3 shows the results on SQuAD v1.1 and v2.0. TernaryBERT significantly outperforms Q-BERT and Q2BERT, and is even comparable as the full-precision baseline. For this task, LAT performs slightly better than TWN.

Table 3: Development set results on SQuAD.

	W/E/A (#bits)	Size (MB)	SQuAD v1.1	SQuAD v2.0
BERT	32-32-32	418	81.5/88.7	74.5/77.7
Q-BERT	2-8-8	43	69.7/79.6	-
Q2BERT	2-8-8	43	-	50.1/50.1
TernaryBERT$_{\text{TWN}}$	2-2-8	28	79.9/87.4	73.1/76.4
TernaryBERT$_{\text{LAT}}$	2-2-8	28	80.1/87.5	73.3/76.6

4.3 Ablation Study

In this section, we perform ablation study on quantization, knowledge distillation, initialization, and data augmentation.

Weight Ternarization Granularity. We evaluate the effects of different granularities (i.e., row-wise and layer-wise ternarization in Section 3.1) of TWN on the word embedding and weights in Transformer layers. The results are summarized in Table 4. There is a gain of using row-wise ternarization over layer-wise ternarization for word embedding. We speculate this is because word embedding requires finer granularity as each word contains different semantic information. For weights in the Transformer layers, layer-wise ternarization performs slightly better than row-wise quantization. We speculate this is due to high redundancy in the weight matrices, and using one scaling parameter per matrix already recovers most of the representation power of Transformer layers. Appendix E shows that the attention maps of TernaryBERT (with layer-wise ternarization for weights in Transformer layers) resemble the full-precision BERT. Thus empirically, we use row-wise ternarization for word embedding and layer-wise ternarization for weights in the Transformer layers.

Table 4: Development set results of TernaryBERT$_{\text{TWN}}$ with different ternarization granularities on weights in Transformer layers and word embedding.

Embedding	Weights	MNLI-m	MNLI-mm
layer-wise	layer-wise	83.0	83.0
layer-wise	row-wise	82.9	82.9
row-wise	layer-wise	**83.3**	**83.3**
row-wise	row-wise	83.2	82.9

Activation Quantization. For activations, we experiment on both symmetric and min-max 8-bit quantization with SQuAD v1.1 in Table 5. The weights are ternarized using TWN. As can be seen, the performance of min-max quantization outperforms the symmetric quantization. As discussed in Section 3.1, this may because of the non-symmetric distributions of the hidden representation.

Table 5: Comparison of symmetric 8-bit and min-max 8-bit activation quantization methods on SQuAD v1.1.

W(#bit)	E(#bit)	A(#bit)	EM	F1
2	2	8 (sym)	79.0	86.9
2	2	8 (min-max)	79.9	87.4

Knowledge Distillation. In Table 6, we investigate the effect of distillation loss over Transformer layers (abbreviated as "Trm") and final output logits (abbreviated as "logits") in the training of TernaryBERT$_{\text{TWN}}$. As can be seen, without distillation over the Transformer layers, the performance drops by 3% or more on CoLA and RTE, and also slightly on MNLI. The accuracy of all tasks further decreases if distillation logits is also not used. In particular, the accuracy for CoLA, RTE and SQuAD v1.1 drops by over 5% by removing the distillation compared to the counterpart.

Table 6: Effects of knowledge distillation on the Transformer layers and logits on TernaryBERT$_{\text{TWN}}$. "-Trm-logits" means we use cross-entropy loss w.r.t. the ground-truth labels as the training objective.

	MNLI-m/mm	CoLA	RTE	SQuADv1.1
TernaryBERT	83.3/83.3	55.7	72.9	79.9/87.4
-Trm	82.9/83.3	52.7	69.0	76.6/84.9
-Trm-logits	80.8/81.1	45.4	56.3	74.3/83.2

Initialization and Data Augmentation. Table 7 demonstrates the effect of initialization from a fine-tuned BERT otherwise a pre-trained BERT, and the use of data augmentation in training TernaryBERT. As can be seen, both factors contribute positively to the performance and the improvements are more obvious on CoLA and RTE.

Table 7: Effects of data augmentation and initialization.

	CoLA	MRPC	RTE
TernaryBERT	55.7	91.2/87.5	72.9
-Data augmentation	50.7	91.0/87.5	68.2
-Initialization	46.0	91.0/87.2	66.4

4.4 Comparison with Other Methods

In Figure 1 and Table 8, we compare the proposed TernaryBERT with (i) Other Quantization Methods: including mixed-precision Q-BERT (Shen et al., 2020), post-training quantization GOBO (Zadeh and Moshovos, 2020), as well as Quant-Noise which uses product quantization (Fan et al., 2020); and (ii) Other Compression Methods: including weight-sharing method ALBERT (Lan et al., 2019), pruning method LayerDrop (Fan et al., 2019), distillation methods DistilBERT and TinyBERT (Sanh et al., 2019; Jiao et al., 2019). The result of DistilBERT is taken from (Jiao et al., 2019). The results for the other methods are taken from their original paper. To compare with the other mixed-precision methods which use 3-bit weights, we also extend the proposed method to allow 3 bits (the corresponding model abbreviated as 3-bit BERT, and 3-bit TinyBERT) by replacing LAT with 3-bit Loss-aware Quantization (LAQ) (Hou and Kwok, 2018). The red markers in Figure 1 are our results with settings 1) 2-2-8 TernaryTinyBERT, 2) 3-3-8 3-bit TinyBERT and 3) 3-3-8 3-bit BERT.

Table 8: Comparison between the proposed method and other compression methods on MNLI-m. Note that Quant-Noise uses Product Quantization (PQ) and does not have specific number of bits for each value.

Method	W-E-A (#bits)	Size (MB)	Accuracy (%)
DistilBERT	32-32-32	250	81.6
TinyBERT-4L	32-32-32	55	82.8
ALBERT-E64	32-32-32	38	80.8
ALBERT-E128	32-32-32	45	81.6
ALBERT-E256	32-32-32	62	81.5
ALBERT-E768	32-32-32	120	82.0
LayerDrop-6L	32-32-32	328	82.9
LayerDrop-3L	32-32-32	224	78.6
Quant-Noise	PQ	38	83.6
Q-BERT	2/4-8-8	53	83.5
Q-BERT	2/3-8-8	46	81.8
Q-BERT	2-8-8	28	76.6
GOBO	3-4-32	43	83.7
GOBO	2-2-32	28	71.0
3-bit BERT (ours)	3-3-8	41	84.2
3-bit TinyBERT (ours)	3-3-8	25	83.7
TernaryBERT (ours)	2-2-8	28	83.5
TernaryTinyBERT (ours)	2-2-8	18	83.4

Other Quantization Methods. In mixed precision Q-BERT, weights in Transformer layers with steeper curvature are quantized to 3-bit, otherwise 2-bit, while word embedding is quantized to 8-bit. From Table 8, our proposed method achieves better performance than mixed-precision Q-BERT on MNLI, using only 2 bits for both the word embedding and the weights in the Transformer layers. Similar observations are also made on SST-2 and SQuAD v1.1 (Appendix B).

In GOBO, activations are not quantized. From Table 8, even with quantized activations, our proposed TernaryBERT outperforms GOBO with 2-bit weights and is even comparable to GOBO with 3/4 bit mixed-precision weights.

Other Compression Methods. From Table 8, compared to other popular BERT compression methods other than quantization, the proposed method achieves similar or better performance, while being much smaller.

5 Conclusion

In this paper, we proposed to use approximation-based and loss-aware ternarization to ternarize the weights in the BERT model, with different granularities for word embedding and weights in the Transformer layers. Distillation is also used to reduce the accuracy drop caused by lower capacity due to quantization. Empirical experiments show that the proposed TernaryBERT outperforms state-of-the-art BERT quantization methods and even performs comparably as the full-precision BERT.

APPENDIX

A Distributions of Hidden Representations on SQuAD v1.1

Figure 4 shows the distribution of hidden representations from the embedding layer and all Transformer layers on SQuAD v1.1. As can be seen, the hidden representations of early layers (e.g. embedding and transformer layers 1-8) are biased towards negative values while those of the rest layers are not.

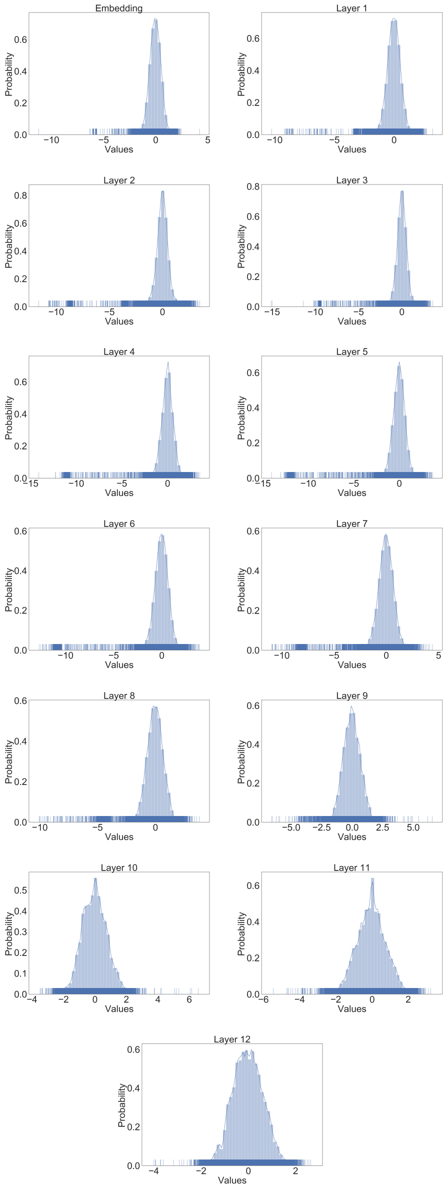

Figure 4: Distribution of Transformer layer's hidden representation of a full-precision BERT trained on SQuAD v1.1.

B More Comparison between TernaryBERT and Q-BERT

We compare with reported results of Q-BERT on SST-2 and SQuAD v1.1 in Table 9. Similar to the observations for MNLI in Section 4.4, our proposed method achieves better performance than mixed-precision Q-BERT on SST-2 and SQuAD v1.1.

Table 9: Comparison between TernaryBERT and mixed-precision Q-BERT.

	W-E-A (#bits)	Size (MB)	SST-2	SQuAD v1.1
BERT	32-32-32	418	93.1	81.5/88.7
Q-BERT	2/3-8-8	46	92.1	79.3/87.0
TernaryBERT$_{\text{TWN}}$	2-2-8	28	**92.8**	**79.9/87.4**

C Training Curve on MNLI

Figure 5 shows the training loss and validation accuracy of TernaryBERT and 8-bit BERT on MNLI-m. As can be seen, 8-bit BERT has smaller loss and higher accuracy than TernaryBERT. There is no significant difference between the learning curve of TernaryBERT using TWN and LAT.

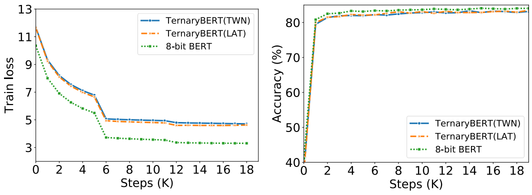

Figure 5: Learning curve of TernaryBERT and 8-bit BERT on MNLI-m.

D 3-bit BERT and TinyBERT

In Table 10, we extend the proposed method to allow 3 bits by replacing LAT with 3-bit Loss-aware Quantization (LAQ). Compared with TernaryBERT$_{\text{LAT}}$, 3-bit BERT performs lightly better on 7 out of 8 GLUE tasks, and the accuracy gap with the full-precision baseline is also smaller.

E Attention Pattern of BERT and TernaryBERT

In Figures 6-9, we compare the attention patterns of the fine-tuned full-precision BERT-base model and the ternarized TernaryBERT$_{\text{TWN}}$ on CoLA and SST-2. CoLA is a task which predicts the grammatical acceptability of a given sentence, and SST-2 is a task of classifying the polarity of movie reviews. As can be seen, the attention patterns of TernaryBERT resemble those in the full-precision BERT.

Table 10: Development set results of 3-bit quantized BERT and TinyBERT on GLUE benchmark.

	W-E-A (#bits)	Size (MB)	MNLI-m/mm	QQP	QNLI	SST-2	CoLA	MRPC	STS-B	RTE
TernaryBERT$_{\text{LAT}}$	2-2-8	28 (×14.9)	83.5/83.4	86.6/90.1	91.5	92.5	54.3	91.1/87.0	87.9/87.6	72.2
3-bit BERT	3-3-8	41 (×10.2)	**84.2/84.7**	86.9/90.4	**92.0**	92.8	**54.4**	**91.3/87.5**	**88.6/88.3**	70.8
3-bit TinyBERT	3-3-8	25 (×16.7)	83.7/84.0	**87.2/90.5**	90.7	**93.0**	53.4	91.2/87.3	86.1/85.9	**72.6**

Abstract

Self-supervised pre-training of transformer models has revolutionized NLP applications. Such pre-training with language modeling objectives provides a useful initial point for parameters that generalize well to new tasks with fine-tuning. However, fine-tuning is still data inefficient — when there are few labeled examples, accuracy can be low. Data efficiency can be improved by optimizing pre-training directly for future fine-tuning with few examples; this can be treated as a meta-learning problem. However, standard meta-learning techniques require many training tasks in order to generalize; unfortunately, finding a diverse set of such supervised tasks is usually difficult. This paper proposes a self-supervised approach to generate a large, rich, meta-learning task distribution from unlabeled text. This is achieved using a cloze-style objective, but creating separate multi-class classification tasks by gathering tokens-to-be blanked from among only a handful of vocabulary terms. This yields as many unique meta-training tasks as the number of subsets of vocabulary terms. We meta-train a transformer model on this distribution of tasks using a recent meta-learning framework. On 17 NLP tasks, we show that this meta-training leads to better few-shot generalization than language-model pre-training followed by finetuning. Furthermore, we show how the self-supervised tasks can be combined with supervised tasks for meta-learning, providing substantial accuracy gains over previous supervised meta-learning.

1 Introduction

Self-supervised learning has emerged as an important training paradigm for learning model parameters which are more generalizable and yield better representations for many down-stream tasks. This typically involves learning through labels that come naturally with data, for example words in natural language. Self-supervised tasks typically pose a supervised learning problem that can benefit from lots of naturally available data and enable pre-training of model parameters that act as a useful prior for supervised fine-tuning (Erhan et al., 2010). Masked language modeling (Devlin et al., 2018), and other related approaches (Peters et al., 2018; Howard and Ruder, 2018; Radford et al., 2019), is an example of such a self-supervised task that is behind the success of transformer models like BERT.

While self-supervised pre-training is beneficial, it has been recently noted that it is not data-efficient and typically requires large amounts of fine-tuning data for good performance on a target task (Yogatama et al., 2019; Bansal et al., 2019). This can be evaluated as a few-shot learning problem, where a model is given only few examples of a new task and is expected to perform well on that task. This paper focuses on this problem of few-shot learning and develops models which demonstrate better few-shot generalization to new tasks.

Large scale pre-training suffers from a train-test mismatch as the model is not optimized to learn an initial point that yields good performance when fine-tuned with few examples. Moreover, fine-tuning of a pre-trained model typically introduces new random parameters, such as softmax layers, and important hyper-parameters such as learning rate, which are hard to estimate robustly from the few examples. Thus, we propose to remove this train-test mismatch, and treat learning an initial point and hyper-parameters jointly from unlabelled data, which allows data-efficient fine-tuning, as a meta-learning problem.

Meta-learning, or learning to learn (Thrun and Pratt, 2012; Schmidhuber, 1987), treats learning a parameterized algorithm, such as a neural net optimized with SGD, that generalizes to new tasks as a learning problem. This typically assumes access

to a distribution over tasks in order to enable learning. Creating tasks which enable meta-learning is one of the main challenges for meta-learning (Bengio et al., 1992; Santoro et al., 2016; Vinyals et al., 2016), and typical supervised meta-learning approaches create task distributions from a fixed task dataset with large number of labels by subsampling from the set of labels (Vinyals et al., 2016; Ravi and Larochelle, 2017). While this enables generalization to new labels, it limits generalization to unseen tasks due to over-fitting to the training task distribution (Yin et al., 2020). Moreover, large supervised datasets with a large label set are not always available for meta-learning, as is often the case in many NLP applications.

To overcome these challenges of supervised meta-learning, we propose a self-supervised approach and create the task-distribution from unlabelled sentences. Taking inspiration from the cloze task (Taylor, 1953), we create separate multi-class classification tasks by gathering tokens-to-be blanked from a subset of vocabulary words, allowing for as many unique meta-training tasks as the number of subsets of words in the language. The proposed approach, which we call Subset Masked Language Modeling Tasks (SMLMT), enables training of meta-learning methods for NLP at a much larger scale than was previously feasible while also ameliorating the risk of over-fitting to the training task distribution. This opens up new possibilities for applications of meta-learning in NLP, such as few-shot learning, continual learning, architecture search and more.

This work focuses on few-shot learning and makes the following contributions: (1) we introduce a self-supervised approach to create tasks for meta-learning in NLP, Subset Masked Language Modeling Tasks (SMLMT), which enables application of meta-learning algorithms for goals like few-shot learning; (2) utilizing SMLMT as the training task distribution, we train a state-of-the-art transformer architecture, BERT (Devlin et al., 2018), using a recent optimization-based meta-learning method which was developed for diverse classification tasks (Bansal et al., 2019); (3) we show that the self-supervised SMLMT can also be combined with supervised task data to enable better feature learning, while still allowing for better generalization by avoiding meta-overfitting to the supervised tasks through the use of SMLMT; (4) we rigorously evaluate the proposed approach on few-shot generalization to unseen tasks as well as new domains of tasks seen during training and show that the proposed approach demonstrates better generalization than self-supervised pre-training or self-supervised pre-training followed by multi-task training; (5) we also study the effect of number of parameters for few-shot learning and find that while bigger pre-trained or meta-trained models generalize better than smaller models, meta-learning leads to substantial gains even for the smaller models.

2 Preliminaries

In supervised meta-learning, we typically assume access to a task distribution $\mathcal{P}(\mathcal{T})$. Practically, this translates to a fixed set of training tasks $\{T_1, \ldots, T_M\}$, which are referred to as meta-training tasks. For supervised classification, each task T_i is an N_i-way classification task. While many meta-learning algorithms assume a fixed N-way classification, we follow the more practical approach of Bansal et al. (2019) and allow for a diverse set of classification tasks with potentially different number of classes.

The goal of a meta-learning algorithm is to utilize the meta-training tasks to learn a learning procedure that generalizes to held-out tasks $T' \sim \mathcal{P}(T)$. Model-agnostic meta-learning (MAML) (Finn et al., 2017) is an example of such a meta-learning algorithm. MAML learns an initial point θ for a classifier $f_\theta : x \to \hat{y}$, that can be optimized via gradient descent on the supervised loss $\mathcal{L}_i$ defined for the task T_i, using its support set $\mathcal{D}^{tr} \sim T_i$:

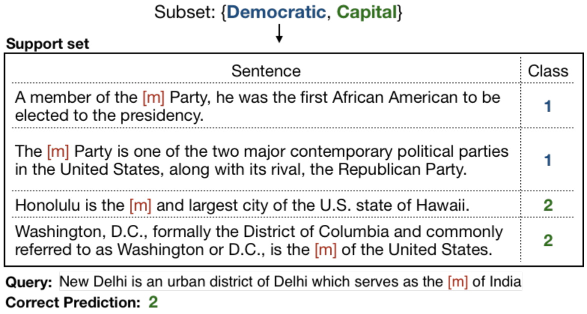
$$\theta_i' \leftarrow \theta - \alpha \nabla_\theta \mathcal{L}_i(\mathcal{D}^{tr}, \theta) \qquad (1)$$

where α is the learning rate. The optimized point θ' is then evaluated on another validation set for the task, $D^{val} \sim T_i$, using the loss function $\mathcal{L}_i$. This loss across meta-training tasks serves as the training error to optimize the initial point and parameters like learning-rate ($\Theta := \{\theta, \alpha\}$):

$$\Theta \leftarrow \Theta - \beta \, \nabla_\Theta \mathbb{E}_{T_i \sim \mathcal{P}(\mathcal{T})} \left[L_i(\mathcal{D}^{val}, \theta_i') \right] \qquad (2)$$

where β is the learning rate for the meta-training process. Training proceeds in an episodic framework (Vinyals et al., 2016), where in each episode a mini-batch of tasks are sampled along with their support and validation sets, and the model parameters are optimized using (1) and (2), which are also referred to as inner and outer loop, respectively.

Meta-training Tasks: We summarize how supervised task data-sets are typically leveraged to



Subset: {**Democratic**, **Capital**}

Support set

Sentence	Class
A member of the [m] Party, he was the first African American to be elected to the presidency.	1
The [m] Party is one of the two major contemporary political parties in the United States, along with its rival, the Republican Party.	1
Honolulu is the [m] and largest city of the U.S. state of Hawaii.	2
Washington, D.C., formally the District of Columbia and commonly referred to as Washington or D.C., is the [m] of the United States.	2

Query: New Delhi is an urban district of Delhi which serves as the [m] of India

Correct Prediction: 2

Figure 1: An example of a 2-way 2-shot task in SMLMT. The support set and one query is shown. Any N-way k-shot task can be constructed similarly.

create meta-training tasks (Vinyals et al., 2016). Assuming access to a supervised task with L classes, an N-way k-shot task is created by first sampling N classes, assuming $N << L$. Then for each of the N sampled classes, $(k + q)$ examples of each class is randomly sampled from the dataset and assigned a unique label in $\{1, \ldots, N\}$. The k examples for each label serve as the support set, while the q examples constitute the validation set described above. Note, that each task consists of a small subset of classes and the class to label (1 to N) assignment is random . This is crucial to avoid learning the sample to label bindings in the parameters of the model, which will make the task-specific training (in (1)) irrelevant and the model will not generalize to new tasks. An example of this approach is MiniImageNet (Ravi and Larochelle, 2017), which is a benchmark dataset for learning few-shot image classification.

3 Self-supervised Tasks for Meta-learning

The existing approach to using a supervised dataset to create tasks, as described above, is fraught with issues, specially for NLP applications. First, note that large classification datasets with large label spaces are not readily available for all NLP tasks, for example sentiment classification which has only few discrete labels. Second, limiting to a fixed supervised dataset to create tasks limits generalization ability and the meta-learned models might generalize to new labels for the task but fail to generalize to new novel tasks (Metz et al., 2019). Lastly, such an approach is also not feasible in all problems where we will like to apply meta-learning (Yin et al., 2020). For example, consider meta-learning a natural language inference (NLI) model across multiple domains which can generalize to new domains. A powerful model can ignore the training data for each task and directly learn to predict the NLI tag for the examples in each training domain, which will lead to low training error but the model will not generalize to new domains. We overcome these issues by utilizing unlabelled data to create meta-learning tasks. See Fig. 1 for an example of generated task.

Subset Masked Language Modeling Tasks (SMLMT): We are given a text corpus split into sentences X_i and each sentence is a sequence of words from a vocabulary of size V. Now, in Subset Masked Language Modeling Tasks, each task is defined from a *subset* of vocabulary words. To create an N-way classification task, we randomly select N unique vocabulary words: $\{v_1, \ldots, v_N\}$. Then we consider all sentences containing these N words, and for each word randomly sample $r = k+q$ sentences: $\mathbf{x}_{v_i} = \{X_1, \ldots, X_r | v_i \in X_i\}$. Now, we mask the corresponding chosen word from the sentences in each of these N sets, so $\mathbf{x}'_{v_i} = \{\text{Mask}(X_1, v_i), \ldots, \text{Mask}(X_r, v_i)\}$ where $\text{Mask}(X, v)$ replaces all occurrences of v in X with the mask token $[m]$. The set $\{\mathbf{x}'_{v_1}, \ldots, \mathbf{x}'_{v_N}\}$ is then a well-defined N-partition of $N \times r$ sentences, that serves as input examples for the N-way classification task. We forget the original word corresponding to the masked tokens in these sets and assign labels in $\{1, \ldots, N\}$ to the N sets. This gives an instance of an SMLMT classification task: $T = \{(x_{ij}, i) | i \in \{1, .., N\}, x_{ij} \in \mathbf{x}'_{v_i}\}$. This can be split into support and validation for meta-training.

In an SMLMT instance, each input sentence consists of exactly one word that is masked throughout the sentence and its label corresponds to that word. This requires a similar reasoning ability as cloze tasks (Taylor, 1953). Moreover, crucially, the SMLMT task creation ensures that a model cannot memorize the input-label mapping as the target masked word is hidden and the label assignment is randomized, requiring the model to infer the labels from the support set. Note that the SMLMT tasks are also closely related to masked language modeling (MLM) (Devlin et al., 2018). While MLM is a word-level classification task, SMLMT is a sentence-level classification task. Each unique subset of words from the vocabulary defines a unique task in SMLMT. This allows for as many unique tasks as the *number of subsets of words in the vocabulary*, enabling large-scale meta-learning from unsupervised data.

Hybrid SMLMT: Tasks from SMLMT can also be combined with supervised tasks to encourage better feature learning (Caruana, 1997) and increase diversity in tasks for meta-learning. We use a sampling ratio $\lambda \in (0, 1)$ and in each episode select an SMLMT task with probability λ or a supervised task with probability $(1 - \lambda)$. The use of SMLMT jointly with supervised tasks ameliorates meta-overfitting, as tasks in SMLMT cannot be solved without using the task support data. λ is a hyper-parameter. In our experiments, we found $\lambda = 0.5$ to work well.

4 Meta-learning Model

We now discuss the meta-learning model for learning new NLP tasks.

Text encoder: The input to the model is natural language sentences. This is encoded using a transformer (Vaswani et al., 2017) text encoder. We follow the BERT (Devlin et al., 2018) model and use the same underlying neural architecture for the transformer as their base model. Given an input sentence, the transformer model yields contextualized token representations for each token in the input after multiple layers of self-attention. Following BERT, we add a special CLS token to the start of the input that is used as a sentence representation for classification tasks. Given an input sentence X, let $f_\pi(X)$ be the CLS representation of the final layer of the transformer with parameters π.

Meta-learning across diverse classes: Our motivation is to meta-learn an initial point that can generalize to novel NLP tasks, thus we consider methods that apply to diverse number of classes. Note that many meta-learning models only apply to a fixed number of classes (Finn et al., 2017) and require training different models for different number of classes. We follow the approach of Bansal et al. (2019) that learns to generate softmax classification parameters conditioned on a task support set to enable training meta-learning models that can adapt to tasks with diverse classes. This combines benefits of metric-based methods (Vinyals et al., 2016; Snell et al., 2017) and optimization-based methods for meta-learning. The key idea is to train a deep set encoder $g_\psi(\cdot)$, with parameters ψ, which takes as input the set of examples of a class n and generates a $(d+1)$ dimensional embedding that serves as the linear weight and bias for class n in the softmax classification layer. Let $\{X_{1n}, \dots, X_{kn}\}$ be the k examples for class n in the support set of a task t:

$$w_t^n, b_t^n = g_\psi(\{f_\pi(X_{1n}), \dots, f_\pi(X_{kn})\}) \quad (3)$$

$$p(y|X) = softmax\,\{\mathbf{W}_t\ h_\phi(f_\pi(X)) + \mathbf{b}_t\} \quad (4)$$

where $\mathbf{W}_t = [w_t^1; \dots ; w_t^N] \in \mathcal{R}^{N\times d}$, $\mathbf{b}_t = [b_t^1; \dots ; b_t^N] \in \mathcal{R}^d$ are the concatenation of the per-class vectors in (3), and h_ϕ is a MLP with parameters ϕ and output dimension d.

Using the above model to generate predictions, the parameters are meta-trained using the MAML algorithm (Finn et al., 2017). Concretely, set $\theta := \{\pi, \phi, \mathbf{W}_t, \mathbf{b}_t\}$ for the task-specific inner loop gradient updates in (1) and set $\Theta := \{\pi, \psi, \alpha\}$ for the outer-loop updates in (2). Note that we do multiple steps of gradient descent in the inner loop. Bansal et al. (2019) performed extensive ablations over parameter-efficient versions of the model and found that adapting all parameters with learned per-layer learning rates performs best for new tasks. We follow this approach. Full training algorithm can be found in the Appendix.

Fast adaptation: Flennerhag et al. (2019) proposed an approach which mitigates slow adaption often observed in MAML by learning to warp the task loss surface to enable rapid descent to the loss minima. This is done by interleaving a neural network's layers with non-linear layers, called warp layers, which are not adapted for each task but are still optimized across tasks in the outer-loop updates in (2). Since introducing additional layers will make computation more expensive, we use existing transformer layers as warp layers. We designate the feed-forward layers in between self-attention layers of BERT, which project from dimension 768 to 3072 to 768, as warp-layers. Note that these parameters also constitute a large fraction of total parameters ($\sim 51\%$). Thus in addition to the benefit from warping, not adapting these layers per task means significantly faster training and smaller number of per-task parameters during fine-tuning. The warp layers are still updated in the outer loop during meta-training.

5 Related Work

Language model pre-training has recently emerged as a prominent approach to learning general purpose representations (Howard and Ruder, 2018; Peters et al., 2018; Devlin et al., 2018; Radford et al., 2019; Yang et al., 2019; Raffel et al., 2019). Refer to Weng (2019) for a review of self-supervised learning. Pre-training is usually a two step process and fine-tuning introduces random parameters making it inefficient when target tasks have few examples (Bansal et al., 2019). Multi-task learning of pre-trained models has shown improved results on many tasks (Phang et al., 2018; Liu et al., 2019a). More recently, and parallel to this work, Brown et al. (2020) show that extremely large language models can act as few-shot learners. They propose a query-based approach where few-shot task data is used as context for the language model. In contrast, we employ a fine-tuning based meta-learning approach that enjoys nice properties like consistency which are important for good out-of-distribution generalization (Finn, 2018). Moreover, we show that self-supervised meta-learning can also improve few-shot performance for smaller models.

Meta-Learning methods can be categorized as: optimization-based (Finn et al., 2017; Li et al., 2017; Nichol and Schulman, 2018; Rusu et al., 2018), model-based (Santoro et al., 2016; Ravi and Larochelle, 2017; Munkhdalai and Yu, 2017), and metric-based (Vinyals et al., 2016; Snell et al., 2017). Refer to Finn (2018) for an exhaustive review. Unsupervised meta-learning has been explored in vision. Hsu et al. (2019) cluster images using pre-trained embeddings to create tasks for meta-learning. Metz et al. (2019) meta-learn a biologically-motivated update rule from unsupervised data in a semi-supervised framework. Compared to these, we directly utilize text data to automatically create unsupervised tasks without relying on pre-trained embeddings or access to target tasks.

In NLP, meta-learning approaches have followed the recipe of using supervised task data and learning models for specific tasks. Such approaches (Yu et al., 2018; Gu et al., 2018; Guo et al., 2018; Han et al., 2018; Mi et al., 2019) train to generalize to new labels of a specific task like relation classification and don't generalize to novel tasks. Bansal et al. (2019) proposed an approach that applies to diverse tasks to enable practical meta-learning models and evaluate on generalization to new tasks. However, they rely on supervised task data from multiple tasks and suffer from meta-overfitting as we show in our empirical results. Holla et al. (2020) studied related approaches for the task of word-sense disambiguation. To the best of our knowledge, the method proposed here is the first self-supervised approach to meta-learning in NLP.

6 Experiments

We evaluate the models on few-shot generalization to new tasks and new domains of train tasks. Evaluation consist of a diverse set of NLP classification tasks from multiple domains: entity typing, sentiment classification, natural language inference and other text classification tasks. Our results[1] show that self-supervised meta-learning using SMLMT improves performance over self-supervised pre-training. Moreover, combining SMLMT with supervised tasks achieves the best generalization, improving over multi-task learning by up to 21%.

6.1 Implementation Details

SMLMT: We use the English Wikipedia dump, as of March 2019, to create SMLMT. This is similar to the dataset for pre-training of BERT (Devlin et al., 2018), which ensures that gains are not due to using more or diverse pre-training corpora (Liu et al., 2019b). The corpus is split into sentences and word-tokenized to create SMLMT. We run task creation offline and create about 2 Million SMLMT for meta-training, including a combination of 2, 3 and 4-way tasks. After task creation, the data is word-piece tokenized using the BERT-base cased model vocabulary for input to the models.

Supervised Tasks: Bansal et al. (2019) demonstrated that better feature learning from supervised tasks helps few-shot learning. Thus, we also evaluate multi-task learning and multi-task meta-learning for few-shot generalization. We also use GLUE tasks (Wang et al., 2018) and SNLI (Bowman et al., 2015) as the supervised tasks. Supervised tasks can be combined with SMLMT for meta-training (see 3). Note that since these are only a few supervised tasks (8 in this case) with a small label space, it is easy for meta-learning models to overfit to the supervised tasks (Yin et al., 2020) limiting generalization as we show in experiments.

Models: We evaluate the following models:
(1) BERT: This is transformer model trained with self-supervised learning using MLM as the pre-training task on Wikipedia and BookCorpus. We use the cased base model (Devlin et al., 2018).
(2) MT-BERT: This is a multi-task learning model trained on the supervised tasks. We follow Bansal et al. (2019) in training this model.
(3) MT-BERT$_{\text{softmax}}$: This is the same model above where only the softmax layer is fine-tuned on downstream tasks.
(4) LEOPARD: This is the meta-learning model proposed in Bansal et al. (2019) which is trained on only the supervised tasks.

---

[1] Code and trained models: `https://github.com/iesl/metanlp`

(5) SMLMT: This is the meta-learning model (in 4) which is trained on the self-supervised SMLMT.
(6) Hybrid-SMLMT: This is the meta-learning model (in 4) trained on a combination of SMLMT and supervised tasks.
Note that all models share the same transformer architecture making the contribution from each component discernible. Moreover, SMLMT and Hybrid-SMLMT models use similar meta-learning algorithm as LEOPARD, so any improvements are due to the self-supervised meta-training. All model are initialized with pre-trained BERT for training.

Evaluation Methodology: We evaluate on few-shot generalization to multiple NLP tasks using the same set of tasks[2] considered in Bansal et al. (2019). Each target task consists of k examples per class, for $k \in \{4, 8, 16, 32\}$, and different tasks can have different number of classes. Since few-shot performance is sensitive to the few examples used in fine-tuning, each model is fine-tuned on 10 such k-shot support sets for a task, for each k, and the average performance with standard deviation is reported. Models are trained using their training procedures, without access to the target tasks, and are then fine-tuned for each of the k-shot task. Results for MT-BERT and LEOPARD are taken from Bansal et al. (2019).

Hyper-parameters: We follow the approach of Bansal et al. (2019) and use validation tasks for estimating hyper-parameters during fine-tuning for all baseline models. Note the meta-learning approach learn the learning rates during training and only require the number of epochs of fine-tuning to be estimated from the validation tasks. Detailed hyper-parameters are in Supplementary.

6.2 Results

6.2.1 Few-shot generalization to new tasks

We first evaluate performance on novel tasks not seen during training. The task datasets considered are: (1) entity typing: CoNLL-2003 (Sang and De Meulder, 2003), MIT-Restaurant (Liu et al., 2013); (2) rating classification (Bansal et al., 2019): 4 domains of classification tasks based on ratings from the Amazon Reviews dataset (Blitzer et al., 2007); (3) text classification: multiple social-media datasets from figure-eight[3].

Results are presented in Table 1. Results on 2 domains of Rating are in Supplementary due to space limitation. First, comparing models which don't use any supervised data, we see that on average across the 12 tasks, the meta-trained SMLMT performs better than BERT specially for small $k \in \{4, 8, 16\}$. Interestingly, the SMLMT model which doesn't use any supervised data, also outperforms even MT-BERT models which use supervised data for multi-task training. Next, comparing among all the models, we see that the Hybrid-SMLMT model performs best on average across tasks. For instance, on average 4-shot performance across tasks, Hybrid-SMLMT provides a relative gain in accuracy of 21.4% over the best performing MT-BERT baseline. Compared to LEOPARD, the Hybrid-SMLMT yields consistent improvements for all $k \in \{4, 8, 16, 32\}$ and demonstrates steady improvement in performance with increasing data (k). We note that on some tasks, such as Disaster, SMLMT is better than Hybrid-SMLMT. We suspect negative transfer from multi-task training on these tasks as also evidenced by the drop in performance of MT-BERT. These results show that SMLMT meta-training learns a better initial point that enables few-shot generalization.

6.2.2 Few-shot domain transfer

The tasks considered here had another domain of a similar task in the GLUE training tasks. Datasets used are (1) 4 domains of Amazon review sentiments (Blitzer et al., 2007), (2) Scitail, a scientific NLI dataset (Khot et al., 2018). Results on 2 domains of Amazon are in Supplementary due to space limitation. A relevant baseline here is MT-BERT$_{\text{reuse}}$ which reuses the softmax layer from the related training task. This is a prominent approach to transfer learning with pre-trained models. Comparing Hybrid-SMLMT with variants of MT-BERT, we see that Hybrid-SMLMT performs comparable or better. Comparing with LEOPARD, we see that Hybrid-SMLMT generalizes better to new domains. LEOPARD performs worse than Hybrid-SMLMT on Scitail even though the supervised tasks are biased towards NLI, with 5 of the 8 tasks being variants of NLI tasks. This is due to meta-overfitting to the training domains in LEOPARD which is prevented through the regularization from SMLMT in Hybrid-SMLMT.

6.3 Analysis

Meta-overfitting: We study the extent of meta-overfitting in LEOPARD and Hybrid-SMLMT. Since these models learn the adaptation learning-

Table 2: k-shot domain transfer accuracy.

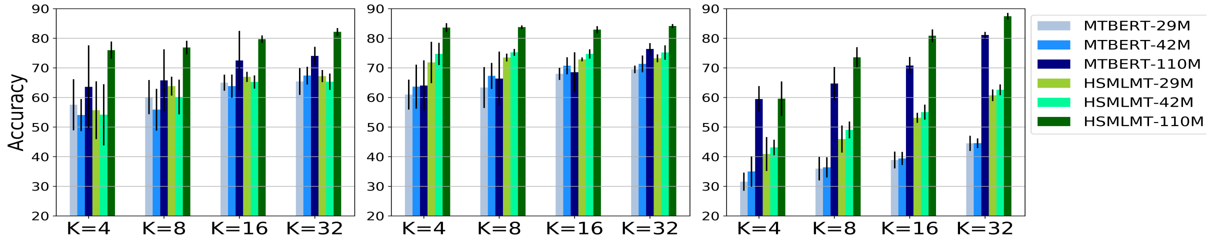

Figure 2: k-shot performance with number of parameters on Scitail (left), Amazon DVD (middle), and CoNLL (right). Larger models generalize better and Hybrid-SMLMT provides accuracy gains for all parameter sizes.

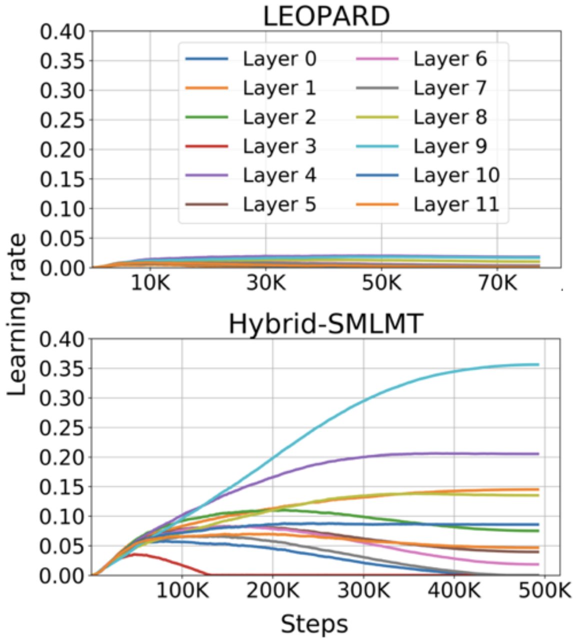

Figure 3: Learning rate trajectory during meta-training. LEOPARD learning-rates converge towards 0 for many layers, indicating meta-overfitting.

rates, we can study the learning rates trajectory during meta-training. Fig. 3 shows the results. We expect the learning rates to converge towards zero if the task-adaptation become irrelevant due to meta-overfitting. LEOPARD shows clear signs of meta-overfitting with much smaller learning rates which converge towards zero for most of the layers. Note that due to this, held-out validation during training is essential to enable any generalization (Bansal et al., 2019). Hybrid-SMLMT doesn't show this phenomenon for most layers and learning rates converge towards large non-zero values even when we continue training for much longer. This indicates that SMLMT help in ameliorating meta-overfitting.

Effect of the number of parameters: We study how the size of the models affect few-shot performance. Recently, there has been increasing evidence that larger pre-trained models tend to generalize better (Devlin et al., 2018; Radford et al., 2019; Raffel et al., 2019). We explore whether this is true even in the few-shot regime. For this analysis we use the development data for 3 tasks: Scitail, Amazon DVD sentiment classification, and CoNLL entity typing. We consider the BERT base architecture with 110M parameters, and two smaller versions made available by Turc et al. (2019) consisting of about 29M and 42M parameters. We train versions of Hybrid-SMLMT as well as MT-BERT corresponding to the smaller models. Results are presented in Fig. 2. Interestingly, we see that bigger models perform much better than the smaller models even when the target task had only 4 examples per class. Moreover, we see consistent and large performance gains from the meta-learned Hybrid-SMLMT, even for its smaller model variants. These results indicate that meta-training helps in data-efficient learning even with smaller models, and enables larger models to learn more generalizable representations.

Representation analysis: To probe how the representations in the proposed models are different from the representations in the self-supervised BERT model and multi-task BERT models, we performed CCA analysis on their representations (Raghu et al., 2017). We use the representations on the CoNLL and Scitail tasks for this analysis. Results on CoNLL task are in Fig. 4. First, we analyze the representation of the same model before and after fine-tuning on the target task. Interestingly, we see that the Hybrid-SMLMT model is closer to the initial point after task-specific fine-tuning than the BERT and MT-BERT models. Coupled with the better performance of Hybrid-SMLMT (in 6.2), this indicates a better initialization point for Hybrid-SMLMT. Note that the representations in lower layers are more similar before and after fine-tuning, and lesser in the top few layers. Next, we look at how representations differ across these mod-

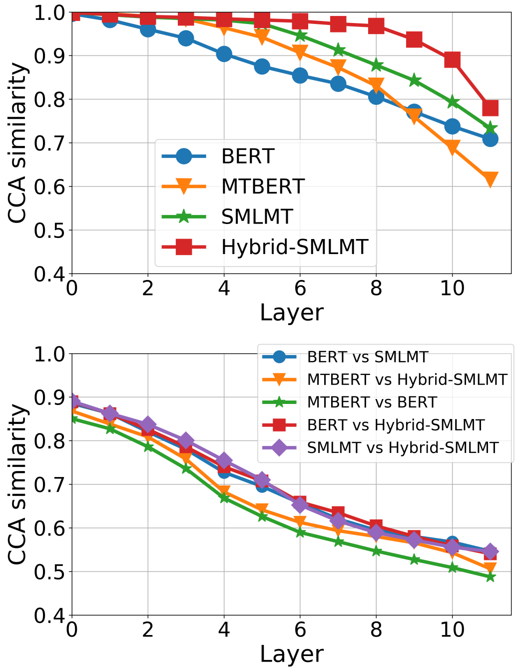

Figure 4: CCA similarity for each transformer layer. Left: similarity before and after fine-tuning for the same model. Right: similarity between different pairs of models post fine-tuning. More results in Appendix.

els. We see that the models converge to different representations, where the lower layer representations are more similar and they diverge as we move towards the upper layers. In particular, note that this indicates that multi-task learning helps in learning different representations than self-supervised pre-training, and meta-learning model representations are different from the other models.

7 Conclusion

We introduced an approach to leverage unlabeled data to crate meta-learning tasks for NLP. This enables better representation learning, learning key hyper-parameters like learning rates, demonstrates data-efficient fine-tuning, and ameliorates meta-overfitting when combined with supervised tasks. Through extensive experiments, we evaluated the proposed approach on few-shot generalization to novel tasks and domains and found that leveraging unlabelled data has significant benefits to enabling data-efficient generalization. This opens up the possibility of exploring large-scale meta-learning in NLP for various meta problems, including neural architecture search, continual learning, hyper-parameter learning, and more.

A Appendix

A.1 Training Algorithm

The meta-training algorithm is given in 1. Note that π^w are the parameters for the warp layers and π are the remaining transformer parameters. $L_T(\cdot)$ is the cross-entropy loss for N-way classification in task T, calculated from the following prediction:

$$p(y|x) = softmax\left\{\mathbf{W}\, h_\phi(f_\pi(x)) + \mathbf{b}\right\} \quad (5)$$

$g_\psi(\cdot)$ and h_ϕ are a two layer MLP with tanh non-linearity (Bansal et al., 2019).

Algorithm 1 Meta-Training

```
Require: SMLMT task distribution $\mathcal{T}$ and supervised tasks $\mathcal{S}$, model parameters $\{\pi^w, \pi, \phi, \psi, \alpha\}$, adaptation steps $G$, learning-rate $\beta$, sampling ratio $\lambda$
    Initialize $\theta$ with pre-trained BERT-base;
while not converged do
    for task_batchsize times do
        $t \sim Bernoulli(\lambda)$
        $T \sim t \cdot \mathcal{T} + (1 - t) \cdot \mathcal{S}$
        $\mathcal{D}^{tr} = \{(x_j, y_j)\} \sim T$
        $C^n \leftarrow \{x_j | y_j = n\}$;    $N \leftarrow |C^n|$
        $w^n, b^n \leftarrow \frac{1}{|C^n|} \sum_{x_j \in C^n} g_\psi(f_\pi(\mathcal{D}^{tr}))$
        $\mathbf{W} \leftarrow [w^1; \ldots; w^N]$;  $\mathbf{b} \leftarrow [b^1; \ldots; b^N]$
        $\theta \leftarrow \{\pi, \phi, \mathbf{W}, \mathbf{b}\}$;    $\theta^{(0)} \leftarrow \theta$
        $\Theta \leftarrow \{\pi^w, \pi, \psi, \alpha\}$
        $\mathcal{D}^{val} \sim T$
        $q_T \leftarrow 0$
        for $s := 0 \ldots G - 1$ do
            $\mathcal{D}^{tr}_s \sim T$
            $\theta^{(s+1)} \leftarrow \theta^{(s)} - \alpha \nabla_\theta \mathcal{L}_T(\{\Theta, \theta^{(s)}\}, \mathcal{D}^{tr}_s)$
            $q_T \leftarrow q_T + \nabla_\Theta \mathcal{L}_T(\{\Theta, \theta^{(s+1)}\}, \mathcal{D}^{val})$
        end for
    end for

Table 3: Hyper-parameters.

CCA similarity on the two datasets: CoNLL and Scitail. Table 7 shows the accuracy for different model sizes on the three evaluation datasets: Scitail, Amazon DVD, CoNLL.

A.3 Datasets

Dataset splits and statistics are in Table 4.

Supervised Training Tasks: We selected the GLUE (Wang et al., 2018) benchmark tasks: MRPC, SST, MNLI (m/mm), QQP, QNLI, CoLA, RTE, and SNLI (Bowman et al., 2015) as the supervised training tasks for the meta-training phase. We used the standard train/dev/test split.

Test Tasks: These are same as the tasks used in Bansal et al. (2019).

A.4 Implementation Details

Training Hyper-parameters: Table 3 lists all the hyper-parameters for the Hybrid-SMLMT and SMLMT models. Both models use the same set of hyper-parameters, the difference being in the training tasks. Note, some hyper-parameters such as λ are not valid for SMLMT. We followed Devlin et al. (2018) in setting many hyper-parameters like dropouts, and Bansal et al. (2019) in setting hyper-parameters related to meta-learning. We use first-order MAML. Meta-training is run for only 1 epoch, so the model always trains on a new SMLMT in every batch. This corresponds to about 500,000 steps of updates during training.

Dataset	Labels	Train	Validation	Test

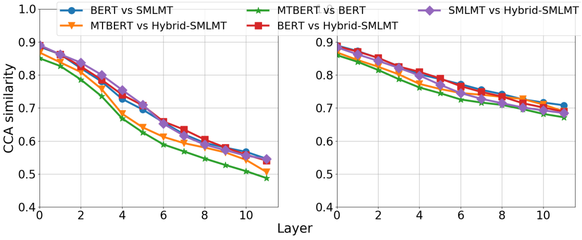

Figure 5: Cross-model CCA similarity for each layer of the transformer after fine-tuning. Left plot is on CoNLL and right on Scitail.

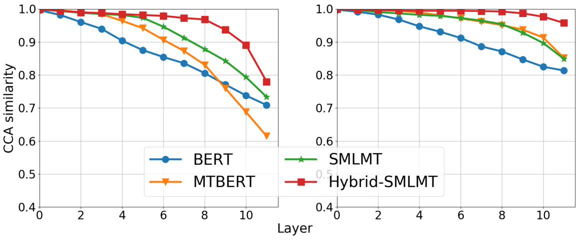

Figure 6: CCA similarity for each layer of the same model before and after fine-tuning. Left plot is on CoNLL and right on Scitail.

Sampling for Hybrid-SMLMT: We restrict the word vocabulary for task creation with a term frequency of at least 50 in the corpus. This is then used to create tasks in SMLMT as described. This word vocabulary is discarded at this point and the data is word-piece tokenized using the BERT-base cased model vocabulary for input to the models. Note that after a supervised task is selected to be sampled based on λ, it is sampled proportional to the square-root of the number of samples in the supervised tasks following Bansal et al. (2019).

Fine-tuning Hyper-parameter: We tune the number of fine-tuning epochs and batch-size using the development data of Scitail and Amazon Electronics tasks following (Bansal et al., 2019). Note

Table 7: k-shot performance for three models sizes.

that best values are determined for each k. Epochs search range is $[5, 10, 50, 100, 150, 200, 300, 400]$ and batch-size search range is $[4, 8, 16]$. The selected values, for $k = (4, 8, 16, 32)$, are: (1) Hybrid-SMLMT: epochs = $(300, 350, 400, 200)$, batchsize = $(8, 16, 8, 16)$; (2) SMLMT: epochs = $(100, 200, 150, 200)$, batchsize = $(8, 16, 8, 16)$. Expected overall average validation accuracy for these hyper-parameters, for $k \in (4, 8, 16, 32)$ are: (1) Hybrid-SMLMT: (0.80, 0.81, 0.83, 0.84); (2) SMLMT: (0.54, 0.56, 0.62, 0.68). Hyper-parameters for BERT, LEOPARD and MT-BERT are taken from Bansal et al. (2019).

Training Hardware and Time: We train the SMLMT and Hybrid-SMLMT models on 4 V100 GPUs, each with 16GB memory. Owing to the warp layers, our training time per step and the GPU memory footprint is lower than LEOPARD (Bansal et al., 2019). However, our training typically runs much longer as the model doesn't overfit unlike LEOPARD (see learning rate trajectory in main paper). Meta-training takes a total of 11 days and 14hours.

Efficient Meta Lifelong-Learning with Limited Memory

Abstract

Current natural language processing models work well on a single task, yet they often fail to continuously learn new tasks without forgetting previous ones as they are re-trained throughout their lifetime, a challenge known as lifelong learning. State-of-the-art lifelong language learning methods store past examples in episodic memory and replay them at both training and inference time. However, as we show later in our experiments, there are three significant impediments: (1) needing unrealistically large memory module to achieve good performance, (2) suffering from negative transfer, (3) requiring multiple local adaptation steps for each test example that significantly slows down the inference speed. In this paper, we identify three common principles of lifelong learning methods and propose an efficient meta-lifelong framework that combines them in a synergistic fashion. To achieve sample efficiency, our method trains the model in a manner that it learns a better initialization for local adaptation. Extensive experiments on text classification and question answering benchmarks demonstrate the effectiveness of our framework by achieving state-of-the-art performance using merely 1% memory size and narrowing the gap with multi-task learning. We further show that our method alleviates both catastrophic forgetting and negative transfer at the same time.

1 Introduction

Humans learn throughout their lifetime, quickly adapting to new environments and acquiring new skills by leveraging past experiences, while retaining old skills and continuously accumulating knowledge. However, state-of-the-art machine learning models rely on the data distribution being stationary and struggle in learning diverse tasks in such a *lifelong learning* setting (Parisi et al., 2019) (see section 2 for a formal definition). In particular, they fail to either effectively reuse previously acquired knowledge to help learn new tasks, or they forget prior skills when learning new ones - these two phenomena are known as *negative transfer* (Wang et al., 2019) and *catastrophic forgetting* (McCloskey and Cohen, 1989), respectively. These downsides limit applications of existing models to real-world environments that dynamically evolve.

Due to its potential practical applications, there is a surge of research interest in the lifelong learning, especially in the vision domain (Rusu et al., 2016; Kirkpatrick et al., 2017; Zenke et al., 2017; Lopez-Paz and Ranzato, 2017; Yoon et al., 2018; Sprechmann et al., 2018; Chaudhry et al., 2019). However, its application to language learning has been relatively less studied. While progress in large-scale unsupervised pretraining (Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019; Yang et al., 2019; Raffel et al., 2020) has recently driven significant advances in the field of natural language processing (NLP), these models require large amounts of in-domain training data and are prone to catastrophic forgetting when trained on new tasks (Yogatama et al., 2019), hindering their deployment in industry or other realistic setups where new tasks/domains continuously emerge.

One successful approach to achieving lifelong learning has been augmenting the learning model with an episodic memory module (Sprechmann et al., 2018). The underlying idea is to first store previously seen training examples in memory, and later use them to perform experience replay (Rolnick et al., 2019) or to derive optimization constraints (Lopez-Paz and Ranzato, 2017; Chaudhry et al., 2019) while training on new tasks. Recently, d'Autume et al. (2019) propose to use such a memory module for sparse experience replay and local adaptation in the language domain, achieving state-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 535–548,
November 16–20, 2020.

of-the-art results for lifelong learning on text classification and question answering tasks. Despite its success, the method has three critical downsides, which we demonstrate later in our experiments:

- It requires an unrealistically large memory module, i.e. storing **all** training examples, in order to achieve optimal performance.
- While the model can mitigate catastrophic forgetting, its local adaptation step is prone to negative transfer such that it performs worse on the most recent task than the naive baseline without any lifelong learning regularization.
- Its inference speed is extremely slow due to a non-trivial amount of local adaptation steps required for **each** test example.

In this paper, we address these limitations and tackle the problem of *efficient* lifelong language learning. That is, we focus on storing limited training examples in memory. Our contributions are three-fold: First, we identify three common principles underlying lifelong learning methods. We seek to characterize them in language learning and glean insights on overlooked downsides of the existing method. Second, stemming from this analysis, we propose a meta-lifelong framework that unifies these three principles. Our approach is a direct extension of d'Autume et al. (2019) and it explicitly meta-learns the model as a better initialization for local adaptation. Finally, we conduct extensive experiments to demonstrate that our proposed approach can use the identified three principles to achieve efficient lifelong language learning. We find that our framework outperforms prior methods while using *100 times* less memory storage. Moreover, we demonstrate that our method can effectively alleviate catastrophic forgetting and negative transfer, closing the performance gap with the multi-task learning upper bound. It can also potentially obtain *22 times* faster inference speed.

2 Background: Principles of Lifelong Language Learning

Following prior work (d'Autume et al., 2019), we consider the lifelong learning setting where a model needs to learn multiple tasks in a sequential order via a stream of training examples without a task descriptor, i.e. the model does not know which task an example comes from during both training and testing. This setup is ubiquitous in practice, as environments consistently evolve without sending an explicit signal.

Formally, during training, the model makes a single pass over the training example stream consisting of N tasks in an ordered sequence, $\mathcal{D}^{train} = \{\mathcal{D}_1^{train}, \cdots, \mathcal{D}_N^{train}\}$, where $\mathcal{D}_t^{train} = \{(\boldsymbol{x}_t^i, y_t^i)\}_{i=1}^{n_t}$ is drawn from the task-specific distribution $P_t(\mathcal{X}, \mathcal{Y})$ of the t-th task. Overall, the goal is to learn a predictor $f_\theta : \mathcal{X} \to \mathcal{Y}$ such as a neural network, parameterized by $\theta \in \mathbb{R}^P$, to minimize the average expected risk of all N tasks:

$$R(f_\theta) := \frac{1}{N} \sum_{t=1}^{N} \mathbb{E}_{\boldsymbol{x},y\sim P_t} \left[\ell(f_\theta(\boldsymbol{x}), y)\right], \qquad (1)$$

with ℓ being the specific task loss. Notice that while the average risk is most commonly evaluated after the model has seen all tasks, we can also evaluate a specific task at different stages to demonstrate the model's training behavior, and evaluate its robustness against catastrophic forgetting and negative transfer.

While different methods have been developed to optimize Eq.(1), we abstract away from their specific assumptions and instead focus on identifying common principles, among which we stress the following three points that are most relevant to language learning:

Generic Representation. Stemming from transfer learning (Weiss et al., 2016; Ganin and Lempitsky, 2015), a key idea of transferring knowledge across diverse tasks is to learn a generic representation (such as a neural network encoder) that is able to encode useful information for all tasks. For instance, regularization based lifelong learning methods (Kirkpatrick et al., 2017; Zenke et al., 2017; Schwarz et al., 2018; Chaudhry et al., 2019) add an extra constraint to prevent the model parameter θ from drastically deviating when training on new tasks, thereby learning a generic model for old tasks as well. In the language domain, as language models have proven success to generate highly generic representation for many language understanding tasks (Yogatama et al., 2019; Raffel et al., 2020), both d'Autume et al. (2019) and Sun et al. (2020) propose utilizing a pretrained language model (Devlin et al., 2019; Radford et al., 2019) to initialize parameters, and further training the model on $\mathcal{D}^{train}$.

Experience Rehearsal. Motivated by the complementary learning systems (CLS) theory (McClelland et al., 1995) that humans rely on episodic memory to store past experiences and conduct experience rehearsal, we can also retrain lifelong learning models on previously seen tasks to reduce forgetting. While prior methods use memory to define optimization constraints (Lopez-Paz and Ranzato, 2017; Chaudhry et al., 2019; Sodhani et al., 2020), recent work use either stored examples (Sprechmann et al., 2018) or generated synthetic data (Shin et al., 2017; Sun et al., 2020) to perform experience replay. Further, d'Autume et al. (2019) shows that a sparse 1% rate of replaying to learning new examples is sufficient for lifelong language learning.

Task-specific Finetuning. In multi-task learning, injecting task-specific parameters and finetuning on individual task have proven effective for different language understanding tasks (Houlsby et al., 2019) or even diverse languages (Bapna and Firat, 2019). Prior work (Rusu et al., 2016; Yoon et al., 2018) exploit this idea to expand model parameters for new tasks in lifelong learning setting. However, all these methods require a task descriptor in order to know when to add new parameters. When no such signal exists, local adaptation (Sprechmann et al., 2018) uses K stored nearest neighbors of each test example to perform extra finetuning at inference time. Recent work (d'Autume et al., 2019; Khandelwal et al., 2020) demonstrate that the sentence embeddings produced by pretrained models can be used to effectively measure query similarity and that local adaptation can improve performance on text classification, question answering and language modelling.

3 Proposed Framework

With these principles in mind, we next turn to the problem of how to achieve efficient lifelong learning. To motivate our proposed framework, we first review the state-of-the-art method, improved MbPA (d'Autume et al., 2019), and show how these principles help us to identify the limitation.

3.1 Model-based Parameter Adaptation

As a notable example, a recent line of work (Sprechmann et al., 2018; d'Autume et al., 2019; Khandelwal et al., 2020) have successfully utilized an episodic memory module as a crucial building block for general linguistic reasoning. Specfically, the improved Model-based Parameter Adaptation (MbPA++) (d'Autume et al., 2019) consists of three main components: (i) a predictor network f_θ, (ii) a key network g_ϕ, and (iii) a memory module $\mathcal{M}$. The end goal is to train f_θ to generalize well across all tasks as in Eq.(1).

To learn a generic representation, MbPA++ utilizes any state-of-the-art text encoder, such as BERT, to initialize both predictor network f_θ and key network g_ϕ. At each time step, the model receives a training example $(\boldsymbol{x}_t^i, y_t^i) \in \mathcal{D}^{train}$ and updates parameter θ by optimizing the task loss:

$$\mathcal{L}_{\text{TASK}}(\theta; \boldsymbol{x}_t^i, y_t^i) = \ell(f_\theta(\boldsymbol{x}_t^i), y_t^i), \qquad (2)$$

To determine if the training example should be added to the memory module $\mathcal{M}$, a Bernoulli random variable is drawn with pre-set probability, which is used to control the memory size.

For experience rehearsal, a subset $\mathcal{S}$ of $\mathcal{M}$ is randomly selected, based on a set ratio of replay examples to learning new examples (i.e. revisit n_{re} examples for every n_{tr} training examples). To avoid catastrophic forgetting, the model then updates the following replay loss to adapt θ towards seen tasks:

$$\mathcal{L}_{\text{REP}}(\theta; \mathcal{S}) = \frac{1}{n_{re}} \sum_{\boldsymbol{x}, y \in \mathcal{S}} \ell(f_\theta(\boldsymbol{x}), y), \qquad (3)$$

At inference time, the key network g_ϕ, which is fixed during training, is used to encode example inputs as keys to obtain the K nearest neighbour context $\mathcal{N}_{\boldsymbol{x}_i}$ of the i-th testing example $\boldsymbol{x}_i$. L local adaptation gradient updates are then performed to achieve task-specific finetuning for the following objective:

$$\begin{aligned}\mathcal{L}_{\text{LA}}(\tilde{\theta}_i; \theta, \mathcal{N}_{\boldsymbol{x}_i}) = \frac{1}{K} \sum_{\boldsymbol{x}, y \in \mathcal{N}_{\boldsymbol{x}_i}} \ell(f_{\tilde{\theta}_i}(\boldsymbol{x}), y) \\ + \lambda_l \|\tilde{\theta}_i - \theta\|_2^2 \qquad (4)\end{aligned}$$

where λ_l is a hyperparameter. The predictor network $f_{\tilde{\theta}_i}$ is then used to output the final prediction for the i-th testing example.

Despite its effectiveness, the performance gain of MbPA++ comes at a cost of large memory storage and slow inference speed. The root of this inefficiency is the non-synergistic nature of the method - the three principles are performed independently without close interaction. In particular: (i) the generic representation learned is not optimized for local adaptation and thus more steps are required for robust performance, (ii) the memory module is selected randomly and lacks a systematic selection method to effectively reduce its size, (iii) local adaptation only utilize a few neighbours for each testing example so it is prone to overfit and negative transfer when memory size is small.

Algorithm 1 Meta-MbPA

```
Procedure Train
Input: training data $\mathcal{D}^{train}$
Output: parameters $\theta$, memory $\mathcal{M}$
Initialize $\theta$ with some pretrained model
for $(\boldsymbol{x}_t^i, y_t^i) \in \mathcal{D}^{train}$ do
    [Generic Representation] Perform a gradient update on $\theta$ to minimize Eq.(5)
    if training step mod $n_{tr}$ = 0 then
        Sample $n_{re}$ examples from $\mathcal{M}$
        [Experience Rehearsal] Perform a gradient update on $\theta$ to minimize Eq.(6)
    end if
    Compute $p(\boldsymbol{x}_t^i)$ according to Eq.(7)
    if Bernoulli($p(\boldsymbol{x}_t^i)$) = 1 then
        Update memory $\mathcal{M} \leftarrow \mathcal{M} \cup (\boldsymbol{x}_t^i, y_t^i)$
    end if
end for
Procedure Test
Input: test examples $\boldsymbol{x}$
Output: predictions $\hat{\boldsymbol{y}}$
for $l = 1, ..., L$ do
    Sample K examples from $\mathcal{M}$
    [Task-specific Finetuning] Perform a gradient update on $\theta$ to minimize Eq.(4)
end for
Output prediction $\hat{\boldsymbol{y}}_i = f_\theta(\boldsymbol{x}_i)$
```

3.2 Synergistic Meta-lifelong Framework

We notice that there is a discrepancy between training and testing in MbPA++. Specifically, the generic representation is trained on the task loss in Eq.(2) directly while it makes prediction *after* the local adaptation at test time. Therefore, the model always overfits to the latest task it has seen, and it never learns how to incorporate experience rehearsal efficiently. According to the CLS theory (McClelland et al., 1995), however, human learning systems are complementary in nature - we learn structured knowledge in a manner that allows us to adapt to episodic information fast. Thus, to resolve the training-testing discrepancy of MbPA++, we change the training goal of generic representation from *how to perform better on the current task* to *how to adapt to episodic memory efficiently*.

In particular, we propose an extension of MbPA++ that exploits a meta learning paradigm to interleave the three key principles: (i) to resolve the training-testing gap, our framework learns a generic representation that is tailored for local adaptation, (ii) to enable robust local adaptation, the memory module uses a diversity-based selection criteria to reduce memory size, (iii) to accommodate small memory, the framework utilizes a coarse local adaptation to alleviate negative transfer. The full framework is outlined in Algorithm 1 and below we detail how each principle is instantiated in a systematic way.

Generic Representation. We incorporate local adaptation into training generic representation. In particular, we exploit the idea of meta learning by formulating local adaptation as the base task and representation learning as the meta task. That is, the generic representation is trained such that it should perform well *after* the local adaptation (a.k.a. learning to adapt). Thus, for each training example $(\boldsymbol{x}_t^i, y_t^i) \in \mathcal{D}^{train}$, we formulate the task loss in Eq.(2) into a meta-task loss as:

$$\begin{aligned} \mathcal{L}_{\text{TASK}}^{\text{meta}}(\theta; \boldsymbol{x}_t^i, y_t^i) &= \ell(f_{\tilde{\theta}_{\boldsymbol{x}_t^i}}(\boldsymbol{x}_t^i), y_t^i) \\ \text{s.t.} \quad \tilde{\theta}_{\boldsymbol{x}_t^i} &= \theta - \alpha \nabla_\theta \mathcal{L}_{\text{LA}}(\theta; \mathcal{N}_{\boldsymbol{x}_t^i}) \end{aligned} \tag{5}$$

where α is the current learning rate. Notice the differentiation requires computing the gradient of gradient, which can be implemented by modern automatic differentiation frameworks. Intuitively, we first approximate local adaptation using gradient step(s), and then optimize the adapted network.

Experience Rehearsal. With similar rationale to the meta-task loss, we reformulate the memory replay loss in Eq.(3) into a meta-replay loss:

$$\begin{aligned} \mathcal{L}_{\text{REP}}^{\text{meta}}(\theta; \mathcal{S}) &= \frac{1}{n_{re}} \sum_{\boldsymbol{x}, y \in \mathcal{S}} \ell(f_{\tilde{\theta}_{\boldsymbol{x}}}(\boldsymbol{x}), y) \\ \text{s.t.} \quad \tilde{\theta}_{\boldsymbol{x}} &= \theta - \alpha \nabla_\theta \mathcal{L}_{\text{LA}}(\theta; \mathcal{N}_{\boldsymbol{x}}) \end{aligned} \tag{6}$$

with the objective to stimulate efficient local adaptation for all tasks.

We use the same replay ratio as in MbPA++ to keep the meta replay sparse. In addition, we propose a diversity-based selection criterion to determine if a training example $(\boldsymbol{x}_t^i, y_t^i) \in \mathcal{D}^{train}$ should be added to the memory module. Here, we exploit the key network g_ϕ to estimate diversity via the minimum distance of $\boldsymbol{x}_t^i$ to existing memory as:

$$\log(p(\boldsymbol{x}_t^i)) \propto -\frac{\min_{\boldsymbol{x}, y \in \mathcal{M}} \|g_\phi(\boldsymbol{x}_t^i) - g_\phi(\boldsymbol{x})\|_2^2}{\beta}, \tag{7}$$

where $p(\boldsymbol{x}_t^i)$ is the probability of the example being selected and β is a scaling parameter. The intuition is to select examples that are less similar to existing memory thereby covering diverse part of data distribution. As shown later, the proposed method outperforms the uncertainty-based selection rule (Ramalho and Garnelo, 2019), which picks examples based on certainty level of the predictor network f_θ. This is because local adaptation is prone to negative transfer when the memory $\mathcal{M}$ misrepresents the true data distribution.

Task-specific Finetuning. With small memory, local adaptation for each testing example is prone to negative transfer. This is because less related memory samples are more likely to be included in $\mathcal{N}_{\boldsymbol{x}_i}$ and the model can easily overfit. Thus, we consider local adaptation with more coarse granularity. For example, we can cluster testing examples and conduct local adaptation for each cluster independently. In our experiments, we find that it is sufficient to take this to the extreme such that we consider all test examples as a single cluster. Consequently, we consider the whole memory as neighbours and we randomly sample from it to be comparable with the original local adaptation formulation (i.e. same batch sizes and gradient steps). As shown in the next section, it has two benefits: (1) it is more robust to negative transfer, (2) it is faster when we evaluate testing examples as a group.

4 Experiments

4.1 Evaluation Dataset

To evaluate the proposed framework, we conduct experiments on text classification and question answering tasks (see Appendix A for details). Following prior work, we consider each dataset as a separate task and the model needs to sequentially learn several tasks of the same category (e.g. all text classification tasks). As pointed out in (McCann et al., 2018), many NLP tasks can be formulated as question answering and thus our setup is general.

Text classification We use five datasets from (Zhang et al., 2015) spanning four text classification tasks: (1) news classification (AGNews), (2) sentiment analysis (Yelp, Amazon), (3) Wikipedia article classification (DBPedia) and (4) questions and answers categorization (Yahoo). To compare our framework with (d'Autume et al., 2019), we follow the same data processing procedure as described by them to produce balanced datasets. In total, we have 33 classes, $575,000$ training examples and $38,000$ test examples from all datasets.

Question Answering Following (d'Autume et al., 2019), we use three question answering datasets: SQuAD v1.1(Rajpurkar et al., 2016), TriviaQA (Joshi et al., 2017) and QuAC (Choi et al., 2018). TriviaQA has two sections, Web and Wikipedia, which we consider as separate datasets. We process the datasets to follow the same setup as (d'Autume et al., 2019). Our processed datasets includes $60,000$-$90,000$ training and $7,000$-$10,000$ validation examples per task.

4.2 Experimental Setup

We consider the prominent baselines corresponding to each one of the three principles as introduced in Section 2. We first consider a standard encoder-decoder model (*Enc-Dec*) which does not utilize any lifelong learning regularization. In the spirit of learning generic representation using parameter regularization, we compare our framework with *Online EWC* (Schwarz et al., 2018) and *A-GEM* (Chaudhry et al., 2019). For experience rehearsal, we implement *Replay*, a model that uses stored examples for sparse experience replay only. Finally, we compare with the state-of-the-art *MbPA++* (d'Autume et al., 2019) which combines experience rehearsal with task-specific finetuning.

Implementation Details We utilize the pretrained $\text{BERT}_{\text{BASE}}$ (Wolf et al., 2019) for initializing the encoder network. $\text{BERT}_{\text{BASE}}$ has 12 Transformer layers, 12 self-attention heads, and 768 hidden dimensions (110M parameters). Similar to (d'Autume et al., 2019), we use a separate pretrained $\text{BERT}_{\text{BASE}}$ for key network and freeze it to prevent from drifting while training on a non-stationary data distribution. For text classification, we use encoded representation of the special beginning-of-document symbol `[CLS]` as our key. For question answering, we use the question part of the input to get the encoded representation. For both tasks, we store the input example as its associated memory value. Further, we use Faiss (Johnson et al., 2019) for efficient nearest neighbor search in the memory, based upon the key network.

We mainly set hyper-parameters as mentioned in (d'Autume et al., 2019). We use Adam (Kingma and Ba, 2014) as our optimizer, set dropout (Srivastava et al., 2014) to 0.1 and the base learning rate to $3e^{-5}$. For text classification, we use a training batch of size 32 and set the maximum total input sequence length after tokenization to 128. For question answering, we use a training batch of size 8,

Table 1: **Accuracy and F_1 scores for text classification and question answering, respectively.** Methods that use the defined lifelong learning setup in Section 2 are listed on the left. Where applicable, all methods use $r_{\mathcal{M}} = 100\%$ memory size unless denoted otherwise. The best result for lifelong learning methods is made **bold**. † Results obtained from (d'Autume et al., 2019). ‡ LAMOL (Sun et al., 2020) is not directly comparable due to their different problem setup where task descriptors are available.

set the maximum total input sequence length after tokenization to 384 and to deal with longer documents we set document stride to 128. We also set the maximum question length to 64.

For Online EWC (Schwarz et al., 2018), we set the regularization strength $\lambda = 5000$ and forgetting coefficient $\gamma = 0.95$. For all models with memory module (Replay, MbPA++, Meta-MbPA), we replay 100 examples for every $10,000$ new examples, i.e., $n_{tr} = 10,000$ and $n_{re} = 100$. As mentioned in (d'Autume et al., 2019), for MbPA++, we set the number of neighbors $K = 32$, the number of local adaptation steps $L = 30$ and $\lambda_l = 0.001$. We tune the local adaptation learning rate α for MbPA++ in our re-implementation (MbPA++ Our Impl.) and report the improved numbers as well as their reported numbers in Table 1, 7, and 8. For text classification, we set $\alpha = 5e^{-5}$ and for question answering we set $\alpha = 1e^{-5}$.

For our framework, Meta-MbPA[1], unless stated otherwise, we set the number of neighbors $K = 32$ and control the memory size through a write rate $r_{\mathcal{M}} = 1\%$. We use $L = 30$ local adaptation steps and perform local adaptation for whole testing set. That is, we randomly draw $K = 32$ examples from the memory and perform a local adaptation step. Through this, the computational cost is equivalent to MbPA++ but we only need to perform the whole process once while MbPA++ requires conducting local adaptation independently for each testing example. We set $\alpha = 1e^{-5}$ (in Eq. (5), (6)), $\beta = 10$ (in Eq. (7)) and $\lambda_l = 0.001$ (in Eq. (4)). All of the experiments are performed using PyTorch (Paszke et al., 2017), which allows for automatic differentiation through the gradient update as required for optimizing the meta-task loss Eq. (5) and meta-replay loss Eq. (6).

4.3 Results

We use four different orderings of task sequences as in (d'Autume et al., 2019) (see Appendix A) and evaluate the model at the end of all tasks. Following prior work, we report the macro-averaged accuracy for classification and F_1 score for question answering. Table 1 provides a summary of our main results. Notice that results on the right are not comparable due to different setups. The complete per-task results are available in Appendix B.

We first compare our framework (Meta-MbPA) with all baselines. Even using only 1% of total training examples as memory, the proposed framework still outperforms existing methods on both text classification and question answering. Specifically, while regularization-based methods (A-GEM and Online EWC) perform better than the standard Enc-Dec model, their performance vary depending on the task ordering and thus are not robust. On the other hand, methods that involve local adaptation (MbPA++ and ours) perform consistently better for all orderings. In particular, our framework improves over MbPA++ while using 100 times less memory, demonstrating the effectiveness of the proposed approach.

MbPA++	73.1	61.9	73.5	62.6
Meta-MbPA	77.3	64.9	78.0	65.5
MTL	50.4	44.1	70.5	56.2

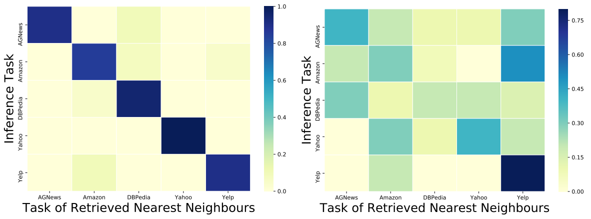
Table 2: **Performance of models using different sizes of memory.**

We then compare lifelong learning methods to the multitask model MTL, which serves as an upper bound of achievable performance. As shown in Table 1, there is still a non-trivial gap between MbPA++ and MTL, albeit MbPA++ stores all training examples as memory. Our framework narrows the gap while using smaller memory.

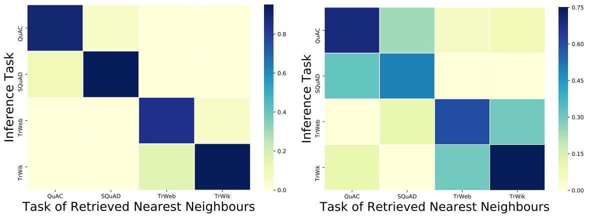
4.4 Analysis

Memory Capacity. In Table 1, MbPA++ uses 100% memory while our framework only uses 1% memory. To test memory efficiency, we present results for models using equivalent memory resources in Table 2. The results demonstrate that the performance of MbPA++ degrades significantly as the memory size decreases. Consequently, the performance gap between MbPA++ and Meta-MbPA enlarges when they both use equal amount of stored examples, compared to results in Table 1. It is then natural to ask if using memory alone is sufficient to obtain good performance. We thus compare with MTL trained on subsampled training data, which is equivalent to only performing local adaptation without training the generic representation. Notice that this variant of MTL is *not* an upper bound as it uses less resources. Our method significantly outperforms it, showing that the meta generic representation in our method is also crucial to achieve good performance. These results validate that the proposed framework can utilize the memory module more effectively than existing methods.

We then study the source of improvement of our method. In particular, we show that prior method is prone to negative transfer. To see this, we first conduct a case study of memory selection rule.



(a) Random (b) Uncertainty



(c) Diversity (d) Forgettable

Figure 1: **Proportions of source of neighbours used in local adaptation for each task when different memory selection rule is used, e.g. 10% of neighbours retrieved for Yelp belong to Amazon.** Numbers in each row sum to 1. Classification figures are at the top while QA at the bottom (Task ordering i.)

	Replay	MbPA++	Meta-MbPA
Text Classification			
Random	69.2	73.1	76.8
Diversity	69.1	73.0	77.3
Uncertainty	65.4	41.2	62.7
Forgettable	62.7	50.5	61.8
Question Answering			
Random	61.2	61.9	63.8
Diversity	61.5	62.2	64.9
Uncertainty	56.1	50.4	54.2
Forgettable	59.7	52.1	57.5

Table 3: **Performance of models using different memory selection criteria.** "Uncertainty" utilizes model's confidence level (Ramalho and Garnelo, 2019). "Forgettable" picks examples according to forgetting events (Toneva et al., 2019). We tune hyperparameters that result in $r_{\mathcal{M}} = 1\%$ memory size for all methods.

Memory Selection Rule. We consider two popular paradigms in active learning (Donmez et al., 2007), namely the diversity-based method that picks the most representative examples and the uncertainty-based method that picks the most unsure examples. In particular, we compare four selection criteria belonging to these two categories: random selection, our proposed diversity-based method in Eq.(7), and two uncertainty-based methods (Ramalho and Garnelo, 2019; Toneva et al., 2019). Notice that random selection is considered as a diversity-based method since it picks examples that represent the true data distribution. As shown in Table 3, we observe that the choice of memory selection criteria clearly impacts performance. While the proposed diversity method slightly outperforms random selection, the two uncertain-based methods perform *worse* than the random baseline, consistent with similar findings reported in d'Autume et al. (2019).

We seek an explanation for this phenomenon and

	Uncertainty		Forgettable	
Model / Task	class.	QA	class.	QA
Meta-MbPA	62.7	54.2	61.8	57.5
w/o LA	65.8	55.8	67.9	59.2
MbPA++	41.2	50.4	50.5	52.1
w/o LA	65.4	56.1	68.4	59.2

Table 4: **Performance of models using the uncertainty-based memory selection methods (correspond to Table 3).** "LA" refers to local adaptation.

visualize the heat maps in Figure 1 to show which tasks each testing example's retrieved neighbours come from during the local adaptation phase. Ideally, the model should always use neighbours from the same task and the heat map should be diagonal. We observe that, compared to diversity-based methods, more examples from other tasks are used as nearest neighbours when models use uncertainty-based methods. This is because the selected uncertain examples are usually less representative in the true distribution and could be outliers. Thus, the resulting memory does not have a good coverage of the data distribution and no similar examples exist for certain test examples. Consequently, less related examples from other tasks are used for the local adaptation, which causes negative transfer. This is verified in Table 4, where models without local adaptation outperform their locally adapted counterparts. More importantly, Meta-MbPA obtains much smaller performance gaps, indicating that it is more robust to negative transfer. We further verify this in the following section.

Trade-off between Catastrophic Forgetting and Negative Transfer. We first verify the models' robustness to catastrophic forgetting. As shown in Table 7 and 8 (Appendix B), the standard Enc-Dec model performs poorly on previously trained tasks, indicating the occurrence of catastrophic forgetting. While all baselines can alleviate the forgetting to some degree, our framework achieves the best performance on previously learned tasks. We also evaluate the model's performance on the first task as it continues to learn more tasks. Figure 2 illustrates how each model retains its previously acquired knowledge as it learns new knowledge. We observe that our framework is consistently better than the baselines at mitigating forgetting.

	Enc-Dec	Replay	MbPA++	Meta-MbPA
class.	82.1	81.8	78.6	82.1
QA	72.6	72.7	70.7	72.1

Table 5: **Average performance on the last task across all four task orderings.**

	$r_{\mathcal{M}} = 1\%$		$r_{\mathcal{M}} = 50\%$	
Model / Task	class.	QA	class.	QA
Meta-MbPA	77.3	64.9	78.2	66.1
w/o Meta	73.1	58.5	74.0	59.6
w/o MS	76.8	63.8	78.1	66.1
w/o LA	75.9	62.0	75.8	62.1

Table 6: **Ablation Study on different memory size.** "Meta" refers to the proposed meta optimization in Eq.(5) and (6)."MS" denotes memory selection based on Eq.(7). "LA" refers to local adaptation.

In addition, as prior work have shown transferring from diversely related sources can hurt performance in the target (Ge et al., 2014; Wang and Carbonell, 2018), we study if transferring from multiple tasks learned in the past can induce negative transfer, which is often overlooked in existing studies on lifelong learning. Table 5 shows the averaged results on the last task in each task ordering (see Appendix B for complete results). Surprisingly, compared to the Enc-Dec baseline, MbPA++ actually performs *worse* on the last task despite its improved macro-averaged performance (Table 1). This suggests that while it is robust to catastrophic forgetting, MbPA++ fails to utilize prior knowledge to benefit later tasks and thus is prone to negative transfer. Apart from some practical bottlenecks such as limited model capacity, local adaptation is a critical factor of negative transfer as Replay[2] outperforms MbPA++ in Table 5. Intuitively, this shows that since Replay already performs well on the last task, further using local adaption can overfit and hurt the performance. On the other hand, the proposed method is trained to learn a more robust initialization for adaptation and uses a coarse adaptation that is less prone to negative transfer. Therefore, it outperforms MbPA++ and closes the gap with Enc-Dec on the last task, consistent with results in Table 4. All of these experiments illustrate that there is a trade-off between catastrophic forgetting and negative transfer, such that more adaptations are desired for earlier tasks while less is better for later tasks. While prior studies focus on catastrophic forgetting only, we are the first to show the importance of balancing the trade-off to avoid both negative effects.

Ablation Study. We report the results of ablation study in Table 6 and analyze the effects of the three components in our framework subject

---

[2] Replay is equivalent to MbPA++ without local adaptation.

Figure 2: **Catastrophic Forgetting of the first dataset as training progresses.** Complete results in Appendix D

to different memory sizes. First, we observe that the model without the meta learning optimization performs the worst, which shows the importance of learning a generic representation tailored for local adaptation. More importantly, Meta-MbPA achieves worse performance without any local adaptation step. This demonstrates that learning the generic representation alone is not sufficient enough, and that the meta learning mechanism and local adaptation are complementary, which mimic the complementary human learning systems in the CLS theory. Finally, while the diversity-based memory selection rule contributes to the performance gain when we use a small memory module, it becomes less effective as the memory size increases. This is expected since the memory distribution can well represent the true data distribution with a larger capacity, and thus it demonstrates that the proposed methods mostly contribute to robustly reducing the memory sizes for better efficiency. Overall, these results validate the effectiveness of each component and highlight the importance of complementary lifelong learning systems. To the best of our knowledge, this is the first work to formulate the slow learning of structured knowledge as meta task and the fast learning from episodic memory as base task.

Inference Speed. The ordinary local adaptation requires customized gradient updates for each testing example and thus it is notoriously slow. Using 1 Nvidia Tesla V100 GPU and 128 GB of RAM, it takes 66.6 hours and 89.3 hours to evaluate on test classification and question answering, respectively. On the other hand, we use coarse local adaptation in our method which uses the same updates for all testing examples. Consequently, it takes 2.9 hours and 4.2 hours for our method to finish the evaluation process, achieving a maximum 22 times speedup. Notice that in a pure online learning setup, our method will obtain similar inference speed as MbPA++. In addition, we hypothesize that using a different granularity (e.g. clustering testing examples) is beneficial for tasks that are more conflicting in nature, as it can balance the trade-off between overfitting to nearest neighbours of small memory and performing more sample-specific adaptation for each test example. We leave this exploration for future work.

5 Conclusion

In this work, we identify three principles underlying different lifelong language learning methods and show how to unify them in a meta-lifelong framework. Our experiments demonstrate the effectiveness of the proposed framework on text classification and question answering tasks. We report new state-of-the-art results while using 100 times less memory space. These results illustrate that it is possible to achieve efficient lifelong learning by establishing complementary learning systems. Our analysis also shows that negative transfer is an overlooked factor that could cause sub-optimal performance, and we highlight the importance of balancing the trade-off tween catastrophic forgetting and negative transfer for future work.

Appendix

A Dataset and Ordering

Text classification We use the following text classification dataset orders for comparing our results with (d'Autume et al., 2019):
i. Yelp→AGNews→DBPedia→Amazon→Yahoo
ii. DBPedia→Yahoo→AGNews→Amazon→Yelp
iii. Yelp→Yahoo→Amazon→DBpedia→AGNews
iv. AGNews→Yelp→Amazon→Yahoo→DBpedia

Question Answering Our processed dataset includes SQuAD with $90,000$ training and $10,000$ validation examples, TriviaQA (Web) with $76,000$ training and $10,000$ validation examples, TriviaQA (Wikipedia) with $60,000$ training and $8,000$ validation examples and QuAC with $80,000$ training and $7,000$ validation examples. We consider following dataset orders for question answering:
i. QuAC→TrWeb→TrWik→SQuAD
ii. SQuAD→TrWik→QuAC→TrWeb
iii. TrWeb→TrWik→SQuAD→QuAC
iv. TrWik→QuAC→TrWeb→SQuAD

B Dataset Specific Results

We report per-dataset specific results for text classification in Table 7 and for question answering in Table 8. For A-GEM and MbPA++ baselines, we obtain results from (d'Autume et al., 2019). A-GEM, Replay, MbPA++ and MbPA++ (Our Impl.) methods use $r_{\mathcal{M}} = 100\%$ memory size while our proposed framework, Meta-MbPA, and MbPA++(1%) use $r_{\mathcal{M}} = 1\%$ memory size.

C Single Task and Multi-task Models Results

We report results for single-task models that uses only single-task data and multi-task learning models using different amounts of training data in Table 9. For text classification, we report accuracy scores and for question answering, we report F_1 scores.

D Catastrophic Forgetting

To understand the severity of the catastrophic forgetting of different models, in Figure 2 and Table 10, we report the performance on the first dataset as training progresses. For example, we show results for AGNews as we train different models on AGNews→Yelp→Amazon→Yahoo→DBpedia dataset order in lifelong learning setup. We also show the results prior to training on any dataset (denoted by "Initial").

Order	Dataset	Enc-Dec	Online EWC	A-GEM†	Replay	MbPA++†	MbPA++ (Our Impl.)	MbPA++ ($r_{\mathcal{M}} = 1\%$)	Meta-MbPA ($r_{\mathcal{M}} = 1\%$)

Don't Use English Dev: On the Zero-Shot Cross-Lingual Evaluation of Contextual Embeddings

Phillip Keung **Yichao Lu** **Julian Salazar** **Vikas Bhardwaj**
Amazon

Abstract

Multilingual contextual embeddings have demonstrated state-of-the-art performance in zero-shot cross-lingual transfer learning, where multilingual BERT is fine-tuned on one source language and evaluated on a different target language. However, published results for mBERT zero-shot accuracy vary as much as 17 points on the MLDoc classification task across four papers. We show that the standard practice of using English dev accuracy for model selection in the zero-shot setting makes it difficult to obtain reproducible results on the MLDoc and XNLI tasks. English dev accuracy is often uncorrelated (or even anti-correlated) with target language accuracy, and zero-shot performance varies greatly at different points in the same fine-tuning run and between different fine-tuning runs. These reproducibility issues are also present for other tasks with different pre-trained embeddings (e.g., MLQA with XLM-R). We recommend providing *oracle* scores alongside zero-shot results: still fine-tune using English data, but choose a checkpoint with the target dev set. Reporting this upper bound makes results more consistent by avoiding arbitrarily bad checkpoints.

1 Introduction

Zero-shot and zero-resource cross-lingual NLP has seen significant progress in recent years. The discovery of cross-lingual structure in word embedding spaces culminated in the work of Lample et al. (2018b), which showed that unsupervised word translation via adversarial mappings is competitive with supervised techniques. Concurrent work in machine translation also showed that it is possible to achieve non-trivial BLEU scores without any bitext (Artetxe et al., 2018; Lample et al., 2018a). Self-supervised multilingual contextual embeddings like mBERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019) have shown remarkably strong performance on cross-lingual named entity recognition, text classification, dependency parsing, and other tasks (e.g., Pires et al., 2019; Keung et al., 2019; Wu and Dredze, 2019).

Much of this recent work has demonstrated that mBERT performs very well on zero-shot tasks, superseding prior techniques as the baseline for zero-shot cross-lingual transfer learning. By *zero-shot*, we mean that no parallel text or labeled data from the target language was used during model training, fine-tuning, or hyperparameter search. In this setting, models are trained on labeled (usually English) text and tested on target (non-English) text. Standard practice prohibits the use of target language data for model selection; the final model is chosen using the English dev set only.

However, we find that zero-shot mBERT results can vary greatly. We present 4 published baselines for zero-shot cross-lingual document classification on MLDoc (Schwenk and Li, 2018) in Table 1:

MLDoc	En	Fr	Ja	Ru	Zh
Eisenschlos et al. (2019)	93.2	**83.0**	64.6	71.6	66.2
Dong and de Melo (2019)	**94.2**	80.0	**73.2**	70.7	75.4
Keung et al. (2019)	**94.2**	73.5	72.8	**73.7**	76.0
Wu and Dredze (2019)	**94.2**	72.6	56.5	**73.7**	**76.9**
Δ	1.0	10.4	16.7	3.0	10.7

Table 1: Published mBERT baselines on zero-shot cross-lingual text classification on 4 of 7 target languages of MLDoc. On non-English languages, we see disagreements of up to 17% (absolute) per column. No paper consistently outperforms the results of another.

Even though the authors report English accuracies which are basically identical, their target language performances are very different. Given that each experiment starts with the same pre-trained mBERT model and MLDoc dataset, it is clear that these cross-lingual results are **not reproducible**.

Table 2: Zero-shot accuracies over 10 independent mBERT fine-tuning experiments on MLDoc and XNLI. For each run, we computed the zero-shot accuracies using the checkpoint with the best En dev performance. We show the minimum and maximum accuracy for each task across the 10 experiments. En dev scores are within 0.9% of each other, but non-En test scores vary by much more depending on the language/corpus. $\Delta \geq 2.5\%$ are **bolded**.

For the listed target languages, the highest accuracy is up to 3 points better than the next best and up to 17 points better than the worst. We investigate this reproducibility issue in both MLDoc and XNLI (Conneau et al., 2018), which is another major dataset for evaluating cross-lingual transfer. The variations in published baselines on these and other datasets are summarized in Sec. 6.

In Section 3, we show that the final zero-shot accuracies **between** and **within** independent mBERT training runs are highly variable. Variations over different random seeds are similar in magnitude to those in Table 1, with variation due to checkpoint selection using English dev being a significant underlying cause. In Section 4, we find that in many cases, **English (En) dev accuracy is not predictive of target language performance**. In fact, for some languages, En dev performance is actually anti-correlated with target language accuracy.

Poor correlation between En dev and target test accuracy, combined with high variance between independent runs, means that published zero-shot accuracies are somewhat arbitrary. In addition to zero-shot results, **we recommend reporting *oracle* results**, where one still fine-tunes using En data, but uses the target dev set for checkpoint selection.

2 Experimental setup

We use cased mBERT (110M parameters) for all of our experiments. We illustrate the reproducibility issues in zero-shot cross-lingual transfer through the document classification task in MLDoc[1] and the natural language inference task in XNLI.[2] For the MLDoc and XNLI experiments, we used their full En training sets (10k and 393k examples, respectively). Unless stated otherwise, we use their En development sets (1k and 2.5k examples) and non-En test sets (4k and 5k examples). When fine-tuning mBERT, we used a constant learning rate of 2×10^{-6} with a batch size of 32 for MLDoc, and a constant learning rate of 2×10^{-5} with a batch size of 32 for XNLI. Checkpoints were saved at regular intervals: one checkpoint for every 2% of the training corpus processed. Models were trained until convergence based on En dev accuracy. We used the mBERT implementation in GluonNLP (Guo et al., 2020) and an AWS p3.8xlarge instance for our MLDoc and XNLI runs, which completed in ~3 and ~12 hours respectively on a single NVIDIA V100 GPU.

3 Between-run and within-run variation

Running mBERT fine-tuning under different random seeds yields highly variable results, similar to what we observed in Table 1. Previous work on evaluation over random initializations (e.g., Melis et al., 2018) reported relatively small effects on the test metric (e.g., ±1 point on En F1 for NER). However, we observed much larger variations in zero-shot accuracy on MLDoc and XNLI.

First, we observed significant variation *between* independent runs (Table 2). We ran mBERT fine-tuning with different random seeds, and for each run, selected the checkpoint with the best En dev performance. The best checkpoint from each run gave very different zero-shot results, varying as much as 15.0% absolute in French (Fr) in MLDoc and 4.3% in Thai (Th) in XNLI.

Second, we observed significant variation *within* each run, which we illustrate in Figure 1. En dev accuracy reaches a stable plateau as mBERT fine-tuning proceeds; however, zero-shot Spanish (Es)

Table 3: Frequency of directional agreement between dev and test accuracy on MLDoc and XNLI (higher is better). We expect dev and test accuracy to generally increase and decrease together between randomly sampled checkpoints, which happens when using the target language dev set, but not when using the English dev set. English dev accuracy can be worse than random chance (50%) at tracking target test accuracy; these values are **bolded**.

and Japanese (Ja) accuracies swing by several percentage points as training proceeds.

Indeed, for all of the MLDoc languages and for 7 of the 14 XNLI languages, the variation across 10 runs exceeds 2.5% (absolute), even though the En dev accuracy only varies within a narrow 0.9% range. To put this variation in context, we note that the MLDoc and XNLI test sets are relatively large, so a 2.5% difference in accuracy would be statistically significant (at the 5% significance level using the usual test of proportions), which means that a paper claiming 'state-of-the-art' performance on these zero-shot tasks may be reporting strong results because of the large between-run variation, rather than a genuine improvement due to their proposed technique.

In other words, using the En dev accuracy for choosing the final model for zero-shot transfer leads to inconsistent results across different runs. The En dev accuracy is similar for each of our independent experiments, but the target test accuracy for each experiment fluctuates in a wide band.

4 English dev accuracy and its relationship with zero-shot accuracy

Experimenters use the En dev set for model selection under the assumption that zero-shot performance improves as En dev performance improves. We show that this assumption is often false.

We compare the abilities of En dev and target dev to predict directional changes in target test accuracy. In Table 3, we report the frequency of *directional agreement* on MLDoc and XNLI; i.e., how often does En dev accuracy increase/decrease in tandem with target test accuracy?

We randomly sample pairs of checkpoints where the change in target test accuracy for the pair is at least 0.5%, and compute the proportion for which the En dev accuracy changed in the same direction. Table 3 shows that for MLDoc, En dev is not much better than a coin flip ($\sim$50%) at predicting the direction of the change in target test accuracy, while target dev tracks target test accuracy 90+% of the time. For XNLI, En dev sometimes approaches target dev in predictive power (i.e., Es and Fr), but can fall short for other languages. In general, we see higher directional agreement in XNLI than

MLDoc, which we attribute to XNLI's target test sets being professional translations of En test.

Remarkably, for some languages (i.e., Ja in MLDoc and Hi, Sw, Tr, and Vi in XNLI), the frequency of directional agreement is less than 50%, which means that, more often than not, when En dev accuracy increases, target test accuracy for these languages decreases; we discuss this in Section 5. Since En dev accuracy does not reliably move in the same direction as target test accuracy, it is an inadequate metric for tracking zero-shot cross-lingual transfer performance.

5 Catastrophic forgetting

The strange phenomenon in Table 3 (where the probability of directional agreement is sometimes less than 50%) occurs even on XNLI, where the dev and test sets are translated from English and therefore have the same semantic content. We believe this phenomenon is a form of catastrophic forgetting (Kirkpatrick et al., 2017), where mBERT loses some cross-lingual knowledge from pre-training because it is fine-tuned on En data only.

In Figure 1, we plotted the En dev accuracy and the target test accuracy over time, for the language with the highest directional agreement (Es, 0.59) and for the language with the lowest directional agreement (Ja, 0.42) for MLDoc (see Table 3). From the figure, Es test accuracy does increase with En dev accuracy, while Ja test accuracy decreases as En dev accuracy increases. The same pattern holds with XNLI for Tr and En (not shown), where Turkish accuracy decreases somewhat as fine-tuning with English training data continues.

We conclude that En dev accuracy cannot detect when mBERT is improving on the En training data at the expense of non-En languages, and should not (solely) be used to assess zero-shot performance.

6 Published results

At the time of writing, over 70 papers have been published on the MLDoc and XNLI corpora. Several new datasets (e.g., Liu et al., 2019; Artetxe et al., 2020; Yang et al., 2019) for zero-shot cross-lingual evaluation have been released and aggregated into benchmark suites like XGLUE (Liang et al., 2020) and XTREME (Hu et al., 2020). There are also more recent multilingual contextual embeddings (e.g., XLM-R large; Conneau et al., 2020) which is trained on significantly more data (2.5 terabytes). Notably, Conneau et al. (2020) uses the target dev sets *jointly* for checkpoint selection.

As with Table 1 for MLDoc, we search for signs of the variability found in our experimental setup across the zero-shot cross-lingual literature. In XNLI (Table 4) we see less drastic variations in Δ. However, for variations in En of 0.6 (XLM-R) and 1.3 (mBERT) points, we see variations of

Table 5: Oracle zero-shot accuracies with mBERT across 10 independent runs, using target dev to select the best checkpoint for each language. This provides an upper bound on the achievable zero-shot accuracy. Published results are derived from sources in Tables 1, 4, and 6. Best En dev results are from Table 2.

≥2.5 points in linguistically distant languages (Ar, Sw, Th, Tr), languages which agreed with En dev ≤56% during finetuning (Table 3). We also include MLQA (Lewis et al., 2020), where a variation of 2.8 in En mBERT results gave even higher variations (≥4.0 points) in all languages except Es. A similar effect occurs with XLM-R and the more distant languages (Ar, Vi, Zh). In particularly, Chinese (Zh) degrades by 5.9 points as En improves, which may be evidence of directional disagreement in MLQA between En dev and Zh test.

In Table 6, results on CoNLL 2002/2003 (Sang and De Meulder, 2003) show slightly increased variation relative to En. We also include the remaining MLDoc languages for completeness.[3]

7 Recommendations and discussion

Using a poor metric like En dev accuracy to select a model checkpoint is similar to picking a checkpoint at random. This would not be a major issue if the variance between different training runs were low; the test performance would, in that case, be consistently mediocre. The problem arises when the variability is high, which we have seen experimentally (Table 2) and in the wild (Table 1).

We showed that independent experiments can report very different results, which prevents us from making meaningful comparisons between different baselines and methods. Currently, it is standard practice to use the En dev accuracy for checkpoint selection in the zero-shot cross-lingual setting. However, we showed that using En dev accuracy for checkpoint selection leads to somewhat arbitrary zero-shot results.

Therefore, we propose reporting *oracle* accuracies, where one still fine-tunes using English data, but selects a checkpoint using target dev. This represents the **maximum achievable zero-shot accuracy**. Note that we do not use target dev for hyperparameter tuning; we are using target dev to avoid selecting bad checkpoints within each fine-tuning experiment. Table 5 shows our oracle results on MLDoc and XNLI. Reporting this upper bound makes results more consistent by avoiding arbitrarily bad checkpoints. To avoid unexpected variation in future cross-lingual publications, we recommend that authors report oracle accuracies alongside their zero-shot results.

Abstract

We present a novel supervised word alignment method based on cross-language span prediction. We first formalize a word alignment problem as a collection of independent predictions from a token in the source sentence to a span in the target sentence. Since this step is equivalent to a SQuAD v2.0 style question answering task, we solve it using the multilingual BERT, which is fine-tuned on manually created gold word alignment data. It is nontrivial to obtain accurate alignment from a set of independently predicted spans. We greatly improved the word alignment accuracy by adding to the question the source token's context and symmetrizing two directional predictions. In experiments using five word alignment datasets from among Chinese, Japanese, German, Romanian, French, and English, we show that our proposed method significantly outperformed previous supervised and unsupervised word alignment methods without any bitexts for pretraining. For example, we achieved 86.7 F1 score for the Chinese-English data, which is 13.3 points higher than the previous state-of-the-art supervised method.[1]

1 Introduction

Over the last several years, machine translation accuracy has been greatly improved by neural networks (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Vaswani et al., 2017). However, word alignment tools, which were developed during the age of statistical machine translation (Brown et al., 1993; Koehn et al., 2007) such as GIZA++ (Och and Ney, 2003), MGIZA (Gao and Vogel, 2008) and FastAlign (Dyer et al., 2013), remain widely used because the improvement of word alignment accuracy has become stagnant.

This situation is unfortunate because word alignment could be used for many downstream tasks including projecting linguistic annotation (Yarowsky et al., 2001), projecting XML markups (Hashimoto et al., 2019), and enforcing terminology constraints (pre-specified translation) (Song et al., 2019). We could also use it for the user interfaces of post-editing to detect such problems as under-translation (Tu et al., 2016).

Word alignment has a long research history. Here, we focus on approaches that use neural networks because they are the state-of-the art. Most previous works that use them for word alignment (Yang et al., 2013; Tamura et al., 2014; Legrand et al., 2016) achieved accuracies that are basically comparable to GIZA++. However, the accuracy of recent works (Garg et al., 2019; Stengel-Eskin et al., 2019; Zenkel et al., 2020) based on the Transformer (Vaswani et al., 2017), which is the state-of-the art neural machine translation model, have started to outperform GIZA++.

Garg et al. (2019) made the attention of the Transformer more closely resembled the word alignment, and achieved better accuracy than GIZA++ when they used alignments obtained from it for supervision. Zenkel et al. (2020) added an alignment layer using a full target context on top of the Transformer and trained it with a loss function that encouraged contiguous alignment and bidirectional agreement. They outperformed GIZA++ without GIZA++ output for supervision. Stengel-Eskin et al. (2019) proposed a supervised word alignment method using the hidden states of the Transformer, and significantly outperformed FastAlign (11-27 F1 points) using a small number of gold word alignments (1.7K-5K sentences). However, both Garg et al. (2019) and Stengel-Eskin et al. (2019) required more than a

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 555–565,
November 16–20, 2020.

million parallel sentences to pretrain their models. Applying these methods to low-resource language pairs and domains is difficult.

In this paper, we present a novel supervised word alignment method that requires no parallel sentences for pretraining and can be trained from fewer gold word alignments (150-300 sentences). It formalizes word alignment as a collection of SQuAD-style span prediction problems (Rajpurkar et al., 2016) and solves them with multilingual BERT (Devlin et al., 2019). We experimentally show that our proposed model significantly outperformed both (Garg et al., 2019) and (Stengel-Eskin et al., 2019).

Our main contribution is that we make supervised word alignment more practical. Stengel-Eskin et al. (2019) argued that supervised word alignment is a viable option. They concluded that alignment annotation could be performed rapidly 4.4 sentences per minute by annotators with minimal experience using a web-based crowd-sourcing interface. Assuming that a small amount of gold word alignment data, which can be annotated in a couple of hours, our proposed method could be used on 104 languages supported by the multilingual BERT.

2 Proposed Method

2.1 Word Alignment as Question Answering

Figure 1 shows an example of Japanese-English word alignment data and Figure 2 is its illustration. It consists of a token sequence of the L1 language (Japanese), a token sequence of the L2 language (English), a sequence of the aligned token pairs, the original L1 sentence, and the original L2 sentence. For example, the first item of the third line "0-1" represents that the first token "足利" of the L1 sentence is aligned to the second token "ashikaga" of the L2 sentence. The index of the tokens starts from zero.

In this paper, we frame word alignment as a cross-language span prediction problem similar to the SQuAD-style question answering task (Rajpurkar et al., 2016). In SQuAD, given a context (a paragraph from Wikipedia) and a question, the question answering system predicts an answer as a span in the context. Similarly, given a target sentence as the context and a source word as a question, the word alignment system predicts a translation of the source word as the answer, which is a span in the target sentence.

Figure 3 shows an example of converting word alignment data to a SQuAD-style span prediction. In its upper half, the L1 (Japanese) sentence is given as the context. A token in the L2 (English) sentence "was" is given as a question whose answer is span "である" in the L1 sentence. It corresponds to the three aligned token pairs "24-2 25-2 26-2" in the third line of Figure 1.

We can convert the word alignments for a sentence to a set of queries from a token in the L1 sentence to a span in the L2 sentence and a set of queries from a token in the L2 sentence to a span in the L1 sentence. If a token is aligned to multiple spans, we treat it as a question with multiple answers. If a token has no alignment, we treat it as a question without answers.

We call the question's language the source language and the context's language (and the answer's language) the target language. In Figure 3, the source language is English and the target language is Japanese. This is an English-to-Japanese query.

Suppose the question is such a high-frequency word as "of", which might be found many times in the source sentence. We might easily experience difficulty finding the corresponding span in the target sentence without the source token's context.

The lower half of Figure 3 shows two examples of a question with the source token's context. In question_2, the two preceding words "Yoshimitsu ASHIKAGA" and two following words "the 3rd" are attached to the source token "was" with '¶' (pilcrow: paragraph mark) as a boundary marker[2]. As shown in the experiment, the longer the context is, the better the result. We used the whole source sentence as a context, as shown in question_3.

Since there are many null alignments in word alignment, we adopted the SQuAD v2.0 format (Rajpurkar et al., 2018), which explicitly defines cases when there are no answer spans to the question in the given context. For converting word alignment data to SQuAD-style question answering, both the question and the context are taken from the original sentences, not the tokenized sequences. The start and end positions of the answer span are indexes to the character position of the original target sentence. Since each dataset has a

---

[2] We used '¶' as a boundary marker because it belongs to the Unicode character category "punctuation" and is included in the multilingual BERT vocabulary. It rarely appears in ordinary text.

```

Figure 1: Word alignment data between Japanese and English (’to1394’ is copied as is).

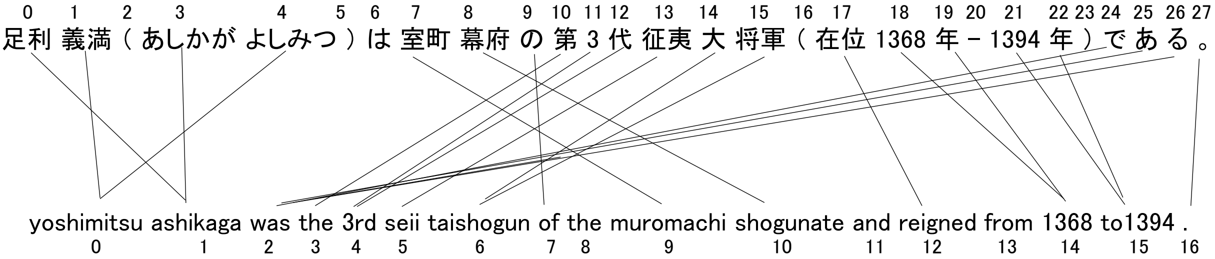

Figure 2: Illustration of the word alignment data. Annotation in Japanese ’ あしかがよしみつ’ enclosed in the first pair of parentheses is the reading of Chinese characters ’ 足利義満’ (ASHIKAGA, Yoshimitsu). Annotation in Japanese ’ 在位 1368 年-1394 年’ enclosed in the second pair of parentheses is plainly translated in English as ’and reigned from 1368 to 1394’.

different standard for tokenization and casing, we only used the tokenization of the source sentence to create a source span in a question.

2.2 Cross-Language Span Prediction using Multilingual BERT

We defined our cross-language span prediction task as follows. Suppose we have a source sentence with $|X|$ characters $X = x_1 x_2 \dots x_{|X|}$, and a target sentence with $|Y|$ characters $Y = y_1 y_2 \dots y_{|Y|}$. Given source token $x_{i:j} = x_i \dots x_j$ that covers (i, j) in source sentence X, the task is to extract target span $y_{k:l} = y_k \dots y_l$ that covers (k, l) in target sentence Y.

We applied multilingual BERT (Devlin et al., 2019) to this task. Although it is designed for such monolingual language understanding tasks as question answering and natural language inference, it works surprisingly well for cross-language span prediction.

For the SQuAD v2.0 task, we used a model described in (Devlin et al., 2019) that added two independent output layers to the pretrained BERT to predict the start and end positions in the context. Suppose p_{start} and p_{end} are the probabilities that each position in the target sentence is the start and end positions of the answer span. We defined score $\omega_{ijkl}^{X \to Y}$ of target span $y_{k:l}$ given source span $x_{i:j}$ as the product of its start and end position probabilities and selected span $(\hat{k}, \hat{l})$ that maximizes $\omega_{ijkl}^{X \to Y}$ as the best answer span:

$$\omega_{ijkl}^{X \to Y} = p_{start}(k|X, Y, i, j) \cdot p_{end}(l|X, Y, i, j) \tag{1}$$

$$(\hat{k}, \hat{l}) = \arg \max_{(k,l):1 \leq k \leq l \leq |Y|} \omega_{ijkl}^{X \to Y} \tag{2}$$

In the SQuAD model of BERT, first, the question and the context are concatenated to generate sequence “[CLS] question [SEP] context [SEP]” as input, where [CLS] and [SEP] are the classification and separator tokens, respectively. Then, the start and end positions are predicted as indexes to the sequence. In the SQuAD v2.0 model, the start and end positions are the indexes to the [CLS] token if there are no answers.

Unfortunately, since the original implementation of the SQuAD model only outputs an answer string, we extended it to output the answer’s start and end positions. Inside BERT, the input sequence is first tokenized by WordPiece. It then splits the CJK characters into a sequence of a single character. Since the start and end positions are indexes to the BERT tokens, we converted them to character indexes to make the input tokenization (word boundary) independent of the BERT tokenization.

Figure 4 shows an example of span prediction where the source token is “Yoshimitsu”, which consists of four BERT tokens. The original token (word) boundaries are shown by dotted lines.

```
context: "足利義満（あしかがよしみつ）は室町幕府の第 3 代征夷大将軍（在位 1368 年–1394 年）である。"
question_1: "was"
answer: "である",

question_2: "Yoshimitsu ASHIKAGA ¶ was ¶ the 3rd"
question_3: "Yoshimitsu ASHIKAGA  ¶ was ¶ the 3rd Seii Taishogun of the Muromachi
Shogunate and reigned from 1368 to1394.
```

Figure 3: English-to-Japanese query without source context (question_1), with limited source context (question_2), and with full source context (question_3)

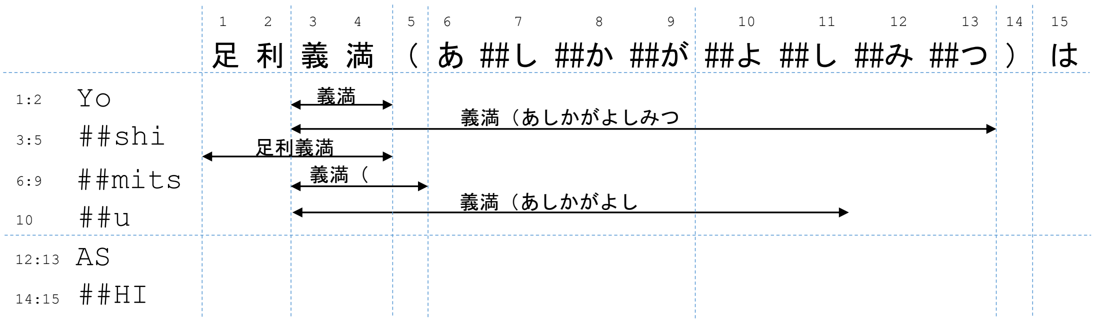

Figure 4: An example of Japanese-to-English span prediction where source token is "Yoshimitsu". Each BERT token is shown with its character index to the original sentence, and word boundaries are shown by dotted lines.

There are five target span candidates, where "義満" is the correct answer. The predicted target spans do not necessarily agree with the target token boundaries because BERT predicts spans based on its tokens. For target spans that do not agree with the target token boundaries such as "義満（あしかがよし", we select the longest sequence of the target tokens that is strictly included in the predicted target span such as "義満", "（", and "あしかが", as a set of aligned target tokens from the source token.

2.3 Symmetrization of Word Alignments

Since the proposed span prediction model predicts a target span for a source token, it is asymmetric like the IBM model (Brown et al., 1993). To make the span predictions more reliable, we designed a simple heuristics to symmetrize the span predictions of two directions.

Symmetrizing IBM model alignments was first proposed by Och and Ney (2003). One of the most popular Statistical Machine Translation Toolkits, Moses (Koehn et al., 2007), supports a variety of symmetrization heuristics, such as intersection and union, where grow-diag-final is the default. The intersection of the two yields an alignment that consists of one-to-one alignments with higher precision and lower recall than either one separately. The union yields higher recall and lower precision.

As a symmetrization method, for an alignment we averaged the probabilities of the best spans for each token for each direction. A token is aligned if it is completely included in the predicted span. We then extracted the alignments with the average probabilities that exceed a threshold.

Let $x_{i:j}$ be a substring of sentence X that spans (i,j), and let $y_{k:l}$ be a substring of sentence Y that spans (k,l). Let $\omega^{X\to Y}_{ijkl}$ be the probability that token $x_{i:j}$ predicts span $y_{k:l}$, and let $\omega^{Y\to X}_{ijkl}$ be the probability that token $y_{k:l}$ predicts span $x_{i:j}$. Let ω_{ijkl} be the probability of alignment a_{ijkl} where token $x_{i:j}$ is aligned to token $y_{k:l}$. We define ω_{ijkl} as the average of probability $\omega^{X\to Y}_{ij\hat{k}\hat{l}}$ of the best predicted span $y_{\hat{k}:\hat{l}}$ from $x_{i:j}$ and probability $\omega^{Y\to X}_{\hat{i}\hat{j}kl}$ of the best predicted span $x_{\hat{i}:\hat{j}}$ from $y_{k:l}$:

$$\omega_{ijkl} = 1/2(I_{\hat{k}\le k\le l\le \hat{l}}(\omega^{X\to Y}_{ij\hat{k}\hat{l}}) + I_{\hat{i}\le i\le j\le \hat{j}}(\omega^{Y\to X}_{\hat{i}\hat{j}kl})) \tag{3}$$

where $I_A(x)$ is an indicator function. $I_A(x)$ returns x if A is true and 0 otherwise. We regard $x_{i:j}$ and $y_{k:l}$ as aligned if ω_{ijkl} is more than or equal to threshold, which we set to 0.4.

We call our proposed symmetrization the bidirectional average (bidi-avg). It is easy to implement and works similarly to grow-diag-final in the sense that it tries to find an intermediate alignment between union and intersection. Figure 5 shows an example where a Japanese-to-English span prediction (left) and an English-to-Japanese span predic-

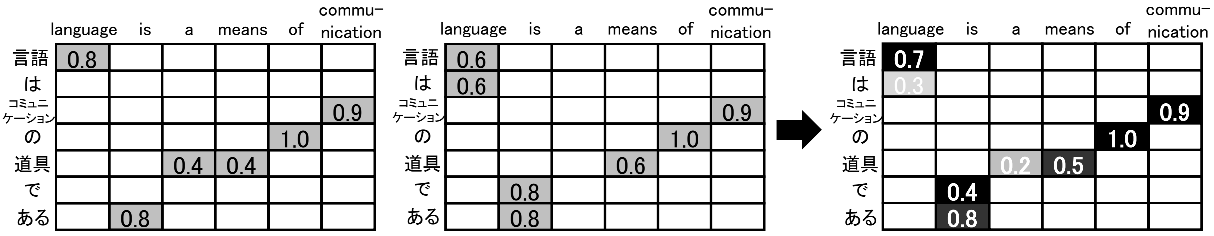

Figure 5: Ja-to-En span prediction (left) and En-to-Ja span prediction (middle) are symmetrized using bidi-avg (right). Alignments whose average probabilities are more than or equal to the threshold are shown in black.

Language	Train	Test	Reserve
Zh-En	4,879	610	610
Ja-En	653	357	225
De-En	300	208	0
Ro-En	150	98	0
En-Fr	300	147	0

Table 1: Number of gold alignment sentences and their training/test splits.

tion (middle) are symmetrized using bidirectional average (right). The token pair “is” and “で” is identified as aligned because its bidirectional average probability equals the threshold, even though it is only predicted in one direction.

We determined a threshold of 0.4 in a preliminary experiment in which we divided the Japanese-English training data into two halves for training and test sets. We used the threshold for all the experiments described in this paper. Although the span prediction of each direction was made independently, we did not normalize the scores because both directions are trained in one model.

Although we only used the best span for each direction, we could use the n-best spans to handle discontinuous alignment such as a pair between “never” and “決して... ない”. It is worth investigating further as future work.

3 Experiments

3.1 Data

Table 1 shows the number of training and test sentences of the five gold word alignment datasets used in our experiments: Chinese-English (Zh-En), Japanese-English (Ja-En), German-English (De-En), Romanian-English (Ro-En), and English-French (En-Fr).

Stengel-Eskin et al. (2019) used the Zh-En dataset and Garg et al. (2019) used the De-En, Ro-En, and En-Fr datasets. We added a Ja-En dataset because Japanese is one of the most distant languages from English[3].

The Zh-En data were obtained from the GALE Chinese-English Parallel Aligned Treebank (Li et al., 2015), which consists of broadcasting news, news wires, and web data. To make the experiment’s condition as close as possible to Stengel-Eskin et al. (2019), we used Chinese character-tokenized bitexts, which we cleaned (by removing mismatched bitexts, time stamps, etc.) and randomly split them into 80% training, 10% testing, and 10% future reserves.

The Japanese-English data were obtained from the KFTT word alignment data (Neubig, 2011). The Kyoto Free Translation Task (KFTT) [4] was made by manually translating Japanese Wikipedia pages about Kyoto into English. KFTT is one of the most popular Japanese-English translation benchmarks and consists of 440k training sentences, 1166 development sentences, and 1160 test sentences. The KFTT word alignment data were made by manually word aligning a part of the dev and test sets. The aligned dev set has eight files and the aligned test set has seven files. We used all eight dev set files for training, four test set files for testing, and three other files for future reserves.

De-En, Ro-En, and En-Fr data are the same ones described in Zenkel et al. (2019). They provide pre-processing and scoring scripts[5]. Garg et al. (2019) used these three datasets for their experiments. The De-En data were originally provided by Vilar et al. (2006)[6]. Ro-En and En-Fr data were used in the shared task of the HLT-NAACL-2003 workshop on Building and Using Parallel Texts (Mihalcea and Pedersen,

---

[3] Stengel-Eskin et al. (2019) also used an Arabic-English (Ar-En) dataset. We did not use it here due to time constraints

[4] http://www.phontron.com/kftt/index.html

[5] https://github.com/lilt/alignment-scripts

[6] https://www-i6.informatik.rwth-aachen.de/goldAlignment/

2003)[7]. The En-Fr data were originally provided by (Och and Ney, 2000). The numbers of the test sentences in the De-En, Ro-En, and En-Fr datasets are 508, 248, and 447. In De-En and En-Fr, we used 300 sentences for training. In Ro-En, we used 150 sentences for training. The other sentences were used for testing.

3.2 Implementation Details

We used BERT-Base, Multilingual Cased (104 languages, 12 layers, 768 hidden states, 12 heads, 110M parameters, November 23rd, 2018) in our experiments[8]. We basically used the script for SQuAD as it is except for the start and end positions. The following are the parameters: train_batch_size = 12, learning_rate = 3e-5, num_train_epochs = 2, max_seq_length = 384, max_query_length = 160, and max_answer_length = 15.

Devlin et al. (2019) used the following threshold for the squad-2.0 model:

$$\hat{s_{ij}} > s_{null} + \tau \tag{4}$$

Here, if the difference of the scores of best non-null span $\hat{s_{ij}}$ and null (no-answer) span s_{null} exceeds threshold τ, a non-null span is predicted. The default value of $\tau = 0.0$, and the optimal threshold is decided by the development set. We used the default value because we assumed the score of a null alignment is appropriately estimated since there are many null alignments in the training data.

We used two NVIDIA TESLA V100 (16GB) for our experiments. If we set the training batch size to 6, the experiments could be performed in NVIDIA GEFORCE RTX 2080 Ti (11GB) with no significant differences in accuracy. It took about 30 minutes to fine-tune an epoch for the Ja-En data (653 sentences). It took 3 to 4 sentences per second for the inferences, excluding the time for loading the model, which was about two minutes.

3.3 Measures for Word Alignment Quality

We evaluated the quality of the word alignment using an F1 score that assigns equal weights to precision (P) and recall (R):

$$F_1 = 2 \times P \times R/(P + R) \tag{5}$$

If necessary, we also used alignment error rate (AER) (Och and Ney, 2003) because some previous works only reported it. Let quality of alignment A be measured against a gold word alignment that contains sure (S) and possible(P) alignments ($S \subseteq P$). Precision, recall, and AER are defined as follows:

$$Precision(A, P) = \frac{|P \cap A|}{|A|} \tag{6}$$

$$Recall(A, S) = \frac{|S \cap A|}{|S|} \tag{7}$$

$$AER(S, P, A) = 1 - \frac{|S \cap A| + |P \cap A|}{|S| + |A|} \tag{8}$$

Fraser and Marcu (2007) pointed out that since AER is broken in a way that favors precision, it should be used sparingly. In previous works, Stengel-Eskin et al. (2019) used precision, recall, and F1, while Garg et al. (2019) and Zenkel et al. (2019) used precision, recall, and AER. Note that, if we distinguish between sure and possible alignments, precision and recall are different from those when we do not make such a distinction. Among our five datasets, De-En and En-FR make a distinction between sure and possible alignments.

3.4 Results

Table 2 compares our proposed method with previous works. In all five datasets, our method outperformed all previous methods. In the Zh-En data, our method achieved an F1 score of 86.7, which is 13.3 points higher than that of DiscAlign 73.4, as reported in (Stengel-Eskin et al., 2019), which is the state-of-the-art supervised word alignment method. Stengel-Eskin et al. (2019) used 4M bitexts for pretraining, while our method needed no bitexts for pretraining. In Ja-En data, our method achieved an F1 score of 77.7, which is 20 points higher than that of GIZA++ 57.8, as reported in (Neubig, 2011).

For the De-EN, Ro-EN, and En-Fr datasets, Garg et al. (2019), which is the state-of-the-art unsupervised method, only reported AER in their paper. We classified their method as unsupervised because they did not use manually created word alignment data. Their method used the GIZA++ output for supervision. For reference, we show the precision, recall, and AER of MGIZA (Zenkel et al., 2019)[9], the AER of

	Our method (only trained on sure)	97.7	93.9	-	**4.0**

Table 2: Best-effort comparison of proposed method with previous works

GIZA++ (Zenkel et al., 2020), as well as the accuracies of previous methods (Taskar et al., 2005; Haghighi et al., 2009; Zenkel et al., 2020) with the same datasets.

For training, we used both the sure and possible alignments for the De-En dataset, but we only used sure alignments for the En-Fr dataset because it is very noisy[10].

We used the scoring script provided by Zenkel et al. (2019). For the De-En, Ro-En, and En-Fr datasets, the AERs of the proposed method were 11.4, 12.2, and 4.0, which are significantly smaller than those of (Garg et al., 2019) and (Zenkel et al., 2020).

It is unfair to compare our supervised method with unsupervised methods. Our experiment's aim is to show that we have made supervised methods practical. We can train our model using a smaller amount of manually created data than the amount originally created for evaluation.

4 Analysis

4.1 Symmetrization Heuristics

To show the effectiveness of our proposed symmetrization heuristics (bidi-avg), Table 3 describes the word alignment accuracies of the predictions of two directions, intersection, unison, grow-diag-final, and bidi-avg.

The accuracies are greatly affected by the orthography of the target language. For languages whose words are not delimited by white spaces, such as Chinese and Japanese, the span prediction accuracy "to English" is significantly higher than that of "from English". In this case, grow-diag-final outperforms bidi-avg. By contract, for languages with spaces between words, such as Ger-

---

[10] In En-Fr data, all "phrasal correspondence" are annotated as possible alignments. For example, if a phrase with three words and a phrase with four words are regarded as mutual translations, 12 word alignments are marked as possible (Mihalcea and Pedersen, 2003). There are 4,038 sure alignments and 13,400 possible alignments in the En-Fr data (447 sentences). If our model is trained on both sure and possible, such numerous possible alignments function as noise, which results in low precision.

Test set	Method	P	R	F1
Zh-En	Zh to En	89.9	85.8	**87.8**
	En to Zh	82.0	81.8	81.9
	intersection	95.5	74.9	83.9
	union	79.4	92.7	85.5
	grow-diag-final	94.7	81.2	87.4
	bidi-avg	84.4	89.2	86.7
Ja-En	Ja to En	80.6	79.7	**80.2**
	En to Ja	61.9	69.0	65.2
	intersection	90.8	63.1	74.5
	union	60.8	85.6	71.1
	grow-diag-final	86.5	71.7	78.1
	bidi-avg	77.3	78.0	77.6
De-En	De to En	86.7	80.7	83.6
	En to De	87.0	82.1	84.5
	intersection	93.8	76.1	84.0
	union	81.5	86.7	84.0
	grow-diag-final	91.1	78.4	84.3
	bidi-avg	81.7	89.9	**85.6**
Ro-En	Ro to En	84.6	86.5	85.5
	En to Ro	87.2	86.3	86.7
	intersection	93.1	82.2	87.3
	union	80.2	90.6	85.0
	grow-diag-final	92.0	83.7	87.6
	bidi-avg	90.4	85.3	**87.8**
En-Fr	En to Fr	79.9	91.7	85.4
	Fr to En	79.5	91.3	85.0
	intersection	85.3	88.1	**86.7**
	union	75.2	94.9	83.9
	grow-diag-final	79.6	92.4	85.5
	bidi-avg	79.6	93.9	86.2

Table 3: Effects of symmetrization for various language pairs

man, Romanian, and French, no significant differences exist between the "to English" and "from English" accuracies. In this case, bidi-avg is better than grow-diag-final. In En-Fr, intersection achieves the best accuracy, probably because the dataset is very noisy. Since the proposed bidi-avg works relatively well for all cases, we used the heuristics as the default symmetrization method in our experiments.

4.2 Importance of Source Context

Table 4 shows the word alignment accuracies for questions of different source contexts. We used the Ja-En data and found that the source context information is critical for predicting the target span. Without it, the F1 score of the proposed method is 59.3, which is only slightly higher than that of GIZA++, 57.6. If we add a short context, namely, the two preceding words and the two following words, the F1 score is improved by more than 10 points to 72.0. If we use the whole source sentence as the context, the F1 score is improved by 5.6 points to 77.6.

Test set	Context	P	R	F1
Ja-En	no context	67.3	53.0	59.3
	±2 words	73.9	70.2	72.0
	whole sentence	77.3	78.0	77.6

Table 4: Importance of source context

Test set	# train	P	R	F1
Zh-En	300	80.9	78.4	79.6
	600	82.9	81.7	82.3
	1200	82.8	85.6	84.1
	2400	83.6	87.4	85.5
	4879	84.4	89.2	86.7

Table 5: Test set performance when trained on subsamples of Chinese gold word alignment data

It is nontrivial to obtain accurate alignments from a set of independently predicted spans. In preliminary experiments, we used Integer Linear Programming (ILP) to optimize the span predictions as in (DeNero and Klein, 2008). We found that using context is simple and more effective.

4.3 Learning Curve

Table5 shows the learning curve of the proposed method using the Zh-En data. Compared to previous methods, our method achieved higher accuracy using less training data. Even for 300 sentences, the F1 score of our method was 79.6, which is 6.2 points higher than that of (Stengel-Eskin et al., 2019) (73.4), which used more than 4800 sentences for training.

A supervised model trained on hand-aligned data must learn the idiosyncrasies of the annotation standard, which varies widely from language to language and across different annotation efforts. Our method allows us to fine-tune the specific peculiarities of the annotation standard using only a few hundred examples.

5 Related Works

For several years, word alignment methods using neural networks (Yang et al., 2013; Tamura et al., 2014; Legrand et al., 2016) failed to significantly outperform those using statistical methods (Brown et al., 1993; Vogel et al., 1996).

Recently, Stengel-Eskin et al. (2019) proposed a supervised method using a small amount of annotated data (1.7K-5K sentences) and significantly outperformed the accuracy of GIZA++. They first mapped the source and target word representations obtained from the encoder and decoder of the Transformer to a shared space using a three-layer feed-forward neural network. They then applied 3 × 3 convolution and softmax to obtain the alignment scores between the source and target words. They used 4M parallel sentences to pretrain the Transformer. We achieved significantly better accuracy than (Stengel-Eskin et al., 2019) with less annotated training data and no parallel sentences.

Garg et al. (2019) proposed an unsupervised method that jointly optimized translation and alignment objectives. They achieved a significantly better alignment error rate (AER) than GIZA++ when they supervised their model using the alignments obtained from GIZA++. Their model requires about a million parallel sentences for training the underlying Transformer. Zenkel et al. (2020) added an alignment layer on top of the Transformer, which uses full target context and a loss function to encourage contiguous alignment and bidirectional agreement. Their unsupervised end-to-end neural word alignment method consistently outperformed GIZA++. We experimentally showed that we can outperform previous unsupervised neural word alignment results with just 150 to 300 annotated sentences for training. Although it is not fair to compare unsupervised methods with supervised ones, our method is a practical option to obtain better word alignment results.

Ouyang and McKeown (2019) proposed a monolingual phrase alignment method that can align phrases of arbitrary lengths. Compared to our span prediction method, their method is inflexible because they first segmented the source and target sentences into chunks and used a pointer-network (Vinyals et al., 2015) to calculate the alignment scores between fixed chunks.

Cao et al. (2020) reported that multilingual BERT is somewhat aligned out-of-the-box, and proposed a method to align pretrained contextual word embeddings. Their method learns a function that maps aligned word pairs to similar representations, while our method implicitly learns a function that maps a word representation to its translation with both contexts.

6 Conclusion

We presented a novel supervised word alignment method using the multilingual BERT, which requires as few as 300 training sentences to outperform previous supervised and unsupervised methods. We made supervised word alignment practical because our method does not require any bitexts for pretraining, and it can be fine-tuned to a specific guideline using fewer gold word alignments.

Future works include using other multilingual pretraining models such as XLM-RoBERTa (Conneau et al., 2019) for a more accurate model and distilmBERT (Sanh et al., 2019) for a more compact model. One significant merit of framing word alignment as a SQuAD-style span prediction task is that we can easily import the progress of the latest question answering and multilingual language modeling technologies.

Our cross-language span prediction method can be used for any alignments between two sequences. We have already applied it to bilingual sentence alignment (Chousa et al., 2020) and we plan to extend it to other related problems.

Abstract

Despite its original goal to jointly learn to align and translate, prior researches suggest that Transformer captures poor word alignments through its attention mechanism. In this paper, we show that attention weights DO capture accurate word alignments and propose two novel word alignment induction methods SHIFT-ATT and SHIFT-AET. The main idea is to induce alignments at the step when the to-be-aligned target token is the decoder input rather than the decoder output as in previous work. SHIFT-ATT is an interpretation method that induces alignments from the attention weights of Transformer and does not require parameter update or architecture change. SHIFT-AET extracts alignments from an additional alignment module which is tightly integrated into Transformer and trained in isolation with supervision from symmetrized SHIFT-ATT alignments. Experiments on three publicly available datasets demonstrate that both methods perform better than their corresponding neural baselines and SHIFT-AET significantly outperforms GIZA++ by 1.4-4.8 AER points.[1]

1 Introduction

The task of word alignment is to find lexicon translation equivalents from parallel corpus (Brown et al., 1993). It is one of the fundamental tasks in natural language processing (NLP) and is widely studied by the community (Dyer et al., 2013; Brown et al., 1993; Liu and Sun, 2015). Word alignments are useful in many scenarios, such as error analysis (Ding et al., 2017; Li et al., 2019), the introduction of coverage and fertility models (Tu et al., 2016), inserting external constraints in interactive machine translation (Hasler et al., 2018; Chen et al., 2020) and providing guidance for human translators in computer-aided translation (Dagan et al., 1993).

Dec. output: i understand this . <eos>

Figure 1: An example to compare our method SHIFT-ATT and the baseline NAIVE-ATT. The left is an attention map from the third decoder layer of the vanilla Transformer and the right are the induced alignments. SHIFT-ATT induces alignments for target word y_i at decoding step $i+1$ when y_i is the decoder input, while NAIVE-ATT at step i when y_i is the decoder output.

Word alignment is part of the pipeline in statistical machine translation (Koehn et al., 2003, SMT), but is not necessarily needed for neural machine translation (Bahdanau et al., 2015, NMT). The attention mechanism in NMT does not functionally play the role of word alignments between the source and the target, at least not in the same way as its analog in SMT. It is hard to interpret the attention activations and extract meaningful word alignments especially from Transformer (Garg et al., 2019). As a result, the most widely used word alignment tools are still external statistical models such as FAST-ALIGN (Dyer et al., 2013) and GIZA++ (Brown et al., 1993; Och and Ney, 2003).

November 16–20, 2020.

Recently, there is a resurgence of interest in the community to study word alignments for the Transformer (Ding et al., 2019; Li et al., 2019). One simple solution is NAIVE-ATT, which induces word alignments from the attention weights between the encoder and decoder. The next target word is aligned with the source word that has the maximum attention weight, as shown in Fig. 1. However, such schedule only captures noisy word alignments (Ding et al., 2019; Garg et al., 2019). One of the major problems is that it induces alignment before observing the to-be-aligned target token (Peter et al., 2017; Ding et al., 2019). Suppose for the same source sentence, there are two alternative translations that diverge at decoding step i, generating y_i and y'_i which respectively correspond to different source words. Presumably, the source word that is aligned to y_i and y'_i should change correspondingly. However, this is not possible under the above method, because the alignment scores are computed before prediction of y_i or y'_i.

To alleviate this problem, some researchers modify the transformer architecture by adding alignment modules that predict the to-be-aligned target token (Zenkel et al., 2019, 2020) or modify the training loss by designing an alignment loss computed with full target sentence (Garg et al., 2019; Zenkel et al., 2020). Others argue that using only attention weights is insufficient for generating clean word alignment and propose to induce alignments with feature importance measures, such as leave-one-out measures (Li et al., 2019) and gradient-based measures (Ding et al., 2019). However, all previous work induces alignment for target word y_i at step i, when y_i is the decoder output.

In this work, we propose to induce alignment for target word y_i at step $i+1$ rather than at step i as in previous work. The motivation behind this is that the hidden states in step $i+1$ are computed taking word y_i as the input, thus they can incorporate the information of the to-be-aligned target token y_i easily. Following this idea, we present SHIFT-ATT and SHIFT-AET, two simple yet effective methods for word alignment induction. Our contributions are threefold:

- We introduce SHIFT-ATT (see Fig. 1), a pure interpretation method to induce alignments from attention weights of vanilla Transformer. SHIFT-ATT is able to reduce the Alignment Error Rate (AER) by 7.0-10.2 points over NAIVE-ATT and 5.5-7.9 points over FAST-ALIGN on three publicly available datasets, demonstrating that if the correct decoding step and layer are chosen, attention weights in vanilla Transformer are **sufficient** for generating accurate word alignment interpretation.
- We further propose SHIFT-AET , which extracts alignments from an additional alignment module. The module is tightly integrated into vanilla Transformer and trained with supervision from symmetrized SHIFT-ATT alignments. SHIFT-AET does not affect the translation accuracy and significantly outperforms GIZA++ by 1.4-4.8 AER points in our experiments.
- We compare our methods with NAIVE-ATT on dictionary-guided decoding (Alkhouli et al., 2018), an alignment-related downstream task. Both methods consistently outperform NAIVE-ATT, demonstrating the effectiveness of our methods in such alignment-related NLP tasks.

2 Background

2.1 Neural Machine Translation

Let $\mathbf{x} = \{x_1, ..., x_{|\mathbf{x}|}\}$ and $\mathbf{y} = \{y_1, ..., y_{|\mathbf{y}|}\}$ be source and target sentences. Neural machine translation models the target sentence given the source sentence as $p(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta})$:

$$p(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}) = \prod_{t=1}^{|\mathbf{y}|+1} p(y_t|y_{0:t-1}, \mathbf{x}; \boldsymbol{\theta}), \tag{1}$$

where $y_0 = \langle \text{bos} \rangle$ and $y_{|\mathbf{y}|+1} = \langle \text{eos} \rangle$ represent the beginning and end of the target sentence respectively, and $\boldsymbol{\theta}$ is a set of model parameters.

In this paper, we use Transformer (Vaswani et al., 2017) to implement the NMT model. Transformer is an encoder-decoder model that only relies on attention. Each decoder layer attends to the encoder output with multi-head attention. We refer to the original paper (Vaswani et al., 2017) for more model details.

2.2 Alignment by Attention

The encoder output from the last encoder layer is denoted as $\mathbf{h} = \{h_1, ..., h_{|\mathbf{x}|}\}$, and the hidden states at decoder layer l as $\mathbf{z} = \{z_1^l, ..., z_{|\mathbf{y}|+1}^l\}$. For decoder layer l, we define the head averaged encoder-decoder attention weights as $\boldsymbol{W}^l \in \mathbb{R}^{(|\mathbf{y}|+1)\times|\mathbf{x}|}$, in which the element $W_{i,j}^l$ measures the relevance between decoder hidden state z_i^l and encoder output h_j. For simplicity, below we use the term "attention weights" to denote the head averaged encoder-decoder attention weights.

Given a trained Transformer model, word alignments can be extracted from the attention weights. More specifically, we denote the alignment score matrix as $\boldsymbol{S} \in \mathbb{R}^{|\mathbf{y}|\times|\mathbf{x}|}$, in which the element $S_{i,j}$ is the alignment score of target word y_i and source word x_j. Then we compute $\boldsymbol{S}$ with:

$$S_{i,j} = W^l_{i,j} \quad (1 \le i \le |\mathbf{y}|, 1 \le j \le |\mathbf{x}|) \tag{2}$$

and extract word alignments $\boldsymbol{A}$ with maximum a posterior strategy following Garg et al. (2019):

$$A_{ij} = \begin{cases} 1 & \text{if } j = \text{argmax}_{j'} S_{i,j'} \\ 0 & \text{otherwise} \end{cases}, \tag{3}$$

where $A_{ij} = 1$ indicates y_i is aligned to x_j. We call this approach NAIVE-ATT. Garg et al. (2019) show that attention weights from the penultimate layer, i.e., $l = L - 1$, can induce the best alignments.

Although simple to implement, this method fails to obtain satisfactory word alignments (Ding et al., 2019; Garg et al., 2019). First of all, instead of the relevance between y_i and x_j, $W^l_{i,j}$ measures the relevance between decoder hidden state z^l_i and encoder output h_j. Considering that the decoder input is y_{i-1} and the output is y_i at step i, z^l_i may better represent y_{i-1} instead of y_i, especially for bottom layers. Second, since $W^l_{i,j}$ is computed before observing y_i, it becomes difficult for it to induce the aligned source token for the target token y_i, as discussed in Section 1.

As a result, it is necessary to develop novel methods for alignment induction. This method should be able to (i) take into account the relationship of z^l_i, y_i and y_{i-1}, and (ii) adapt the alignment induction with the to-be-aligned target token.

3 Method

In this section, we propose two novel alignment induction methods SHIFT-ATT and SHIFT-AET. Both methods adapt the alignment induction with the to-be-aligned target token by computing alignment scores at the step when the target token is the decoder input.

3.1 SHIFT-ATT: Alignment from Vanilla Transformer

Alignment Induction NAIVE-ATT (Garg et al., 2019) induces alignment for target token y_i at step i when y_i is the decoder output and defines the alignment score matrix with Eq. 2. They find the best layer l to extract alignments by evaluating the AER of all layers on the test set.

We instead propose to induce alignment for target token y_i at step $i + 1$ when y_i is the decoder input. We define the alignment score matrix $\boldsymbol{S}$ as:

$$S_{i,j} = W^l_{i+1,j} \quad (1 \le i \le |\mathbf{y}|, 1 \le j \le |\mathbf{x}|). \tag{4}$$

This is because $W^l_{i+1,j}$ measures the relevance between z^l_{i+1} and h_j, and we use z^l_{i+1} and h_j to represent y_i and x_j respectively. With the alignment score matrix $\boldsymbol{S}$, we can extract word alignments $\boldsymbol{A}$ using Eq. 3. We call this method SHIFT-ATT. Fig. 1 shows an alignment induction example to compare NAIVE-ATT and SHIFT-ATT.

SHIFT-ATT uses z^l_{i+1} to represent the to-be-aligned target token y_i while NAIVE-ATT uses z^l_i. We argue using z^l_{i+1} is better. First, at bottom layers, we hypothesize that z^l_{i+1} could better represent the decoder input y_i than output y_{i+1}. Therefore we can use z^l_{i+1} with small l to represent y_i. Second, z^l_{i+1} is computed after observing y_i, indicating that SHIFT-ATT is able to adapt the alignment induction with the to-be-aligned target token.

Our proposed method involves inducing alignments from source-to-target and target-to-source vanilla Transformer models. Following Zenkel et al. (2019), we merge bidirectional alignments using the grow diagonal heuristic (Koehn et al., 2005).

Layer Selection Criterion To select the best layer l_b to induce alignments, we propose a surrogate layer selection criterion without manually labelled word alignments. Experiments show that this criterion correlates well with the AER metric.

Given parallel sentence pairs $\langle \mathbf{x}, \mathbf{y} \rangle$, we train a source-to-target model $\boldsymbol{\theta}_{\mathbf{x}\rightarrow\mathbf{y}}$ and a target-to-source model $\boldsymbol{\theta}_{\mathbf{y}\rightarrow\mathbf{x}}$. We assume that the word alignments extracted from these two models should agree with each other (Cheng et al., 2016). Therefore, we evaluate the quality of the alignments by computing the AER score on the validation set with the source-to-target alignments as the hypothesis and the target-to-source alignments as the reference. For each model, we can obtain L word alignments from L different layers. In total, we obtain $L \times L$ AER scores. We select the one with the lowest AER score, and its corresponding layers of the source-to-target and target-to-source models are the layers we will use to extract alignments at test time:

$$l_{\mathrm{b},\mathbf{x}\rightarrow\mathbf{y}}, l_{\mathrm{b},\mathbf{y}\rightarrow\mathbf{x}} = \underset{i,j}{\text{argmin}}\, \text{AER}(\boldsymbol{A}^i_{\mathbf{x}\rightarrow\mathbf{y}}, \boldsymbol{A}^j_{\mathbf{y}\rightarrow\mathbf{x}}).$$

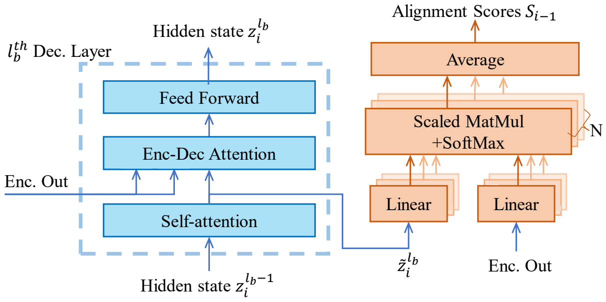

Figure 2: Illustration of the alignment module at decoding step i. The decoder input token is y_{i-1}, while the output token is y_i. The alignment module predicts S_{i-1}, the alignment scores corresponding to the input target token y_{i-1}. During the alignment module training process, parameters of the blue blocks are frozen, and only parameters of the orange blocks are updated.

3.2 SHIFT-AET: Alignment from Alignment-Enhanced Transformer

To further improve the alignment accuracy, we propose SHIFT-AET, a word alignment induction method that extracts alignments from Alignment-Enhanced Transformer (AET). AET extends the Transformer architecture with a separate alignment module, which observes the hidden states of the underlying Transformer at each step and predicts the alignment scores for the current decoder **input**. Note that this module is a plug and play component and it neither makes any change to the underlying NMT model nor influences the translation quality.

Fig. 2 illustrates the alignment module of AET at decoding step i. We add the alignment module only at layer l_b, the best layer to extract alignments with SHIFT-ATT. The alignment module performs multi-head attention similar to the encoder-decoder attention sublayer. It takes the encoder outputs $\mathbf{h} = \{h_1, ..., h_{|\mathbf{x}|}\}$ and the current decoder hidden state $\tilde{z}_i^{l_b}$ inside layer l_b as input and outputs S_{i-1}, the alignment score corresponding to target word y_{i-1}:

$$S_{i-1} = \frac{1}{N}\sum_{n} \text{softmax}\Big(\frac{(\mathbf{h}\boldsymbol{G}_n^K)(\tilde{z}_i^{l_b}\boldsymbol{G}_n^Q)^\top}{\sqrt{d_k}}\Big), \tag{5}$$

where $\boldsymbol{G}_n^K, \boldsymbol{G}_n^Q \in \mathbb{R}^{d_{\text{model}} \times d_k}$ are the key and query projection matrices for the n-th head, N is the number of attention heads and $d_k = d_{\text{model}}/N$. Since we only care about the attention weights, the value-related parameters and computation are omitted in this module.

Dataset	Train	Validation	Test
de-en	1.9M	994	508
fr-en	1.1M	1,000	447
ro-en	0.5M	999	248

Table 1: Number of sentences in each dataset.

To train the alignment module, we use the symmetrized SHIFT-ATT alignments extracted from vanilla Transformer models as labels. Specifically, while the underlying Transformer is pretrained and fixed (Fig. 2), we train the alignment module with the loss function following Garg et al. (2019):

$$\mathcal{L}_a = -\frac{1}{|\mathbf{y}|}\sum_{i=1}^{|\mathbf{y}|}\sum_{j=1}^{|\mathbf{x}|}(\hat{A}^p_{i,j} \odot \log S_{i,j}), \tag{6}$$

where $\boldsymbol{S} = \{S_1;...;S_{|\mathbf{y}|}\}$ is the alignment score matrix predicted by the alignment module, and $\hat{\boldsymbol{A}}^p$ denotes the normalized reference symmetrized SHIFT-ATT alignments.[2] In this way, we transfer the alignment knowledge implicitly learned in two vanilla Transformer models $\boldsymbol{\theta}_{\mathbf{x}\to\mathbf{y}}$ and $\boldsymbol{\theta}_{\mathbf{y}\to\mathbf{x}}$ into the alignment module of a single AET model.

Once the alignment module is trained, we extract alignment scores $\boldsymbol{S}$ from it given a parallel sentence pair and induce alignments $\boldsymbol{A}$ using Eq. 3.

4 Experiments

4.1 Settings

Dataset We follow previous work (Zenkel et al., 2019, 2020) in data setup and conduct experiments on publicly available datasets for German-English (de-en)[3], Romanian-English (ro-en) and French-English (fr-en)[4]. Since no validation set is provided, we follow Ding et al. (2019) to set the last 1,000 sentences of the training data before preprocessing as validation set. We learn a joint source and target Byte-Pair-Encoding (Sennrich et al., 2016) with 10k merge operations. Table 1 shows the detailed data statistics.

NMT Systems We implement the Transformer with fairseq-py[5] and use the `transformer_iwslt_de_en` model configuration following Ding et al. (2019). We train the models with a batch size of 36K tokens and set the maximum updates as 50K and 10K for

---

[2] We simply normalize rows corresponding to target tokens that are aligned to at least one source token of $\hat{\boldsymbol{A}}$.

Table 2: AER on the test set with different alignment methods. *bidir* are symmetrized alignment results. The column Inter. represents whether the method is an interpretation method that can extract alignments from a pretrained vanilla Transformer model. The column Fullc denotes whether full target sentence is used to extract alignments at test time. The lower AER, the better. We mark best symmetrized interpretation results of vanilla Transformer with underlines, and best symmetrized results among all with boldface.

Transformer and AET respectively. The last checkpoint of AET is used for evaluation. All models are trained in both translation directions and symmetrized with *grow-diag* (Koehn et al., 2005) using the script from Zenkel et al. (2019).[6]

Evaluation We evaluate the alignment quality of our methods with Alignment Error Rate (Och and Ney, 2000, AER). Since word alignments are useful for many downstream tasks as discussed in Section 1, we also evaluate our methods on dictionary-guided decoding, a downstream task of alignment induction, with the metric BLEU (Papineni et al., 2002). More details are in Section 4.3.

Baselines We compare our methods with two statistical baselines FAST-ALIGN and GIZA++ and nine other baselines:

- NAIVE-ATT (Garg et al., 2019): the approach we discuss in Section 2.2, which induces alignments from the attention weights of the penultimate layer of the Transformer.
- NAIVE-ATT-LA (Garg et al., 2019): the NAIVE-ATT method without layer selection. It induces alignments from attention weights averaged across all layers.
- SHIFT-ATT-LA: SHIFT-ATT method without layer selection. It induces alignments from attention weights averaged across all layers.
- SMOOTHGRAD (Li et al., 2016): the method that induces alignments from word saliency, which is computed by averaging the gradient-based saliency scores with multiple noisy sentence pairs as input.
- SD-SMOOTHGRAD (Ding et al., 2019): an improved version of SMOOTHGRAD, which defines saliency on one-hot input vector instead of word embedding.
- PD (Li et al., 2019): the method that computes the alignment scores from Transformer by iteratively masking each source token and measuring the prediction difference.
- ADDSGD (Zenkel et al., 2019): the method that explicitly adds an extra attention layer on top of Transformer and directly optimizes its activations towards predicting the to-be-aligned target token.
- MTL-FULLC (Garg et al., 2019): the method that trains a single model in a multi-task learning framework to both predict the target sentence and the alignment. When predicting the alignment, the model observes full target sentence and uses symmetrized NAIVE-ATT alignments as labels.
- MTL-FULLC-GZ (Garg et al., 2019): the same method as MTL-FULLC except using symmetrized GIZA++ alignments as labels. It is a statistical and neural method as it relies on GIZA++ alignments.

Among these nine baselines and our proposed methods, SMOOTHGRAD, SD-SMOOTHGRAD and PD induce alignments using feature importance measures, while the others from some form of attention weights. Note that the computation

---

[6] `https://github.com/lilt/alignment-scripts`

cost of methods with feature importance measures is much higher than those with attention weights.[7]

4.2 Alignment Results

Comparison with Baselines Table 2 compares our methods with all the baselines. First, SHIFT-ATT, a pure interpretation method for the vanilla Transformer, significantly outperforms FAST-ALIGN and all neural baselines, and performs comparable with GIZA++. For example, it outperforms SD-SMOOTHGRAD, the state-of-the-art method with feature importance measures to extract alignments from vanilla Transformer, by 8.7-11.1 AER points across different language pairs. The success of SHIFT-ATT demonstrates that vanilla Transformer has captured alignment information in an implicit way, which could be revealed from the attention weights if the correct decoding step and layer are chosen to induce alignments.

Second, the method SHIFT-AET achieves new state-of-the-art, significantly outperforming all baselines. It improves over GIZA++ by 1.4-4.8 AER across different language pairs, demonstrating that it is possible to build a neural aligner better than GIZA++ without using any alignments generated from statistical aligners to bootstrap training. We also find SHIFT-AET performs either marginally better (de-en and ro-en) or on-par (fr-en) when comparing with MTL-FULLC-GZ, a method that uses GIZA++ alignments to bootstrap training. We evaluate the model sizes: the number of parameters in vanilla Transformer and AET are 36.8M and 37.3M respectively, and find that AET only introduces 1.4% additional parameters to the vanilla Transformer. In summary, by supervising the alignment module with symmetrized SHIFT-ATT alignments, SHIFT-AET improves over SHIFT-ATT and GIZA++ with negligible parameter increase and without influencing the translation quality.

Comparison with Zenkel et al. (2020) Concurrent with our work, Zenkel et al. (2020) propose a neural aligner that can outperform GIZA++. Table 3 compares the performance of SHIFT-AET and the best method BAO-GUIDED (Birdir. Att. Opt. + Guided) in Zenkel et al. (2020). We observe that SHIFT-AET performs better than BAO-GUIDED in terms of alignment accuracy.

Method	de-en	fr-en	ro-en
BAO-GUIDED	16.3	5.0	23.4
SHIFT-AET	**15.4**	**4.7**	**21.2**

Table 3: Comparison of our method SHIFT-AET with BAO-GUIDED (Zenkel et al., 2020). We report the symmetrized AER on the test set.

Direction	zh→en	en→zh	bidir
GIZA++	19.6	23.3	18.5
NAIVE-ATT	36.9	40.3	28.9
SHIFT-ATT	28.1	27.3	20.2
SHIFT-AET	20.1	22.0	**17.2**

Table 4: AER on the test set of zh-en. *bidir* are symmetrized alignment results.

SHIFT-AET is also much simpler than BAO-GUIDED. The training of BAO-GUIDED includes three stages: (i) train vanilla Transformer in source-to-target and target-to-source directions; (ii) train the alignment layer and extract alignments on the training set with bidirectional attention optimization. This alignment extraction process is computational costly since bidirectional attention optimization fine-tunes the model parameters separately for each sentence pair in the training set; (iii) re-train the alignment layer with the extracted alignments as the guidance. In contrast, SHIFT-AET can be trained much faster in two stages and does not involve bidirectional attention optimization.

Similar with MTL-FULLC (Garg et al., 2019), BAO-GUIDED adapts the alignment induction with the to-be-aligned target token by requiring full target sentence as the input. Therefore, BAO-GUIDED is not applicable in cases where alignments are incrementally computed during the decoding process, e.g., dictionary-guided decoding (Alkhouli et al., 2018). In contrast, SHIFT-AET performs quite well on such cases (Section 4.3). Therefore, considering the alignment performance, computation cost and applicable scope, we believe SHIFT-AET is more appropriate than BAO-GUIDED for the task of alignment induction.

Performance on Distant Language Pair To further demonstrate the superiority of our methods on distant language pairs, we also evaluate our methods on Chinese-English (zh-en). We use NIST corpora[8] as the training set and v1-tstset released by TsinghuaAligner (Liu and Sun, 2015) as the test

---

[7] For each sentence pair, PD forwards once with $|\mathbf{x}| + 1$ masked sentence pairs as the input, while SMOOTHGRAD and SD-SMOOTHGRAD forward and backward once with m ($m = 30$ in Ding et al. (2019)) noisy sentence pairs as the input. In contrast, attention weights based methods forward once with one sentence pair as the input.

[8] The corpora include LDC2002E18, LDC2003E07, LDC2003E14, LDC2004T07, LDC2004T08 and LDC2005T06

Task	Naive-Att	Shift-Att	Shift-AET
de→en	33.7	34.3*	**34.8***
en→de	26.5	26.8	**28.0***

Table 5: Comparison of dictionary-guided decoding with different alignment methods. We report BLEU scores on the test set. Without dictionary-guided decoding, we obtain 32.3 and 24.2 BLEU on de→en and en→de translations respectively. "*" indicates the result is significantly better than that of Naive-Att ($p<0.05$). All significance tests are measured by paired bootstrap resampling (Koehn, 2004)

set. The test set includes 450 parallel sentence pairs with manually labelled word alignments.[9] We use *jieba*[10] for Chinese text segmentation and follow the settings in Section 4.1 for data pre-processing and model training. The results are shown in Table 4. It presents that both Shift-Att and Shift-AET outperform Naive-Att to a large margin. When comparing the symmetrized alignment performance with GIZA++, Shift-AET performs better, while Shift-Att is worse. The experimental results are roughly consistent with the observations on other language pairs, demonstrating the effectiveness of our methods even for distant language pairs.

4.3 Downstream Task Results

In addition to AER, we compare the performance of Naive-Att, Shift-Att and Shift-AET on dictionary-guided machine translation (Song et al., 2020), which is an alignment-based downstream task. Given source and target constraint pairs from dictionary, the NMT model is encouraged to translate with provided constraints via word alignments (Alkhouli et al., 2018; Hasler et al., 2018; Hokamp and Liu, 2017; Song et al., 2020). More specifically, at each decoding step, the last token of the candidate translation will be revised with target constraint if it is aligned to the corresponding source constraint according to the alignment induction method. To simulate the process of looking up dictionary, we follow Hasler et al. (2018) and extract the pre-specified constraints from the test set and its reference according to the golden word alignments. We exclude stop words, and sample up to 3 dictionary constraints per sentence. Each dictionary constraint includes up to 3 source tokens.

(a) Validation AER for Layer Selection

de→en / en→de	1	2	3	4	5	6
1	42.2	35.4	35.7	67.5	89.2	88.8
2	45.1	39.5	39.1	67.1	87.8	88.2
3	42.5	34.6	**34.2**	65.2	87.4	87.6
4	74.4	73.0	72.3	80.6	89.5	89.7
5	84.8	86.7	86.1	87.3	88.7	88.9
6	87.1	88.2	87.6	88.1	88.7	88.6

(b) Test AER for Verification

layer	1	2	3	4	5	6
de→en	31.5	22.7	**20.9**	55.7	80.5	81.5
en→de	27.4	31.3	**25.7**	68.5	83.4	85.1

Table 6: Layer selection criterion verification with Shift-Att on de-en alignment. (a) For each cell, we induce hypothesis alignment from de→en translation and reference alignment from en→de translation. $l_{\mathrm{b}} = 3$ for both translation directions in this table. (b) Test AER when inducing alignments from different layers. Layer 3 induces the best alignment for both translation directions, which verifies l_{b} selected in (a).

Table 5 presents the performance with different alignment methods. Both Shift-Att and Shift-AET outperform Naive-Att. Shift-AET obtains the best translation quality, improving over Naive-Att by 1.1 and 1.5 BLEU scores on de→en and en→de translations, respectively. The results suggest the effectiveness of our methods in application to alignment-related NLP tasks.

4.4 Analysis

Layer Selection Criterion To test whether the layer selection criterion can select the right layer to extract alignments, we first determine the best layer $l_{\mathrm{b},\mathbf{x}\rightarrow\mathbf{y}}$ and $l_{\mathrm{b},\mathbf{y}\rightarrow\mathbf{x}}$ based on the layer selection criterion. Then we evaluate the AER scores of alignments induced from different layers on the test set, and check whether the layers with the lowest AER score are consistent with $l_{\mathrm{b},\mathbf{x}\rightarrow\mathbf{y}}$ and $l_{\mathrm{b},\mathbf{y}\rightarrow\mathbf{x}}$. The experiment results shown in Table 6 verify that the layer selection criterion is able to select the best layer to induce alignments. We also find that the best layer is always layer 3 under our setting, consistent across different language pairs.

Relevance Measure Verification To investigate the relationship between z_i^l and y_{i-1}/y_i, we design an experiment to probe whether z_i^l contain the identity information of y_{i-1} and y_i, following Brunner et al. (2019). Formally, for decoder hidden state z_i^l, the input token is identifiable if there exists a func-

---

[9] TsinghuaAligner labels the word alignments based on segmented Chinese sentences and does not provide the segmentation model. Therefore, we convert the manually labelled word alignments to our segmented Chinese sentences for evaluation.

[10] `https://github.com/fxsjy/jieba`

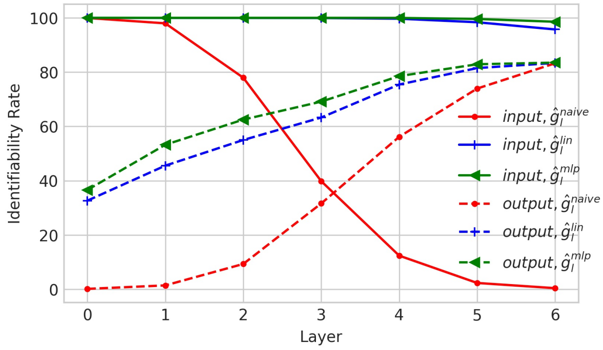

Figure 3: Identifiability rate of the input and output tokens for decoder hidden states at different layers.

tion g such that $y_{i-1} = g(z_i^l)$. We cannot prove the existence of g analytically. Instead, for each layer l we learn a projection function $\hat{g}_l$ to project from the hidden state space to the input token embedding space $\hat{y}_i^l = \hat{g}_l(z_i^l)$ and then search for the nearest neighbour y_k within the same sentence. We say that z_i^l can identify y_{i-1} if $k = i - 1$. Similarly, we follow the same process to identify the output token y_i. We report the identifiability rate defined as the percentage of correctly identified tokens.

Fig. 3 presents the results on the validation set of de→en translation. We try three projection functions: a naive baseline $\hat{g}_l^{\text{naive}}(z_i^l) = z_i^l$, a linear perceptron $\hat{g}_l^{\text{lin}}$ and a non-linear multi-layer perceptron $\hat{g}_l^{\text{mlp}}$. We observe the following points: (i) With trainable projection functions $\hat{g}_l^{\text{lin}}$ and $\hat{g}_l^{\text{mlp}}$, all layers can identify the input tokens, although more hidden states cannot be mapped back to their input tokens anymore in higher layers. (ii) Overall it is easier to identify the input token than the output token. For example, when projecting with mlp, all layers can identify more than 98% of the input tokens. However, for the output tokens, we can only identify 83.5% even from the best layer. Since z_i^l even may not be able to identify y_i, this observation partially verifies that it is better to represent y_i using z_{i+1}^l than z_i^l. (iii) At bottom layers, the input tokens remain identifiable and the output tokens are hard to identify, regardless of the projection function we use. This confirms our hypothesis that for small l, z_i^l is more relevant to y_{i-1} than y_i.

AER v.s. BLEU During training, vanilla Transformer gradually learns to align and translate. To analyze how the alignment behavior changes at different layers with checkpoints of different translation quality, we plot AER on the test set v.s. BLEU on the validation set for de→en translation. We compare NAIVE-ATT and SHIFT-ATT, which align the decoder output token (*align output*) and decoder input token (*align input*) to the source tokens based on current decoder hidden state, respectively.

The experiment results are shown in Fig. 4. We observe that at the beginning of training, layers 3 and 4 learn to align the input token, while layers 5 and 6 the output token. However, with the increasing of BLEU score, layer 4 tends to change from aligning input token to aligning output token, and layer 1 and 2 begin to align input token. This suggests that vanilla Transformer gradually learns to align the input token from middle layers to bottom layers. We also see that at the end of training, layer 6's ability to align output token decreases. We hypothesize that layer 5 already has the ability to attend to the source tokens which are aligned to the output token, therefore attention weights in layer 6 may capture other information needed for translation. Finally, for checkpoints with the highest BLEU score, layer 5 aligns the output token best and layer 3 aligns the input token best.

Alignment Example In Fig. 5, we present a symmetrized alignment example from de-en test set. Manual inspection of this example as well as others finds that our methods SHIFT-ATT and SHIFT-AET tend to extract more alignment pairs than GIZA++, and extract better alignments especially for sentence beginning compared to NAIVE-ATT.

5 Related Work

Alignment induction from RNNSearch (Bahdanau et al., 2015) has been explored by a number of works. Bahdanau et al. (2015) are the first to show word alignment example using attention in RNNSearch. Ghader and Monz (2017) further demonstrate that the RNN-based NMT system achieves comparable alignment performance to that of GIZA++. Alignment has also been used to improve NMT performance, especially in low resource settings, by supervising the attention mechanisms of RNNSearch (Chen et al., 2016; Liu et al., 2016; Alkhouli and Ney, 2017).

There is also a number of other studies that induce word alignment from Transformer. Li et al. (2019); Ding et al. (2019) claim that attention may not capture word alignment in Transformer, and propose to induce word alignment with prediction difference (Li et al., 2019) or gradient-based measures (Ding et al., 2019). Zenkel et al. (2019) modify the Transformer architecture for better align-

ment induction by adding an extra alignment module that is restricted to attend solely on the encoder information to predict the next word. Garg et al. (2019) propose a multi-task learning framework to improve word alignment induction without decreasing translation quality, by supervising one attention head at the penultimate layer with GIZA++ alignments. Although these methods are reported to improve over head average baseline, they ignore that better alignments can be induced by computing alignment scores at the decoding step when the to-be-aligned target token is the decoder input.

6 Conclusion

In this paper, we have presented two novel methods SHIFT-ATT and SHIFT-AET for word alignment induction. Both methods induce alignments at the step when the to-be-aligned target token is the decoder input rather than the decoder output as in previous work. Experiments on three public alignment datasets and a downstream task prove the effectiveness of these two methods. SHIFT-AET further extends Transformer with an additional alignment module, which consistently outperforms prior neural aligners and GIZA++, without influencing the translation quality. To the best of our knowledge, it reaches the new state-of-the-art performance among all neural alignment induction methods. We leave it for future work to extend our study to more downstream tasks and systems.

ChrEn: Cherokee-English Machine Translation for Endangered Language Revitalization

Shiyue Zhang **Benjamin Frey** **Mohit Bansal**
UNC Chapel Hill
`{shiyue, mbansal}@cs.unc.edu`; `benfrey@email.unc.edu`

Abstract

Cherokee is a highly endangered Native American language spoken by the Cherokee people. The Cherokee culture is deeply embedded in its language. However, there are approximately only 2,000 fluent first language Cherokee speakers remaining in the world, and the number is declining every year. To help save this endangered language, we introduce *ChrEn*, a Cherokee-English parallel dataset, to facilitate machine translation research between Cherokee and English. Compared to some popular machine translation language pairs, ChrEn is extremely low-resource, only containing 14k sentence pairs in total. We split our parallel data in ways that facilitate both in-domain and out-of-domain evaluation. We also collect 5k Cherokee monolingual data to enable semi-supervised learning. Besides these datasets, we propose several Cherokee-English and English-Cherokee machine translation systems. We compare SMT (phrase-based) versus NMT (RNN-based and Transformer-based) systems; supervised versus semi-supervised (via language model, back-translation, and BERT/Multilingual-BERT) methods; as well as transfer learning versus multilingual joint training with 4 other languages. Our best results are 15.8/12.7 BLEU for in-domain and 6.5/5.0 BLEU for out-of-domain Chr-En/En-Chr translations, respectively, and we hope that our dataset and systems will encourage future work by the community for Cherokee language revitalization.[1]

1 Introduction

The Cherokee people are one of the indigenous peoples of the United States. Before the 1600s, they lived in what is now the southeastern United States (Peake Raymond, 2008). Today, there are three federally recognized nations of Cherokee people: the Eastern Band of Cherokee Indians (EBCI), the United Keetoowah Band of Cherokee Indians (UKB), and the Cherokee Nation (CN). The Cherokee language, the language spoken by the Cherokee people, contributed to the survival of the Cherokee people and was historically the basic medium of transmission of arts, literature, traditions, and values (Nation, 2001; Peake Raymond, 2008). However, according to the Tri-Council Res. No. 02-2019, there are only 2,000 fluent first language Cherokee speakers left, and each Cherokee tribe is losing fluent speakers at faster rates than new speakers are developed. UNESCO has identified the dialect of Cherokee in Oklahoma is "definitely endangered", and the one in North Carolina is "severely endangered". Language loss is the loss of culture. CN started a 10-year language revitalization plan (Nation, 2001) in 2008, and the Tri-Council of Cherokee tribes declared a state of emergency in 2019 to save this dying language.

To revitalize Cherokee, language immersion programs are provided in elementary schools, and second language programs are offered in universities. However, students have difficulty finding exposure to this language beyond school hours (Albee, 2017). This motivates us to build up English (En) to Cherokee (Chr) machine translation systems so that we could automatically translate or aid human translators to translate English materials to Cherokee. Chr-to-En is also highly meaningful in helping spread Cherokee history and culture. Therefore, in this paper, we contribute our effort

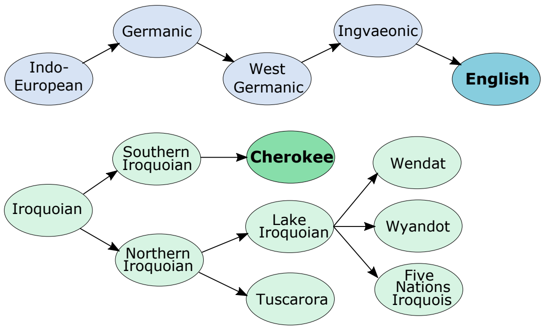

Figure 1: Language family trees.

to Cherokee revitalization by constructing a clean **Cher**okee-**En**glish parallel dataset, **ChrEn**, which results in 14,151 pairs of sentences with around 313K English tokens and 206K Cherokee tokens. We also collect 5,210 Cherokee monolingual sentences with 93K Cherokee tokens. Both datasets are derived from bilingual or monolingual materials that are translated or written by first-language Cherokee speakers, then we manually aligned and cleaned the raw data.[2] Our datasets contain texts of two Cherokee dialects (Oklahoma and North Carolina), and diverse text types (e.g., sacred text, news). To facilitate the development of machine translation systems, we split our parallel data into five subsets: Train/Dev/Test/Out-dev/Out-test, in which Dev/Test and Out-dev/Out-test are for in-domain and out-of-domain evaluation respectively. See an example from *ChrEn* in Table 1 and the detailed dataset description in Section 3.

The translation between Cherokee and English is not easy because the two languages are genealogically disparate. As shown in Figure 1, Cherokee is the sole member of the southern branch of the Iroquoian language family and is unintelligible to other Iroquoian languages, while English is from the West Germanic branch of the Indo-European language family. Cherokee uses a unique 85-character syllabary invented by Sequoyah in the early 1820s, which is highly different from English's alphabetic writing system. Cherokee is a polysynthetic language, meaning that words are composed of many morphemes that each have independent meanings. A single Cherokee word can express the meaning of several English words, e.g., ᏫᏓᏥᏁᎩᏏ (widatsinegisi), or *I am going off at a distance to get a liquid object*. Since the semantics are often conveyed by the rich morphology, the word orders of Cherokee sentences are variable. There is no "basic word order" in Cherokee, and most word orders are possible (Montgomery-Anderson, 2008), while English generally follows the Subject-Verb-Object (SVO) word order. Plus, verbs comprise 75% of Cherokee, which is only 25% for English (Feeling, 1975, 1994).

Hence, to develop translation systems for this low-resource and distant language pair, we investigate various machine translation paradigms and propose phrase-based (Koehn et al., 2003) Statistical Machine Translation (SMT) and RNN-based (Luong et al., 2015) or Transformer-based (Vaswani et al., 2017) Neural Machine Translation (NMT) systems for both Chr-En and En-Chr translations, as important starting points for future works. We apply three semi-supervised methods: using additional monolingual data to train the language model for SMT (Koehn and Knowles, 2017); incorporating BERT (or Multilingual-BERT) (Devlin et al., 2019) representations for NMT (Zhu et al., 2020), where we introduce four different ways to use BERT; and the back-translation method for both SMT and NMT (Bertoldi and Federico, 2009; Lambert et al., 2011; Sennrich et al., 2016b). Moreover, we explore the use of existing X-En parallel datasets of 4 other languages (X = Czech/German/Russian/Chinese) to improve Chr-En/En-Chr performance via transfer learning (Kocmi and Bojar, 2018) or multilingual joint training (Johnson et al., 2017).

Empirically, NMT is better than SMT for in-domain evaluation, while SMT is significantly better under the out-of-domain condition. RNN-NMT consistently performs better than Transformer-NMT. Semi-supervised learning improves supervised baselines in some cases (e.g., back-translation improves out-of-domain Chr-En NMT by 0.9 BLEU). Even though Cherokee is not related to any of the 4 languages (Czech/German/Russian/Chinese) in terms of their language family trees, surprisingly, we find that both transfer learning and multilingual joint training can improve Chr-En/En-Chr performance in most cases. Especially, transferring from Chinese-English achieves the best in-domain Chr-En performance, and joint learning with English-German obtains the best in-domain En-Chr performance. The best results are 15.8/12.7 BLEU for in-domain Chr-En/En-Chr translations; and 6.5/5.0 BLEU for out-of-domain Chr-En/En-Chr translations. Finally, we conduct a 50-example human (expert) evalua-

---

[2] Our co-author, Prof. Benjamin Frey, is a proficient second-language Cherokee speaker and a citizen of the Eastern Band of Cherokee Indians.

tion; however, the human judgment does not correlate with BLEU for the En-Chr translation, indicating that BLEU is possibly not very suitable for Cherokee evaluation. Overall, we hope that our datasets and strong initial baselines will encourage future works to contribute to the revitalization of this endangered language.

2 Related Works

Cherokee Language Revitalization. In 2008, the Cherokee Nation launched the 10-year language preservation plan (Nation, 2001), which aims to have 80% or more of the Cherokee people be fluent in this language in 50 years. After that, a lot of revitalization works were proposed. Cherokee Nation and the EBCI have established language immersion programs and k-12 language curricula. Several universities, including the University of Oklahoma, Stanford University, etc., have begun offering Cherokee as a second language. However, given Cherokee has been rated at the highest level of learning difficulty (Peake Raymond, 2008), it is hard to be mastered without frequent language exposure. As mentioned by Crystal (2014), an endangered language will progress if its speakers can make use of electronic technology. Currently, the language is included among existing Unicode-compatible fonts, is supported by Gmail, and has a Wikipedia page. To revitalize Cherokee, a few Cherokee pedagogical books have been published (Holmes and Smith, 1976; Joyner, 2014), as well as several online learning platforms.[3] Feeling (2018) provided detailed English translations and linguistic analysis of a number of Cherokee stories. A Digital Archive for American Indian Languages Preservation and Perseverance (DAILP) has been developed for transcribing, translating, and contextualizing historical Cherokee language documents (Bourns, 2019; Cushman, 2019).[4] However, the translation between Cherokee and English still can only be done by human translators. Given that only 2,000 fluent first-language speakers are left, and the majority of them are elders, it is important and urgent to have a machine translation system that could assist them with translation. Therefore, we introduce a clean Cherokee-English parallel dataset to facilitate machine translation development and propose multiple translation systems as starting points of future works. We hope our work could attract more attention from the NLP community in helping to save and revitalize this endangered language. An initial version of our data and its implications was introduced in (Frey, 2020). Note that we are not the first to propose a Cherokee-English parallel dataset. There is Chr-En parallel data available on OPUS (Tiedemann, 2012).[5] The main difference is that our parallel data contains 99% of their data and has 6K more examples from diverse domains.

Low-Resource Machine Translation. Even though machine translation has been studied for several decades, the majority of the initial research effort was on high-resource translation pairs, e.g., French-English, that have large-scale parallel datasets available. However, most of the language pairs in the world lack large-scale parallel data. In the last five years, there is an increasing research interest in these low-resource translation settings. The DARPA's LORELEI language packs contain the monolingual and parallel texts of three dozen languages that are considered as low-resource (Strassel and Tracey, 2016). Riza et al. (2016) proposed several low-resource Asian language pairs. Lakew et al. (2020) and Duh et al. (2020) proposed benchmarks for five and two low-resource African languages, respectively. Guzmán et al. (2019) introduced two low-resource translation evaluation benchmarks: Nepali–English and Sinhala–English. Besides, most low-resource languages rely on the existing parallel translations of the Bible (Christodouloupoulos and Steedman, 2015). Because not many low-resource parallel datasets were publicly available, some low-resource machine translation research was done by sub-sampling high-resource language pairs (Johnson et al., 2017; Lample et al., 2018), but it may downplay the fact that low-resource translation pairs are usually distant languages. Our *ChrEn* dataset can not only be another open resource of low-resource MT research but also challenge MT methods with an extremely morphology rich language and a distant language pair. Two methods have been largely explored by existing works to improve low-resource MT. One is semi-supervised learning to use monolingual data (Gulcehre et al., 2015; Sennrich et al., 2016b). The other is cross-lingual transfer learning or multilingual joint learning (Kocmi and Bojar,

2018; Johnson et al., 2017). We explore both of them to improve Chr-En/En-Chr translations.

3 Data Description

It is not easy to collect substantial data for endangered Cherokee. We obtain our data from bilingual or monolingual books and newspaper articles that are translated or written by first-language Cherokee speakers. In the following, we will introduce the data sources and the cleaning procedure and give detailed descriptions of our data statistics.

3.1 Parallel Data

Fifty-six percent of our parallel data is derived from the *Cherokee New Testament*. Other texts are novels, children's books, newspaper articles, etc. These texts vary widely in dates of publication, the oldest being dated to 1860. Additionally, our data encompasses both existing dialects of Cherokee: the Overhill dialect, mostly spoken in Oklahoma (OK), and the Middle dialect, mostly used in North Carolina (NC). These two dialects are mainly phonologically different and only have a few lexical differences (Uchihara, 2016). In this work, we do not explicitly distinguish them during translation. The left pie chart of Figure 2 shows the parallel data distributions over text types and dialects, and the complete information is in Table 14 of Appendix A.1. Many of these texts were translations of English materials, which means that the Cherokee structures may not be 100% natural in terms of what a speaker might spontaneously produce. But each text was translated by people who speak Cherokee as the first language, which means there is a high probability of grammaticality. These data were originally available in PDF version. We apply the Optical Character Recognition (OCR) via Tesseract OCR engine[6] to extract the Cherokee and English text. Then our co-author, a proficient second-language speaker of Cherokee, manually aligned the sentences and fixed the errors introduced by OCR. This process is time-consuming and took several months.

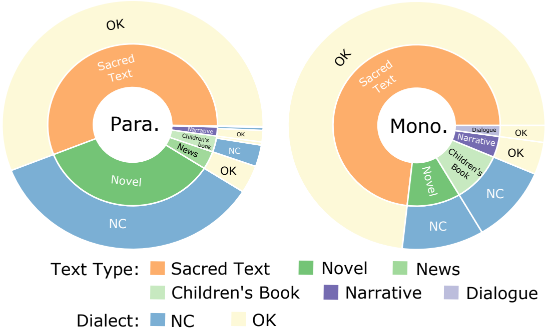

Figure 2: The distributions of our parallel (Para.) and monolingual (Mono.) data over text types and dialects.

The resulting dataset consists of 14,151 sentence pairs. After tokenization,[7] there are around 313K English tokens and 206K Cherokee tokens in total with 14K unique English tokens and 38K unique Cherokee tokens. Notably, the Cherokee vocabulary is much larger than English because of its morphological complexity. This casts a big challenge to machine translation systems because a lot of Cherokee tokens are infrequent. To facilitate machine translation system development, we split this data into training, development, and testing sets. As our data stems from limited sources, we find that if we randomly split the data, some phrases/sub-sentences are repeated in training and evaluation sets, so the trained models will over-

---

[6] `https://github.com/tesseract-ocr/`

[7] We tokenize both English and Cherokee by Moses tokenizer (Koehn et al., 2007). For Cherokee, it is equivalent to tokenize by whitespace and punctuation, confirmed to be good enough by our Cherokee-speaker coauthor.

fit to these frequent patterns. Considering that low-resource translation is usually accompanied by out-of-domain generalization in real-world applications, we provide two groups of development/testing sets. We separate all the sentence pairs from newspaper articles, 512 pairs in total, and randomly split them in half as out-of-domain development and testing sets, denoted by **Out-dev** and **Out-test**. The remaining sentence pairs are randomly split into in-domain **Train**, **Dev**, and **Test**. About 13.3% of unique English tokens and 37.7% of unique Cherokee tokens in Dev have not appeared in Train, while the percentages are 42.1% and 67.5% for Out-dev, which shows the difficulty of the out-of-domain generalization. Table 2 contains more detailed statistics; notably, the average sentence length of Cherokee is much shorter than English, which demonstrates that the semantics are morphologically conveyed in Cherokee.

Note that Cherokee-English parallel data is also available on OPUS (Tiedemann, 2012), which has 7.9K unique sentence pairs, 99% of which are the *Cherokee New Testament* that are also included in our parallel data, i.e., our data is bigger and has 6K more sentence pairs that are not sacred texts (novels, news, etc.). The detailed comparison will be discussed in A.2.

3.2 Monolingual Data

In addition to the parallel data, we also collect a small amount of Cherokee monolingual data, 5,210 sentences in total. This data is also mostly derived from Cherokee monolingual books.[8] As depicted by the right pie chart in Figure 2, the majority of monolingual data are also sacred text, which is *Cherokee Old Testament*, and it also contains two-dialect Cherokee texts. Complete information is in Table 15 of Appendix A.1. Similarly, we applied OCR to extract these texts. However, we only manually corrected the major errors introduced by OCR. Thus our monolingual data is noisy and contains some lexical errors. As shown in Table 2, there are around 93K Cherokee tokens in total with 20K unique Cherokee tokens. This monolingual data has a very small overlap with the parallel data; about 72% of the unique Cherokee tokens are unseen in the whole parallel data. Note that most of our monolingual data have English translations, i.e., it could be converted to parallel data. But it requires more effort from Cherokee speakers and will be part of our future work. For now, we show how to effectively use this monolingual data for semi-supervised gains.

4 Models

In this section, we will introduce our Cherokee-English and English-Cherokee translation systems. Adopting best practices from low-resource machine translation works, we propose both Statistical Machine Translation (SMT) and Neural Machine Translation (NMT) systems, and for NMT, we test both RNN-based and Transformer-based models. We apply three semi-supervised methods: training language model with additional monolingual data for SMT (Koehn and Knowles, 2017), incorporating BERT or Multilingual-BERT representations into NMT (Zhu et al., 2020), and back-translation for both SMT and NMT (Bertoldi and Federico, 2009; Sennrich et al., 2016b). Further, we explore transfer learning (Kocmi and Bojar, 2018) from and multilingual joint training (Johnson et al., 2017) with 4 other languages (Czech/German/Russian/Chinese) for NMT.

4.1 SMT

Supervised SMT. SMT was the mainstream of machine translation research before neural models came out. Even if NMT has achieved state-of-the-art performance on many translation tasks, SMT is still very competitive under low-resource and out-of-domain conditions (Koehn and Knowles, 2017). Phrase-based SMT is a dominant paradigm of SMT (Koehn et al., 2003). It first learns a phrase table from the parallel data that translates source phrases to target. Then, a reordering model learns to reorder the translated phrases. During decoding, a scoring model scores candidate translations by combining the weights from translation, reordering, and language models, and it is tuned by maximizing the translation performance on the development set. A simple illustration of SMT is shown in Figure 3. Note that, as Cherokee and English have different word orders (English follows SVO; Cherokee has variable word orders), one Cherokee phrase could be translated into two English words that are far apart in the sentence. This increases the difficulty of SMT that relies on phrase correspondence and is not good at distant word reordering (Zhang et al., 2017). We implement our SMT systems by Moses (Koehn et al., 2007).

---

[8] We considered parsing Cherokee Wikipedia. But, according to our coauthor, who is a Cherokee speaker, its content is mostly low-quality.

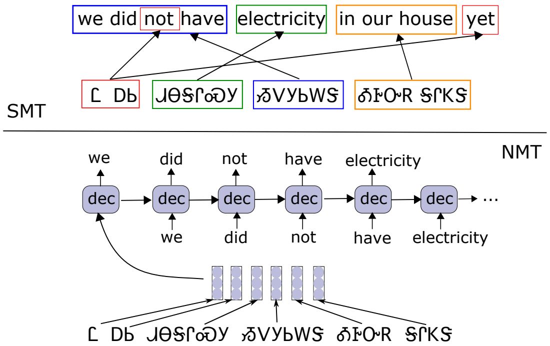

Figure 3: A simple illustration of SMT and NMT.

Semi-Supervised SMT. Previous works have shown that SMT can be improved by two semi-supervised methods: (1) A big language model (Koehn and Knowles, 2017), i.e., a language model trained with big target-side monolingual data; (2) Synthesizing bilingual data by back-translating monolingual data (Bertoldi and Federico, 2009; Lambert et al., 2011). Using our Cherokee monolingual data and the publicly available English monolingual data, we test these two methods. For the first method, we use both parallel and monolingual data to train the language model; for the second method, we back-translate target-language monolingual data into the source language and then combine them with the training set to retrain a source-target SMT model.

4.2 NMT

Supervised NMT. NMT has mostly dominated recent machine translation research. Especially when a large amount of parallel data is available, NMT surpasses SMT by a large margin; moreover, NMT is good at generating fluent translations because of its auto-regressive generation nature. Koehn and Knowles (2017) pointed out the poor performance of NMT under low-resource and out-of-domain conditions; however, recent work from Sennrich and Zhang (2019) showed that low-resource NMT can be better than SMT by using proper training techniques and hyper-parameters. NMT models usually follow encoder-decoder architecture. The encoder encodes the source sentence into hidden representations, then the decoder generates the target sentence word by word by "reading" these representations, as shown in Figure 3. We investigate two paradigms of NMT implementations: RNN-based model (Bahdanau et al., 2015) and Transformer-based model (Vaswani et al., 2017). We implement both of them via OpenNMT (Klein et al., 2017). For RNN-NMT, we follow the global attentional model with general attention proposed by Luong et al. (2015). For Transformer-NMT, we mainly follow the architecture proposed by Vaswani et al. (2017) except applying layer normalization before the self-attention and FFN blocks instead of after, which is more robust (Baevski and Auli, 2019).

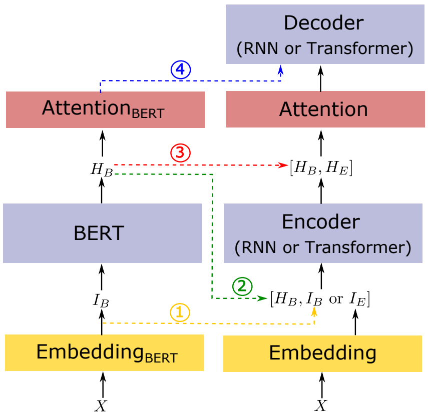

Figure 4: The four different ways we proposed to incorporate BERT representations into NMT models.

Semi-Supervised NMT. NMT models can often be improved when more training data is available; therefore, a lot of works have studied semi-supervised approaches that utilize monolingual data to improve translation performance. Similar to SMT, we mainly investigate two semi-supervised methods. The first is to leverage pre-trained language models. Early works proposed shallow or deep fusion methods to rerank NMT outputs or add the language model's hidden states to NMT decoder (Jean et al., 2015; Gulcehre et al., 2015). Recently, the large-scale pre-trained language model, BERT (Devlin et al., 2019), has achieved impressive success in many NLP tasks. Zhu et al. (2020) showed that incorporating the contextualized BERT representations can significantly improve translation performances. Following but different from this work, we explore four different ways to incorporate BERT representations into NMT models for English-Cherokee translation only.[9] As depicted in Figure 4, we apply BERT representations by: ① Initializing NMT models' word embedding matrix with BERT's pre-trained word embedding matrix I_B; ② Concatenating NMT encoder's input I_E with BERT's output H_B; ③ Concatenating NMT encoder's output H_E with BERT's output H_B; ④ Using another atten-

---

[9] Because there is no Cherokee BERT. We tried to initialize the decoder embeddings with BERT pre-trained embeddings for Chr-En translation; however, it does not work well.

tion to leverage BERT's output H_B into decoder. Note that ③ and ④ will not be applied simultaneously, and all the combination of these four methods are treated as hyper-parameters, details are in Appendix B.4. In general, we hope BERT representations can help encoder understand English sentences better and thus improve translation performance. We also test Multilingual-BERT (Devlin et al., 2019) to see if a multilingual pre-trained model can generalize better to a newly encountered language. The second semi-supervised method we try is again the back-translation method. Sennrich et al. (2016b) has shown that applying this method on NMT obtains larger improvement than applying it on SMT, and it works better than the shallow or deep fusion methods.

Transferring & Multilingual NMT. Another important line of research is to improve low-resource translation performance by incorporating knowledge from other language pairs. As mentioned in Section 1, Cherokee is the sole member of the southern branch of the Iroquoian language family, so it seems that Cherokee is not "genealogically" related to any high-resource languages in terms of their language family trees. However, it is still interesting to see whether the translation knowledge between other languages and English can help with the translation between Cherokee and English. Hence, in this paper, we will explore two ways of leveraging other language pairs: Transfer learning and Multilingual joint training. Kocmi and Bojar (2018) proposed a simple and effective continual training strategy for the transfer learning of translation models. This method will first train a "parent" model using one language pair until convergence; then continue the training using another language pair, so as to transfer the translation knowledge of the first language pair to the second pair. Johnson et al. (2017) introduced the "many-to-one" and "one-to-many" methods for multilingual joint training of X-En and En-X systems. They achieve this by simply combining training data, except for the "one-to-many" method, every English sentence needs to start with a special token to specify the language to be translated into. We test both the transferring and multilingual methods for Chr-En/En-Chr translations with 4 other X-En/En-X language pairs (X=Czech/German/Russian/Chinese).

5 Results

5.1 Experimental Details

We randomly sample 5K-100K sentences (about 0.5-10 times the size of the parallel training set) from News Crawl 2017[10] as our English monolingual data. We randomly sample 12K-58K examples (about 1-5 times the size of parallel training set) for each of the 4 language pairs (Czech/German/Russian/Chinese-English) from News Commentary v13 of WMT2018[11] and Bible-uedin (Christodouloupoulos and Steedman, 2015) on OPUS[12]. We apply tokenizer and truecaser from Moses (Koehn et al., 2007). We also apply the BPE tokonization (Sennrich et al., 2016c), but instead of using it as default, we treat it as hyper-parameter. For systems with BERT, we apply the WordPiece tokenizer (Devlin et al., 2019). We compute detokenized and case-sensitive BLEU score (Papineni et al., 2002) using SacreBLEU (Post, 2018).[13]

We implement our SMT systems via Moses (Koehn et al., 2007). **SMT** denotes the base system; **SMT+bigLM** represents the SMT system that uses additional monolingual data to train its language model; SMT with back-translation is denoted by **SMT+BT**. Our NMT systems are implemented by OpenNMT toolkit (Klein et al., 2017). Two baselines are **RNN-NMT** and **Transformer-NMT**. For En-Chr, we also test adding BERT or Multilingual-BERT representations (Devlin et al., 2019), **NMT+BERT** or **NMT+mBERT**, and with back-translation, **NMT+BT**. For Chr-En, we only test **NMT+BT**, treating the English monolingual data size as hyper-parameter. For both En-Chr and Chr-En, we test **T**ransfer learning from and **M**ultilingual joint training with 4 other languages denoted by **NMT+X (T)** and **NMT+X (M)** respectively, where X = Czech/German/Russian/Chinese. We treat the X-En data size as hyper-parameter. All other detailed model designs and hyper-parameters are introduced in Appendix B.

5.2 Quantitative Results

Our main experimental results are shown in Table 3 and Table 4.[14] Overall, the translation perfor-

Table 3: Performance of our supervised/semi-supervised SMT/NMT systems. **Bold** numbers are our best out-of-domain systems together with Table 4, selected by performance on Out-dev. (±x) shows 95% confidence interval.

mance is poor compared with the results of some high-resource translations (Sennrich et al., 2016a), which means that current popular SMT and NMT techniques still struggle to translate well between Cherokee and English especially for the out-of-domain generalization.

Chr-En vs. En-Chr. Overall, the Cherokee-English translation gets higher BLEU scores than the English-Cherokee translation. It is reasonable because English has a smaller vocabulary and simpler morphology; thus, it is easier to generate.

SMT vs. NMT. For in-domain evaluation, the best NMT systems surpass SMT for both translation directions. It could result from our extensive architecture hyper-parameter search; or, it supports our conjecture that SMT is not necessarily better than NMT because of the different word orders. But, SMT is dominantly better than NMT for out-of-domain evaluation, which is consistent with the results in Koehn and Knowles (2017).

RNN vs. Transformer. Transformer-NMT performs worse than RNN-NMT, which contradicts the trends of some high-resource translations (Vaswani et al., 2017). We conjecture that Transformer architecture is more complex than RNN and thus requires larger-scale data to train properly. We also notice that Transformer models are very sensitive to hyper-parameters, so it can be possibly improved after a more extensive hyper-parameter search. The best Transformer-NMT has a 5-layer encoder/decoder and 2-head attention, which is smaller-scale than the model used for high-resource translations (Vaswani et al., 2017). Another interesting observation is that previous works have shown applying BPE and using a small vocabulary by setting minimum word frequency are beneficial for low-resource translation (Sennrich et al., 2016c; Sennrich and Zhang, 2019); however, these techniques are not always being favored during our model selection procedure, as shown in Appendix B.4.

Supervised vs. Semi-supervised. As shown in Table 3, using a big language model and back-translation both only slightly improve SMT baselines on both directions. For English-Cherokee translation, leveraging BERT representations improves RNN-NMT by 0.4/0.5 BLEU points on Dev/Test. Multilingual-BERT does not work better than BERT. Back-translation with our Cherokee monolingual data barely improves performance for both in-domain and out-of-domain evaluations, probably because the monolingual data is also out-of-domain, 72% of the unique Cherokee tokens are unseen in the whole parallel data. For Cherokee-English translation, back-translation improves the out-of-domain evaluation of RNN-NMT by 0.9/0.9 BLEU points on Out-dev/Out-test, while it does not obviously improve in-domain evaluation. A possible reason is that the English monolingual data we used is news data that is not of the same domain as Dev/Test but closer to Out-dev/Out-test so that it helps the model to do domain adaptation. We also investigate the influence of the English monolingual data size. We find that all of the NMT+BT systems perform best when only using 5K English monolingual data, see Figure 5 in Appendix B.5.

Transferring vs. Multilingual. Table 4 shows the transfer learning and multilingual joint training results. It can be observed that, in most cases, the in-domain RNN-NMT baseline (N4) can be improved by both methods, which demonstrates

ID	System	Cherokee-English				English-Cherokee			
		Dev	Test	Out-dev	Out-test	Dev	Test	Out-dev	Out-test
N4	RNN-NMT	15.7	15.1	2.7	1.8	12.4	11.7	1.1	1.8
N12	+ Czech (T)	15.8	14.7	2.3	1.8	12.7	12,6	1.8	2.4
N13	+ German (T)	15.9	14.8	2.3	1.1	12.9	12.1	1.8	1.4
N14	+ Russian (T)	16.5	15.8	1.9	1.9	12.6	11.8	1.8	2.3
N15	+ Chinese (T)	**16.9**	**15.8** (±1.2)	2.0	1.5	12.9	12.9	1.2	0.8
N16	+ Czech (M)	16.6	15.7	2.4	2.0	13.2	12.4	1.1	2.1
N17	+ German (M)	16.6	15.4	2.3	1.4	**13.4**	**12.7** (±1.0)	0.8	2.0
N18	+ Russian (M)	16.5	15.9	1.9	1.6	13.2	13.1	1.2	1.8
N19	+ Chinese (M)	16.8	16.1	2.2	1.8	13.0	13.0	1.1	1.4

Table 4: Performance of our transfer and multilingual learning systems. **Bold** numbers are our best in-domain systems together with Table 3, selected by the performance on Dev. (±x) shows the 95% confidence interval.

that even though the 4 languages are not related to Cherokee, their translation knowledge can still be helpful. Transferring from the Chinese-English model and joint training with English-German data achieve our best in-domain Cherokee-English and English-Cherokee performance, respectively. However, there is barely an improvement on the out-of-domain evaluation sets, even though the X-En/En-X data is mostly news (same domain as Out-dev/Out-test). On average, multilingual joint training performs slightly better than transfer learning and usually prefers a larger X-En/En-X data size (see details in Appendix B.4).

5.3 Qualitative Results

Automatic metrics are not always ideal for natural language generation (Wieting et al., 2019). As a new language to the NLP community, we are also not sure if BLEU is a good metric for Cherokee evaluation. Therefore, we conduct a small-scale human (expert) pairwise comparison by our coauthor between the translations generated by our NMT and SMT systems. We randomly sample 50 examples from Test or Out-test, anonymously shuffle the translations from two systems, and ask our coauthor to choose which one they think is better.[15] As shown in Table 5, human preference does not always follow the trends of BLEU scores. For English-Cherokee translation, though the RNN-NMT+BERT (N5) has a better BLEU score than SMT+BT (S3) (12.2 vs. 9.9), it is liked less by humans (21 vs. 29), indicating that BLEU is possibly not a suitable for Cherokee evaluation. A detailed study is beyond the scope of this paper but is an interesting future work direction.

Condition		System IDs	Win	Lose
Chr-En	Test	N7 vs. S3	43	7
	Out-test	N7 vs. S2	16	34
En-Chr	Test	N5 vs. S3	21	29
	Out-test	N7 vs. S3	2	48

Table 5: Human comparison between the translations generated from our NMT and SMT systems. If A vs. B, "Win" or "lose" means that the evaluator favors A or B. Systems IDs correspond to the IDs in Table 3.

6 Conclusion and Future Work

In this paper, we make our effort to revitalize the Cherokee language by introducing a clean Cherokee-English parallel dataset, *ChrEn*, with 14K sentence pairs; and 5K Cherokee monolingual sentences. It not only can be another resource for low-resource machine translation research but also will help to attract attention from the NLP community to save this dying language. Besides, we propose our Chr-En and En-Chr baselines, including both SMT and NMT models, using both supervised and semi-supervised methods, and exploring both transfer learning and multilingual joint training methods with 4 other languages. Experiments show that SMT is significantly better and NMT under out-of-domain condition while NMT is better for in-domain evaluation; and the semi-supervised learning, transfer learning, and multilingual joint training can improve simply supervised baselines. Overall, our best models achieve 15.8/12.7 BLEU for in-domain Chr-En/En-Chr translations and 6.5/5.0 BLEU for out-of-domain Chr-En/En-Chr translations. We hope these diverse baselines will serve as useful strong starting points for future work by the community. Our future work involves converting the monolingual data to parallel and collecting more data from the news domain.

Appendix

A Data

A.1 The Sources of Our Data

Table 14 and Table 15 list the original sources of our parallel and monolingual data, which include the title of original article/book/etc., the name of the speaker/translator, the date of the source, text type, the dialect, and the number of sentences/pairs. OK and NC denote the two existing dialects of Cherokee: the Overhill dialect, most widely spoken in Oklahoma (OK), and the Middle dialect, most widely used in North Carolina (NC).

Statistics	Ours	OPUS
Sentence Pairs	14,101	7,974
Dialects	2	1
Text Types	5	2
English tokens	312,854	210,343
Unique English tokens	13,620	6,550
Average English sentence length	22.2	26.4
Cherokee tokens	205,564	144,126
Unique Cherokee tokens	38,494	25,762
Average Cherokee sentence length	14.6	18.1

Table 6: The comparison between our parallel data and the data provided on OPUS.

A.2 Comparison with Existing Data

Here, we compare our parallel data with the data provided on OPUS (Tiedemann, 2012). OPUS has 4 Cherokee-English parallel data resources: Tatoeba, Wikimedia, Bible-uedin, and Ubuntu. Wikimedia's Cherokee sentences are mostly English, and Ubuntu only has several word mappings. We mainly compare with Tatoeba and Bible-uedin. Tatoeba has 22 daily dialogue sentence pairs. Bible-uedin has 15.9K sentence pairs, and after deduplicating,[16] 7.9K pairs are left. It is the translation of the Bible (Cherokee New Testament) (Christodouloupoulos and Steedman, 2015), which is also present in our data. Table 6[17] shows the detailed statistics of our versus OPUS's parallel data. In summary, 99% of the OPUS data is also present in our parallel data, i.e., our data has 6K more sentence pairs that are not sacred texts (novels, news, etc.).

B Experimental Details

B.1 Data and Preprocessing

For semi-supervised learning, we sample additional English monolingual data from News Crawl 2017.[18] We randomly sample 5K, 10K, 20K, 50K, and 100K sentences, which are about half, equal, double, 5-times, 10-times the size of the parallel

---

[16] The deduplication is based on Cherokee sentences not sentence pairs, because we notice that in Bible-uedin two English sentences can be different just because of one additional white space in the sentence.

[17] Note that we apply the same deduplication on our data, so the numbers are slightly different from those in Table 2.

[18] `http://data.statmt.org/news-crawl/en/`

training set. For transfer and multilingual training experiments, we use 12K, 23K, or 58K X-En (X=Czech/German/Russian/Chinese) parallel examples, which are equal, double, and 5-times the size of Chr-En training set. We sample these examples either only from News Commentary v13 of WMT2018[19] or from both News Commentary and Bible-uedin (Christodouloupoulos and Steedman, 2015) on OPUS[20], because half of in-domain Chr-En data is the Bible. Whenever we sample from Bible-uedin, we keep the sample size as 6K and sample the rest from News Commentary.

For all the data we used, the same tokenizer and truecaser from Moses (Koehn et al., 2007) are applied. For some NMT systems, we also apply the BPE subword tokenization (Sennrich et al., 2016c) with 20,000 merge operations for Cherokee and English separately. For NMT systems with BERT, we apply the WordPiece tokenizer from BERT (Devlin et al., 2019) for English. Before evaluation, the translation outputs are detokenized and detruecased. We use SacreBLEU (Post, 2018)[21] to compute the BLEU (Papineni et al., 2002) scores of all translation systems.

B.2 SMT Systems

We implement SMT systems via Moses (Koehn et al., 2007). We train a 3-gram langauge model (LM) by KenLM (Heafield et al., 2013) and conduct word alignment by GIZA++ (Och and Ney, 2003). Model weights are tuned on the Dev or Our-dev by MERT (Och, 2003).

B.3 NMT Systems

Our NMT systems are all implemented by OpenNMT (Klein et al., 2017). As shown in Table 3 and Table 4, there are 16 NMT systems in total (N4-N19). For each of these systems, We conduct a limited amount of hyper-parameter grid search on Dev or Out-dev. The search space includes applying BPE or not, minimum word frequency threshold, number of encoder/decoder layers, hidden size, dropout, etc. The detailed hyper-parameter tuning procedure will be discussed in the next subsection. During decoding, all systems use beam search with beam size 5 and replace unknown words with source words that have the highest attention weight.

B.4 Hyper-parameters

We observed the NMT models, especially the Transformer-NMT models, are sensitive to hyper-parameters. Thus, we did a limited amount of hyper-parameter grid search when developing NMT models. For building vocabulary, we take BPE (Sennrich et al., 2016c) (use or not) and the minimum word frequency (0, 5, 10) as two hyper-parameters. For the model architecture, we explore different number of encoder/decoder layers (1, 2, 3 for RNN; 4, 5, 6 for Transformer), hidden size (512, 1024), embedding size (equals to hidden size, except 768 for BERT), tied decoder embeddings (Press and Wolf, 2017) (use or not), and number of attention heads (2, 4, 8). For training techniques, we tune dropout (0.1, 0.2, 0.3), label smoothing (Szegedy et al., 2016) (0.1, 0.2), average decay (1e-4 or not use), batch type (tokens or sentences), batch size (1000, 4000 for tokens; 32, 64 for sents), and warmup steps (3000, 4000). We take the English monolingual data size (5K, 10K, 20K, 50K, 100K) as hyper-parameter when we do back-translation for Cherokee-English translation. We take the size of Czech/German/Russian/Chinese-English parallel data (12K, 23K, 58K) and whether sampling from Bible-uedin (yes or no) as hyper-parameter when we do transfer or multilingual training. Besides, we take how we incorporate BERT as hyper-parameter, and it is chosen from the following five settings and their combinations:

- BERT embedding: Initializing NMT models' word embedding matrix with BERT's pre-trained word embedding matrix I_B, corresponding to ① in Figure 4;
- BERT embedding (fix): The same as "BERT embedding" except we fix the word embedding during training;
- BERT input: Concatenate NMT encoder's input I_E with BERT's output H_B, corresponding to ② in Figure 4;
- BERT output: Concatenate NMT encoder's output H_E with BERT's output H_B, corresponding to ③ in Figure 4;
- BERT output (attention): Use another attention to leverage BERT's output H_B into decoder, corresponding to ④ in Figure 4;

Table 7: The hyper-parameter settings of **Supervised and Semi-supervised Cherokee-English NMT systems in Table 3**. Empty fields indicate that hyper-parameter is the same as the previous (left) system.

"BERT embedding" and "BERT embedding (fix)" will not be applied simultaneously, and "BERT output" and "BERT output (attention)" will not be applied simultaneously. Multilingual-BERT is used in the same ways. At most, there are 576 searches per model, but oftentimes, we did less than that because we early cut off unpromising settings. All hyper-parameters are tuned on Dev or Out-dev for in-domain or out-of-domain evaluation, and the model selection is based on translation accuracy on Dev or Out-dev. Table 7, Table 8, Table 9, Table 10, Table 11, Table 12, and Table 13 list the hyper-parameters of all the systems shown in the Table 3 and Table 4. Since our parallel dataset is small (14K sentence pairs), even the slowest experiment, Transformer-NMT+mBERT, only takes 2 minutes per epoch using one Tesla V100 GPU. We train 100 epochs at most and using early stop when the translation accuracy on Dev or Out-dev does not improve for 10 epochs.

B.5 English Monolingual Data Size Influence

In the semi-supervised experiments of Cherokee-English, we investigate the influence of the English monolingual data size. As mentioned above, we use 5K, 10K, 20K, 50K, and 100K English monolingual sentences. Figure 5 shows its influence on translation performance. It can be observed that increasing English monolingual data size does not lead to higher performance, especially, all NMT+BT systems achieve the best performance when only use 5K English sentences.

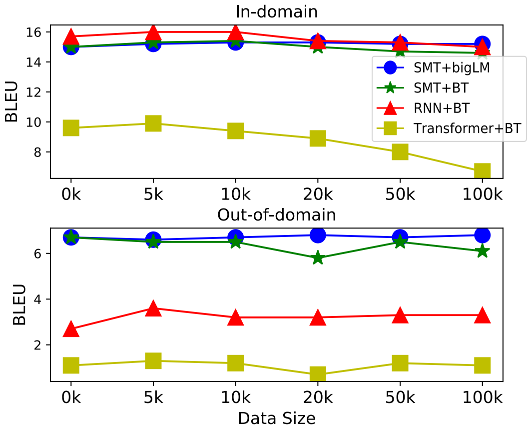

Figure 5: The influence of the English monolingual data size on semi-supervised learning performance. The results are on Dev or Out-dev.

Unsupervised Discovery of Implicit Gender Bias

Abstract

Despite their prevalence in society, social biases are difficult to identify, primarily because human judgements in this domain can be unreliable. We take an *unsupervised* approach to identifying gender bias against women at a comment level and present a model that can surface text likely to contain bias. Our main challenge is forcing the model to focus on signs of implicit bias, rather than other artifacts in the data. Thus, our methodology involves reducing the influence of confounds through propensity matching and adversarial learning. Our analysis shows how biased comments directed towards female politicians contain mixed criticisms, while comments directed towards other female public figures focus on appearance and sexualization. Ultimately, our work offers a way to capture subtle biases in various domains without relying on subjective human judgements.[1]

1 Introduction

Despite widespread documentation of the negative impacts of bias, stereotypes, and prejudice (Krieger, 1990; Goldin, 1990; Steele and Aronson, 1995; Logel et al., 2009; Schluter, 2018), these concepts remain difficult to define and identify, especially for non-experts. Social biases appear to be a natural component of human cognition that allow people to make judgments efficiently (Kahneman et al., 1982). As a result, they are often *implicit*—people are unaware of their own biases (Blair, 2002; Bargh, 1999)—and manifest subtly, e.g., as microaggressions or condescension (Huckin, 2002; Sue, 2010).

Much NLP literature has examined biases in data, algorithms, or model performance, and the negative pipeline between them: models absorb and amplify data biases, which impacts performance (Sun et al., 2019). However, little work has looked further up the pipeline and relied on the assumption that biases in data originate in human cognition.

In contrast, this assumption motivates our work: an unsupervised approach to detecting implicit gender bias in text. Text provides an ideal avenue for studying bias, because human cognition is closely tied to natural language. Psychology studies often examine human perceptions through word associations (Greenwald et al., 1998). However, the implicit nature of bias suggests that human annotations for bias detection may not be reliable, which motivates an unsupervised approach.

The goals of our work align with prior work in NLP that has examined biases in real-world data. However, prior work examines bias at a broad corpus level or relies on supervised models. While corpus-level analyses, e.g. associations between gendered words and stereotypes, can be insightful (Bolukbasi et al., 2016; Fast et al., 2016; Caliskan et al., 2017; Garg et al., 2018; Friedman et al., 2019; Chaloner and Maldonado, 2019), they are difficult to interpret over short text spans. They also often rely on human-defined "known" stereotypes, such as lists of traditionally male and female occupations obtained through crowd-sourcing, which restricts analysis to a narrow surface-level domain. Similarly, supervised approaches can provide insight into carefully defined types of bias (Wang and Potts, 2019; Breitfeller et al., 2019; Sap et al., 2020), but they rely on human annotations tasks, which are difficult to design or generalize to other domains, especially because social concepts differ across contexts and cultures (Dong et al., 2019).

Our work offers a new approach to surfacing gender bias that does not require direct supervision and is meaningful at a sentence or paragraph level. We create a model that takes text in the 2$^{\text{nd}}$-person perspective as input and predicts the gender of the person the text is addressed to. If the classifier predicts the gender of the addressee with high confidence based only on the text directed to them, we

---

[1] Code and pre-trained models are available at `https://github.com/anjalief/unsupervised_gender_bias`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 596–608,
November 16–20, 2020.

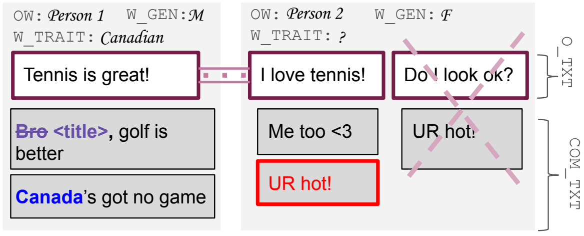

Figure 1: We train a classifier to predict the gender (W_GEN) of the person that text is addressed to (COM_TXT), while demoting features that are predictive of gender but not predictive of bias. Posts with similar content are matched through propensity scores; unmatched posts are discarded. Latent traits of the addressee (e.g., nationality) are demoted through an adversarial objective. Overtly gendered language ("Bro") is substituted. Comments indicative of gender despite these restrictions are likely to contain bias.

hypothesize that the text is likely to contain bias. The main challenge is encouraging the model to focus on text features that are indicative of bias, rather than artifacts in data that correlate with the gender of the addressee but occur because of confounding variables (*confounds*). Thus, the core of our methodology focuses on reducing the influence of confounds. Our goal is not to improve accuracy of the gender-prediction task, but rather to validate that our methodology demotes confounds and surfaces comments likely to contain gender bias.

In §2, we define the problem and intuition behind our approach. We describe our methods for confound demotion in §3, and we evaluate them in §5. Our evaluation involves examining how confound control affects performance on in-domain and out-of-domain classification tasks, including detection of gender-based microaggressions. Our results suggest that our model successfully identifies text likely to contain bias against women, allowing us to analyze how this bias differs across domains (§6). To the best of our knowledge, this is the first work that aims to analyze bias in short text spans by learning implicit associations from data sets.

2 Problem Formulation

Our primary task is to detect gender bias in a communicative domain, specifically in texts targeting an addressee (i.e., 2^{nd}-person) without relying on explicit bias annotations. Our goals align with a causality framework in that we seek to identify content that occurs because of the gender of the addressee rather than other factors. We can define a counterfactual: *Would the addressee have received different text if their gender were different?*

While our framework is broadly applicable, in order to define consistent notation, we consider a setup where our primary text is a comment written in reply to text written by someone else. This includes domains like replies on social media posts, or comments on newspaper articles, and can be generalized other media, e.g., comments on YouTube videos. We identify the following variables:

- **OW**: "Original Writer", the person who wrote the original text, e.g., the addressee
- **O_TXT**: content of the original text
- **W_GEN**: the gender (**M**, **F**) of OW. We use a binary variable because all of the individuals in our corpus identify as men or women, but our methodology is generalizeable and can be used to examine bias against other genders.
- **W_TRAITS**: any traits of OW other than gender, e.g., social role, age, nationality.
- **COM_TXT**: comments replying to O_TXT

Our goal is to detect bias in COM_TXT values that occurs because of W_GEN. A naive approach would train a classifier to predict W_GEN from COM_TXT and assume that any COM_TXT values for which the classifier correctly predicts W_GEN with high confidence contain bias. However, COM_TXT may contain features that are predictive of W_GEN but are not indicative of bias.

For example, in Figure 1, when the comment "UR hot!" (COM_TXT) is addressed to someone who said "I love tennis!" (O_TXT), it is an objectification and unsolicited reference to appearance, which could indicate bias. However, when it is addressed to someone who said "Do I look ok?", it is likely not indicative of bias. If women ask "Do I look ok?" more frequently than men, this naive classifier would identify "UR hot!" is likely addressed towards a woman and identify it as biased. However, we only want the model to learn that references to appearance are indicative of gender if they occur in unsolicited contexts. Thus our model needs to account for the effects of O_TXT: Because of correlations between W_GEN and O_TXT, COM_TXT values may contain features that are *predictive* of W_GEN, but are *caused* by O_TXT, rather than by W_GEN. We face a similar problem with W_TRAITS. From the synthetic example in Figure 1, if our data set contains more men from Canada than women, the model might learn that references to Canada indicate W_GEN $=$ M.

We provide additional empirical examples in §4.

We refer to factors that might influence COM_TXT as *confounding variables* and the artifacts that they produce in COM_TXT as *confounds*. We distinguish two types: *observed* and *latent*. Latent confounding variables cannot be controlled if they are entirely unknown; instead, we assume there are observed signals that can be used to infer them, but the values themselves are difficult to explicitly enumerate. In addition to confounds introduced by O_TXT and W_TRAITS, COM_TXT may also contain overt signals, e.g. titles like "Ma'am" or "Sir", that are predictive of gender, but not indicative of bias. We thus identify 3 factors to account for: O_TXT, W_TRAITS, and overt signals.

3 Methodology

Our overall methodology centers on creating a classifier that predicts gender of the addressee while controlling for the effects of observed confounding variables (O_TXT), latent confounding variables (W_TRAITS), and overt signals. The input to the prediction model is COM_TXT, while the output is W_GEN, and we aim to identify bias in COM_TXT.

3.1 Controlling Observed Confounding Variables through Propensity Matching

Our primary method for controlling for O_TXT is *propensity matching*. Propensity matching was developed to replicate the conditions of randomized trials in causal inference studies (Rosenbaum and Rubin, 1983, 1985). In this step, we discard any COM_TXT training samples whose associated O_TXT is heavily affiliated with only one gender. In Figure 1, if we assume that only women post "Do I look ok?", we would discard all comments posted in reply to the O_TXT "Do I look ok?". We ultimately seek to balance our data set, so that the set of all COM_TXT where W_GEN $= \mathbf{M}$ has similar associated O_TXT as the set of all COM_TXT where W_GEN $= \mathbf{F}$. Thus, we match each O_TXT where W_GEN $= \mathbf{F}$ with a similar O_TXT where W_GEN $= \mathbf{M}$ and discard all unmatched data.

Ideally, we would match O_TXT values written by men with identical O_TXT values written by women, but this is infeasible in practice. Instead, the key insight behind propensity matching is that it is sufficient to match data points based on the probability of the target variable, e.g., the probability that W_GEN $= \mathbf{F}$ (Rosenbaum and Rubin, 1983, 1985). Thus, the propensity score e_i for a COM_TXT$_i$ is defined as the probability that W_GEN $= \mathbf{F}$, given the confounding variable, O_TXT$_i$:

$$e_i(\text{COM\_TXT}_i) = P(\text{W\_GEN}_i = \mathbf{F} | \text{O\_TXT}_i)$$

To balance our data set, we need to ensure that the set of COM_TXT where W_GEN $= \mathbf{M}$ has a similar propensity score distribution as the set of COM_TXT where W_GEN $= \mathbf{F}$. Because propensity scores are dependent on O_TXT, all COM_TXT replied to the same O_TXT have the same propensity score. We can then equate $e_i(\text{COM\_TXT}_i) = e_i(\text{O\_TXT}_i)$, and focus estimating O_TXT scores.

Propensity scores can be estimated by using a classification model that is trained to predict the target attribute W_GEN$_i = \mathbf{F}$ from the observed confounding variable O_TXT$_i$ (Westreich D, 2010; Lee et al., 2010). We use a bidirectional LSTM encoder followed by two feedforward layers with a $\tanh$ activation function and a softmax in the final layer. Then, we use greedy matching to match each O_TXT$_i$ where the true value of W_GEN$_i$ is $\mathbf{F}$ with O_TXT$_j$ where the true value of W_GEN$_j$ is $\mathbf{M}$ and $|e_i(\text{O\_TXT}_i) - e_j(\text{O\_TXT}_j)|$ is minimal (Gu and Rosenbaum, 1993).

We institute a threshold c (Stuart, 2010), where we discard O_TXT$_i$ if we cannot find a O_TXT$_j$ such that $|e_i(\text{O\_TXT}_i) - e_j(\text{O\_TXT}_j)| \leq c$. Thus, for example, we would match a post written by a woman that is "stereotypically female" (e.g., e_i is large) with a post written by a man that is also "stereotypically female" (e.g., e_j is also large). In Figure 1, we match "Tennis is great" with "I love tennis", and we discard "Do I look ok?" as unable to be matched. However, using propensity matching rather than direct matching allows us to match O_TXT values that are about different topics, as long as they are equally likely to have been written by a woman.

Finally, our actual model input consists of COM_TXT, not of O_TXT. Once we have matched pairs of O_TXT values, we need to ensure that we have an equal number of COM_TXT values for each O_TXT in the pair in order to have a balanced data set. Then, for each matched $[\text{O\_TXT}_i, \text{O\_TXT}_j]$, we randomly downsample to have an equal number of COM_TXT values for each O_TXT in the pair. In this way, we balance the training set of COM_TXT in terms of how predictive the confounding variable O_TXT is of the target attribute W_GEN.

3.2 Controlling Latent Confounding Variables through Adversarial Training

While propensity matching is a desirable way to control for confounding variables because of established literature, matching is only possible for observed variables (Gu and Rosenbaum, 1993; Rosenbaum, 1988). In our data, while O_TXT is observed, W_TRAITS is not possible to match on (further discussion in §4). Instead, we use an adversarial objective drawn from Kumar et al. (2019) to encourage the model to ignore W_TRAITS.

Confound representation While we cannot explicitly enumerate W_TRAITS, we know that they are associated with the identity of OW, and we can infer them from COM_TXT addressed to OW. We use associations between OW and COM_TXT to derive a feature vector for each COM_TXT$_i$ that reflects W_TRAITS$_i$. The latent confounds to demote are represented as multinomial distributions, derived from log-odds scores (Monroe et al., 2008).

For each label OW $= k$ and each word type w in all COM_TXT, we calculate the log-odds score $lo(w, k) \in \mathbf{R}$, where higher scores indicate stronger associations between k and the word. In Figure 1, $lo(\texttt{Canada}, \texttt{Person 1})$ would be high, as COM_TXT values addressed to `Person 1` often contain the word Canada. Then, following Kumar et al. (2019), we define a distribution: for all $k \in$ OW and an input COM_TXT$_i$, $= \langle w_1, \ldots, w_n \rangle$:

$$p(k|\text{COM\_TXT}_i) \propto$$

$$p(k)p(\text{COM\_TXT}_i|k) = p(k)\prod_{i=1}^{n} p(w_i|k)$$

$p(k)$ is estimated from the distribution of k in the training data, i.e., the proportion of COM_TXT values addressed to OW $= k$. $p(w_i|k)$ is proportional to $\sigma(lo(w, k))$, where we use the sigmoid function (σ) to map log-odds scores to the range [0,1] and then normalize them over the vocabulary to obtain valid probabilities. For each input COM_TXT$_i$, we then obtain a vector whose elements are $p(k|\text{COM\_TXT}_i)$ and whose dimensionality is the number of OW individuals in the training set. We normalize these vectors to obtain multinomial probability distributions which reflect COM_TXT$_i$'s association with each OW individual. Thus, when we demote this vector during training, we force the classifier to learn features that are indicative of the group W_GEN and not features that are indicative of individual members of this group (e.g., some group members are from Canada). We refer to the confound vector as t_i. Justification for the log-odds representation as opposed to alternatives is presented in Kumar et al. (2019).

Training Procedure Our goal is to obtain a model that can predict W_GEN, but cannot predict the latent confounds represented by t_i. To achieve this, the model is trained in an alternate GAN-like procedure (Goodfellow et al., 2014).

First, the input $x \in$ COM_TXT is encoded using an encoder neural network $h(x; \theta_h)$ to obtain a hidden representation $\mathbf{h}_x$. This representation is then passed through two feedforward networks: (1) $c(h(x); \theta_c)$ to predict the label $y \in \{\mathbf{M}, \mathbf{F}\}$; and (2) an adversary network $\text{adv}(h(x); \theta_a)$ to predict the vector representation of the latent confounds.

We train the encoder, so that $\mathbf{h}_x$ does not contain any information predictive of the confound vector, but does contain information predictive of the target attribute. Thus our primary training objective is:

$$\min_{c,h} \frac{1}{N}\sum_{i=1}^{N} \text{CE}(c(h_{x_i}), y_i) + \text{KL}(\text{adv}(h_{x_i}), \mathbb{U}_K)$$

where $\mathbb{U}$ represents a uniform distribution, CE represents cross-entropy loss, and KL represents KL-divergence. We refer to Kumar et al. (2019) for the training procedure that alternates minimizing this objective and training the adversary.

3.3 Overt Signals

Finally, we control for overt signals using word substitutions that replace gendered terms with more neutral language, for example woman → ⟨person⟩ and man → ⟨person⟩. We create a 66-term list of substitutions from existing resources (Zhao et al., 2018; Bolukbasi et al., 2016) as well as our observations of the data. We also use substitutions to remove the names of addressees from comment, replacing OW's "Firstname" and "Lastname" with "⟨name⟩" in COM_TXT. We do not attempt to identify nicknames, as the confound demotion method described in §3.2 should already mitigate the influence of individual names, and we perform the substitution as merely an extra precaution.

4 Experimental Setup

Our primary data is the Facebook subsection of the RtGender corpus (Voigt et al., 2018). The data contains two subsections: *Politicians* (400K posts and 13.9M replies addressed to 412 then-current U.S.

members of Congress), and *Public Figures* (118K posts and 10.7M replies addressed to 105 famous people such as actresses and tennis players).

We can show that O_TXT is a confounding variable by computing log-odds scores between the words in O_TXT and W_GEN (Monroe et al., 2008). In the Politicians data, the most female-associated words are *women*, *Congresswoman*, *sexual*, and *assault*. The most male-associated words are *Obamacare*, *Iran*, *EPA*, and *spending*. It is evident that male and female politicians post about different topics, e.g., female politicians likely post more about sexual assault. A naive model may predict that comments using sexual language are addressed towards women, but increased sexual language may occur because of O_TXT, rather than gender bias.

A similar problem occurs with W_TRAITS, e.g., the corpus has more comments addressed to female tennis players (9 players; 184K comments) than male players (1 player; 29K comments). The model can obtain high accuracy by predicting W_GEN $=$ **F** for COM_TXT with the word "tennis". Unlike O_TXT, which is observable from the data, we have no way of enumerating every possible value in W_TRAITS. Even if we could enumerate them, we do not expect propensity matching over W_TRAITS to work, because we cannot find reasonable matches, e.g., there is only one senior senator from Massachusetts. Additionally, W_TRAITS can be as fine-grained as names: we cannot find a male senator whom commenters call "Liz Warren".

We divide each data set into train, dev, and test sets, enforcing no OW overlap between subsets. We perform propensity matching and derive the confound vectors to demote using only the training data. We apply word substitutions to all subsets.[2]

5 Evaluation

We train our model to predict W_GEN from COM_TXT, employing propensity matching over O_TXT, word substitutions over COM_TXT, and W_TRAITS demotion. We focus on evaluating how well our model controls for confounds and whether or not it captures gendered language. Successful demotion of confounds would suggest that our model learns to identify text indicative of gender bias.

Observed Confounding Variable Demotion In Figure 2, we show log-odds scores, measuring association between O_TXT and W_GEN in the training set before and after propensity matching. For comparison, we also show scores for a randomly matched data set, in which we balance O_TXT to have an equal proportion of $\mathbf{F}$ and $\mathbf{M}$ labels by random sampling (constructed to be the same size as the propensity matched set). In the Politicians and Public Figures data, propensity matching reduces the magnitude of the most polar words: log-odds scores for the matched data are closer to zero than for the non-matched or randomly matched data.[3] Further, propensity matching can even cause the polarity to change direction: words that were originally female-associated (e.g. "her") become slightly male-associated. These figures suggest that propensity matching effectively reduces the confounding influence of O_TXT.

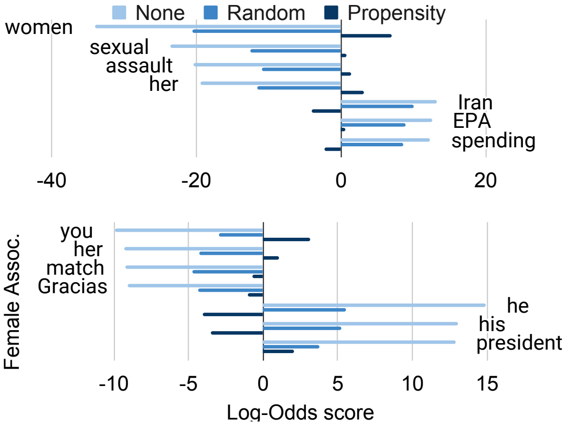

Figure 2: Log-odds scores for most polar words in Politicians (top) and Public Figures (bottom) data, with different matching methods. Propensity matching best reduces polarity.

Latent Confounding Variable Demotion We evaluate how well our model demotes the influence of latent confounding variables over the held-out test sets (Table 1). We created data splits so that there is no overlap in OW values between the train and test sets. While there may still be overlap in some latent W_TRAITS, we expect there to be less overlap in W_TRAITS between the train and test set than within the train set. Thus, improved performance over the held-out test set would suggest that demotion effectively reduces the influence of the latent confounding variables—the model learns characteristics of comments addressed to women generally rather than characteristics specific to the

---

[2] We provide additional details in Appendix A.

[3] Polarities were reduced without producing new ones: in the Politicians data, the magnitude of the 2 most polar words decreased from -34.0 and 17.9 to -7.68 and 8.52, and in the Public Figures data, from -45.5 and 39.3 to -5.29 and 9.43.

Table 1: Evaluation over held-out test sets, where W_GEN = **F** is considered the positive class. Latent confound demotion improves performance.

individual people in the training set. We do not necessarily expect propensity matching to improve performance, as this method reduces the influence of confounding variables that have high overlap between the train and test sets.

Because the data set is imbalanced (the Politicians test set is $82\%\mathbf{M}$ and the Public Figures test set is $35.9\%\mathbf{M}$), we report F1 and accuracy scores in Table 1, where W_GEN = **F** is considered the positive class. As expected, models with demotion perform best on all metrics, with the exception of recall in the Politicians data.[4] We note that in general lack of performance improvement on the test set does not necessarily mean the model is not working, and it could indicate that there is not biased language in the data set. However in this case, since we do observe biased comments in this data (e.g. Table 3), and we do observe a performance increase, the performance increase suggests that confound demotion improves the model's ability to generalize beyond the individuals in the training set and capture characteristics of language addressed to women in general.

Detection of Sexist Comments Finally, we evaluate if our model captures gender-biased language by using it to identify gender-based microaggressions, i.e.,"you're too pretty to be a computer scientist!". This task is notoriously difficult because words like "pretty" often register as positive content (Breitfeller et al., 2019; Jurgens et al., 2019). Our goal is not to maximize accuracy over microaggression classification, but rather to assess whether or not our model has encoded any indicators of gender bias from the RtGender data set, which would be indicated by better than random performance.

We use a corpus of self-reported microaggressions.[5] In the absence of negative examples that contain no microaggressions, we focus on distinguishing gender-tagged microaggressions (704 posts) from other forms of microaggressions, e.g., racism-tagged (900 posts). We train our model on either the Politicians or Public Figures training data sets, and then we test our model on the microaggressions data set. Because most gender-related microaggressions target women, if our model predicts that the reported microaggression was addressed to a woman (e.g. W_GEN = **F**), we assume that the post is a gender-tagged microaggression. Thus, our models are *not trained at all* for identifying gender-tagged microaggressions.

Table 2 shows results from our models and two random baselines. "Random" guesses gender-tagged or not with equal probability. "Class Random" guesses gender-tagged or not according to true test distributions (56.1% gender-tagged). All models outperform "Class random", and all models with demotion also outperform "Random".

Propensity matching improves F1 when training on the Politicians data, but not Public Figures. Several differences could explain this: the Public Figures set is smaller, so propensity matching causes a more substantial size reduction. Also, the Politicians data is more heavily imbalanced, though notably, it is imbalanced in the same direction as the microaggressions data, while the Public Figures data is imbalanced oppositely. Finally, many microaggressions contain references to appearance, which are also common in the Public Figures data. Many comments to people like actresses focus on their looks, especially because they often post photos. However, by controlling for O_TXT, propensity matching discards many of these comments. Thus, by demoting a confounding variable, we make the prediction task more difficult. Our goal in confound demotion is not to improve accuracy, but to increase confidence in model outputs.

Nevertheless, the general better-than-random performance of all models is striking, as it suggests strong bias in the underlying training data, which is encoded by our models.

6 Analysis of Encoded Bias

Finally, we analyze what type of bias our model learns: (1) we identify words that most impact model confidence; (2) we compare posts surfaced

---

[4] Appendix B reports precision and recall. The discrepencies between F1 and Accuracy are explained by the imbalance in the data set, particularly in the Politicians data set, which is imbalanced in favor of **M** while we report metrics assuming **F** is the positive class.

Table 2: Evaluation over the microaggressions data set. Despite not being trained for this task, our models achieve better-than-random performance.

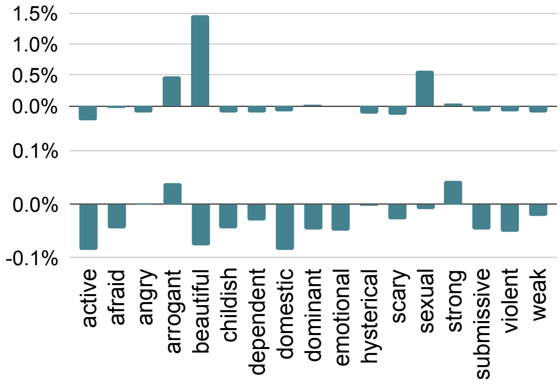

Figure 3: Lexicon differentials between comments with a high likelihood of bias and random samples with W_GEN $=$ **W** for Public Figures (top) and Politicians (bottom) data. In the Public Figures data, high-likelihood comments are more focused on appearance.

by our model with prior work on stereotypes; (3) we show example posts surfaced by our model. Throughout this section, we use *prediction score* to refer to the output of the final softmax layer of the prediction model, which we take as an estimate of model confidence. We generally focus on COM_TXT for which our model predicts W_GEN $=$ **F** with a high prediction score. These are the posts our model identifies as likely to contain bias against women: despite the matching and demotion methods, the model still predicts W_GEN $=$ **F** with high confidence.

Influential words We identify words that strongly influence the model's decisions by masking out words from comments in the test set and examining the impact on prediction score. For each data set, we take the 500 comments from the test set for which the model predicts W_GEN $=$ **F** with maximal prediction scores. We then generate masked posts: for every word w in the post, we generate a version of the post that omits w. We run these masked posts through our gender-prediction model and compare the prediction scores where w is omitted and where w is not omitted, averaging across all occurrences of w in the 500 posts. We then examine the set of w words with the highest differential in prediction score - these are words that, when omitted, cause the model to less associate W_GEN with **F**.

In the Public Figures data, the most influential words are appearance-driven and sexualized: *beautiful*, *bellissima*, *amore*, *amo*, *love*, *linda*, *sexo*. In contrast, influential words in the Politicians data are more mixed. Words include references to strength and competence, e.g., *force*, *situation*, as well as traditionally domestic terms, e.g., $\langle$*spouse*$\rangle$[6], *family*, *love*. When we repeat this process using the 500 highest-confidence posts from the training set instead of the test set, we find similar results. Influential words in the Public Figures training data primarily refer to appearance, while ones in the Politicians training data include terms like *DINO*.[7] However, influential words from the training data also includes some correlative terms, like names of states, that we would expect the latent confound demotion to de-emphasize. While §5 suggests that our model successfully reduces the influence of confounding variables, more work is needed to eliminate them entirely.

Comparison to stereotype lexicons In order to better understand these trends, we draw from prior work on stereotype detection (Fast et al., 2016). We take the set of test comments for which our model predicts W_GEN $=$ **F** with a high prediction score (≥ 0.99 for Public Figures; ≥ 0.95 for Politicians). Then, we compute the difference in frequency of words from a stereotype lexicon (Fast et al., 2016) in this high-confidence prediction set with their frequency in a random sample of the same number of comments where the true value of W_GEN $=$ **F**.[8]

Figure 3 reports results, which reflect the same trends observed in the influential words. In the Public Figures data, the lexicons that overlap the most with the high-bias posts are “Beautiful”, “Arrogant”, and “Sexual”, which suggests that bias

---

[6] “$\langle\rangle$” indicate overt terms substituted out. “$\langle$spouse$\rangle$” replaced “husband”, “husbands”, “wife”, and “wives”.

[7] “Democrat in Name Only” a political insult

[8] We ignore non-English comments and lemmatize the comment text and lexicons. We randomly sample twice and average frequencies between samples. Lexicon counts are normalized by total number of words in the sample.

O_TXT	From reintroducing my legislation to curb sexual assault on college campuses to...
COM_TXT	DINO I hope another real Democrat challenges you next election
O_TXT	Donald Trump is the President, not our ruler...Speak up! Call the White House...
COM_TXT	⟨name⟩ Shea-Porter, I did not vote for you and have no clue why anyone should have. You do not belong in politics
O_TXT	I am wondering about the guy who actually cried over spilt milk? He must have had...
COM_TXT	Total tangent I know but, you're gorgeous.
O_TXT	Bob and I join Bill Hemmer on America's Newsroom to discuss whether or not...
COM_TXT	I like Bob, but you're hot, so kick ⟨theirs⟩ butt.

Table 3: Example comments surfaced by our model from Politicians (top) and Public Figures (bottom) data sets.

in these comments focuses on appearance and sexualization. In contrast, bias in comments directed towards politicians are less focused, and differences between the high-confidence prediction posts and the random sample are smaller. The two most prominent lexicons are "Arrogant" (primarily driven by lexicon words *special*, *proud*) and "Strong". Notably, we do not account for negation of lexicon words. A narrative of power is reflected in comments surfaced by our model: "you & Nikki Haley lost my vote on the flag issue *your both weak*". We provide more examples in Table 3.

Because the stereotype lexicons are small and scores can be dominated by a few words, we also compare LIWC scores (Pennebaker et al., 2001). While most LIWC categories are too broad to align with well-known stereotypes, results are consistent with Figure 3; for Public Figures, the high-bias data scores higher than the random sample for the "Sexual" (0.32 vs. 0.10) and "Body" (0.70 vs. 0.56). For Politicians, the high-bias comments score lower than the random sample in the "Drives" (8.76 vs. 9.71), which encompasses Affiliation, Achievement, Power, Reward, and Risk focus.

The difficulty in evaluating our model against existing lexicons as well as the differences between the two data sets motivates our goal in learning to detect bias automatically. Bias can differ in different contexts, making it difficult to crowdsource through annotations or define through lexicons.

Examples Table 3 shows training and test examples surfaced by our model. We identify them by selecting posts where O_TXT is not strongly gendered (propensity score model described in §3 outputs a prediction score < 0.6), but where COM_TXT is strongly gendered (> 0.9 prediction score). While posts from the Politicians data are diverse, posts from the Public Figures data focus on appearance. These comments reflect the broader trends shown in the influential words and in Figure 3.

7 Related Work

Our work differs from prior work on bias detection in NLP in that we infer bias from data in an unsupervised way, whereas prior work relies on crowd-sourced annotations (Fast et al., 2016; Bolukbasi et al., 2016; Wang and Potts, 2019; Sap et al., 2020). This work typically focuses on specific types of bias, such as condescension (Wang and Potts, 2019) or microaggressions (Breitfeller et al., 2019) and involves carefully constructed annotations schemes that are difficult to generalize to other data sets or types of bias. In contrast, our unsupervised approach is not limited to any particular domain and does not rely on human annotations, which can be subjective.

Less-supervised approaches focus on corpus-level analyses, such as associations between gendered terms and occupational stereotypes (Wagner et al., 2015; Bolukbasi et al., 2016; Fu et al., 2016; Joseph et al., 2017; Nakandala et al., 2017; Friedman et al., 2019; Chaloner and Maldonado, 2019; Hoyle et al., 2019). Methodologies for identifying gender-related differences in text have varied, including word-embedding similarity (Bolukbasi et al., 2016), language model perplexity (Fu et al., 2016), and predictive words identified by logistic regression (Nakandala et al., 2017). These metrics are meaningful over a corpus-level, but are often difficult to interpret over short text spans. Additionally, none of these methods focus on controlling for confounds.

While matching is a well-established method for controlling for confounding variables in causality literature (Rosenbaum and Rubin, 1983, 1985; Stuart, 2010), considerably less work has drawn this methodology into NLP. Most work takes one of two approaches. In the first scenario, text maybe be a confounding variable that needs to be controlled in order to measure the effect of a non-text variable (Roberts et al., 2020; Veitch et al., 2019). For example, Roberts et al. (2020) examine whether or not papers written by male authors are cited more than ones by female authors, while controlling for the content of the paper. Roberts et al. (2020) also offer a specific method for matching text, which relies on the output of a topic model. In this work, we use the output of an LSTM, which is generally more appropriate for short text, does not make the simplifying BOW assumption, and scales well to large data sets.

In the second scenario, it may be desirable to control for non-text confounds before analyzing text. Chandrasekharan et al. (2017) use matching to identify similar users on Reddit before comparing the content that they post. Our work requires both of these perspectives, as the variable we control for (O_TXT) and the outcome we analyze (COM_TXT) are both text. Egami et al. (2018) do consider a similar setting where text is both an outcome and a confound. While their goals differ greatly from ours, our framework is generally consistent with their recommendations. Keith et al. (2020) provide a more complete overview of using text to reduce the influence of confounding variables.

8 Limitations and Future Work

While our work serves as an initial approach toward unsupervised detection of comment-level gender bias, we identify several limitations and areas for future work. We first focus on limitations within our proposed framework. First, while our results in §5 suggest that adversarial training does help reduce the influence of latent confounding variables, the analysis in §6 suggests that there is scope for improvement. Furthermore, while we focus on some confounds in the data, there may be additional ones that our model does not account for, such as the impact of videos, photos, or links shared with O_TXT. Similarly, while our model uses O_TXT for propensity matching in the training data, thus encouraging the model to encode indicators of bias, a model to classify comments as biased or unbiased should also incorporate O_TXT when assessing test data. Additionally, we assume that all comments are directly addressed to OW, but some comments may be addressed to other commenters. Finally, our assumption that human judgements are not reliable for this task makes evaluation difficult, and this task would benefit from the development of additional evaluation metrics.

There are additional avenues for future work beyond our proposed framework. Notably, we focus on the perspective of OW and examine what bias social media users may be exposed to, i.e. what comments men and women might expect to receive in response to their posts. We do not examine why comments addressed toward men and women may differ, whether because the same commenters write different comments to men and women, or because men and women attract comments from different types of people. This perspective would require controlling for traits of the commenter, such as gender, age, and occupation. Nevertheless, our work stands without this perspective: biased comments are harmful to the recipient, regardless of who wrote them.

9 Conclusions

Bias detection is useful for fostering civil communication on social media, as it allows recipients to screen out biased comments. Further, our intention is to detect implicit bias that people may not know they have - revealing these biases to social media users could proactively prevent them from posting unintentionally biased comments. Detecting and analyzing bias is a first step towards mitigating it, and we hope our work will encourage future work in this area.

A Data and Model Implementation Details

	Politicians	Pub. Figures
Raw train size	6.9M	4.2M
Test/Dev size	2.3M/2.5M	1.9M/0.55M
% M in train	71.3%	33.9%
Matched train size	256K	77K
Raw dem. dim.	240	63
Matched dem. dim.	239	60

Table 4: Data Statistics. “Matched train size” refers to the size of the training set after propensity matching, and “dem. dim.” refers to the size of the latent confound vector that is demoted during training.

All data is lowercased and tokenized, and we discard data points with fewer than 4 tokens. Table 4 reports details of our data set after preprocessing.

For the primary prediction models, we use the same architectures as Kumar et al. (2019), including training multiple (2) adversaries. We perform minimal hyper-parameter tuning, primarily using the same parameters as Kumar et al. (2019), with the exception of the learning rate, which we changed slightly to decrease fluctuations in validation accuracy, and the number of training epochs for each phase of the model, which we increased or decreased as needed based on how long the validation accuracy improved for. These changes were determined by manual tuning over < 10 trials. For the propensity score model, we use a learning rate of 1e-3. For all other models we use a learning rate of 1e-4. For the models without confound demotion, we train for 5 epochs. For the models with confound demotion, we train the classifier for 3 epochs, the adversary for 10 epochs, and we repeat the alternating cycle for 3 epochs. For all models, we choose the best model as measured by W_GEN classification accuracy over the validation set. Each model was trained using 1 GPU. The models without latent confound demotion and the propensity score estimation model have 4.2M parameters each. The adversary in the latent confound demotion models adds an additional 61.7K parameters to the Politicians model and 16.2K parameters to the Public Figures model.

B Additional Evaluation Metrics

Table 5 provides the same results as Table 1, with the addition of precision and recall scores. Table 6 shows results for the same experiments as Table 5, but provides metrics over the validation sets instead of the test sets. Table 7 extends Table 2 by additionally showing precision and recall scores.

	Prec.	**Rec.**	**F1**	**Acc.**

C Microaggressions Data Set

The dataset of microagressions is taken from Breitfeller et al. (2019), who collected the corpus from `www.microaggressions.com`. On this website, posters describe a microaggression that they experienced. They can using quotes, transcripts, or narrative text to describe the experience, and these posts are tagged with type of bias expressed, such as “gender”, “ableism”, “race”, etc. We discard all posts that contain only narrative text, since it is not 2^{nd} person perspective and thus very different than our training data, which leaves 1,604 posts for analysis.

Condolence and Empathy in Online Communities

Abstract

Offering condolence is a natural reaction to hearing someone's distress. Individuals frequently express distress in social media, where some communities can provide support. However, not all condolence is equal—trite responses offer little actual support despite their good intentions. Here, we develop computational tools to create a massive dataset of 11.4M expressions of distress and 2.8M corresponding offerings of condolence in order to examine the dynamics of condolence online. Our study reveals widespread disparity in what types of distress receive supportive condolence rather than just engagement. Building on studies from social psychology, we analyze the language of condolence and develop a new dataset for quantifying the empathy in a condolence using appraisal theory. Finally, we demonstrate that the features of condolence individuals find most helpful online differ substantially in their features from those seen in interpersonal settings.

1 Introduction

Millions of individuals experience emotional distress each year from diverse circumstances such as personal loss or abuse. After such experiences, people often turn to their social circle in social media to convey their experiences and seek out emotional support (Brubaker et al., 2012; Brubaker and Hayes, 2011; De Choudhury and Kiciman, 2017). Often, support comes in the form of condolence where individuals connect with the distressed person, and express forms of sympathy, empathy, advice, and social connection, among others (Burleson, 2003). However, not all expressions of distress receive emotional support, nor do all condolence messages offer equal levels of support (Davidowitz and Myrick, 1984). Given the wide-spread use of social media for seeking social support, what makes for an effective supportive message? Here, we perform the first major study of condolence in social media, examining what type of distress individuals seek support for, what linguistics factors are more likely to elicit condolence, and what types of condolence viewed as more helpful.

Distress and emotional support have long been explored in work in social psychology and counseling (Burleson et al., 2009; Rack et al., 2008), frequently around bereavement and helping victims of abuse. NLP works have only recently examined emotional support in online spaces for mental and physical health (Biyani et al., 2014; Navindgi et al., 2016; Wang et al., 2015) and in communities oriented around goals like weight-loss (Manikonda et al., 2014); however, these focus on the general concept of supportiveness. In this work, we examine distress as a universal phenomenon—not just related to health and death—and examine the strategies and helpfulness of responses to this distress.

This study aims to computationally identify mechanisms and strategies for delivering effective and impactful condolence on social media. Conveying condolence is often difficult for many people (Cameron et al., 2019), who fall back to common responses to distress such as "thoughts and prayers" or "I'm so sorry for your loss" due to the emotional and mental effort required to relate to the distressed person. To identify effective strategies of condolence, we construct a dataset of 14.1M expressions of distress from Reddit by developing computational models for recognizing distress and condolence. We then use this dataset to analyze how the community embraces the individual and which condolence responses were found helpful.

This work offers the following three contributions. First, we introduce a new massive dataset of 11.4M public expressions of distress and 2.8M of condolence labeled using two deep learning models for identifying each, showing that our data mirrors known trends in seasonality and theme. Sec-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 609–626,
November 16–20, 2020.

ond, using an analysis of 11.4M expressions of distress, we demonstrate that the community selectively engages in condolence; not all distress messages which attract attention actually receive support. Third, we introduce a new dataset and model for identifying empathy in condolences and, using the empathy estimates, find that distressed individuals less frequently offer gratitude for deeply empathetic condolences and instead prefer compassionate, positive messages, which runs counter to observations from in-person settings.

2 Recognizing Distress and Condolence

Distress and condolence are expressed in a variety of ways. As no standard dataset exists for detecting these constructs, we first create one for training models using distant supervision to heuristically label data. Then, two classifiers are trained to recognize each in expressions on social media and finally fine-tuned to attain high precision. For both, we use Reddit comments as our base data. Additional details for classification and training are reported in supplemental section A.

Recognizing Distress A set of stereotypical condolence expressions, e.g., "sorry for your loss" or "my heart goes out to you" is first manually identified. Due to their ubiquitous use in the face of distress, such expressions act as heuristics to identify posts containing a variety of circumstances and topics. All Reddit comments receiving at least one of these stereotypical-condolence replies are treated as positive examples of distress, identified from all Reddit comments in the year 2017.[1] An equivalent number of randomly-selected comments that do *not* receive any of these stereotyped-condolence responses are sampled from the same communities in the same month, which ensures the corpus is topically and temporally balanced. In total, 229,204 comments are collected as training data from Reddit during the year 2017.

Two classifiers are trained from this balanced dataset. The first is a SVM classifier using unigrams and bigrams, which is known to be a robust baseline (Wang and Manning, 2012). The second is a BERT-based classifier (Devlin et al., 2019) trained using a linear layer on top of the pooled [CLS] token for classification over 2 epochs. The base pretrained model was `bert-base-uncased` from the Hugging Face transformers library (Wolf et al., 2019). For both models, comments are preprocessed to remove markdown, links, and non-ASCII characters. Table 1 (top) shows that models are able to accurately identify distress expressions. Because many contexts can elicit an emotional response, distress is challenging to identify; further, because the data is heuristically labeled, we do not expect high performance in this initial model.

		Precision	Recall	F1 Score
Distress	Random	0.5	0.5	0.5
	SVM	0.597	0.631	0.617
	BERT	0.725	0.686	0.705
Condol.	Random	0.5	0.5	0.5
	SVM	0.745	0.897	0.815
	BERT	0.908	0.767	0.831

Table 1: Model performances at recognizing expressions of distress (top) and condolence (bottom) from the heuristically-labeled data.

Recognizing Condolence Condolence-giving comments are heuristically identified in a similar manner to those for distress. When a comment receives a reply containing one of the stereotyped-condolence expressions, a single different reply to that same comment is selected as another expression of condolence. The assumption is that distress attracts multiple condolences, allowing us to learn a variety of condolence expressions. To minimize potential confounds, condolence comments were collected from all Reddit comments from a different year than distress comments (2016). Negative examples of condolence are randomly sampled from replies to different non-distress comments under the same post, which ensures a balance in time and subreddit between positive and negative examples.

SVM and BERT-based classifiers were tested to recognize condolence in comments, using the same setup as those for recognizing distress. Performance at recognizing condolence, shown in Table 1 (bottom) was even higher than that for recognizing distress. Since there are relatively common strategies in condolence expressions (e.g., expressing sympathy with phrases like "I'm so sorry for your loss"), we suspect these condolence comments are easier to recognize.

---

[1] No filtering was done to pre-select only those posts that might elicit distress-like comments that might receive such condolences.

Tuning for Precision Decision thresholds were set at 0.9 for both classifiers to focus on precision after a manual review of a subset of classifications found this to produce sufficiently correct results.

Dataset Description Our final condolence and distress datasets were collected by running the respective classifiers on a random sample of 2018 Reddit comments made in the top ten thousand most popular safe-for-work subreddits. Condolence comments have a length centered around a median of 21 words, with a long right tail (mean of 47.7 words, standard deviation of 79.8 words). Distress comments have a similarly shaped distribution, with a median of 25 words, mean of 41.3 words, and standard deviation of 57.8 words.

3 Condolence Behavior in Social Media

As an initial demonstration of the model, we label a random sample of Reddit comments from 2018 made in the top ten thousand most popular safe-for-work subreddits and examine where and when distress and condolence are exhibited.

Distress and condolence communities Figure 1 (left) shows that while health topics are prominent, individuals frequently seek out communities based around bereavement (e.g., r/Miscarriage) and abuse (e.g., r/domesticviolence). This result confirms that our model is able to identify a diverse set of circumstances in which individuals experience distress, mirroring some of those highlighted in prior work for online support of distress (Krysinska and Andriessen, 2013; Huh et al., 2014; Döveling, 2017). Surprisingly, the location of condolence behavior (Figure 1, right) does not mirror that of distress. Instead, condolence is frequently offered to those suffering from the loss of a pet and, less frequently, those experiencing the death of a loved one. Many people find the death of a pet more relatable compared with other circumstances like domestic violence, lessening the effort required to relate to the person experiencing the loss and offer condolence (Lim and DeSteno, 2016). Indeed, to express effective condolence, an empathetic response requires effort to relate on a personal level to the feelings of the affected person (Cameron et al., 2019), which many may find more challenging emotionally in circumstances like abuse.

Seasonal effects in distress Changes in seasons and holidays are both known to increase distress and anxiety levels (Cattell, 1955; Rosenthal et al., 1984; Harmatz et al., 2000). As Figure 2 shows, expressions of distress in Reddit mirror these trends with a substantial increase around commonly-celebrated holidays. There are spikes around Valentine's Day (February) and increases leading to Thanksgiving (November), Christmas and New Year's (December). Surprisingly, the rate of a community's support of these individuals—expressed through condolence—largely does not mirror this trend. Instead, we observe that spikes in condolence were associated with significant events, including school shootings and celebrity deaths; these self-contained events triggered mass outpourings of condolence.

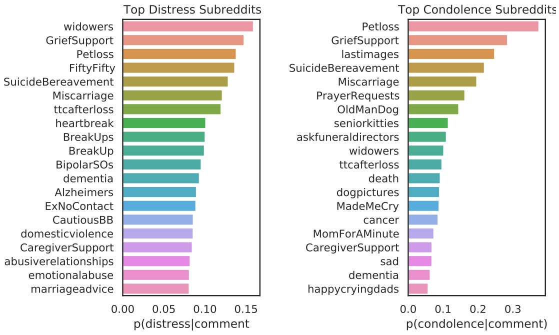

Figure 1: Subreddits with highest proportion of condolence and distress comments.

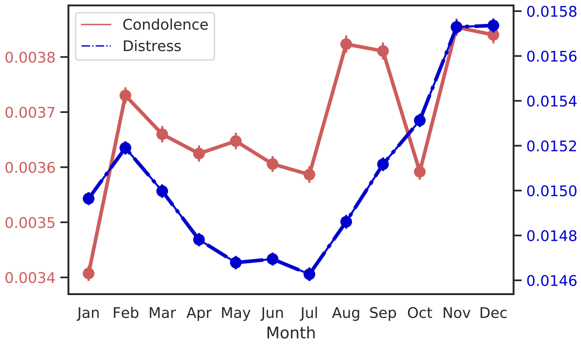

Figure 2: Relative rates for distress (right axis) and condolence (left axis) show that while distress mirrors expected seasonal trends, condolence does not; instead, condolence trends are partially driven by response to events, e.g., mass shootings. Throughout the paper, error bars show 95% confidence intervals.

4 What Distress Receives Condolence?

As individuals turn to social platforms for emotional support for a variety of reasons, which types of distress messages receive condolence? We contrast whether an expression of distress receives condolence with receiving any reply.

Methods To understand what factors lead to a distress message receiving a reply or a condolence, we fit separate mixed-effect logistic regression models on the dependent variable of receipt of the respective type. To capture thematic trends across messages, we train a 20-topic LDA model and manually label each topic with its prominent theme (topics are shown in supplemental section C). Offering a condolence can require empathetic alignment with another person (Trobst et al., 1994; Cameron et al., 2019), which could be difficult for certain emotions; therefore, we include estimates of the emotions expressed in a distress message using the NRC-emotion lexicon (Mohammad and Turney, 2013). Pronouns reflect the narrative focus of the distress, e.g., frequent mentions of "I" center the content on the distressed person whereas "he" focus on what was done to the distressed person; therefore we include counts of how many times first, second, and third-person pronouns appear using LIWC categories (Pennebaker et al., 2001). Individuals on Reddit are known to be sensitive to the perceived gender of the author when providing support (Wang and Jurgens, 2018), so we include a variable for the user's estimated gender using `genderperformr`. As controls, we include comment length by space-delimited words, the comment age in hours after the post was created, the depth of the comment, the score of the post as a measure of popularity, and temporal factors for hour of day, day of week, and month. To control for differences within specific subreddits and posts, we include nested random effects for subreddit and the post in which the distress comment is made; for computational tractability, we include only random effects for posts with 30 or more distress comments. The Reddit-based models were fit using a random sample of 1M comments from the 2018 data identified as distress expressions.

Table 2: When expressing distress, the effect of social, contextual, and linguistic factors on receiving any reply to distress (left) versus receiving condolence (right).

Results The factors affecting whether a distress comment receives a reply differed substantially from those receiving condolence. Whereas distress comments relating to politics, dieting, or sports are likely to receive a reply, such comments are far less likely to receive condolence. Differences in topical effects show that while the Reddit community is likely to engage with distress in all topics, the community selectively supports only a few of these. While the model for receiving a reply is similar to De Choudhury and De (2014, table 8) who examined mental health, these results point to the importance of looking at the content of the replies, as not all replies are actually supportive.

5 The Structure of Condolence

Individuals regularly employ a common set of strategies in condolence (e.g., Davidowitz and Myrick, 1984; Lehman et al., 1986; Burleson, 2003), from trope-like expressions ("sorry for your loss") to thoughtful and empathetic statements that validate the other's experience. These statements often fall along a spectrum of person-centeredness (High and Dillard, 2012) with respect to their acknowledgment, understanding, and legitimization of the distressed person's state. Here, we analyze the structure of Reddit condolences to examine regularities in strategies individuals employ in crafting their responses. We use a data-driven approach to identify themes by fitting a 20-topic LDA model to identify broad themes; to test for structure, we measure the probability of each topic in the sequence of sentences for condolences of different lengths.

Results Condolences follow regular patterns in their strategies for support. Figure 3 shows the presence of different topics by position in the sentence across condolences of different lengths; the most probable words for each topic are listed in Table 3. Three notable trends occur, showing increasing focus on the person experiencing distress.

First, sympathy features prominently in shorter condolences, which focus largely on acknowledging the person's suffering as a result of the distress. These comments serve as bookends to the overall statement, but largely disappear in longer condolences. The use of swearing in these contexts acts not only as an intensifier in expressing the speaker's perception of unpleasantness but also as a way of expressing solidarity through emphasizing in-group membership by transgressing social norms (Fägersten, 2012; Stapleton, 2010).

Second, as condolences become longer, individuals begin adding their own experience within the response (PERSONAL EXPERIENCE). This behavior features prominently in middle-length condolences that still begin with sympathy and then try to relate their own personal experience to that of the suffering. At a high-level, these experiences aim to help the person experiencing distress reframe their own mindset and correspond to a higher-level of person-centeredness (Servaty-Seib and Burleson, 2007; High and Dillard, 2012).

Finally, the longest condolences contain significant amounts of advice and reframing, with less focus on the condolence giver. These condolences can correspond to even higher levels of person-centeredness by trying to engage with the other's experience through advice.

6 Empathy in Condolence

At a high level, empathy requires a person to imagine the experience of another as they felt it—to put themselves in the other's shoes. In condolence, empathy provides a powerful, person-centered framing for validating and connecting with those in distress. Distressed individuals have found empathetic condolences more supportive than sympathetic messages (Davidowitz and Myrick, 1984; Shapiro, 2001) and more effective in clinical settings at helping the distressed resolve their emotions (Worden et al., 2018).

ESTATE	you your they can money them estate their pay funeral

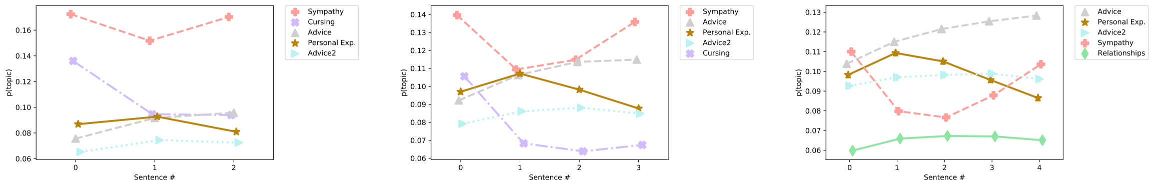
ADVICE2	you it's don't your i'm you're people can they them

Table 3: Topics for condolence speech reveal broad themes around types of distress (e.g., MEDICAL) as well as condolence strategies (e.g., SYMPATHY)

Empathy itself has many varying definitions in social psychology (Basch, 1983; Cuff et al., 2016) and the limited computational work employing empathy has largely focused only on mirroring emotional state as a way of empathizing (Collins, 2014; Litvak et al., 2016; Fung et al., 2016; Khanpour et al., 2017). More recently Abdul-Mageed et al. (2017) and Buechel et al. (2018) have gone beyond these simple models to develop and use a corpus for distress and empathy in reactions to news stories. These works adopt a broader definition drawn from multiple sources of empathy which mixes empathy with related concepts of compassion, altruism, and prosocial behavior. (Batson et al., 1987; Sober and Wilson, 1999; Goetz et al., 2010; Mikulincer and Shaver, 2010). In this work, we adopt a stricter definition of measuring empathy based on *appraisal theory* (Lamm et al., 2007; Wondra and Ellsworth, 2015). Here, empathy occurs when an observer appraises a person's situation in the same way as the person experiencing the distress. This definition more closely mirrors the person-centeredness of the response in terms of how the observer acknowledges and validates different aspects of the distressed person's mental state. Following this definition, we create a new corpus around appraisal-based empathy and develop a classifier that can be used to label condolences for their empathy.

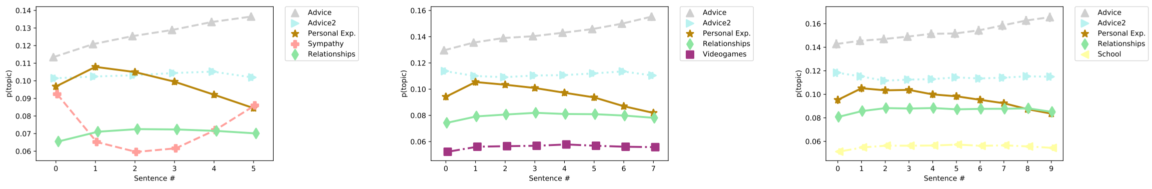
Data and Annotation Distress-condolence pairs were sampled from the Reddit dataset. Condolence



(a) 3 Sentences

(b) 4 Sentences

(c) 5 Sentences



(d) 6 Sentences

(e) 8 Sentences

(f) 10 Sentences

Figure 3: Plots of sentence-level topic distribution across condolences of different lengths reveal categorically different strategies (Topics described in Table 3). Shorter condolences focus on expressing sympathy, middle-length include more personal experience, and longer condolences offer substantial amounts of advice.

lengths followed a log-log-normal distribution, and shorter condolences tended to be trite or repetitive, e.g., “so sorry to hear.” To introduce diversity in the annotated condolence data, we binned comment pairs by condolence length using Jenks optimization, then reweighted the probability of sampling from each bin to flatten the distribution of lengths. Two annotators identified a set of 1000 distress comments with a self-contained message, without being shown the condolence to avoid bias. Individuals may express their distress over multiple comments in a discussion thread, so this process was aimed at reducing the prior context needed to estimate appraisal to a single distress comment.

Annotators were shown a condolence reply to a comment and asked to rate on a five-point Likert scale to what degree did the observer appraise the other person’s situation in the same way along the following dimensions: (1) pleasantness, (2) anticipated effort in dealing with the situation, (3) situational control, (4) how much oneself or another person was responsible for the situation, (5) attentional activity, and (6) certainty about what was happening in the situation or what would happen next. High scoring comments acknowledge and validate the distressed person’s experience.

Prior to annotating the full dataset, annotators collaboratively developed guidelines and completed five rounds of training on 100 items of held-out data in each round and discussed each case of disagreement. Annotators attained Krippendorff’s $\alpha \approx 0.6$ for the final two rounds. Following training and adjudication, the final 1,000 condolence replies were annotated. After an initial pass, Krippendorff’s α was 0.359. While this initial value seems low, α is strongly affected by the large class skew from most condolences not being empathetic (score 1). A second pass was made across the 25 comment pairs where annotators disagreed by 3 or more points, where annotators discussed their disagreements and updated their individual ratings, after which α=0.431; these disagreements were largely due to unintentional mistakes or misinterpretations, rather than substantive disagreements on empathy. In the final dataset, annotators differentiated by at most one scale point on 91.2% of the items (Pearson r=0.58). While the agreement value is moderate, it matches similar agreement levels seen when annotation requires inferring mental states and intentions from text (e.g., Card et al., 2015; Rashkin et al., 2016; Rashid and Blanco, 2017; Breitfeller et al., 2019). The difficulty of annotation stems from interpreting the intentions, appraisals, and alignment between the distress comment and observer’s comment. Further, the choice to diversity the data by sampling across longer replies likely depressed agreement, as shorter replies often are low-empathy (e.g., trite messages) which annotators readily agreed on. The final empathy rating is the mean of the two annotations.

Recognizing Empathy Two types of regression models were trained for predicting the empathy rating of a condolence using our dataset, which use either the target’s and observer’s texts or just the observer's text. The first type of models uses a random forest regressor that is trained on unigram and bigrams of the target and observers comments, using separate feature spaces for each. The second type of model uses RoBERTa (Liu et al., 2019) as a base, starting from the pretrained `roberta-base` parameters. When using the target and observer text as inputs, the texts are separated by the [SEP] token. The [CLS] representations of each input were concatenated and passed through a fully-connected linear layer, using sigmoid activation to bound the output value in [1, 5]. Due to the empathy rating imbalance in the data, we construct randomized stratified partitions for training (80%), validation (10%), and test (10%) using the rounded value of the empathy rating. Models are compared with the mean empathy rating.

Both models surpassed the baseline of predicting the mean value from the training data, as seen in Table 4, with the RoBERTa models performing best.[2] For both the RoBERTa and Random Forest models, knowledge of the target's comments improved performance, suggesting that models benefit from being able to align the two inputs in determining empathy. Nonetheless, performance of the best model is moderate at best and we view these results as a preliminary step at identifying appraisal-based empathy in text.

As a follow-up analysis, we used the Target & Observer model to rate unlabeled condolence replies and manually examined a random 100 responses rated with empathy ≥ 2, which signals more than the minimal empathetic alignment. Of these replies, 84% contained at least two empathetic alignments (e.g., aligning with the target's perception of pleasantness and situational control), suggesting the model is effective at recognizing empathetic speech and any misclassifications are more likely to be underestimates of empathy.

As a further comparison, we computed the empathy scores for the model of Buechel et al. (2018) on our data; the two scores had a Pearson r=0.343, indicating that, while related, both are capturing substantially different notions of empathy.

	MSE	R^2
Baseline: mean value	0.565	-0.008
Random Forest: Target & Obs.	0.492	0.128
Random Forest: Obs. Text Only	0.517	0.044
RoBERTa: Target & Obs.	**0.429**	**0.297**
RoBERTa: Obs. Text Only	0.555	0.094

Table 4: Empathy model performances

7 What Makes a Good Condolence?

Not all condolences are equally effective at offering support. Multiple works on bereavement have surveyed the effectiveness of different condolences (Burleson, 2009), noting that many fall along a spectrum of helpfulness to the distressed. For example, individuals typically find empathetic and validating comments more helpful, unlike advice or trope-like messages (Davidowitz and Myrick, 1984; Lehman et al., 1986; Rack et al., 2008). Here, we build a logistic regression model to evaluate which condolences Redditors found helpful and identify what features make for effective condolences.

7.1 Data

Authors of distress comments occasionally respond to condolence comments, which can include acknowledgment of the helpfulness of the condolence, e.g., "your comment made my day." We identify all such responses and treat the 23,301 paired condolences as positive examples of a good condolence. As negative examples, we use all remaining 149,992 condolence comments that did not receive such a reply. While some of the negative examples are likely effective condolences, these false negatives only result in an underestimate of the effect of the explanatory coefficients.

7.2 Model and Features

Condolence effectiveness is modeled using a nested-effects logistic regression with the dependent variable of whether the condolence was responded to with gratitude. Random effects are added for the subreddit with a nested effect for condolences made to posts receiving 30 or more replies; posts receiving fewer are modeled with a common nested effect. Note that these random effects control for relative differences in the level of gratitude and behavioral norms in each subreddit, allowing more accurate estimates of which content features contribute to effective condolences. Three groups of regression features were selected:

---

[2] Additional RoBERTa models were trained using a language model that had first been fine-tuned using masked language modeling on the distress and condolence comments for 10 epochs; however, these models resulted in slightly worse performance: the Observer-only had MSE=0.561 and R^2=0.082 and the Target & Observer model had MSE=0.516 and R^2=0.156.

two from theory for known helpful and unhelpful strategies, with an additional group of data-driven controls, all described next.

Helpful Strategy Features In the first group, we include the macro-empathy estimates of Buechel et al. (2018) and our appraisal-based empathy estimate of the comment, as person-centered empathetic responses are known to be more helpful in clinical therapy (Nienhuis et al., 2018). As a third test, we include uses of first-, second-, and third-person pronominal referents from LIWC (Pennebaker et al., 2001). Increased use of each pronoun category reflects narrative focus on the condoler, distressed person, or the situation being described, respectively; in particular, mentions of the distressed person are more aligned with a person-centered message. Fourth, individuals will mirror the language as a way of decreasing social distance which can increase trust (Scissors et al., 2008); Wang et al. (2015) found that lexical alignment is associated with increased emotional support. Therefore, we include a feature for lexical alignment as the % of the condolence's words that were also used in the distress comment.

Unhelpful Strategy Features Some well-intentioned responses may include strategies that are unhelpful in practice. Lehman et al. (1986) note that forced positivity in the face of distress is often viewed poorly; therefore, to test this effect, we include a sentiment estimate of the condolence using VADER (Hutto and Gilbert, 2014). Similarly, minimizing phrases such as "it's not that bad" or "I'm sorry you feel sad" invalidate the experience and emotions of the distressed persons (Lehman et al., 1986; Hogan et al., 1994); to test for these effects, we include the presence of a list of such phrases drawn from observational studies and matched using regular expressions. Third, we include a separate minimizing phrase for trivializing "just" (Kiesling, 2011)—e.g., "it's *just* an exam"—which is modeled by identifying the presence of an adverbial use in the text.

Control Features As controls, we include (i) the topics of the condolence (Table 3), which act as coarse proxies of the strategy and content, (ii) the score of the comment containing the distress and the time between the distress comment and condolence reply (minutes), (iii) the length of the condolence, and (iv) temporal factors for the month, day of week, and hour of day. Finally, multiple studies have reported gender differences in strategies of support, with women typically offering more emotionally complex and empathetic condolences (Knight et al., 1998; Rack et al., 2008; Burleson et al., 2009); to test for this effect, we include the gender prediction from `genderperformr`.

7.3 Results

The linguistic factors associated with helpful condolences largely followed expectations from observational studies, with one significant exception. As predicted from observational studies, condolences with markers of person-centered responses were rated as more helpful, which included lexical alignment and narrative focus on the other person (second-person pronouns). In annotation, we observed that condolences shift between the "personal you" of the distress person and use of the "generic you," which is known to be evoked in meaning making (Orvell et al., 2017, 2019); given the positive coefficient for second-person pronouns, future work may attempt to distinguish between these uses to test whether such meaning-making comments contribute to more effective condolence.

Also predicted, advice is strongly negative to good condolence—despite being the most commonly-used strategy (cf. Figure 3). Replies with the ADVICE 2 topic contained more references to third parties than ADVICE; some of these included popular supportive quotes, not actually condolence, or assessment of and advice for a third-party outside of the interaction being modeled in this regression. Similarly, sympathy and invocations of religious language (which we found often contains minimizing tropes) are known to be found less helpful and have negative coefficients here as well. Last, our study confirms the expected disparity for men and women in condolence helpfulness.

However, our results disagree with prior observations on empathy and we find that, while the compassion-like empathy of Buechel et al. (2018) is found helpful, condolences with the more person-centered appraisal-based empathy were less likely to receive gratitude. We speculate that people may turn to Reddit for lighter, less-personal forms of support in times of distress, whereas the more compassion-like empathy of Buechel et al. (2018) is helpful when more personal responses are not licensed by the relative anonymity of the platform.[3]

Our results also disagree with expectations around forced positivity (Lehman et al., 1986), where positive sentiment replies are consistently more helpful. We interpret this result pointing to a different goal of support by Reddit users who seek out positive reinforcement, rather than comments that require emotional effort to engage with complex emotions.

While we are only able to speculate on negative impact of appraisal-based empathy, the effect could be due to different goals for the desired support received online, where individuals seek out information instead of empathy (Yao et al., 2015). Alternatively, here, we have modeled condolence helpfulness using a fixed set of phrases to identify thanks in replies; it could be that the more empathetic responses generate replies that, while not containing these thanks-expressions, still signal the condolence's positive utility. Our results motivate future work to understand online users' preferences for empathy in support: as millions of people already respond to distress with good intentions each year, improving these supportive efforts has the potential to better the lives of millions.

8 Ethics

Distress is inherently personal and computational studies on such matters warrant ethical consideration. In weighing the risks and benefits of our studies, the largest risk has been the loss of privacy, as individuals expressing their distress may have contextual expectations of privacy or anonymity (Fiesler and Proferes, 2018). To mitigate this risk, we report only paraphrased examples and aggregate statistics. Further, we only release this data to researchers upon request and provided they follow similar privacy practices. As a counter balance, this study has considerable benefit by providing better information on what makes for effective condolences; the insights from this study can be distilled into practical advice that can make for more supportive online communities.

9 Conclusion

Distress is an omnipresent part of life, and individuals turn to their social circle and social platforms for support when experiencing it. In this paper, we have developed new computational models for recognizing distress, condolences to that distress, and empathy within condolence. Applying those models, we examine the dynamics of distress and condolence, showing that not all distress is treated equally online, and there exist regular structures within condolence. Through analyzing millions of condolence responses, we test what makes for effective condolence online, showing that while some features predicted from observation studies hold true online, e.g., increasing person-centeredness of the message (High and Dillard, 2012), distressed individuals did not find empathetic comments more helpful, suggesting different goals from online support. Our results have important implications for (i) individuals by providing concrete suggestions of how to express one's distress to make it more likely to receive support, (ii) site operators by allowing them to observe the emotional health and responsiveness of their community, potentially reaching out to underserved individuals who have yet to receive support, and (iii) the general public for authoring more effective supportive messages. Models and reproducible code are available at `https://blablablab.si.umich.edu/projects/condolence/` and data is made available upon request.

---

[3] As a follow-up analysis, we also tested whether a binary encoding of higher appraisal empathy (score ≥ 2) instead of a continuous marker would be found to be more helpful; after re-running the regressions, the appraisal-based empathy still had a negative coefficient.

Acknowledgments

The authors thank members of the Blalablab for their helpful feedback, the anonymous reviewers for their thoughtful insight which definitely made this paper better, and the highly empathetic Redditors for restoring our faith in the goodness of humanity. This material is based upon work supported by the National Science Foundation under Grants No IIS-1850221 and IIS-2007251. The last author was supported in part through the Amazon Alexa Prize Competition 3.

A Condolence and Distress Models

A.1 Dataset

Both the condolence and distress datasets are collected using the heuristic method detailed in the paper. An initial set of stereotypical “seed” condolence phrases is augmented by performing the process of retrieving sibling comments to comments containing these condolence phrases and then performing an n-grams analysis to discover other common phrases. This final list of 21 phrases, shown in Table 6 was used to identify distress comments as described in the main paper.

The final condolence dataset had 431,283 positive examples and 430,311 negative examples. The final distress dataset contained 112,265 positive examples and 116,939 negative examples.

When training, the raw text was extracted from markdown, code blocks were removed, links were stripped, and only ASCII characters were kept. Newlines were replaced with a single space.

A.2 BERT Models

Both deep learning classifiers were fine-tuned on a pretrained BERT model with 12 heads and 110M parameters, trained on lower case English text (the HuggingFace `bert-base-uncased` model), and share the same architecture and training method.

For both models, we feed 768-long hidden output into a fully-connected layer with 2 outputs, which are then fed through a softmax activation function.

During training, a dropout with probability 0.5 was added between the BERT output and the fully connected layer. The fully-connected layer was initalized using Xavier initialization (Glorot and Bengio, 2010). ADAM optimizer was used to minimize cross-entropy loss with learning rate 0.001 for the fully connected layer and 0.00001 for BERT parameters initially, and decreased by a factor of 10 every three epochs. The training set was shuffled every epoch. The models were trained overnight with batches of 16 comments on a single NVIDIA GTX 1080 Ti.

A.3 SVM Classifiers

SVM classifiers are trained as a baseline for comparison. The inputs are preprocessed in the same way (text extracted from markdown, links and code blocks stripped, and Unicode symbols removed). Again, both the condolence and distress classifiers were trained the same way with the same hyperparameters.

”made me tear up”
”take care of yourself”
”my heart goes out”
”please take care of”
”heart goes out to”
”do not blame yourself”
”my thoughts and prayers”
”this made me cry”
”my deepest condolences”
”can not even imagine”
”sorry for your loss”
”you dodged a bullet”
”even begin to imagine”
”not beat yourself up”
”keep your head up”
”can not even begin”
”hope you find peace”
”there are no words”
”remember the good times”
”can not imagine losing”
”god bless you and”

Table 6: The stereotypical condolence phrases used to identify distress comments in the initial dataset collection process.

	Test	**Validation**
Distress SVM	0.629	0.617
Condolence SVM	0.829	0.830
Distress BERT	0.714	0.717
Condolence BERT	0.844	0.846

Table 7: Table of model accuracies on train and test splits

The same random seed is set as when training the deep learning models, so the training, validation, and test datasets are the same between the BERT and SVM classifiers. We trained the linear SVM on comments count-encoded with the 50,000 most common uni- and bigrams. Each classifier took a few minutes to train.

Table 7 shows test and validation accuracies for all four models, and Table 8 shows test and validation F-1 scores for all four models.

B Empathy Model

B.1 Dataset

The dataset was collected as detailed in the paper, then cleaned to be stripped of markdown, links, and images.

B.2 Random Forest Regressor

A random forest regressor is trained to predict empathy (as an average of the two annotator scores) given unigram and bigram features of either (i) only the Observer’s condolence reply as input or (ii) the Target’s comment and Observer’s reply. When both the Observer’s and Target’s texts are used, separate features are used to record the presence of unigrams and bigrams in each. The random forest has 100 estimators using the default parameters from Scikit

	Test	Validation
Distress SVM	0.617	0.604
Condolence SVM	0.815	0.815
Distress BERT	0.714	0.707
Condolence BERT	0.844	0.833

Table 8: Table of model F-1 Scores on train and test splits

Learn 0.21.3 (Pedregosa et al., 2011). Training the regressor on 80% of the annotated dataset took approximately 10 minutes.

B.3 Deep Learning Model

Two RoBERTa (Liu et al., 2019) models were trained on the same dataset as the random forest model using the `roberta-base` set of parameters to initialize. Models were trained either providing (i) only the Observer's condolence reply as input or (ii) the Target's comment and Observer's reply. In the latter case, the two texts are separated by the [SEP] token. In both cases, classification is done using the [CLS] token. Both RoBERTa models were implemented using the `simpletransformers` package using the default hyperparameters, including learning rate 4e-5, batch size 8, and Adam ϵ=1e-8. Models were trained for 20 epochs Each model is trained on a single NVIDIA GTX 1080 Ti graphics card, and took about 30 minutes for 20 epochs. No hyperparameter tuning was performed and performance is reported over a single run using a fixed seed.

C Topic Modeling

For both distress and condolence comments, we trained LDA topic models using MALLET using its default hyperparameters for all options and using 20 topics to reflect high-level themes in the data. To preprocess, we stripped markdown, images, and links. We show the top 20 words associated with each topic, as well the topic label we decided, in Table 9 for distress topics and Table 10 for condolence topics.

D Regression Experiments

We run mixed effects regressions for several experiments: predicting whether a distress comment receives any response, predicting whether a distress comment receives a condolence response, and predicting whether a condolence comment receives an appreciative response from the distressed individual. In measuring helpful condolences, the expressions described in Table 11 were used to recognize minimizing condolences.

In these regressions, temporal controls were included, but were excluded in the regression output in the main paper. We include all regression results, including the controls, here. Table 12 shows regression results for receiving any reply (left) and the results for receiving a condolence reply (right). Finally, Table 13 shows regression results for what condolence receives a reply expressing gratitude (i.e., a helpful condolence).

possessions	car they bought them years when sold back it’s buy lost ago can mine put you good i’ve time year

Abstract

Legislator preferences are typically represented as measures of general ideology estimated from roll call votes on legislation, potentially masking important nuances in legislators' political attitudes. In this paper we introduce a method of measuring more specific legislator attitudes using an alternative expression of preferences: tweeting. Specifically, we present an embedding-based model for predicting the frequency and sentiment of legislator tweets. To illustrate our method, we model legislators' attitudes towards President Donald Trump as vector embeddings that interact with embeddings for Trump himself constructed using a neural network from the text of his daily tweets. We demonstrate the predictive performance of our model on tweets authored by members of the U.S. House and Senate related to the president from November 2016 to February 2018. We further assess the quality of our learned representations for legislators by comparing to traditional measures of legislator preferences.

1 Introduction

Legislator preferences are typically estimated as general measures of ideology using roll-call votes on legislation. However, such measures fail to capture aspects of preferences not reflected in legislation, such as attitudes towards a sitting president. For instance, Sen. Bob Corker (R-TN) famously referred to the Trump White House as an "adult day-care center," John McCain (R-AZ) said Trump "is often poorly informed,"and Jeff Flake (R-AZ) called him a "danger to a democracy," yet all of these Republican Senators cast more than 80% of their legislative votes in line with president (Silver and Bycoffe, 2019). Generally, the political science research recognizes that the public's views of the president have spillover effects on evaluations of legislators, which incentivizes strategic communication about the president. For example, Senate Majority Leader Mitch McConnell recently encouraged Republican senators in vulnerable re-election campaigns to distance themselves from Trump. Understanding legislators' attitudes toward the president enables greater understanding and measurement of such strategic communications. Furthermore, these attitudes also matter for understanding the president's ability to pass his legislative agenda.

In this paper, we propose a new method for estimating legislator preferences from the frequency and sentiment of their tweets using a novel combination of spatial models based on item response theory and the modeling of count data. We use this method to estimate legislator preferences about Donald Trump using tweets by members of Congress and Donald Trump in the 15-month period following election day in November 2016. In our model, legislator embeddings interact with embedding representations of Donald Trump himself, constructed from a neural network using the text (and timing) of his tweets during the same time frame. Thus, our model leverages the text feature extraction capabilities of neural networks and incorporates the legislator sentiment in tweets about Trump as well as the strategic decision about whether and when to tweet about him. We quantitatively assess the quality of our learned legislator representations by demonstrating the model's predictive performance on a test set of tweets, and we also compare our model-obtained embeddings to DW-NOMINATE scores, traditional measures of legislator ideology.[1] Our analysis not only validates the modeling approach but also highlights that attitudes towards Trump are not being entirely captured by legislative voting behavior. More

---

[1] In Appendix C we also include comparisons with the percent of the time legislators vote with Trump and Trump's vote share in legislators' districts in the 2016 election.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 627–641,
November 16–20, 2020.

broadly, a method for estimating domain-specific preferences, rather than general ideological ideal points, broadens the range of hypotheses than can be tested by political researchers.

2 Measuring Legislator Preferences

The predominant method of measuring legislator preferences over the past half-century has been the modeling of the *ideal point* of a legislator from recorded votes on policy legislation. These ideal points constitute a spatial model for legislative behavior, as both legislators and policies are represented in a low-dimensional Euclidean space (Poole and Rosenthal, 1997; Clinton et al., 2004). Such ideal points are interpreted as measures of ideological preferences and have been used to test hypotheses on topics such as political polarization, political representation, and cross-institutional relationships (Tausanovitch and Warshaw, 2018).

A key limitation of initial methods for estimating ideal points was the inability to perform out-of-sample predictions. Thus, they could not be used to predict votes on new legislation. To address this shortcoming, Gerrish and Blei (2011) extended the ideal point model by placing legislation into a "political space" based upon the latent topics of the legislation's text and perform prediction using these topics. Xing et al. (2017) use a nonparametric Bayesian model to incorporate constituency data into a factor model for legislative roll calls and text, with the text again being analyzed using a topic model. Further efforts to incorporate bill text using topic models come from Wang et al. (2010), Gerrish and Blei (2012), Nguyen et al. (2015), and Gu et al. (2014). The incorporation of text into ideal point modeling is not limited to legislators: Sim et al. (2016) model U.S. Supreme Court behavior using a generative model for amicus briefs.

Efforts to incorporate text into vote prediction were improved by moving to an embedding paradigm rather than topic models. Kraft et al. (2016) incorporate word embeddings into a model for vote prediction by representing a piece of legislation as the average of its word embeddings and further representing legislators using *ideal vectors* as a multi-dimensional extension to ideal points. Kornilova et al. (2018) augment bill text with bill metadata (i.e., bill sponsor information) to improve the predictive capabilities of legislator embeddings, and use a convolutional neural network (CNN, Kim (2014)), rather than the average over bill word embeddings, to model bill text.

While tweets have increasingly been used to measure political preferences of the mass public (Wang et al., 2016; Preoţiuc-Pietro et al., 2017), little attention has been paid to the potential of using tweets to measure legislators' preferences. One notable exception, Barbera (2015), uses the structure of social networks on Twitter to learn ideological positions of both political elites and the general public, but does not incorporate information from the tweets themselves. As all legislators in the U.S. House and Senate now use Twitter to communicate with constituents on a wide variety of topics, we recognize an opportunity to observe nuances in legislator preferences not captured by broader ideological measures that rely on roll call votes.

Here we focus specifically on legislators' attitudes toward the sitting president. While attitudes toward the president are among the most frequently measured aspects of public opinion, there is currently no method for explicitly measuring these preferences among legislators. We develop an embedding model that jointly predicts the frequency and sentiment of legislator tweets about Donald Trump. Similar to the Kraft et al. (2016) modeling of legislator votes in response to the text of legislation, here legislator tweets are considered as a response to text features extracted from Donald Trump's tweets. Whereas embedding models for vote prediction analyze only one outcome of legislator behavior (i.e., the vote itself), our embedding model is trained to predict multiple outcomes of legislator behavior in both tweet counts and content in the form of sentiment. Moreover, because our model does not rely on votes casts by legislators, it could be used to estimate preferences among a wider range of political actors (e.g., candidates, cabinet members) on a variety of domains, and with texts other than tweets.

3 Tweet Dataset

We obtained all publicly-available tweets by members of Congress from TweetCongress, a Sunlight Foundation initiative. We restricted the sample to only those tweets that contained any of a specific set of terms related to Donald Trump (in addition to his Twitter handle): "Donald Trump," "Trump," "realDonaldTrump," "MAGA," (an acronym for Trump's campaign slogan "Make America Great Again") "whitehouse," "WhiteHouse," "POTUS," (acronym for "President of the United States"), and

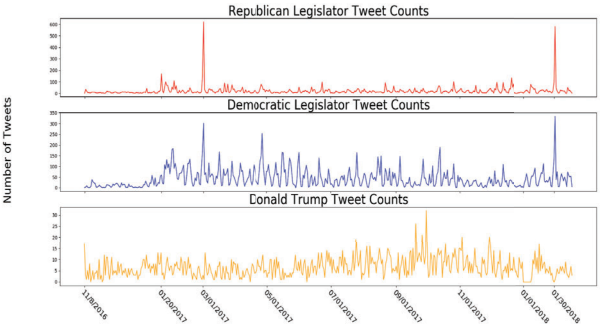

Figure 1: Number of tweets by Republican and Democratic legislators about Trump, as well as tweets by Trump, over time.

"potus." Of these, we further restricted the tweets to span in time from November 2016 to February 2018, when the data was collected. This culling process yielded 29,696 tweets from 451 legislators.

The model also incorporates tweets from Trump, which we obtained from the website `www.trumptwitterarchive.com`. For each day included in the dataset, the text of all tweets by Donald Trump was agglomerated and preprocessed by removing excess whitespace and lowercasing all letters. The text was tokenized and each word-token mapped to an integer identifier, with a vocabulary mapping of 2783 words. For each day, we obtain a sequence of integers representing the words composing the text of Donald Trump's tweets from that day, and these are the inputs to the model described in Section 4.3.

Figure 1 plots the number of tweets by Republicans, Democrats, and Trump over time for the period we examine. There were only 13 days for which Trump did not tweet (2.79%), and the most tweets that he sent in a single day was 32. The most tweets by a Democrat in a single day was 99, while the most tweets by a Republican in a single day was 25. The variation in tweets across time highlights one of the key features of the model—the incorporation of not only the sentiment of tweets about Trump by also the number of daily tweets.

Of the 29,696 Trump-related legislator tweets, a subset of 4,661 tweets were randomly selected to be manually labeled with respect to their sentiment about Trump, using a three-point "positive," "negative," "neutral" scale based on the text of the tweet[2] from November 2016 to February 2018.

We divided the tweets temporally by day into disjoint training, validation, and test sets, such that all tweets from each day were randomly assigned to one of the three sets. The training, validation, and test sets contain 70%, 10%, and 20% of all days, respectively. Table 1 outlines how many days and tweets are included in each set.

	# Days	# Labeled	# Total
Training	324	3069	20116
Validation	47	412	2441
Test	95	1180	7139

Table 1: Split of Training, Validation, and Test sets.

4 Legislator Tweet Model Formulation

Our proposed model combines an embedding model for legislators with models for ordinal and count data, predicting both the number of daily tweets about Donald Trump sent by each legislator and the sentiment of labeled tweets. The joint nature of this model not only enables a more nuanced representation of legislators, but also accounts for the fact that a legislator who consistently tweets in favor (or against) the president is different from one who tweets occasionally, even if both express similar sentiment. The model also incorporates text features from Trump's tweets to provide context for legislator tweets as reactions to Trump.

Underpinning our model is the assumption of a latent political space of dimension K. In this space, we learn a set of "day embeddings" (or "Trump embeddings") that interact with a set of legislator embeddings. For a particular day t, let $\boldsymbol{\tau}_t \in \mathbb{R}^K$ be a vector that represents Donald Trump on that day. Indexing legislators by $i \in \{1, 2, \ldots, N\}$, we endow a legislator i with a vector $\mathbf{v}_i \in \mathbb{R}^K$ as well as a bias term $b_i \in \mathbb{R}$, which captures a legislator's propensity to react to Trump regardless of how he presents himself via Twitter. While the legislator embeddings are learned as free parameters of the model, the Trump embeddings are constructed using the text of Donald Trump's tweets. We now describe how we use legislator and Trump embeddings to predict tweet counts and sentiment.

---

[2] See Appendix A for full description of the dataset construction.

4.1 Tweet Count Model

Understanding legislator-president interactions requires understanding not only the sentiment of legislators' remarks about the president, but also whether and how often they remark about him. This distinguishes, for instance, a legislator who criticizes Trump every week from one who criticizes Trump only once during his tenure. Even when the sentiment expressed in these two legislators' tweets is identical, the fact that one legislator expresses that sentiment more frequently likely reflects a more negative attitude toward Trump. Furthermore, since we model tweets as a response to a daily representation of Trump, modeling counts reveals legislators who respond in concert with each other and may share similar preferences.

Let x_{it} be the number of tweets that legislator i sends about Donald Trump on day t. We consider two distributions with which to construct our tweet count model: Poisson and Negative Binomial. While the former offers simplicity, the latter is more flexible and suitable for overdispersed data because of its additional parameter. In Section 5, we compare the Poisson and Negative Binomial model performances. We will parameterize the Negative Binomial using (p_{it}, r):

$$x_{it} \sim \text{NegBin}(p_{it}, r), \;\; p_{it} = \sigma(\boldsymbol{\tau}_t^\top \mathbf{v}_i) \quad (1)$$

where $\sigma(\cdot)$ is the sigmoid function defined by $\sigma(x) = \frac{1}{1+\exp(-x)}$, which is used to transform the input onto $(0,1)$ to represent a probability. The remaining parameter r is learned as a common free parameter for all legislators and days. For the Poisson case, we model the rate parameter of the distribution as the exponential of the dot-product between the Trump and legislator embeddings. This choice ensures the rate parameter is non-negative while also modeling an "interaction" between legislators and Trump.

We train the count model by minimizing the negative log-likelihood (NLL) of the training data under either of the assumed distributions. We denote the total count-loss over a training set $\mathcal{X}_{tr}$ as:

$$\mathcal{L}_{count} = \sum_{x_{it} \in \mathcal{X}_{tr}} \text{NLL}_{count}(x_{it}; \boldsymbol{\tau}_t, \mathbf{v}_i) \quad (2)$$

4.2 Tweet Sentiment Model

Let y_{it} be an ordinal variable that encodes the sentiment legislator i expresses in a tweet about Donald Trump on day t. We consider an ordinal model to account for the possible gradations of approval. Assuming L sentiment levels, the model is parameterized by a set of cutpoints, $\mathcal{C} = \{c_0 < c_1 \leq c_2 \leq \cdots \leq c_{L-1} < c_L\}$, where c_0 and c_L are defined to be $-\infty$ and ∞, respectively. The remaining cutpoints are learned during model training.

Let $z_{it} \in \mathbb{R}$ be a latent variable underlying the ordinal response. Then for a thresholded ordinal model, the predicted sentiment takes value l for which: $c_{l-1} < z_{it} < c_l$. Under a cumulative link model (CLM)[3] for ordinal regression, the predicted probability of a particular sentiment level l is:

$$p(y_{it} = l | z_{it}; \mathcal{C}) = \sigma(c_l - z_{it}) - \sigma(c_{l-1} - z_{it}) \quad (3)$$

where again $\sigma(\cdot)$ is the sigmoid function. The latent variable z_{it} is a function of the attributes of legislator i and of Trump at day t. As with the count model, we seek to employ a map that captures the interaction between the legislator and Trump embeddings, and thus we employ a weighted inner product. Additionally, we expect that legislators maintain a concrete bias towards Trump, which we include in the term b_i for each legislator. Thus, we obtain the variable z_{it} through the following map:

$$z_{it} = g(\mathbf{v}_i, \boldsymbol{\tau}_t, b_i) = \boldsymbol{\tau}_t^\top \mathbf{H}_g \mathbf{v}_i + b_i \quad (4)$$

where $\mathbf{H}_g \in \mathbb{R}^{K \times K}$ is a learned weight matrix.

As with the count model, the sentiment model is trained by optimizing the negative log-likelihood of the sentiment-labeled tweets in the training set. With the predicted probability of the correct label, $p(y_{it} = l)$, given by equation 3, and the set of all labeled tweets in the training set being $\mathcal{Y}_{tr}$ then the total loss for the sentiment model is given by:

$$\mathcal{L}_{sent} = \sum_{y_{it} \in \mathcal{Y}_{tr}} \sum_{l \in \{1,2,\ldots L\}} -\mathbb{I}(y_{it} = l) \log p(y_{it} = l) \quad (5)$$

where $\mathbb{I}(\cdot)$ denotes the indicator function, in which $\mathbb{I}(\cdot) = 1$ when the argument is true and 0 otherwise.

4.3 Trump Embedding Construction

In the ideal point/vector models that consider roll call data, legislator behavior is a response to policies as captured by the text of bills. As we seek an alternative to legislation as a method of measuring

---

[3] See Gutiérrez et al. (2016) for ordinal model overview.

preferences, we rely instead on Twitter behavior but similarly construct embeddings that legislators respond to. Since Donald Trump is our entity of investigation, we use the text of his tweets to construct such embeddings.

To map Donald Trump's tweet text to a political embedding representation, we employ a Simple Word-Embedding Model (SWEM), (Shen et al., 2018). SWEMs rely upon word embeddings (Bengio et al., 2003; Mikolov et al., 2013) and pooling operations to encode the compositionality of text without the heavy parameterization required of such models as recurrent neural networks (RNNs, see Socher et al., 2011) or CNNs (Kalchbrenner et al., 2014; Kim, 2014). Endowing each word-token u_i in a lexicon with an embedding $\mathbf{w}_i \in \mathbb{R}^d$, we may represent a sequence of n words as a matrix of stacked embeddings: $\{\mathbf{w}_1, \dots, \mathbf{w}_L\} = \mathbf{W} \in \mathbb{R}^{n \times d}$. To extract the most salient features from every word-embedding dimension, we employ a max-pooling operation, which amounts to a column-wise maximum of matrix $\mathbf{W}$. Supposing that $\mathbf{W}_t$ contains the embeddings from *all* Donald Trump tweets on day t, then we will denote $\boldsymbol{\alpha}_t \in \mathbb{R}^d$ as the max-pooled vector, These text features are subsequently mapped to the daily Trump vector by an affine transformation:

$$\boldsymbol{\tau}_t = \mathbf{M}\boldsymbol{\alpha}_t + \mathbf{a} \tag{6}$$

where $\mathbf{M} \in \mathbb{R}^{d \times K}$ and $\mathbf{a} \in \mathbb{R}^K$ are a weight matrix and bias vector that are shared by all days t. This transformation can be made more flexible by introducing a non-linear activation function, $\phi(\cdot)$, such as the rectified linear unit (ReLU). This nonlinear "hidden" layer is described by:

$$\boldsymbol{\tau}_t = \mathbf{M}_2\, \boldsymbol{\phi}(\mathbf{M}_1\boldsymbol{\alpha}_t + \mathbf{a}_1) + \mathbf{a}_2 \tag{7}$$

where an additional weight matrix and bias vector have been appended.

4.4 Model Training & Parameter Learning

The parameters in the model to be learned include the legislator embeddings and biases, the word embeddings, the parameters of the maps to count and ordinal variables, and the parameters of the map from text features to Trump embeddings. We refer to this collection as Θ. The optimization objective is the combination loss of the negative-log likelihood of the count and ordinal models:

$$\mathcal{L}(\Theta) = \gamma\mathcal{L}_{count} + (1-\gamma)\mathcal{L}_{ord} \tag{8}$$

where $\mathcal{L}_{count}$ and $\mathcal{L}_{ord}$ are given by equations 2 and 5, respectively, and γ is a hyperparameter that controls the relative importance of the two component losses. The construction of equation 8 allows the researcher to only admit tweet count information by setting $\gamma = 1$ and only admit tweet sentiment information by setting $\gamma = 0$; a balance may be achieved by choosing $\gamma \in (0, 1)$. The Adam algorithm (Kingma and Ba, 2015) is used for gradient-based optimization of 8 with a learning rate of $\eta = 10^{-4}$.

5 Predictive Results

To demonstrate the efficacy of our model for legislator tweeting behavior with respect to President Donald Trump, we first show that the construction of Trump embeddings from the language of his own tweets provides an informational signal for legislators to react to. We train our model using the days for the training set and present the predictive results for days in the test set. Since the model seeks to capture two aspects of legislator tweeting behavior, we evaluate the model using two metrics: the negative-log likelihood of the count model and the mean-absolute-error (MAE) of the sentiment model. Overall model performance is also captured by the total loss of the model, which is the weighted negative-log likelihood of both the count and sentiment models, equation 8. MAE is used rather than accuracy to account for the ordinal nature of the sentiment model.

The hyperparameter γ controls the balance between the two components of our model, counts and sentiment. We present our results for three settings of γ, which allows us to analyze the two components of our model separately before analyzing the joint model. A full description of the process used to tune hyperparameters and a comparison of the model with linear and nonlinear text maps can be found in Appendix B. For all results presented here, we set $K = 2$, and use a linear text map. The number of epochs for which the model was trained varies depending on model setting, but in all cases each training batch comprises 128 tweets. The model was implemented in TensorFlow (Abadi et al., 2015) and trained on a single NVIDIA Titan X GPU. Code can be found on the author's Github at: `github.com/gspell/CongressionalTweets`.

5.1 $\gamma = 1$ (only count model):

When $\gamma = 1$, only the loss from the part of the model that handles tweet counts contributes to the total loss in equation 8. We present the final negative log-likelihood of the count model for both the Poisson and Negative Binomial models described in Section 4.1, and for both the case in which the text of Donald Trump's tweets is used to construct his daily embedding representation and the case in which the Trump embeddings are free parameters of the model. For the negative binomial model, the model was trained for 75 epochs, which was the amount of training required to perform best on the validation (rather than test) set of tweets. The Poisson model was trained for 100 epochs while using the text and 2000 epochs without text. The predictive results are shown in Table 2.

	Text		No Text	
	Loss	MAE	Loss	MAE
Poisson	20,882	0.692	49,128	0.693
Neg. Bin.	**16,692**	0.726	18,461	0.696

Table 2: Predictive evaluation metrics on test for our model with $\gamma = 1$. Note that because only the count loss is being optimized, MAE does not reflect model performance here. Best model result bolded.

Modeling legislator tweet counts using the Negative Binomial distribution achieves superior performance to modeling using the Poisson distribution, as the Negative Binomial can better accomodate the overdispersion in the tweet counts. Additionally, using the text of Donald Trump's tweets to construct his daily embedding that legislator embeddings interact with provides significantly better results than neglecting the text and allowing the Trump embeddings to be free parameters of the model. This effect is more pronounced for the Poisson distribution, but is present for the Negative Binomial model as well. Indeed, this aspect of the model is to be expected, since the model is evaluated on days of which there are no examples in the training set. Without using the text, there is no way for the model to represent an "unseen" day.

5.2 $\gamma = 0$ (only sentiment model):

When $\gamma = 0$, only the loss from the part of the model that handles legislator tweet sentiment contributes to the total loss in equation 8. We present the final model loss — which is the negative log-likelihood of the sentiment model — as well as the model MAE. Again, we show results for the case in which Trump's tweet text is used to construct embeddings and the case in which the text is not used. We also toggle an additional model setting for analysis: the inclusion of the legislator bias term, b_i, from equation 4. We adjust the number of epochs to 150 for training with text. We train the model without text for 1000 and 3000 epochs, including and excluding the legislator bias term, respectively. The results are presented in Table 3.

	Text		No Text	
	Loss	MAE	Loss	MAE
No Bias	549.63	0.140	1714.48	0.878
Bias	**548.80**	**0.140**	831.24	0.390

Table 3: Predictive evaluation metrics on test for our model with $\gamma = 0$. Best model result with respect to MAE is bolded. Comparison between the sentiment model with/without the legislator bias term as well as with/without Trump tweet text

In addition to the MAE of the ordinal model, we note that the model accuracy — which is more intuitive but less exact than MAE — is 88.4% for the best performing model, when both the legislator bias and Trump's tweet text are used. Note that when the text of Donald Trump's tweets is used, the model performs as well with respect to MAE with the inclusion of the legislator bias as without it. Additionally, when the bias term is included but Trump's text is excluded, the model is able to achieve better performance than when both the text and bias term are excluded. In fact, for the case of no Trump text and no legislator bias, the model is incapable of achieving test MAE better than how it performs upon initialization. We note that while the model does train, performance on the test (and validation) never improves in that case.

Table 3 suggests that the legislator bias (when present) accounts for much of the model's ability to predict legislator tweet sentiment, since the model achieves decent results even when no Trump text is used to construct meaningful Trump embeddings to interact with the trained legislator embeddings. Without the bias term, the interaction between Trump and legislator embeddings is the only means toward predicting tweet sentiment, which is why the necessity of text is so critical in that case.

5.3 $\gamma = 0.03$ (both counts & sentiment):

For any other value of $\gamma \in (0, 1)$, the total loss in equation 8 will have contributions from both the count and sentiment losses, and thus both aspects of the model are trained jointly. Using the validation set, we determined that setting $\gamma = 0.03$ achieves a good balance between both the count and sentiment parts of the model[4], obtaining a good MAE without neglecting modeling of the counts. Given the considerations discussed for $\gamma = 0, 1$, we only examine the Negative Binomial count model and the inclusion of the legislator bias term. When the model was trained using the text of Donald Trump's tweets, it was trained for 200 epochs, while it was trained for 1500 epochs when the text was not used, and the runtimes were 3.12 and 12.9 minutes, respectively. The joint model performance is shown in Table 4, with MAE, total loss, and unweighted count model negative log-likelihood shown.

	Count NLL	MAE	Total Loss
No Text	28,571	0.213	1583.97
Text	**16,782**	**0.127**	**994.76**

Table 4: Predictive evaluation metrics on test for our model with $\gamma = 0.03$. Best model result bolded

As with the cases for $\gamma = 0, 1$, we have found that for our final model configuration with $\gamma = 0.03$, model predictive performance is superior when Donald Trump's tweet text is used to construct his daily embedding representation. Additionally, the MAE on the test set for $\gamma = 0.03$ is less than the MAE for the case that $\gamma = 0$ when only the sentiment model is trained. This demonstrates that the inclusion of tweet count information mitigates sentiment prediction as well, since more information is being used to model legislators.

6 Legislator Embeddings

Training our legislator tweeting model yields a key byproduct: the legislator embeddings. As with previous spatial representations of legislator preferences, our model enables the visualization of the positions of legislators in space. In Figure 2 we plot the two dimensions of legislator embeddings from the model presented in Table 4.[5]

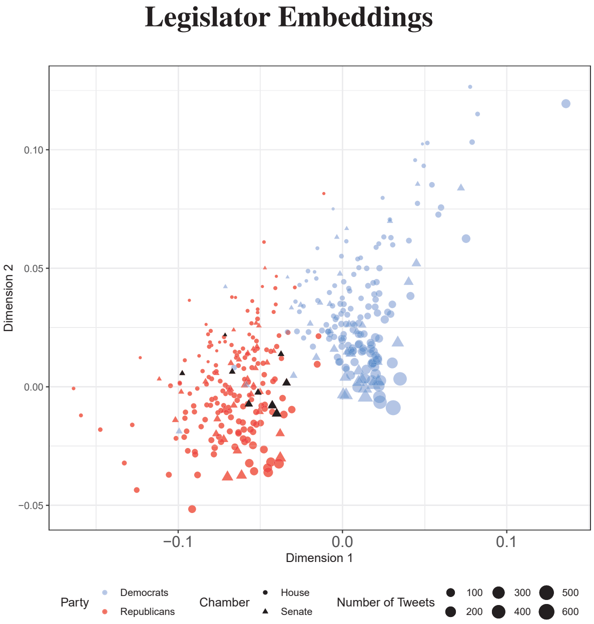

Figure 2: Learned legislator embeddings. Legislators are identified by party, chamber, and the number of tweets authored about Trump. The darker points indicate known Senate Republican critics of Trump.

The most noticeable characteristic of the embeddings is how they separate legislators across party lines into Democrats and Republicans, even though party affiliations were not incorporated into the model. In the first dimension, senators are perfectly separated by party with the exception of five Democrats who have *lower* values on the first embedding dimension than John McCain, the Republican Senator with the highest value: Dianne Feinstein, Heidi Heitkamp, Claire McCaskill, Angus King, and Joe Manchin. Excepting Dianne Feinstein, these senators are generally considered to be more conservative Democrats.

In the figure we also see that embeddings are not simply an artifact of the number of tweets about Trump authored by the legislator, nor whether the legislator is a member of the House or Senate. Legislators with more extreme values of Twitter sentiment relative to other members of their party can be found in both chambers of Congress and range from having authored fewer than 100 tweets about Trump to over 500.[6]

Another initial validating characteristic of the embeddings is the clustering of prominent Republican senators who have been publicly critical of Trump. We examine the spatial positions of Republican senators whom a 2017 *Washington Post* analysis identified as critical of the President based on their responses to controversial events in Trump's presidency, such as Trump's firing of FBI Director James Comey and response to the Charlottesville protests, as well as overall rhetoric used when discussing Trump (Lewis et al., 2017). The positions

[4] See Appendix B.2 for a discussion of choosing γ.

[5] See Appendix B.1 for a discussion of selecting model dimension

[6] For visualization, legislators with fewer than 5 tweets are omitted from Figure 2.

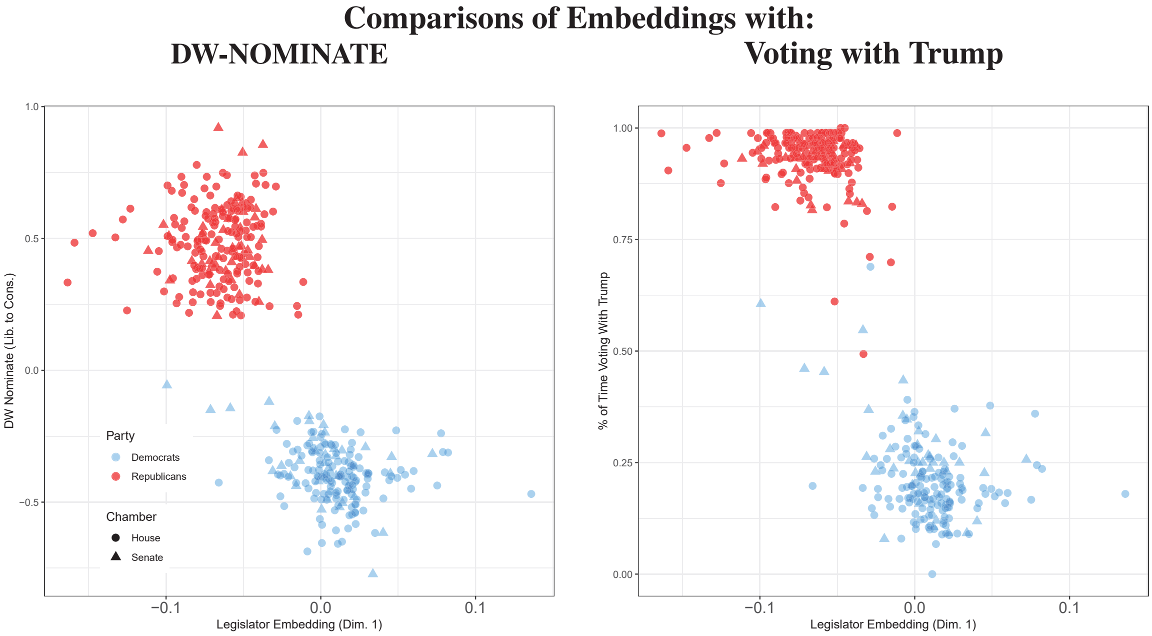

Figure 3: Comparisons of the learned legislator embeddings to DW-NOMINATE (left) and percentage of time voting with Trump (right) as measures of legislator preferences.

of these senators are highlighted (dark black points) in Figure 2. These senators are clustered together in the two-dimensional embedding space: John McCain, Jeff Flake, Joe Hoeven, Bob Corker, Marco Rubio, Shelley Capito, Dean Heller, Dan Sullivan, Lamar Alexander, and Lisa Murkowski.

Considering which Democratic legislators are interspersed near the cluster of Republicans in the two-dimensional embedding space is also informative. The two most extreme Democratic outliers were Angus King, an Independent Senator from Maine who caucuses with the Democratic party but has openly considered caucusing with the Republican party and Joe Manchin, a notably conservative Democratic senator in whose state Trump won 68.5% of the vote. We observe fewer outliers among Republicans. Among the most extreme outliers, are Ileana Ros-Lehtinen and Carlos Curbelo, whose districts Hillary Clinton won in 2016 by 19.6 and 16.3 percentage points, respectively. Ros-Lehtinen, in particular, tweeted many scathing responses to Trump regarding his controversial stance on immigration.

We next compare the embeddings to an existing measure of general legislator preferences. Figure 3 illustrates the relationship between the first dimension of DW-NOMINATE — a canonical measure of legislator ideology in political science — and the first dimension of our learned legislator embeddings. Generally, legislators who are ideologically conservative have lower embedding values, whereas liberals have higher values. At the same time, this comparison does identify legislators who are more or less critical of Trump than might be expected based on ideology alone, thereby offering new empirical leverage to scholars examining the behavior and attitudes of legislators.

Figure 3 also compares our legislator embeddings to an approximation of how legislators might feel toward Trump: the proportion of time that they vote in line with him during the period in which legislator tweets were collected. This metric was calculated using a dataset published by Fivethirtyeight and includes only legislation on which the Trump administration publicly expressed a clear position (Silver and Bycoffe, 2019). While this measure is limited by many of the same constraints as other vote-based measures (e.g., DW-NOMINATE), it is the closest existing measure of legislators' attitudes toward Trump. In the right panel of Figure 3, we observe little variation in the extent to which legislators vote with Trump, particularly for Republicans. Indeed, many of the President's most prominent critics frequently voted with the president during this time period. For instance, John McCain voted with Trump 85% of the time, Bob Corker voted with Trump 84% of the time, and Jeff Flake voted with Trump 83% of the time. Meanwhile, we observe far more variation in legislator embeddings among both Republicans and Democrats. In Appendix C, we further compare our embeddings to alternative measures of legislative preferences: Campaign Finance Scores (Bonica, 2018) and Trump vote-share in a legislator's constituency during the 2016 presidential election.

7 Conclusion

In this paper, we modeled legislator tweeting behavior towards Donald Trump, predicting the frequency and sentiment of their tweets. The proposed model yields embedding representations for legislators that we interpret as measures of legislator attitudes towards Trump. Our application suggests that ideal points estimated from roll call votes can miss this critical aspect of political preferences for members of Congress. Whereas legislative voting might recover ideological similarities and differences with the president, it is not well suited to measure attitudes toward the president orthogonal to policy preferences, such as criticisms of his rhetoric and tone. To address this shortcoming and obtain representations of legislators' attitudes toward Trump, we have proposed a model that assigns a vector to each legislator based on the content of their tweets about Trump. We similarly represent Donald Trump with a vector for each day he tweets, constructed using the text of his daily tweets. Legislator vectors and Trump vectors interact to produce predictions of both the sentiment of legislator tweets about Donald Trump and the number of tweets produced each day. From this model we obtain representations of legislators that capture their attitudes toward the president.

Our model's predictive performance is robust to a variety of settings and achieves sentiment predictive performance of 0.127 mean-absolute-error and 89.3% accuracy, demonstrating its capability to predict legislator tweeting behavior. When visualizing the two dimensions of learned legislator embeddings we find that the model separates legislators across party lines (despite not being trained on the party of legislators) and groups together Republican senators who are well-known critics of Trump (despite overwhelmingly voting with him on legislation).

Though our model demonstrates the capability of representing legislators' attitudes toward Trump and performs well with respect to predicting tweet counts and sentiment based upon Donald Trump's tweets, our method has some limitations. For one, as is the case for Rheault and Cochrane (2020), our model is not able to produce uncertainty bounds, as deriving uncertainty measures from neural networks remains an open area of research without a clear solution within the field of machine learning.[7] An avenue for improving the model is to allow it to capture legislators' dynamic attitudes toward Trump over time. While legislator attitudes are currently modeled as *static* embeddings, allowing each legislator's embedding to change over time would enable the exploration of temporal dynamics and hypothesis testing about when legislators are more likely to tweet negatively about Trump, what factors contribute to a legislator's decision to tweet about Trump, and how the Trump's tweets interact with legislator's tweets over time.

While our aims in this paper were to develop a method of modeling attitudes toward Trump beyond legislative policy preferences, this method can be used to test a wide range of hypotheses about modern U.S. politics. Legislator embeddings can be used to explore how legislators appeal to different audiences, such as party leaders and constituents. The method presented here could similarly be used to evaluate how members of Congress are punished and rewarded in elections for their criticism of praise of the president. Moreover, because our model does not rely on roll call votes, it can also be used to model attitudes by any of the growing number of political elites using Twitter, such as non-incumbent political candidates, state legislators, and pundits. Possible extensions of this work could investigate enriching Trump vectors by incorporating other sources of text, such as White House press releases and speeches. While we restrict ourselves to Twitter data in this paper to maintain consistency across the sources of data for vectors representing Trump and legislators, the incorporation of auxiliary text data could provide additional context.

Acknowledgments

We thank Chris McCroskey, Tweet Congress, and Todd Shields for enabling access to the sample of legislator tweets. Gregory Spell thanks David Carlson for his invaluable mentorship and encouragement in practicing the craft of Deep Learning.

---

[7] To be sure, we are not the only ideal point method to share this limitation. See e.g., Imai et al. (2016).

A Data Description

In Section 3, we describe how tweets were selected for our dataset. We provide more information about the dataset here. In total, legislators sent 29,696 tweets about Trump. On average, each legislator sent 65.84 tweets about Trump, though there is substantial variation (standard deviation = 88.78, median number of tweets about Trump = 36.0).

Democratic legislators tweeted about Trump more than twice as much as Republicans. The mean number of tweets about Trump among Democrats was 97.12 (standard deviation = 115.27), but only 40.22 among Republicans (standard deviation = 44.81). In both cases, the mean was inflated by outliers with a large number of tweets (e.g., one Democrat authored 746 tweets about Trump and one Republican authored 288 tweets about Trump). Still, the median number of tweets among Democrats (56) was still substantially larger than among Republicans (27). Only 8.6% of legislators had fewer than 5 tweets related to Trump.

The 10 Republicans with the most tweets about Trump were, in order: Paul Ryan Bradley Byrne, Sean Duffy, Paul Gosar, Bill Flores, Orrin Hatch, Mitch McConnell, Roger Wicker, Steve Scalise, Kevin McCarthy. The 10 Democrats with the most tweets about Trump were: Donald Beyer, Betty McCollum, Yvette Clarke, Jerrold Nadler, Edward Markey, James McGovern, Nancy Pelosi, Tom Udall, Robert Case, Joseph Crowley. In both cases we observe leadership in both parties among the most frequent authors of tweets about the president. Perhaps unsurprisingly, the days with both the most positive and the most negative tweets about Trump were those in which Trump addressed Congress: his joint address on February 28, 2017 (597 positive, 288 negative) and the 2018 State of the Union (512 positive and 340 negative).

Of the 29,696 Trump-related tweets from legislators, a subset of 4,661 tweets were randomly selected to be coded with respect to their sentiment about Trump. Five undergraduate research assistants were trained to categorize the sentiment of each tweet about Trump given the text of the tweet, the name of the legislator who sent it, and the legislator's party affiliation. A random 1% sample of tweets was selected to be coded by each of the five coders in order to assess inter-coder reliability. [8] The mean level of agreement in the coding of the tweets as positive, neutral, or negative was 91.7% [9] A table describing the percentage breakdowns for the labeled tweet sentiment classes according to party is provided in Table 5.

	% Positive	% Negative	% Neutral
Democratic	1.56	92.04	6.40
Republican	81.87	2.17	15.96

Table 5: Breakdown of labeled tweet sentiment classes according to party

See Section 3 for description of the splits into training, validation, and test datasets.

---

[8] After coding, we identified sixty-eight mislabeled tweets that were then corrected in the data set.

[9] The tweets were coded on a five-point scale (very positive, somewhat positive, neutral, somewhat negative, very negative), but the intercoder reliability was not sufficient to justify distinguishing "somewhat" from "very." (91.7% vs. 60.0%).

B Model Selection Decisions

We examine our proposed model's performance under different hyperparameters, including the dimensionality of the latent political space and the parameter γ that controls the tradeoff between the sentiment and count components of the model loss.

We select model hyperparameters based upon performance on a held-out validation set. We described in Section 3 the creation of our validation dataset. Using a validation set allows for evaluation of the model as it is developed, without exposing the model to the test set. This practice prohibits overfitting by ensuring a tuned model generalizes to wholly unseen data.

B.1 Tuning Model Dimension

We begin our selection of model hyperparameters with the model dimension: the dimension, K, of the political space of the legislator embeddings and Trump embeddings. In choosing this dimension, we fix all other attributes of the model and sweep through a range of possible model dimensions. For our dimension sweep, we fixed $\gamma = 0.01$. For each possible dimension, we fully train the model and obtain evaluative metrics – MAE on the labeled data, loss of the count model, and total loss – on the validation set. We then compare these metrics across dimension.

In Figure 4, we show the three evaluation metrics across of sweep of dimensions from 1 to 64. Between particularly the metrics of count loss and MAE, there is a trend of sharp decrease between dimension 1 and 2 and then a less discernible trend between dimension and metric for dimensions greater than 2. This indicates that across model dimension (greater than $K = 2$), performance with respect to our evaluative metrics remains relatively consistent. This allows the researcher a degree of flexibility in choosing model dimension. We further note that the evaluation metrics across dimension do not necessarily increase or decrease together. This further obfuscates the choice in model dimension, since the researcher may value optimizing a different metric depending on the chosen application. For the work presented in this paper – with predictive results and legislator embeddings shown in Sections 5 and 6, respectively – we selected a dimension of $K = 2$ to balance multiple research-defined objectives: to balance MAE, total loss, and count loss; to facilitate comparison to canonical DW-Nominate legislator representations; to inhibit overfitting; and to allow for easy analysis. Furthermore, choosing $K = 2$ lends parsimony to our model without sacrificing performance across our evaluative metrics. We note that Cranmer and Desmarais (2017) discuss using predictive performance as an impartial means for choosing the parsimony of a model and refer interested readers to their discussion.

B.2 Tuning Loss Tradeoff Parameter γ

Similarly to tuning model dimension, K, we tune the loss tradeoff parameter γ by fixing all other attributes of the model and performing a sweep through a range of possible loss tradeoff values. We fixed the model dimension at $K = 2$. As with tuning model dimension, we fully train the model at each possible tradeoff value, and we again evaluate using the metrics of MAE, loss of the count model, and total loss on the validation set.

In Figure 5, we show the three evaluation metrics across of sweep of loss tradeoff values from 0.005 to 0.25. Unlike with model dimension, K, there is a discernible trend between evaluative metrics and the tradeoff parameter as it is swept. To balance the tradeoffs between the count model and sentiment model, we choose $\gamma = 0.03$ for the predictive results presented in our paper.

B.3 Comparing Model with Nonlinear Map

As mentioned in Section 4.3, when mapping from the text of Trump's tweets to an embedding representation for Donald Trump, we may insert a nonlinear hidden layer to the model on top of an affine transformation. In this appendix, we compare the performance of the affine model against using a nonlinearity. The nonlinearity that we investigate is the rectified linear unit (ReLU).

Rather than comparing the affine and nonlinear models for only one dimension, we again perform a sweep over model dimension to investigate whether the superior model setting depends on region of the parameter space. In Figure 6, we show our three evaluation metrics, with a series for the model with and without the nonlinearity. The plots demonstrate that, in general, the affine model actually outperforms the nonlinear model. This is contrary to our initial expectation, since we would expect the nonlinear model to admit more flexibility, but given the results presented here, we use an affine model for our investigaton in Sections 5 and 6.

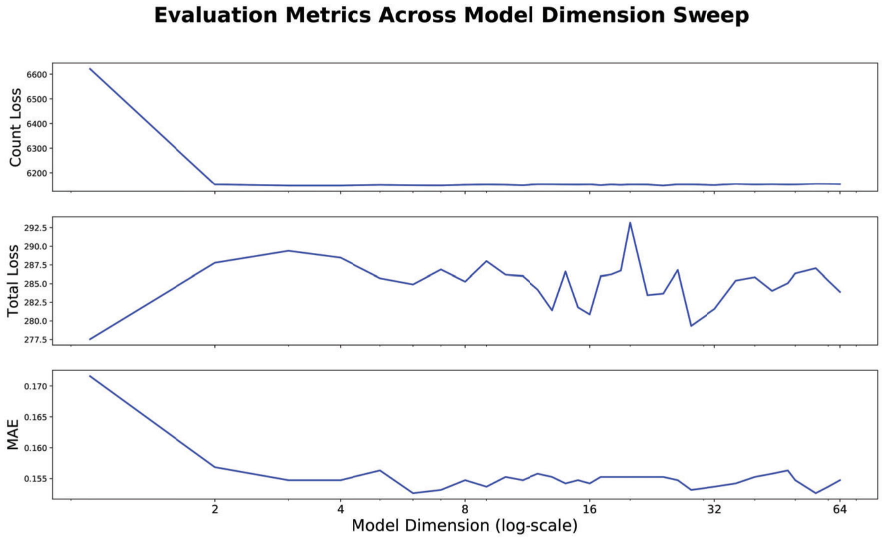

Figure 4: Evaluation metrics for the Basic model across a sweep of different model dimensions

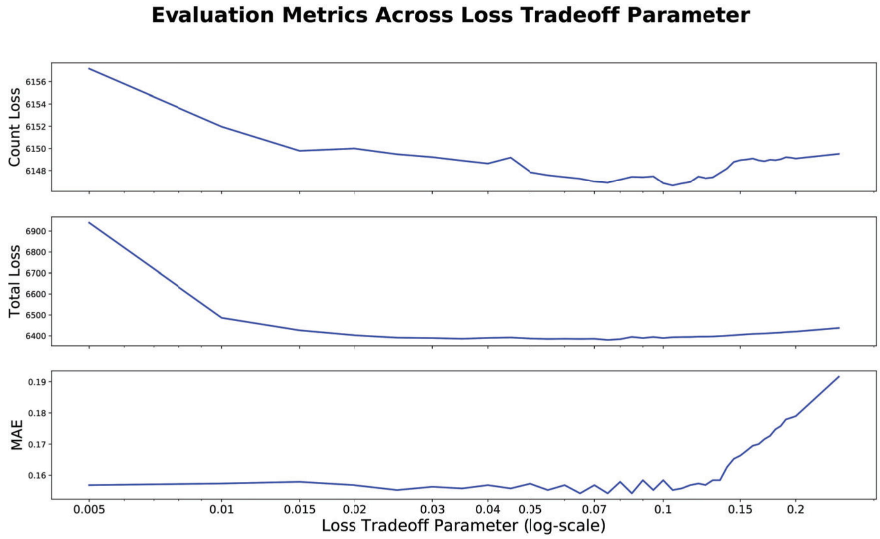

Figure 5: Evaluation metrics for the Basic model across a sweep of different loss tradeoff parameter values

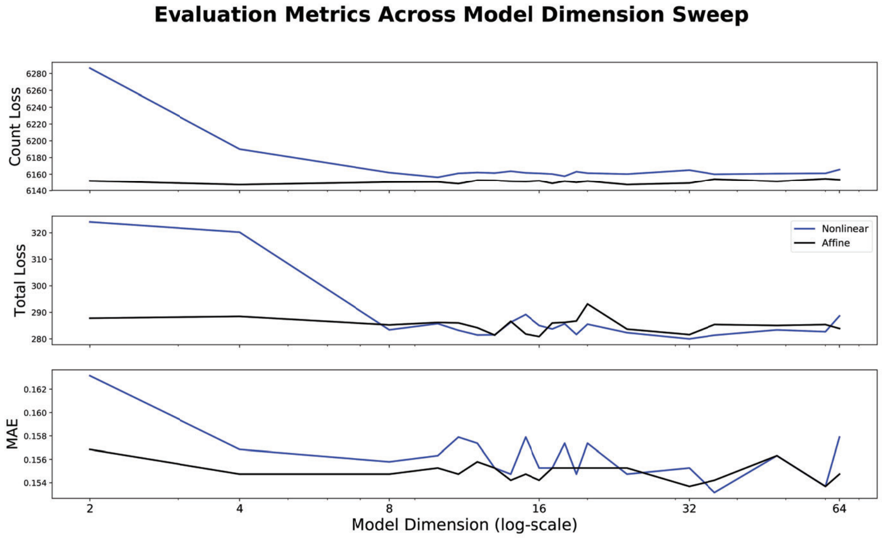

Figure 6: Evaluation metrics for the nonlinear and affine models over a sweep of model dimension

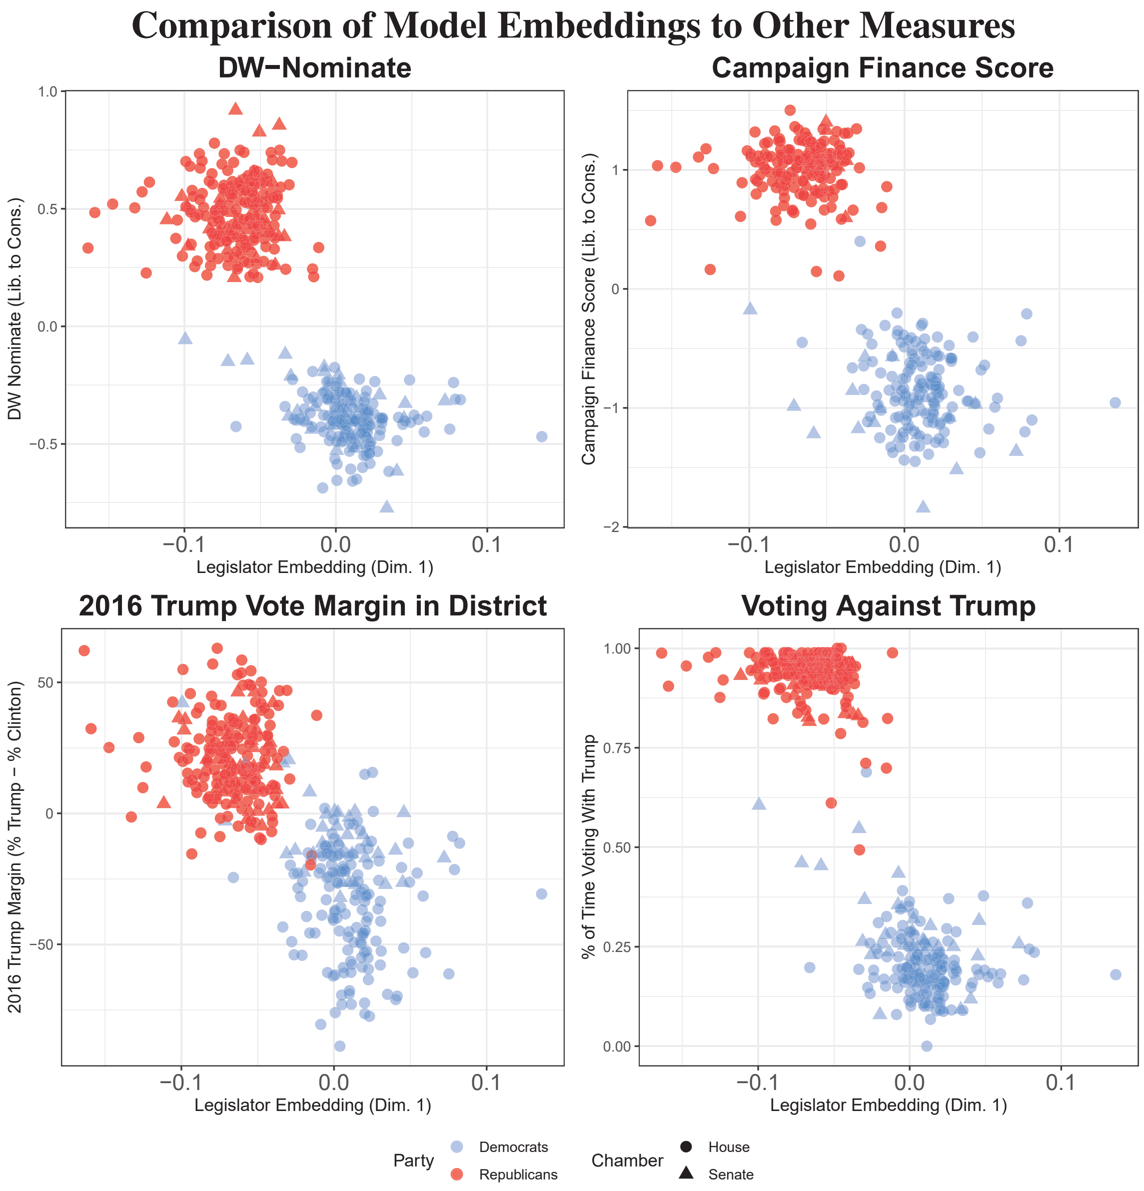

Figure 7: Comparisons of the learned legislator embeddings to general measures of legislator preferences and proxies for a legislator's support for Trump.

C Comparison with Other Preference Measures

In addition to the embedding comparisons provided in Section 6, we provide comparisons to Campaign Finance Scores Bonica (2018) and Trump's vote margin in the 2016 presidential election for each legislator's district or state, for representatives and senators, respectively. In the fourth panel of Figure 7 we observe a clear relationship between support for the president in the election and legislator embeddings—legislators representing constituencies that voted for Trump have lower embedding values.

D Legislator Embeddings with Labels

We reproduce the plot of our model-learned embeddings from Section 6 with explicit labels for Republican senators whom a 2017 *Washington Post* analysis identified as critical of the President based on their responses to controversial events in Trump's presidency, such as Trump's firing of FBI Director James Comey and response to the Charlottesville protests, as well as overall rhetoric used when discussing Trump (Lewis et al., 2017). This is presented in Figure 8.

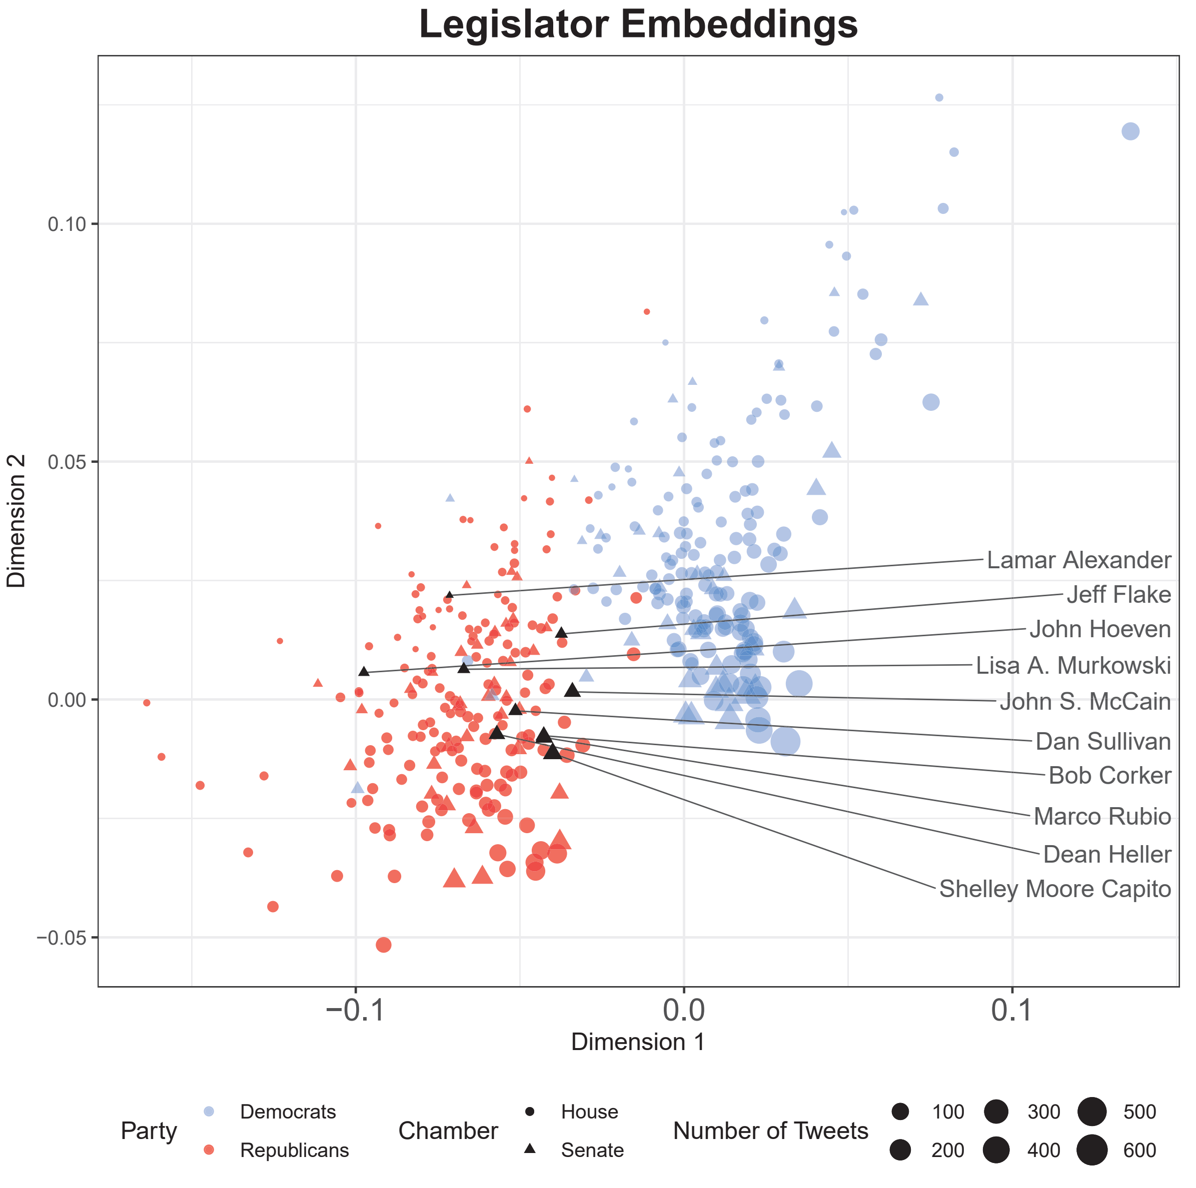

Figure 8: The two dimensions of learned legislator embeddings. Legislators are identified by party, chamber, and the number of tweets authored about Trump. The darker points represent the location of known Republican critics of Trump in the Senate.

Measuring Information Propagation in Literary Social Networks

Abstract

We present the task of modeling information propagation in literature, in which we seek to identify pieces of information passing from character A to character B to character C, only given a description of their activity in text. We describe a new pipeline for measuring information propagation in this domain and publish a new dataset for speaker attribution, enabling the evaluation of an important component of this pipeline on a wider range of literary texts than previously studied. Using this pipeline, we analyze the dynamics of information propagation in over 5,000 works of English fiction, finding that information flows through characters that fill structural holes connecting different communities, and that characters who are women are depicted as filling this role much more frequently than characters who are men.

1 Introduction

With the rise of sociological approaches to narrative, work in literary criticism has increasingly turned to the ways in which authors depict social networks in their texts. This includes critical attention to both *network topologies*, such as understanding characters and their structural relationships with others (Levine, 2009), and *information flow*, such as theorizing the representation of disease and gossip (Levine, 2009; Margolis, 2012; Spacks, 1985). Much computational work in NLP has arisen to support the former line of research, including extracting social networks from text (Elson et al., 2010), predicting familial relationships (Makazhanov et al., 2014), and modeling the interactions between characters (Iyyer et al., 2016; Chaturvedi et al., 2017). This in turn has driven work in the digital humanities examining the structure of literary networks (Moretti, 2011; Algee-Hewitt, 2017; Piper et al., 2017; Alexander, 2019).

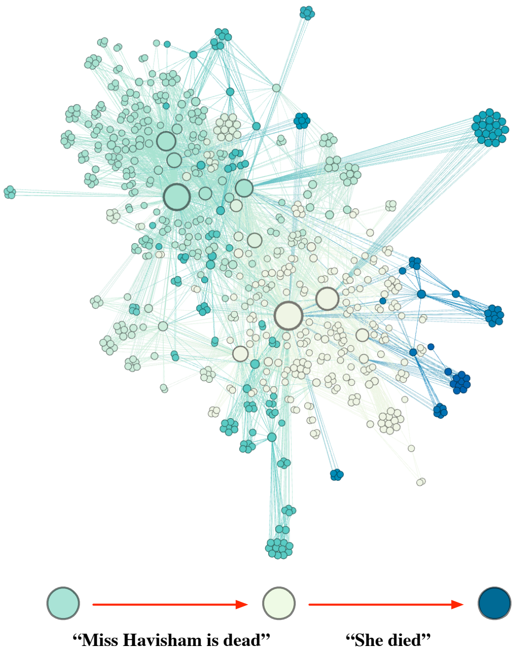

Figure 1: The character co-occurrence network for *Great Expectations*. Nodes represent characters and edges represent conversational interactions. Below the network, we illustrate an example of information transmission across a character triad.

At the same time, however, there remains a substantial gap in computational work to support the latter research goal of modeling the flow of information within depicted networks. Yet understanding how the transmission of information is represented in these imagined worlds has the potential to be of great value to scholars in the humanities, since the resulting models can serve as a basis for broader insights about the social structures embedded in narratives, the role of characters based on attributes such as race and gender, and the informational dynamics of gossip (Spacks, 1982, 1985; Martin, 2014).

In this work, we specifically aim to fill this gap by developing methods to track the flow of information in novels by extracting instances of a message

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 642–652,
November 16–20, 2020. ©2020 Association for Computational Linguistics

passing from character A to character B to character C, only given a depiction of their conversational interactions. We develop a methodology for modeling this mode of propagation in both *explicit* networks (where one character provides information that is explicitly attributed to another character, such as "Bob told me that Jack escaped"); and in *implicit* networks, where information is repeated by multiple characters without such attribution. While the results of the methods enable a range of potential analyses—for instance, comparative analysis between authors, characters, and dyads—we focus on two illustrative case studies. First, we examine the linchpins of information flow—the characters who are most responsible for the propagation of information—and how they are positioned relative to the overall network topology; and second, we examine the gender dynamics of information propagation and what it tells us about how novelists represent men and women as the means and agents for transmitting facts, gossip, and other details about the social workings of these imagined worlds.

We make the following contributions with this work:

1. We present a new NLP pipeline for determining information propagation in literary texts, incorporating a range of different sub-tasks, including coreference resolution, speaker attribution, character network identification, and information extraction.

2. We present a new dataset for speaker attribution, comprised of 1,765 quotations linked to their speakers in 100 different literary texts, allowing us to evaluate a critical component of this pipeline on a wider range of literary texts than previously studied.

3. We leverage our pipeline to analyze the dynamics of information propagation in a collection of 5,345 works of English fiction from Project Gutenberg. We find that information flows through characters that fill structural holes connecting different communities, and that characters who are women are depicted as filling this role much more frequently than characters who are men.

2 Related work

Much of the computational research into information propagation and diffusion has focused on the domain of social media (Bakshy et al., 2012). Research in this area includes analyses of information diffusion in blogs (Gruhl et al., 2004; Leskovec et al., 2007), the spread of news across online networks (Leskovec et al., 2009), and in particular, the spread of rumor and misinformation (Kwon et al., 2013; Friggeri et al., 2014; Del Vicario et al., 2016; Vosoughi et al., 2018).

A core aspect of this work that strongly differs from networks in fiction is that the individual components of social media networks (the nodes, edges, and instances of propagation) are often directly observed. In modeling retweet dynamics in Twitter, for instance, nodes are defined as unique users, edges are directly observed friend and follow links defined by the platform, and propagation occurs when one user retweets a message posted by another they are connected to. More closely related to the challenges posed by detecting propagation in fiction is work that may directly observe the node and edge structure of a network, but must infer an act of *propagation*, including work in tracking the diffusion of memes (Leskovec et al., 2009), text reuse across legislative bills (Wilkerson et al., 2015) and quotations in news (Niculae et al., 2015).

While information propagation has yet to inform work in narrative (hence the purpose of this study), network structure has increasingly informed literary scholarship. Following the work of Bourdieu (1996), literary scholars have in recent years begun to explore the role that social networks play both in authorial composition (So and Long, 2013; Mazanec, 2018) and in the narrative representation of "networked social experience" (Levine, 2009).

Treating literary works *themselves* as networks, however, poses distinct computational challenges. While research into information propagation in social media tends to presume access to explicit networks, the character networks represented in novels are implicit. To determine these networks, we draw on previous work by Elson et al. (2010), who build edges between character nodes through conversational interactions. Various computational work to extract social networks from literature has built on this research over the past ten years,[1] including fundamental methods designed to extract networks for other languages like German (Jannidis et al., 2016), incorporate other categories of nodes such as locations (Lee and Yeung, 2012) and objects (Sudhahar and Cristianini, 2013), and analyze the

---

structure of networks to test specific hypotheses (Elson et al., 2010; Agarwal et al., 2012; Coll Ardanuy and Sporleder, 2014; Piper et al., 2017). Our work builds on this tradition by introducing methods to reason about the phenomenon of propagation in fiction based on these constructed networks.

3 Methods

Our goal in this work is to investigate the behavior of information propagation in literary texts. In order to identify acts of propagation in this context, we need to determine the underlying network structure of a novel, including the nodes (by inferring characters) and the edges (by inferring some interaction between them). We describe first our pipeline for doing so, which involves identifying a set of unique characters from their mention in a text using coreference resolution (§3.1), attributing dialogue to those characters (§3.2), building a social network of speakers and listeners from that data (§3.3), and operationalizing a measure of "information" that we can treat as an atomic unit involved in propagation using slot-based information extraction (§3.4). With these constructed networks, we can measure acts of implicit propagation (§3.5) and explicit propagation (§3.6) within it.

3.1 Coreference resolution

Most contemporary systems for coreference resolution are trained on the benchmark OntoNotes dataset (Hovy et al., 2006), which primarily consists of news and conversation; literature is represented there only in the narrow genre of the Bible.

In order to use coreference resolution specifically trained on literature, we use the coreference annotations and trained model described in Bamman et al. (2020). This model is a neural coreference system inspired by Lee et al. (2017), augmented with BERT contextual representations (Devlin et al., 2019), and trained on 210,532 tokens in LitBank, comprising 100 different works of English-language fiction. Bamman et al. (2020) report its cross-validated average F-score on LitBank to be 68.1, notably higher than the performance for a model trained on OntoNotes (which has an average F1 score of 62.9).

3.2 Speaker attribution

Data. Previous work in literary speaker attribution has focused on a relatively small set of novels. Both He et al. (2013) and Muzny et al. (2017) annotate Austen's *Pride and Prejudice* and *Emma* as well as Chekhov's *The Steppe*. Similarly, the Columbia Quoted Speech Corpus includes six texts by Austen, Dickens, Flaubert, Doyle and Chekhov. While these datasets have been able to drive much work in the development of models for speaker attribution, they represent a comparatively narrow slice of how dialogue is depicted in literature.

In order to evaluate the robustness of models across a diverse range of novels and authors, we annotate all 100 texts in LitBank (Bamman et al., 2019) with the boundaries for all true quotations and link each to the entity who spoke it. Here we are able to draw on the coreference annotations present in LitBank, which already link each mention to a unique entity. All annotations were carried out using the BRAT annotation interface (Stenetorp et al., 2012) by four annotators after a period of initial training, prompted to identify all quotations and attribute each one to the speaker who uttered it. Given the high agreement rate observed by Muzny et al. (2017) (κ of 0.97 for quote-speaker labels), each quotation is attributed by a single annotator. To check consistency, we double-annotate a sample of 10 texts (10% of the entire collection) at the end of the annotation process and find a similarly high inter-annotator agreement rate (Cohen's κ of 0.962). In total, 1765 quotations were annotated across all 100 works of fiction. This data is freely available under a Creative Commons ShareAlike 4.0 license at `https://github.com/dbamman/litbank`.

Quotation identification. For the task of quotation identification, we use the method implemented in BookNLP (Bamman et al., 2014), which uses simple regular expressions (text contained between an opening quote and a closing quote). On our gold annotations, this method results in an F1 score of 90.8 for quotation identification (87.1 precision and 95.0 recall). False positive failure cases of strings wrapped in quotation marks that do not constitute dialogue include various typographical uses of quotation for signifying other phenomena, including scare quotes for emphatic use (to introduce jargon, neologisms, or irony), titles of works of art, the mention of a term (as distinct from its use), and written use (see Brendel et al. (2011) for a survey). False negatives primarily arise due to regex matching errors (such as a stray quotation mark that results in an inversion of the subsequent speech and narration), or texts that do not delimit speech with

Table 1: Metrics for cluster overlap between the gold set of clusters $\mathcal{G}$ and predicted set of clusters $\mathcal{C}$. Each cluster is defined as the set of quotations spoken by the same speaker. We also present the upper bound of carrying out speaker attribution using gold coreference labels (oracle coreference), which suggests that there is much to be gained in improving quotation attribution not only by improving coreference, but independently of it as well.

quotation marks at all (such as Joyce's *Ulysses*, which introduces direct speech with dashes).

Attribution. For speaker attribution, we reimplement the deterministic method of Muzny et al. (2017) using the full coreference information predicted above. Muzny et al. (2017) describes a series of deterministic sieves for the two tasks of a.) mapping quotes to the nearest speaker mention and b.) linking identified speaker mentions to character entities. The Quote→Mention phase includes sieves such as high-precision regular expressions for predefined Quote/Mention/Verb patterns (e.g., [“. . . ,”]$_{QUOTE}$ [said]$_{VERB}$ [Jane]$_{MENTION}$), originally defined in Elson and McKeown (2010); dependency structure information (identifying mentions that hold an NSUBJ relation to a verb of communicating); and vocatives in the previous quotation. Quotations unattributed after running all sieves are assigned the majority speaker in the context.

To separate out the task of quotation identification from quotation attribution, we evaluate quotation attribution with gold quotation boundaries. While previous work on quotation attribution in literary texts, including Muzny et al. (2017) and He et al. (2013), evaluate system performance using classification accuracy and precision/recall (where each quotation in a test book is judged to be assigned to the correct true speaker from a predefined gold character list), we do not presume access to a gold character list during prediction time. Like Almeida et al. (2014), we evaluate performance using a measure of cluster overlap (here, the suite of metrics used in evaluating coreference resolution), where each cluster is defined by the set of quotations spoken by the same speaker.

As Table 1 illustrates, our reimplementation of Muzny et al. (2017) for the task of speaker attribution yields an average F1 score of 71.3 across the three cluster metrics when evaluated on all 100 books in our newly annotated data. As we ablate different aspects of the Muzny et al. (2017) model, performance generally degrades, attesting to the value of individual sieves.

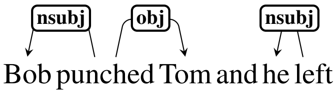
3.3 Identifying character networks

Similar to previous approaches for determining character networks in literary fiction (Elson and McKeown, 2010; Moretti, 2011), we use conversation as the basis for determining the edges in our graph. However, rather than trying to identify specific speaker-listener interactions, we instead extract dialogue blocks, drawing an edge between all characters mentioned outside of a quotation in a given block. Edges are weighted by the total number of dialogue blocks in which a given pair of characters are found to be co-present. We use a simple heuristic to identify these conversation blocks: if three or more contiguous sentences do not contain any quoted dialogue, we treat this as the termination of the block. The resulting graph serves as the basis for identifying information propagation in a given novel, as detailed in the following subsections.

3.4 Defining information

Whereas large-scale corpora such as social media data sets provide networks in which fuzzy matching of information may be appropriate and in which information repetition is often substantial (Leskovec et al., 2009), in the context of novels such methods are unlikely to have sufficient precision. As a result, we select an information approach which allows us to maximize precision at the cost of potentially missing some instances of propagation. Our approach entails identifying quoted speech that references at least one character. One way to define this type of speech would be to simply describe it as *gossip*, though we feel that this is an overly narrow term given the general nature of our approach. Specifically, we select propositional tuples of the form (subject, verb, object), such that the subject holds an `nsubj` dependency relation to the verb and the object holds an `obj` relation (using the terminology of the Universal Dependencies (Nivre et al., 2016)); the subject and object may be filled by a character entity, a non-character nominal phrase, or a null token if neither is present. We ignore any tuples which contain *I*, *you*, or *we* (along with their variants) in either the subject or object slots, since they have comparatively higher errors in coreference. For the verb slot, we always select the lemma form of the proposition's head verb. Character entities in a proposition are identified by their unique character IDs established through coreference resolution (and not by the surface form of their mention).

Consider the following hypothetical example:



Given the operation of coreference resolution mapping "Bob" and "he" to the entity `Bob-id1` and "Tom" to `Tom-id2`, the extracted tuples for this sentence would be: [`Bob-id1`, punch, `Tom-id2`] and [`Bob-id1`, leave, $\emptyset$]. We extract all propositional tuples using a set of rules applied to the dependency parse of a given sentence. Although reductive to some degree, defining and extracting information in this way allows us to avoid informational noise and only select consistent propositional units.

To further reduce potential informational noise, we also only select tuples containing words that are likely to have some intrinsic interest to the plot and which have a relatively fixed meaning. After analyzing the 100 words that occur most frequently across all the tuples extracted from our corpus, we select tuples containing terms associated with the following four categories: *amorous*, *hostile*, *juridical*, and *vital*. For each category, we include the following words along with any synonyms that are also present in the top 100 tuple words: *amorous* (love, marriage), *hostile* (hurt, hit, shoot, kill), *juridical* (arrest, escape, innocent, guilty), and *vital* (alive, sick, dead). Since the Gutenberg corpus primarily contains nineteenth-century novels, these topics reflect many of the key events that these works of fiction tend to focalize.

3.5 Defining implicit propagation

We identify instances of implicit information propagation simply by determining whether a propositional tuple passes between a minimum of three characters. In other words, we look for an informational triad of the form character A → character B → character C, such that character A and character B are co-present when character A voices the initial instance of the proposition (but character C is not), and character B and character C are co-present when character B repeats the proposition during a different conversation block.

3.6 Defining explicit propagation

Along with implicit instances of information propagation, we note that novels often contain explicit propagation as well. We define explicit propagation as occurring when a character reports what another character said to a third character. In other words, we simply search for variations of the pattern "`[character-id]` said" in the context of quoted speech. Specifically, the variations considered include synonyms for "say" along with any arguments or modifiers that are relevant to introducing reported speech (e.g., "declared," "told me," "mentioned that," "claimed to," etc.).

The benefit to capturing instances of explicit propagation is that such instances can be extracted with very high precision regardless of the informational topic being discussed. Consequently, unlike for implicit propagation, we make no constraints on the nature of the information itself (in contrast to the four topics defined above). After identifying instances of explicit propagation, we incorporate coreference resolution and speaker attribution to determine the specific characters of a given propagating triad. Section 5.2 discusses how the resulting data from this approach can be used to analyze the role that gender plays in the depiction of information propagation within novels.

4 Experiments

Given instances of information propagation extracted from novels, we seek to understand the structural roles of the literary network and its topography that contribute to information passing between dyads. In particular, we seek to disentangle two possible alternatives:

H1. Information propagates through bridges who pass information between otherwise disconnected communities.

H2. Information propagates among densely connected strong ties (such as between members of the same family who interact frequently).

These alternatives correspond to different functions of gossip in literature, as theorized by Spacks (1985): while gossip primarily involves the "deliberate circulation of information," it also functions to reinforce existing relationships among strong ties (a point taken up in real-world social networks in Foster (2004)). We operationalize this distinction for understanding the dynamics of implicit propagation by describing information-propagating characters and non-information-propagating characters through six network measures that capture their topological properties within the network:

1. **Closeness centrality**: the average inverse distance between a given node and all other nodes in a graph.
2. **Betweenness centrality**: the fraction of shortest paths that pass through a node, summed over all node pairs.
3. **Average neighbor degree**: the average degree of the nodes in a given node's neighborhood.
4. **Effective size**: the measure of the non-redundancy between a node and its contacts—specifically how connected a node's contacts would be in its absence (i.e., the resulting structural hole).
5. **Efficiency**: the effective size of a node divided by its degree.
6. **Triangle count**: the number of triangles for which a node serves as a vertex, where a triangle is defined as a set of three nodes that are directly connected to each other.

We use the above measures to describe all nodes that either function as the B node in an $A \rightarrow B \rightarrow C$ information triad, or could function as such a node. More specifically, whenever we observe an instance of propagation $A \rightarrow B \rightarrow C$, in which at least one separate character B' was co-present with B when hearing A's information (but did not propagate it further), we select a pair comprised of B as a propagating node and B' as a non-propagating node (sampling B' from the set of co-present characters if more than one was present). In cases in which no non-propagating character was co-present, we instead sample a B' from the set of propagating instances that had multiple co-present characters. When sampling the non-propagating B' nodes, we only select characters that have been observed to speak at least once in the text based on our speaker attribution model (we hypothesize that selecting these characters is a better way to judge the efficacy of a propagation model, since they at least vocalize some information in the narrative, and hence are more likely to resemble propagating nodes in terms of their narrative functions).

4.1 Results

In order to test implicit information propagation in literature, we run tuple extraction on 5,345 works of fiction from the Project Gutenberg corpus. We find that roughly 3,600 of these books contain at least one instance of a repeated tuple containing a word from our four topics of interest (indicating the possibility of propagation based on our criteria). We proceed to run the rest of our pipeline on this subset of books.[2] In total, we find that 35% of these works contain at least one instance of implicit information propagation.

To distinguish between the two hypotheses outlined above, we scale all the features of the data between 0 and 1 and train a non-regularized logistic regression model to distinguish between information propagating B nodes and non-propagating B' nodes. We run the model on 1,730 B nodes and 1,730 B' nodes. The results are shown in Table 2 and discussed in more detail in the next section.

To ensure that our results are not simply caused by aspects of each network's general topology (irrespective of the unique qualities of propagating B nodes) we also run a degree-preserving randomiza-

---

[2] We process all books on a high-performance computing cluster using 24-core Intel Xeon Haswell processors and 64 GB of RAM; the average runtime of this pipeline on one book on this platform is five minutes and two seconds.

Graph Measure	Coefficient
Efficiency	3.0^*
Effective size	2.7
Betweenness centrality	0.5
Closeness centrality	0.1
Triangles	-0.4
Average neighbor degree	-4.9^*

Table 2: Logistic regression model coefficient values. Stronger positive values are indicative of information-propagating nodes; stronger negative values are indicative of non-propagating nodes. * denotes $p < 0.01$.

tion experiment (Miller and Hagberg, 2011) as a more stringent means for testing significance. For each network containing a propagating node, we generate 10 expected degree graphs and use them to calculate network measures for the corresponding propagating B and non-propagating B' nodes in the original network, producing a set of 10 randomized measures for each of the 1,730 original nodes in each class. We then randomly sample a single measure from each of these sets, yielding 1,730 randomized node measures for both classes, and rerun our logistic regression model on that resample. We repeat this process 10,000 times to generate an expected null distribution for each coefficient and assess the frequency with which a null coefficient value was observed to be as extreme as the value we observe under the true network—analogous to a p-value in a bootstrap hypothesis test (Efron, 1982; Berg-Kirkpatrick et al., 2012; Dror et al., 2018).

For the two node measures found to be significant under our original model, efficiency has a p-value of 0.08 (8% of 10,000 random trials observe a statistic as extreme as 3.0), no longer rising to the level of significance at $\alpha = 0.01$, while average neighbor degree has a p-value of 0 (no random trial sees as a statistic as extreme as -4.9), providing further evidence of its significance as a feature for discriminating information-propagating nodes.

5 Analysis

5.1 Implicit propagation and weak ties

As Table 2 shows, average neighbor degree and efficiency are both found to be significant at a threshold of $\alpha = 0.01$, while average neighbor degree is confirmed to be significant under a degree-preserving randomization experiment. These results support the first of our two postulated hypotheses (introduced in §4): information in novels propagates through characters that serve as bridges between otherwise disconnected communities.

Average neighbor degree has the largest coefficient (by absolute value) and is negatively correlated with propagation. High values of average neighbor degree denote communities that are already well-connected (both to each other and to the rest of the network). In such a information-rich neighborhood, instances of propagation would be of less value or necessity, and hence would be less likely to be observed.

Support for the first hypothesis is further confirmed by the strong positive coefficient for efficiency. Like effective size, efficiency is a means of determining the extent to which a structural hole would occur if a specific node were removed from the network. Whereas effective size indicates the possibility of such a structural hole in general, efficiency measures how much each one of a node's connections on average contribute to linking otherwise disconnected neighborhoods. Thus high efficiency suggests that a node is not only serving as a useful bridge between other nodes, but that it is doing so productively relative to its total number of connections.

In a sense, these results suggest that we are observing a version of the weak tie theory first proposed by Granovetter (1973). By virtue of the fact that a character's connections are not themselves closely connected, that character can in turn serve an essential informational role for the community.

5.2 Explicit propagation and gender

While our methods for extracting implicit propagation for amorous, hostile, juridical and vital events identified 1,730 instances in 5,345 novels, our method for identifying explicit propagation yields far more—93,948 instances of propagation involving 258,619 triads (since there may be multiple listeners for a single instance). Although the analysis carried out on implicit propagation is not possible for the explicit case (since there is no way to identify co-present B' nodes when the initial instance of a proposition remains unobserved in the text), the size of the explicit results are conducive to other analyses. Specifically, we consider here the role that gender plays in the depiction of propagation. As Spacks (1985) points out, women are often stereotyped (both within the real world and in representations in literature) as more likely to engage in gossip; from a networked perspective, they are also often cast as intermediaries between men, "serving as points through which to triangulate male-to-male desire or power" (Selisker, 2015). Analyzing gender (and other demographic attributes) in the context of information propagation enables scholars to consider how authors construct the informational ecology of their novels given the functional roles played by different characters.

To measure the role that gender plays in how authors represent information propagation in novels, we calculate the relative proportion of different gender configurations for propagating triads compared to all triads present across our entire data set (we determine the gender of a character by counting up all the male and female nouns and pronouns in that character's coreference chain). This allows us to answer the question: given the overall structural opportunity to transmit information, how often does transmission actually occur based on gender?

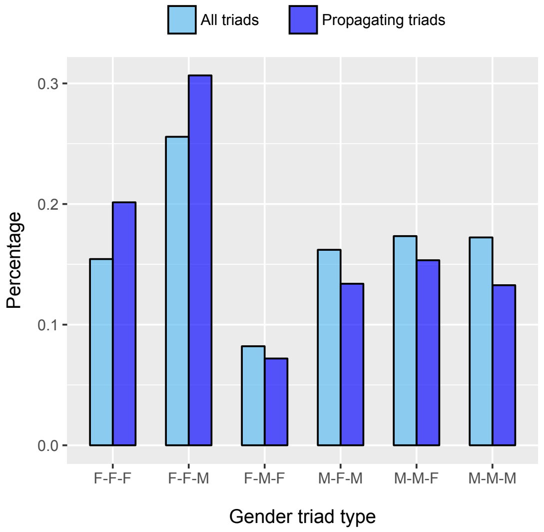


Figure 2: Comparison of the relative proportions of triad variations based on gender. All triads (light blue, n = 158,250,238) represent every observed triad across 5,345 books. Propagating triads (dark blue, n = 258,619) indicate only those triads observed to explicitly propagate information. The widest 95% confidence interval across all proportions is ±0.0018, so that all differences within a gender triad type are significant.

Figure 2 illustrates the proportion of each gender configuration compared to the total; for instance, while 15.4% of all character triads are comprised of three women (`F-F-F`), 20.1% of triads involved in information propagation involve three women. Overall, we find that not only are female characters more likely to serve as propagators than male characters in this dataset, but that female characters fill this role more frequently than one would expect given the proportion of female connector nodes across all triads. The proportion of propagation when the middle node is male, conversely, is lower than the expected value for every configuration. In other words, authors represent women as information propagators comparatively more frequently than men relative to their overall expectation.

Although literary criticism tends to envision the role of women in novels as being intermediaries between men (Woolf, 1929; Sedgwick, 1985; Schantz, 2008; Selisker, 2015), our analysis of information propagation tells a slightly different story. While women do indeed appear to serve as intermediaries/connectors more frequently than men do, women propagate information *between* men much more rarely than they do in other configurations (i.e., `F-F-F`, `F-F-M`). Though women may of course still connect men in these narratives, they do not appear to do so by notably passing on information. We leave determining the broader significance of this result to future work.

6 Conclusion

We introduce the task of identifying information propagation in literary social networks, designing an NLP pipeline for extracting both *implicit* and *explicit* propagation. This work offers a new perspective on the analysis of social networks in literary texts by considering the dynamics of how information flows through them—both as a result of the structural topology of the network (characters who successfully propagate are information bridges between communities), and as a result of the specific characteristics of each node (women are depicted more frequently as successful propagators than men).

This study, of course, contains limitations: readers of fictional works are only afforded a partial perspective of the world that is represented—namely the interactions an author chooses to describe (and not, for example, the dialogue we might presume takes place "off-screen"). Considered from a narratological perspective, however, this is a benefit rather than a drawback, since our goal is not to understand the underlying reality of these imagined worlds but rather how authors opt to represent the informational dynamics from which their stories are constructed. In developing this pipeline to examine how authors depict the transmission of information within narrative texts, we hope to drive a variety of future research in this space, including not only such narratological questions as how "gossip impels plots" (Spacks, 1985), but also questions pertaining to issues of bias in representation, the flow of information, and factuality. Code to support this work can be found at `https://github.com/mbwsims/literary-information-propagation`.

SOCIAL CHEMISTRY 101:
Learning to Reason about Social and Moral Norms

Abstract

Social norms—the unspoken commonsense rules about acceptable social behavior—are crucial in understanding the underlying causes and intents of people's actions in narratives. For example, underlying an action such as *"wanting to call cops on my neighbor"* are social norms that inform our conduct, such as *"It is expected that you report crimes."*

We present SOCIAL CHEMISTRY, a new conceptual formalism to study people's everyday social norms and moral judgments over a rich spectrum of real life situations described in natural language. We introduce SOCIAL-CHEM-101, a large-scale corpus that catalogs 292k **rules-of-thumb** such as *"It is rude to run a blender at 5am"* as the basic conceptual units. Each rule-of-thumb is further broken down with 12 different dimensions of people's judgments, including social judgments of good and bad, moral foundations, expected cultural pressure, and assumed legality, which together amount to over 4.5 million annotations of categorical labels and free-text descriptions.

Comprehensive empirical results based on state-of-the-art neural models demonstrate that computational modeling of social norms is a promising research direction. Our model framework, NEURAL NORM TRANSFORMER, learns and generalizes SOCIAL-CHEM-101 to successfully reason about previously unseen situations, generating relevant (and potentially novel) attribute-aware social rules-of-thumb.

1 Introduction

Understanding and reasoning about social situations relies on unspoken commonsense rules about *social norms*, i.e., acceptable social behavior (Haidt, 2012). For example, when faced with situations like "*wanting to call the cops on my neighbors*," (Figure 1), we perform a rich variety of reasoning about about legality, cultural pressure, and even morality of the situation (here, "*reporting a crime*" and "*being friends with your neighbor*" are conflicting norms). Failure to account

Figure 1: This figure illustrates an intuitive subset of our formalism to reason about social norms in language. Our approach centers around Rules-of-Thumb (RoTs; text in colored tubes), which describe social expectations given a situation (text in the center hexagon). Rather than prescribing what is right or wrong, RoTs reveal ethical judgments about social propriety from varying perspectives.[1] Structured categorical (in smaller hexagons; e.g., "social judgment" and "cultural pressure") annotations provide richer understanding. All RoTs shown here in tubes are generated by our NEURAL NORM TRANSFORMER conditioning on the center situation and the categorical types.

---

[1] Note that the social identities of the participants of situations would further inform which social norms are most

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 653–670,
November 16–20, 2020.

Figure 2: Three different slices of a complete annotation for a single situation, meant to illustrate our approach. Each **RoT** (text in colored boxes, e.g., "It's not right to tell...") is written for a particular real life **situation** (text in pale grey boxes, e.g., "asking my boyfriend to stop being ...") and a specific **person** in that situation ("narrator" vs "my boyfriend"). *(a)* A situation often includes multiple people with distinct perspectives, evoking different (and possibly conflicting) RoTs. *(b)* Even a single person may have multiple, conflicting RoTs—key ingredients for moral dilemmas. *(c)* Each RoT is further broken down with categorical and free text annotations (shown in tiny colored buttons. e.g., "strong" for *cultural pressure*). The full definition of the low-level RoT attributes are in Figure 4.

for social norms could significantly hinder AI systems' ability to interact with humans (Pereira et al., 2016).

In this paper, we introduce SOCIAL CHEMISTRY as a new formalism to study people's social and moral norms over everyday real life situations. Our approach based on crowdsourced descriptions of norms is inspired in part by studies in *descriptive* or *applied* ethics (Hare et al., 1981; Kohlberg, 1976), which takes a *bottom-up* approach by asking people's judgements on various ethical situations. This is in contrast to the *top-down* approach taken by *normative* or *prescriptive* ethics to prescribe the key elements of ethical judgements. The underlying motivation of our study is that we, the NLP field, might have a real chance to contribute to the studies of computational social norms and descriptive ethics through large-scale crowdsourced annotation efforts combined with state-of-the-art neural language models.

To that end, we organize *descriptive* norms via free-text *rules-of-thumb (RoTs)* as the basic conceptual units.

> **Rule-of-Thumb (RoT)** — A descriptive cultural norm structured as the judgment of an action. For example, *"It's rude to run the blender at 5am."*

Each RoT is further broken down with 12 theoretically-motivated dimensions of people's judgments such as social judgments of good and bad, theoretical categories of moral foundations, expected cultural pressure, and assumed legality. All together, these annotations comprise SOCIAL-CHEM-101, a new type of NLP resource that catalogs 292k RoTs over 104k real life situations, along with 365k sets of structural annotations, which break each RoT into 12 dimensions of norm attributes. Together, this amounts to over 4.5M categorical and free-text annotations.

We investigate how state-of-the-art neural language models can learn and generalize out of SOCIAL-CHEM-101 to accurately reason about social norms with respect to a previously unseen situation. We term this modeling framework NEURAL NORM TRANSFORMER, and find it is able to generate relevant (and potentially novel) rules-of-thumb conditioned on all attribute dimensions. Even so, this breadth of this task proves challenging to current neural models, with humans rating model's adherence to different attributes from 0.28 to 0.91 micro-F1.

In addition, we showcase a potential practical use case of computational social norms by analyzing political news headlines through the lens of our framework. We find that our empirical results align with the *Moral Foundation Theory* of Graham et al. (2009); Haidt (2012) on how the moral norms of different communities vary depending on their political leanings and news reliability. Our empirical studies demonstrate that computational modeling of social norms is a feasible and promising research direction that warrants further investigation. SOCIAL-CHEM-101 provides a new resource to teach AI models to learn people's norms, as well

---

relevant. For example, if the neighbors are African American, it might be worse to call the cops due to racial profiling (Eberhardt, 2020).

as to support novel interdisciplinary research across NLP, computational norms, and descriptive ethics.

2 Approach

The study of social norms have roots in descriptive ethics and moral psychology. They tell us that social norms are culturally-sensitive standards of appropriate conduct. Alongside explicit laws and regulations that govern our society, social norms perform the role of providing guidelines on socially appropriate behaviors (Elster, 2006; Bowdery, 1941; Kohlberg, 1976) and are responsible for setting implicit expectations of what is socially right or wrong (Malle et al., 2014; Haidt, 2012; Hare et al., 1981). They influence a wide-range of social functions such as preserving biological needs to survival (e.g., refraining from harming or killing), maintaining social civility and order (e.g., maintaining politeness, recognizing personal space), and providing identity and belonging to a community (e.g., respecting the elderly). In turn, these social norms influence how we judge, communicate, and interact with each other.

RoTs Our aim is then to forefront these implicit expectations about social norms via RoTs. We formalize the definition of RoTs as situationally-relevant evaluative judgments of social norm, and posit that for any given **situation**, one or more RoTs will be evoked in the minds of the interpreter. Consider the following situation and its RoT.

> **Punching someone.**
> RoT: It is unacceptable to injure a person.

Most readers can instantly recognize the situation is in violation of an unspoken social rule: *"Do not injure others."* This rule is responsible for the series of natural questions that probe at the morality of the action, like "why did the narrator punch someone?" "was the action justified?" and "do I want to sympathize with the narrator?" The role of the RoT is to identify the unspoken rule in the situation by specifying the behavior or **action** ("injuring a person") and its **acceptability judgment** ("it is unacceptable"). More complex situations can be associated with multiple RoTs, as seen in the example below:

> **Punching a friend who stole from me.**
> RoT 1: It is unacceptable to injure a person.
> RoT 2: People should not steal from others.
> RoT 3: It is bad to betray a friend.
> RoT 4: It is OK to want to take revenge.

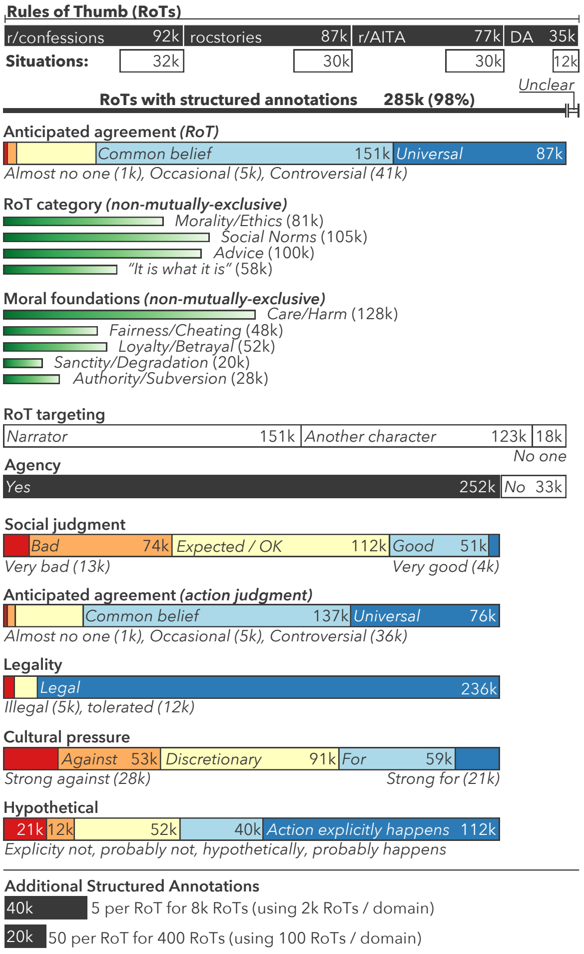

Figure 3: SOCIAL-CHEM-101 Dataset statistics. Bars are drawn to scale. Individual values for all of the different attributes are also given in Figure 4.

The RoTs represent a variety of social norms that elaborate on various perspectives available in the situation: RoTs about stealing (RoT 1) vs. punching (RoT 2), RoTs targeting the different characters in the situation (RoTs 1, 4 target the narrator; RoTs 2, 3 target narrator's friend), and RoTs that elaborate on additional social interpretation implicit in the situation (RoT 3: theft from a friend is cast as an act of betrayal). Effectively, RoTs represent evaluative judgments about a social situation in light of unspoken but accepted social norms.[2] Figure 2 shows three subsets of a situation's annotation to illustrate the perspectives RoTs capture.

Cultural Scope of this study We recognize that social norms are often culturally sensitive (Haidt et al., 1993; Kagan, 1984) and judgments of morality and ethics concerning individuality, community and society do not always hold universally (Shweder, 1990). While some situations (e.g.,

---

[2] Our definition of RoTs corresponds to the first of the two evaluative moral judgments defined in Malle et al. (2014).

"punching someone") might have similar levels of acceptability across a number of cultures, others might have drastically varied levels depending on the culture of its participants (e.g., "kissing someone on the cheek as a greeting"). As a starting point, our study focuses on the socio-normative judgments of English-speaking cultures represented within North America. While we find some variation of judgments in our annotations (e.g., with respect to certain worker characteristics, see §A.6), extending this formalism to other countries and non-English speaking cultures remains a compelling area of future research.

3 SOCIAL-CHEM-101 Dataset

We obtained 104k source situations from 4 text domains (§3.1), for which we elicited 292k RoTs from crowd workers (§3.2). We then define a structured annotation task where workers isolate the central action described by the RoT and provide a series of judgments about the RoT and the action (§3.3). In total, we collect 365k structured annotations, performing multiple annotations per RoT for a subset of the RoTs to study the variance in annotations. Figure 3 illustrates our dataset statistics.

3.1 Situations

We use a *situation* to denote the one-sentence prompt given to a worker as the basis for writing RoTs. We gather a total of 104k real life situations from four domains: scraped titles of posts in the subreddits `r/confessions` (32k) and `r/amitheasshole` (`r/AITA`, 30k), which largely focus on moral quandaries and interpersonal conflicts; 30k sentences from the ROCStories corpus (`rocstories`, Mostafazadeh et al., 2016); and scraped titles from the Dear Abby advice column archives[3] (`dearabby`, 12k).[4]

3.2 Rules-of-Thumb (RoTs)

To collect RoTs, we provide workers with a situation as a prompt and them to write 1 – 5 RoTs inspired by that situation. From the 104k situations, we elicit a total of 292k RoTs. Despite RoTs averaging just 10 words, we observe that 260k/292k RoTs are unique across the dataset.

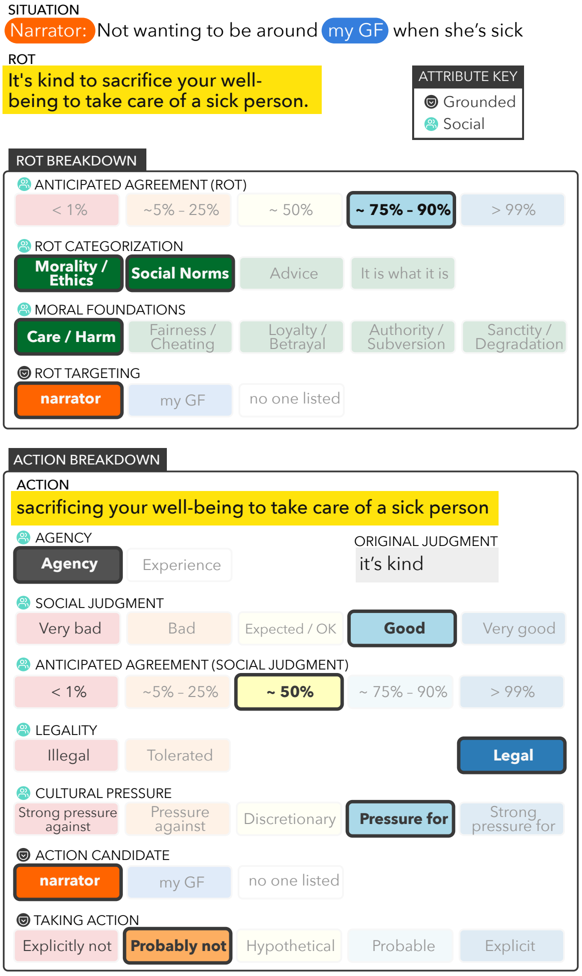

Figure 4: All attribute values for structured RoT annotations, with one complete example annotation filled in.

For the development of RoTs, we instruct the workers to produce RoTs that *explain the basics of social norms*, just as one would instruct a five-year-old child on the ABCs of acceptable conduct. RoTs are to be:

1. **inspired by the situation**, to maintain a lower bound on relevance;
2. **self-contained**, to be understandable without additional explanation; and
3. structured as **judgment** of acceptability (e.g., good/bad, (un)acceptable, okay) and an **action** that is assessed.

In order to encourage RoT diversity, we also ask that an RoT should counterbalance *vagueness* against *specificity* so that RoTs generalize across multiple situations (e.g., *"It is rude be selfish."*) without being too specific (e.g., *"It is rude not to share your mac'n'cheese with your younger brother."*). We also ask workers to write RoTs illustrating *distinct ideas* and *avoid trivial inversions*

---

[3] https://www.uexpress.com/dearabby/archives

[4] See Appendix A.1 for further data preprocessing details.

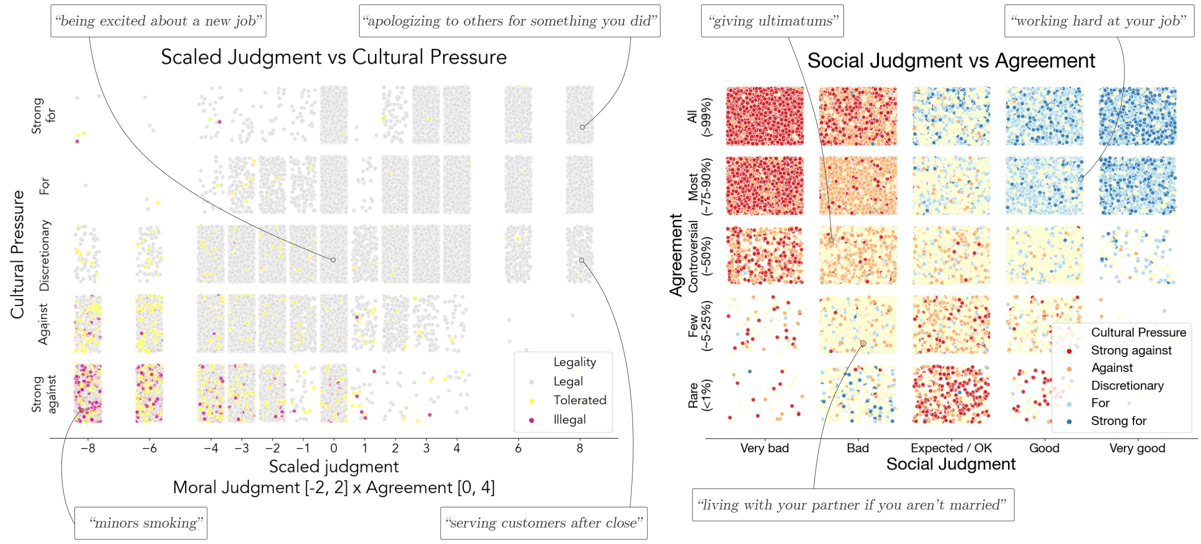

Figure 5: Plotting the distribution of RoTs in SOCIAL-CHEM-101 along axes of *moral judgment, agreement, cultural pressure,* and *legality.* **Left:** Moral judgment is scaled with agreement (how commonly held the belief is) and plotted against cultural pressure. Illegal activities fall in the bottom left: actions that are universally understood to be wrong and people feel negative cultural pressure for. **Right:** Moral judgment is plotted against agreement. Discretionary actions span a range of moral values (yellow ranging horizontally) and fringe beliefs often evoke strong negative cultural pressure even when morally neutral (bottom of plot).

to prevent low-information RoTs that rephrase the same idea or simply invert the judgement and action.

Character Identification. We ask workers to identify phrases in each situation that refer to people. For example, in a situation, like *"My brother chased after the Uber driver,"* workers mark the underlined spans. We collect three workers' spans, calling each span a *character*. All characters identified become candidates for grounding RoTs and actions in the structured annotation. As such, we optimize for recall instead of precision by using the largest set of characters identified by any worker. We also include a *narrator* character by default.

3.3 RoT Breakdowns

We perform a structured annotation, which we term a *breakdown*, on each RoT. In an RoT breakdown, a worker isolates the underlying action contained in the RoT. Then, they assign a series of categorical attributes to both the RoT and the action. These categorical annotations allow for additional analyses and experiments relative to the text-only RoTs.

The attributes fall into two categories corresponding to the central annotation goals. The first goal is to tightly *ground* RoTs to their respective situations. The second goal is to partition *social* expectations using theoretically motivated categories.

A subset of the attributes are labeled on the RoT (e.g., *"It is expected that you report a crime"*), while others are on the action (e.g., *"reporting a crime"*). Figure 4 provides the complete set of labels available for an RoT breakdown.[5]

Grounding Attributes We call three attributes *grounding attributes*. Their goal is to ground the RoT and action to the situation and characters. At the RoT-level, workers mark which character should heed the RoT with the **RoT Targeting** attribute. At the action level, workers first pick the **action's best candidate** character, for whom the action is most relevant. However, since RoTs can identify actions that are both explicit and hypothetical in the situation, we additionally annotate whether the candidate character is explicitly **taking the action** in the situation.

Social Attributes The second set of attributes characterize social expectations in an RoT. The first two social attributes both label **anticipated agreement**. For an RoT, this attribute asks how many people probably *agree* with the RoT as stated. At the action level, it asks what portion of people probably agree with the *judgment* given the *action*.

Four social attributes relate to the theoretical underpinnings of this work in §2. An RoT-level

---

[5] Workers are given the choice to mark the RoT as confusing, vague, or low quality, and move on (2% of RoTs).

attribute is the set of **Moral Foundations**, based on a well-known social psychology theory that outlines culturally innate moral reasoning (Haidt, 2012). The action-level attributes **legality** and **cultural pressure** are designed to reflect the two-coarse-grained categories proposed by the Social Norms Theory (Kitts and Chiang, 2008; Perkins and Berkowitz, 1986). Legality corresponds to prescriptive norms: what one ought to do. Cultural pressure corresponds to descriptive norms: what one is socially influenced to do. Finally, the **social judgment** aims to capture subjective moral judgment. A base judgment of what is good or bad is thought to intrinsically motivate social norms (Malle et al., 2014; Haidt et al., 1993).

The final two attributes provide a coarse categorization over RoTs and actions. The **RoT Category** attribute estimate distinctions between morality, social norms, and other kinds of advice. This aims to separate moral directives from tips or general world knowledge (e.g., "It is good to eat when you are hungry"). The attribute **agency** is designed to let workers distinguish RoTs that involve agentive action from those that indicate an an experience (e.g., "It is sad to lose a family member").

3.4 Analysis

We briefly highlight three key aspects of our formalism: social judgment, anticipated agreement, and cultural pressure. Figure 5 shows two plots partitioning RoTs based on these three attributes (with legality also highlighted in the left plot (a)).

In the left plot (Figure 5 (a)), the x-axis contains a new quantity, where social judgment ($\in [-2, 2]$) is multiplied by agreement ($\in [0, 4]$) to scale it.[6] The result is that x values range from universally-agreed bad actions (-8) to universally-agreed good actions (+8). Intuitively, the bottom-left group shows illegal actions, which are both "bad" (left x) and people feel strong pressure not to do (bottom y). The data are generally distributed in a line towards the top right, which are "good" (right x) actions that people feel strong pressure to do (top y).

However, the spread of the data in Figure 5 (a) illustrates the difference between morality and cultural pressure. There are a range of morally charged actions, but for which people don't feel cultural pressure (the horizontal range in x values across the central y = *Discretionary*). Conversely, we observe actions that are morally neutral, but for which people do feel cultural pressure (the vertical range in y values along the middle $x = 0$).

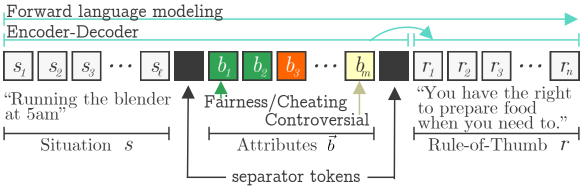

Figure 6: Illustration of modeling setup for the objective $p(r|s, \vec{b_r})$.

The right plot, Figure 5 (b), shows social judgment against agreement, colored by cultural pressure. At high levels of agreement (top of graph), cultural pressure (color) follows social judgment (horizontal changes in x values). However, for controversially-held judgments (lower y values), we see a range of cultural pressure. This includes morally good or bad actions that are still discretionary (middle y values), as well as morally neutral actions for which people feel strong cultural pressure (lower y values).

These plots illustrate two ways of stratifying actions along socially relevant dimensions. We anticipate considerable further dataset exploration remains.

4 Model

We investigate neural models based on pre-trained language models for learning various sub-tasks derived from SOCIAL-CHEM-101.

4.1 Training Objectives

Our main modeling formulation is straightforward. Given a situation (s), we wish to model the conditional distribution of RoTs (r), actions (a), and set of attributes from the breakdown ($\vec{b}$). We can partition the attributes $\vec{b} = \{\vec{b_r}, \vec{b_a}\}$ into disjoint sets relevant to the RoT and action, and write

$$p(r, a, \vec{b}|s) = \underbrace{p(a, \vec{b_a}|r, \vec{b_r}, s)}_{\textit{action transcription}} \times \underbrace{p(r, \vec{b_r}|s)}_{\textit{RoT prediction}} . \quad (1)$$

Equation 1 allows us to model all components of interest given a situation s. However, the *action transcription* term is quite strongly conditioned, because actions are so closely related to their RoTs.

---

[6] Strict statisticians will note that plotting ordinal values numerically is an abuse of notation, much less scaling two values together. We present these graphs for illustrative purposes to observe the stratification of our dataset, not to make quantitative claims.

Objective		
RoT	**Action**	**Interpretation**
$p(r \mid s)$	$p(a \mid s)$	Text-only generation
$p(\vec{b}_r \mid s)$	$p(\vec{b}_a \mid s)$	Attribute prediction
$p(r \mid s, \vec{b}_r)$	$p(a \mid s, \vec{b}_a)$	Controlled generation
$p(\vec{b}_r \mid s, r)$	$p(\vec{b}_a \mid s, a)$	Attribute labeling
$p(r, \vec{b}_r \mid s)$	$p(a, \vec{b}_a \mid s)$	Model choice generation

Table 1: Generative model objectives corresponding to the training setups we consider. Each model (RoT or action) is trained on all objectives simultaneously.

In this paper, we instead focus our study of actions on a more difficult distribution that conditions only on the situation:

$$\underbrace{p(a, \vec{b}_a \mid r, \vec{b}_r, s)}_{\textit{action transcription}} \xrightarrow{\textit{omit RoT}} \underbrace{p(a, \vec{b}_a \mid s)}_{\textit{action prediction}} . \qquad (2)$$

We model both the *RoT prediction* (Eq. 1) and *action prediction* (Eq. 2) distributions with conditional forward language modeling. We tokenize all quantities $(s, r, a, \vec{b})$, creating unique tokens for each attribute value b_i, and concatenate them together in a canonical order to form strings $p(x_{\text{out}} \mid x_{\text{in}})$. We then train to maximize the standard language modeling objective:

$$x = [x_{\text{in}}; x_{\text{out}}], \quad p(x) = \prod_{i=1}^{n} p(x_i \mid x_{<i}). \qquad (3)$$

Both the *RoT prediction* (Eq. 1) and *action prediction* (Eq. 2) distributions have similar forms $p(y, \vec{b}_y \mid s)$ for $y \in \{r, a\}$. We take advantage of this symmetry to study variations of both distributions. Inspired by recent work (Zellers et al., 2019), we construct permutations of our data that omit different fields while maintaining the canonical order. Table 1 shows the setups that we consider, and Figure 6 illustrates an example objective.

We train each model (either RoT or action) on all relevant objectives in Table 1 (i.e., one of the columns). Intuitively, this allows the model to condition on and generate a range of fields.[7] We can do this by simply treating each objective as defining a subset of the fields, as well as their ordering, for each data point. Then, we combine and shuffle all objectives' views of the data.

4.2 Architectures

We present results for the GPT and GPT-2 architectures (Radford et al., 2018, 2019), as well as two encoder-decoder language models (BART and T5, Lewis et al., 2019; Raffel et al., 2019). We train forward language models with loss over the entire sequence x, whereas encoder-decoder models only compute loss for the output sequence x_{out}. Collectively, we term these architectures trained on our objectives the NEURAL NORM TRANSFORMER.

5 Experiments and Results

5.1 Tasks

While we train each model on all (RoT or action) objectives at once, we pick two particular objectives to asses the models. The first is $p(y, \vec{b}_y \mid s)$ — *"model choice."* In this setting, each model is allowed to pick the most likely attributes $\vec{b}_y$ given a situation s, and generate an RoT (or action) y that adheres to those attributes. This setup should be easier because a model is allowed to pick the conditions of its own generation ($\vec{b}_y$).

The second setting is $p(y \mid s, \vec{b}_y)$ — *"conditional."* We provide models with a set of attributes $\vec{b}_y$ that they must follow when generating an RoT (or action) y. This presents a more challenging setup, because models cannot simply condition on the set of attributes that they find most likely. We select sets of attributes $\vec{b}_y$ provided by the human annotators for the situation s to ensure models are not tasked with generating from impossible constraints.

Setup We split our dataset into 80/10/10% train/dev/test partitions by situation, such that each domain's situations are proportionally distributed. This guarantees previously unobserved dev and test situations. For all models we use top-p decoding with $p = 0.9$ (Holtzman et al., 2020).

Baselines We use a *Random RoT* baseline to verify the dataset diversity (selections should have low relevance to test situations) and evaluation setup (RoTs and actions should still be internally consistent). We also use a *BERT-Score* (Zhang et al., 2020) retrieval baseline that finds the most similar training situation. If attributes $\vec{b}_y$ are provided, the retriever picks the RoT (or action) from the retrieved situation with the most similar attributes.

Ablations We report two model ablations. For *-Small*, we finetune GPT-2 Small with the same general architecture. For *-No pretrain*, we randomly

---

[7] It is possible to remove the assumption that the situation is provided, which would allow the model to generate s as well. We leave such experiments for future work.

Table 2: Human evaluation results for conditionally generating RoTs and actions, either letting the models choose the attributes (top half), or providing the attributes as input constraints (bottom half). All columns are micro-F1 scores (0–1), except *Relevance* (1–3). **Takeaway:** While state-of-the-art models are able to generate relevant RoTs and actions that generally follow constraints (moderately high scores in some columns), correctly conditioning on a complete set of attributes remains challenging (several columns show poor model performance in bottom half).

Model	**Ppl.**	**BLEU-4**	**Attr. μF1**
→ **RoT**			
GPT	1.81	5.41	0.42
Bart-large	1.76	6.65	0.47
T5-large	1.94	**10.79**	0.34
GPT-2 Small	1.97	4.97	0.38
GPT-2 XL - No fine-tune	-	0.46	0.20
GPT-2 XL - No pre-train	2.54	4.39	0.42
GPT-2 XL	1.75	6.53	**0.53**
→ **Action**			
GPT	1.80	6.75	0.60
BART-Large	1.72	8.34	0.66
T5-Large	2.00	**8.93**	0.58
GPT-2 Small	1.94	6.62	0.56
GPT-2 XL - No fine-tune	-	0.25	0.52
GPT-2 XL - No pre-train	2.51	5.43	0.55
GPT-2 XL	1.73	7.98	**0.68**

Table 3: Test set performance by automatic metrics, including an attribute classifier. Perplexities are not comparable between encoder-decoder models (Bart and T5, loss on x_{out} only) and other models (loss on full sequence x). **Takeaway:** Automatic metrics corroborate human evaluation results: while T5 is most adept at BLEU, GPT-2 XL more consistently adheres to attributes (Attr. μF1).

initialize the model's weights.[8]

5.2 Results

Human Evaluation Table 2 presents a human evaluation measuring how effective models are at generating RoTs and actions for both task settings. While most columns measure attribute adherence, the *Relevance* score is critical for distinguishing whether RoTs actually apply to the provided situation (e.g., see low scores for the *Random RoT* baseline). In both setups, T5's generations rank as most tightly relevant to the situation. But in terms of correctly following attributes, GPT-2 is more consistent, especially in the *controlled* task setup (lower; top scores on 5/9 attributes). However, no model is able to achieve a high score on all columns in the bottom half of the table. This indicates that fully constrained conditional generation may still present a significant challenge for current models.

Automatic Evaluation We also provide automatic metrics of the generated outputs. We train attributes classifiers using RoBERTa (Liu et al., 2019), and use them to classify the model outputs.[9]

Table 3 presents test set model performance on perplexity, BLEU (Papineni et al., 2002), and attribute micro-F1 classifier score. The automatic metrics are consistent with human evaluation. T5 is a strong generator overall, achieving the highest BLEU score and the highest *relevance* score in §5.2. However, GPT-2 more consistently adheres to attributes, outperforming T5 in attribute F_1 with nearly 20 points gap for RoTs, and over 10 points for actions.

6 Morality & Political Bias

To demonstrate a use case of our proposed formalism, we analyze the social norms and expectations evoked in news headlines from news sources of

---

[8] We omit the evaluation of an "out-of-the-box GPT2-XL" baseline (i.e. no fine-tuning) whose outputs predictably do not resemble RoTs or actions.

[9] BERT and BART performed worse across attributes.

		Left (-) or Right (+)	Reliability
	Agreement	-0.015**	-0.008*
ROT Cat.	Morality / Ethics	-0.069***	-0.022***
	Social Norms	0.019***	-0.006*
	It is what it is	0.039***	-0.007**
	Advice	0.031***	0.033***
Moral F.	Care / Harm	-0.033***	-0.016***
	Authority / Subversion	*n.s.*	*n.s.*
	Fairness / Cheating	-0.050***	*n.s.*
	Loyalty / Betrayal	0.026***	-0.007**
	Sanctity / Degradation	0.014**	-0.017***

Table 4: Correlations between generated RoT attributes for headlines and the news source's political leaning (left: neg., right: pos.) and reliability (controlled for political leaning). Results shown are significant after Holm-correction for multiple comparisons ($p < 0.001$: ***, $p < 0.01$: **, $p < 0.05$: *, $p > 0.05$: *n.s.*). **Takeaway:** We see evidence that a model trained on the SOCIAL-CHEM-101 Dataset can naturally uncover moral and topical leanings in news sources, mirroring results found in previous news studies.

various political leanings and trustworthiness, using the NEURAL NORM TRANSFORMER (GPT-2 XL). Specifically, we generate ROTs and attributes for 50,000 news headlines randomly selected from Nørregaard et al. (2019), a large corpus of political headlines from 2018 paired with news source ratings of political leaning (5-point scale from left- to right-leaning) and factual reliability (5-point scale from least reliable to most reliable).[10]

Table 4 shows the correlations between RoT attributes and the political leaning and reliability of sources. Our results strongly corroborate findings by Graham et al. (2009), showing that liberal headlines evoke more "fairness" and "care," while right-leaning headlines evoke more "sanctity" and "loyalty." Furthermore, in line with findings by Volkova et al. (2017), more reliable news source tend to evoke more advice and less morality.

7 Related Work

Our formalism heavily draws from works in descriptive ethics and social psychology, but is also inspired by studies in social implicatures and cooperative principles in pragmatics (Kallia, 2004; Grice, 1975) and the theories of situationally-rooted evocation of frames (Fillmore and Baker, 2001).

Our work adds to the growing literature concerned with distilling reactions to situations (Vu et al., 2014; Ding and Riloff, 2016) as well as social and moral dynamics in language (Van Hee et al., 2015). Commonly used for coarse-grained analyses of morality in text (Fulgoni et al., 2016; Volkova et al., 2017; Weber et al., 2018), Graham et al. (2009) introduce the Moral Foundations lexicon, a dictionary of morality-evoking words (later extended by Rezapour et al., 2019).

A recent line of work focused on representing social implications of everyday situations in free-form text in a knowledge graph (Rashkin et al., 2018; Sap et al., 2019). Relatedly, Sap et al. (2020) introduce Social Bias Frames, a hybrid free-text and categorical formalism to reason about biased implications in language. In contrast, our work formalizes a new type of reasoning around expectations of social norms evoked by situations.

Finally, concurrent works have developed rich and exciting resources studying similar phenomena. Tay et al. (2020) study *Would you rather?* questions, and Acharya et al. (2020) investigate ritual understanding across cultures. Hendrycks et al. (2020) study ethical questions, attempting to assign a real-valued utility to scenarios across a range of ethical cateogires. And Lourie et al. (2020) define the challenge of predicting the *r/AITA* task using the full posts. In contrast to these studies, our work addresses norms by distilling cultural knowledge to a new conceptual level of Rules-of-Thumb and corresponding structural annotations.

8 Conclusion

We present SOCIAL-CHEM-101, an attempt at providing a formalism and resource around the study of grounded social, moral, and ethical norms. Our experiments demonstrate preliminary success in generative modeling of structured RoTs, and corroborate findings of moral leaning in an extrinsic task. Comprehensive modeling of social norms presents a promising challenge for NLP work in the future.

A Additional Dataset Details

A.1 Situations

Domains We provide here a more thorough description how we collected situations from the four domains we consider. Figure 7 gives more example situations from each domain.

1. `r/amitheasshole` (30k) — The *Am I the Asshole? (AITA)* subreddit. This posts of this subreddit pose moral quandries, such as *"AITA for wanting to uninvite an (ex?)-friend from my wedding for shit-talking our marriage?"* We use the data from Lourie et al. (2020). They scrape the titles of posts, omitting the preamble (e.g., *"AITA for"*), normalizing to present tense, and filtering out administrative posts. We do not use any annotations provided by that community (where other posters vote who had the moral high ground).
2. `r/confessions` (32k) — The *Confessions* subreddit. This posts of this subreddit discuss personal stories,

[r/amitheasshole]
- telling my friend and her family to move out
- choosing to spend time with my friends or boyfriend rather than my family
- not wanting to hangout with sick girlfriend
- not wanting to do household chores
- banning my ex from my Spotify account

[r/confessions]
- My SO thinks I hate pickles, I like pickles but he LOVES pickles so I always pretend to hate them so he can have them.
- Best friend just got engaged.
- My girlfriend cheated and im cheating back on her
- I hate myself because I couldn't save my mother
- I'm scared of being a dad

[rocstories]
- Clark Ryder was proud of his job as a photojournalist.
- They had so many questions that I couldn't answer.
- Her husband surprised her on her birthday with plane tickets!
- She decided to wear slippers to protect her feet from Jason's toys.
- When he got to the assembled class he became very nervous.

[dearabby]
- Family of Six Tries Not to Be a Burden on Weekend Hosts
- Breakup Letter to Soldier Could Jeopardize Comrades in Arms
- Gentle Nudge Has Not Worked to Dislodge Mom From House
- Planning Helps Students Get Good Letter of Recommendation
- Man With Breast Cancer Experiences Extra Stress

Figure 7: Five randomly sampled situations from each of the four domains we consider.

often with interpersonal conflicts, such as *"I feel threatened by women prettier than me."* As with `r/AITA`, we scrape only the titles of these posts. This subreddit contains a high volume of hateful or disturbing content; we attempt to filter the worst of this using keywords, and also allow annotators to mark dark or disturbing items.

3. **`rocstories`** (30k) — The ROCStories corpus from (Mostafazadeh et al., 2016). ROCStories involve stories about everyday situations, and are generally less controversial than the other sources, e.g., *"They weren't sure either so he started asking friends."*. We select a subset of the sentences from ROCStories which are likely to involve two character references based on POS tagging (Toutanova et al., 2003), personal pronouns, and WordNet (Miller, 1995). We then randomly sample to pick 30k sentences.

4. **`dearabby`** (12k) — Titles of the Dear Abby advice column. These titles are usually information dense summaries of interpersonal situations written in the style of news headlines, e.g., *"Pushy Party Guests Make Themselves Too Much at Home."* We scrape all of the titles found in the archives, and use heuristics to attempt to filter out all posts that do not match this style, such as announcements and holiday greetings.

We attempt to balance the number of situations collected for each domain. However, we are limited by the complete set of examples from `dearabby` (12k).

Additional Labels We allow annotators to mark each situation with any of the following labels that apply.

- **Unclear** The situation was too simple, vague, or confusing to understand what happened.
- **NSFW** The situation contains suggestive or adult content.
- **Dark / disturbing / controversial.** The situation contained content that may make folks uncomfortable, like suicide, torture, or abuse.

Annotators may pass on writing RoTs for a situation marked with any of those boxes, or they may still choose to do so. We keep all of the labels collected. They are included in the dataset as additional fields. For example, they could be used to omit certain training data to keep a model biased away from potentially controversial subjects.

A.2 Character Identification

Our goal during character identification is to find the most descriptive phrase referring to each unique non-narrator person in the passage exactly once.

The reason for this goal is that always having a single, best reference to each person in the situation enables more consistent grounding.

While this goal is relatively straightforward, we find many edge cases arise. In cases where it is unclear if a person should be marked, our central criteria is **whether someone might write RoTs involving that person**. If so, that person should be included so they are a candidate for grounding. We found handling all of these edge cases complex enough to require human annotation instead of heuristics. We provide here the character identification guidelines that we give to the crowd worker annotators, along with an example illustrating each one.

Character Identification Guidelines

- **Don't include the (first person) narrator.** For example, *"I ate pizza"* would have no people highlighted.
- **Only include people.** For example, *"My horse George provides good conversation"* would have no people highlighted.
- **Only highlight each person once.** For example, *"I gave my brother a hug, I like him, he's so nice"*, we would only include my brother, not *"him"* or *"he."*
- **Highlight the most descriptive mention of a person.** For example, *"I can't stand him, my brother is so mean."*, we would pick my brother even though it comes after *"him."*
- **Include the full phrase referring to the person.** Include words like *"a"*, *"the"*, *"my"*, and longer phrases. For example, *"The strange guy talked to my brother and my oldest uncle,"* we would pick The strange guy, my brother, and my oldest uncle, instead of just *"guy"*, *"brother"*, and *"uncle."*

- **Don't include phrases where a generic person-looking word is used without referring to a particular person.** This often happens when describing a place or thing. For example, *"I walked into the men's room,"* we would not pick anything, because *"mens' room"* is a generic phrase. Similarly, we would not pick anything for, *"I am a child,"* because *"child"* is just used as a description. But for, *"I walked into my brother's room"*, we would pick my brother.

- **Include people used to refer to someone.** For example, *"**My brother's girlfriend** is so cool,"* we would pick both my brother and **my brother's girlfriend**.

- **Include pronouns (she, her, hers, etc.) *if* they're the most specific word available.** For example, in a sentence like *"I love him,"* we would pick him. However, for a sentence like, *"I love my brother, I can always talk to him."* we would instead pick my brother because it's more specific.

- **Include pronouns like *"they"* and *"them"*, also *if* they're the most specific word available.** For example, if we had the sentence *"They went to the party."* we would pick they. However, if we had the sentence *"My friends went to the party and they had a good time."* we would instead pick My friends since it is more specific.

- **Include plural first person pronouns (us, we, etc.) once.** For example, in a sentence like *"We went to the park."* we would pick we. Or for a sentence like *"They spent hours talking to us and we had a good time."* we would pick they and us.

- **Include other groups of people like *"her siblings," "their class,"* and *"his team."*** For example, in a sentence like *"I talked to all of **his uncles** for a while."* we would pick both his and **his uncles**.

- **Include proper names of people that aren't the narrator.** For example, in a sentence like *"Mary chased John at the park."* we assume they are people (unless otherwise specified), and we would pick both Mary and John.

- **Include people with titles like *"the policeman"* and *"the mailman."*** For example, in the sentence *"I chased the store clerk."* we would select the store clerk.

- **Include words like *"someone"* and *"everyone."*** For example, in the sentence *"I am going to dinner with someone."* we would select someone.

A.3 Rules-of-Thumb (RoTs)

This section provides more information on how RoTs are written. Figure 8 shows a sample of RoTs organized both by situation domain and topic.

As mentioned briefly in Section 3.2 of the paper body, we present workers with a series of guidelines for how to write RoTs. All RoT writing guidelines are in service of the goal that RoTs capture social, ethical, moral, and cultural norms. Unlike the guidelines for character identification, which are largely syntactic, the guidelines for writing RoTs are semantic. This makes them more challenging both to define and check.

To motivate these guidelines, and to help readers intuitively characterize what RoTs are, we present the RoT writing guidelines here at greater length, annotated with examples and explanations. For each guideline (**in bold**), we provide an example situation (*in italics*) along with candidate RoTs that **violate** or **follow** the guideline.

RoT Writing Guidelines

- **Explain the basics of good and bad behavior.** RoTs should describe cultural expectations, as if to a file-year-old child who doesn't yet know how the world works.
  - Example situation: *Not wanting to take tests to apply for college*
  - **Violates:** "Studies have shown people perform best on tests after sleeping at least seven hours"
  - **Follows:** "It's normal to be stressed out by exams"
  - **Why:** This broad guideline attempts to distinguish RoTs from encyclopedic knowledge. Instead, RoTs should contain everyday, commonsense knowledge about social norms and expectations.

- **Judgment and action.** An RoT must comtain a judgment and an action.
  - Example situation: *Telling my husband he shouldn't buy his dream boat*
  - **Violates:** "Boats are expensive"
  - **Follows:** "It's mean to squash someone's dreams"
  - **Follows:** "People should be open to discussing big purchases with their spouses"
  - **Why:** Requiring an *action* helps ensure RoTs are about things peoeple do. Requiring a *judgment* pushes statements to contain some information about norms and expectations.

- **Self-contained.** An RoT must be fully understandable on its own, without the situation it came from.
  - Example situation: *Being angry at my sister for not attending our fathers funeral because of his criminal history.*
  - **Violates:** "It makes them feel bad"
  - **Violates:** "The father caused emotional distress to his daughter and the narrator should not judge her actions too harshly."
  - **Follows:** "If someone commits serious crimes, it's OK for family to cut off contact with them."
  - **Why:** Without this requirement, RoTs would not naturally generalize to new situations, and would trend too specific. The would also could contain much less information, as much of the semantic content could be left in the situation and only referred to by the RoT.

- **Inspired by situation.** An RoT should be inspired by the situation it came from.
  - Example situation: *Wanting to uninvite a friend from my wedding.*
  - **Violates:** "It's rude to point at people you don't know"
  - **Follows:** "It's devastating to be excluded from a wedding you were invited to"

`[r/amitheasshole]`
Wanting to uninvite an (ex?)-friend from my wedding for shit-talking our marriage
- When you are paying for a celebration, you are allowed to invite whoever you want.
- It is reasonable to rescind an invitation to a wedding if someone is no longer your friend.
- Telling someone they can't come to your wedding after they were already invited is tacky.

`[r/confessions]`
I feel threatened by women prettier than me
- It's bad to feel threatened.
- It's normal to feel intimidated by others.
- It's ok for someone to be prettier than you.

It's normal to compare yourself with others.

`[dearabby]`
Pushy Party Guests Make Themselves Too Much at Home
- You should respect other people's property.
- You should admit to breaking something rather than convering it up.
- It's OK to turn down an invitation if you're not interested in going.
- It's rude to exclude others from a get-together.

`[rocstories]`
They weren't sure either so he started asking friends.
- It's okay to ask your friends about something you need to know.
- It's understandable if you're uncertain of what to do.
- You should ask for advice when you aren't sure what the right course of action is.
- It's good to give your friend advice when they ask for it.
- It's okay to be scared when you're not sure what to do.

- Trying to warn a coworker about the dangers of smoking is caring.
- It's okay to ask someone not to smoke in your car.
- It's wrong to pretend that you're smoking because it's unhealthy to smoke and you shouldn't idolize people that do.
- You shouldn't accept cigarettes from friends when you don't smoke.
- You should not smoke inside.
- It is bad to expose others to second hand smoke
- It's bad to smoke.
- It's bad for your health to smoke cigarettes.
- You shouldn't smoke weed.

`9/451 RoTs randomly sampled, searching for “smok*” across RoTs from all four domains.`

Figure 8: **Top:** An example situation (bold) and corresponding RoTs (bullets) from each of the four domains we consider. **Bottom:** Random sample of RoTs about smoking, found by searching for *smok** across the dataset.

  - **Why:** Maintaining a link between RoT and situation allows for grounding RoTs during the structured annotation. Furthermore, since a different worker will likely provides the structural annotation for an RoT, relevance to the source situation helps ensure the worker understands the RoT's context and implications.

- **Balance Specificity and Vagueness.** An RoT should be inspired by, and relevant to, the provided situation. However, a rule-of-thumb should also give a general rule for how people behave in society, so should apply to more than just the given situation.
  - Example situation: *Not tipping my cashier last Tuesday*
  - **Violates:** “Not tipping a cashier last Tuesday is rude”
  - **Violates:** “It's rude to be cheap”
  - **Follows:** “It's usually OK not to tip cashiers in retail or grocery stores”
  - **Why:** This requirement can be the hardest to assess because of its subjectivity. RoTs that are too specific are usually slight modifications of the situation that include a judgment, and don't describe underlying expectations. RoTs that are too vague often do describe norms, but the link to the situation can be so distant as to be misleading. Good RoTs may be somewhat specific, but explain both the underlying norms at play, and apply to other situations.

- **Distinct ideas.** When multiple RoTs are provided for a situation, each should contain a distinct idea. This includes inversions of the same idea.
  - Example situation: *Never taking out the trash*
  - **Violates:** “It's irresponsible to avoid the chores you are assigned” *with* “It's bad to not do chores you're supposed to do”
  - **Violates:** “It's irresponsible to avoid the chores you are assigned” *with* “It's responsible to do the chores you are assigned”
  - **Follows:** “It's irresponsible to avoid the chores you are assigned” *with* “You're generally expected to have a clean home”
  - **Why:** This requirement is to prevent merely collecting paraphrases of the same RoT. Furthermore, we assume that inversions are usually trivial semantic mutations, so they are also not worth collecting at scale.

A.4 RoT Breakdowns

In this section, we provide more information about the structural RoT annotations, which we call “RoT Breakdowns.” In particular, we illustrate the potential values for each attribute with an example.

A.4.1 RoT Categorization

RoT categories are originally designed to distinguish more desired annotation topics (morality/ethics, social norms) from less desired ones (advice and “it is what it is” statements). RoT categories are not mutually-exclusive, and the lines are not always clear. While we use all data regardless of RoT category in this paper's experiments, future work using this dataset may consider filtering based on RoT category. Annotators are allowed to select from none through all, but are encouraged to select the 1 – 2 best.

Information	
Type	Social
Annotated	RoT
Prompt	*What category best fits this RoT?*

Values

Label	Description	Example
Morality/ Ethics	Rules or guiding principles of right or wrong conduct	*It's wrong to turn your back on your friends who need your help.*
Social Norms	Standards of appropriate behavior in a society; emphasizes social conventions	*It's good to shake hands with your opponent even if you lost.*
Advice	Prudent behaviors that are aimed at improving one's life	*It's good to take medicine your doctor prescribes.*
It is what it is	Describes how things are; avoids ethics, morality or social norms	*It is nice to be tall.*

A.4.2 Moral Foundations

To simplify the annotation, we label *axes* of moral foundations. For example, *Care/Harm* are annotated together, rather than as *Care* and *Harm* separately. Other social attributes, such as *social judgment*, attempt to explicitly capture the goodness or badness of the act. Additionally, we omit the sixth moral foundation, *Liberty/Oppression*, which was later added to the formalism after the first five. Some examples are drawn from literature on Moral Foundations (Haidt, 2012). Note that these labels are not mutually exclusive, and annotators may choose from none through all.

Information

Type	Social
Annotated	RoT
Prompt	*Which moral foundations best fit this RoT?*

Values

Label	Description	Example
Care/Harm	Preventing or inflicting pain or suffering	*It's mean to tell someone they aren't attractive as someone else.*
Fairness/ Cheating	Notions of equity, justice, and rights	*It's wrong to copy someone else's answers in an exam.*
Loyalty/ Betrayal	Obligations or concerns for group, family, and nation.	*It's rude for a cheerleader to boo their own team.*
Authority/ Subversion	Submission and deference to traditions or legitimate authority.	*It's rude to walk away from your boss while they are talking to you.*
Sanctity/ Degradation	Abhorrence for disgusting things or actions; purity	*It's disgusting to pee into a public pool full of people.*

A.4.3 Action and Judgment

Each RoT should contain and action and a judgment. An essential step in the RoT brekadown is to identify the action so that it may be annotated with action attributes. We have annotators write both the action and the judgment, conjugating to the action to gerund tense, and rewriting when needed.

If the annotator is unable to clearly separate and action and a judgment from the RoT, they can simply mark the RoT as unclear and move on.

We provide here a few examples of RoTs along with corresponding actions and judgments. Some are straightforward, while others require more substantial rewriting.

- **RoT:** It's good to care for the elderly.
    - **Action:** caring for the elderly
    - **Judgment:** it's good

- **RoT:** It's okay to be angry if your friend talks to someone you used to date
    - **Action:** being angry when your friend talks to someone you used to date
    - **Judgment:** it's okay

- **RoT:** The holidays are expected to be especially difficult for those that are grieving.
    - **Action:** finding the holidays difficult while grieving
    - **Judgment:** expected

A.4.4 Agency

It can be challenging to distinguish *agency* from *experience* in cases where the action involves thinking thoughts or feeling emotions. We provide the following additional examples to workers for these cases, and allow their discretion during the annotation:

- **Experience:** Feeling upset when someone calls you a name
- **Agency:** Being mad for two days when someone calls you a name
- **Agency:** Taking revenge on someone for calling you a name

Information

Type	Social
Annotated	Action
Prompt	*Is the action $action something you do or control, or is it something you experience?*

Values

Label	Description	Example
Agency	You can do this	*Doing the dishes*
Experience	This happens to you; you have no control	*Being stuck in an earthquake*

A.4.5 Social Judgment

For social judgment, we ask workers to transcribe the intent of RoT's original judgment, rather than pick their own. Then, workers can mark their disagreement through their annotation of the *anticipated agreement* attribute. This allows us to faithfully capture controversial opinions, while also marking them as controversial.

Information

Type	Social
Annotated	Action
Prompt	*Which best matches the RoT's original judgment ($judgmentSpan) of $action ?*

Values

Label	Description	Example
🟥 Very bad	Spiteful, malicious, or insulting	*Slashing tires; Destroying someone's phone*
🟧 Bad	Frowned upon, rude, unkind, bad	*Littering; saying something mean to a friend*
🟨 Expected / OK	Normal; generally expected by society	*Wearing clothes; showing up to work on time*
🟦 Good	Kind of considerate	*Driving a friend to the airport*
🟦 Very good	Generous, self-sacrificing, perhaps even heroic	*Buying groceries for a financially struggling neighbor*

A.4.6 Anticipated Agreement

Anticipated agreement is theoretically continuously valued, compared to other attributes that are more naturally ordinal. Inspired by Wang et al. (2018), we bin this attribute into intuitive ranges, primarily to reduce cognitive load during annotation.

Information

Type	Social
Annotated	RoT, Action
Prompts	**RoT:** *What portion of people probably agree that $RoT ?* **Action:** *What portion of people probably agree that $action is $socialJudgment ?*

Values

Label	Description	Example
🟥 $< 1\%$	Almost no one	*Murdering people is great*
🟧 $\sim$ 5–25%	People occasionally think this.	*Ghosts exist*
🟨 $\sim$ 50%	Controversial (people naturally disagree)	*It's okay to have an abortion*
🟦 $\sim$ 75–90%	Common belief	*It's okay to try again when you fail*
🟦 $> 90\%$	Universally true	*It's bad to deliberately hurt your pets*

A.4.7 Legality

Annotations of legality are usually straightforward. Whether an action is illegal but tolerated can vary depending on location and knowledge of the law.

Information

Type	Social
Annotated	Action
Prompt	*Where you live, how legal is the action $action ?*

Values

Label	Description	Example
🟥 Illegal	Legal consequences if caught	*Theft; murder*
🟧 Depends/ Tolerated	Generally "illegal", but often unenforced depending on circumstances	*Using a cellphone while driving*
🟦 Legal	Not illegal	*Coughing without covering one's mouth*

A.4.8 Cultural Pressure

We provide instructions that cultural pressure could come from one's family, friends, community, culture, or society at large. We ask annotators to evaluate cultural pressure according to their own feelings.

Information

Type	Social
Annotated	Action
Prompt	*How much cultural pressure do you (or those you know) feel about $action ?*

Values

	Label	Description	Example
🟥	Strong pressure against	Culture frowns upon this action	*Intentionally harming an animal*
🟧	Pressure against	Culture generally discourages this action	*Spending money on jewelry if you can't afford it*
🟨	Discretionary	Culture has little or nothing to say about this action	*Choosing to read before bed*
🟦	Pressure for	Culture generally encourages this action	*Being honest with people*
🟦	Strong pressure for	Culture strongly promotes this action	*Wearing clothes in public*

A.4.9 Taking Action

RoTs are written for a range of both hypothetical and actual actions related to the provided situation. Furthermore, sometimes the action is one that is explicitly not happening. This attribute labels how likely it is that the action is being taken by the relevant character. *Note: a subset of the* `r/AITA` *annotations were performed before the "probably not" label was introduced; for those, "hypothetical" is marked instead.*

Information

Type	⊜ Grounded
Annotated	Action
Prompt	*Is $candidateCharacter explicitly doing the action $action? Or is it the action* ***might*** *happen?*

The upcoming examples use *narrator* and the following situation for context: *Not tipping the bartender at the club.*

Values

	Label	Description	Example
🟥	Explicitly not	It's explicitly written that they don't do this	*Tipping the bartender*
🟧	Probably not	Most likely not; they probably don't do this	*Enjoying the drinks*
🟨	Hypothetical	We can't say / no evidence	*Going clubbing every day*
🟦	Probable	Most likely; hints are written	*Paying for drinks*
🟦	Explicit	It's written in the situation	*Going to the club*

A.5 Crowdsourcing

Workers undergo an extensive vetting process before working on RoTs. This includes a paid qualification (qual) with a quiz on each of the guidelines and a manual review of sample RoTs. Workers then pass the qual move to a staging pool where they can work on a small number of situations, and all of their RoTs are manually reviewed for adherence to the guidelines. After graduating from the staging pool, workers enter the main group of RoT writers and annotators. For every batch of data, we perform spot checks on the RoTs written and annotated by the main group, as well as send feedback to all of the workers answering any questions we receive. We continuously update the instructions with clarifications, new examples, and answers to questions.

A.6 Annotator Demographics

With an extensive qualification process, 137 workers participated in our tasks. Of those, 55% were women and 45% men. 89% of workers identified as white, 7% as Black. 39% were in the 30-39 age range, 27% in the 21-29 and 19% in the 40-49 age ranges. A majority (53%) of workers were single, and 35% were married. 47% of workers considered themselves as middle class, and 41% working class. In terms of education level, 44% had a bachelor's degree, 36% some college experience or an associates degree. Two-thirds (63%) of workers had no children, and most lived in a single (25%) or two-person (31%) household. Half (48%) our workers lived in a suburban setting, the remaining half was evenly split between rural and urban. Almost all (94%) of our workers had spent 10 or more years in the U.S.

A.7 Demographics and Annotations

We analyze the demographic variation in RoT and action annotations, using a set of 400 RoTs that were annotated by 50 workers each. In addition to the demographic variables described in §A.6, we also consider the political leaning of the state in which the worker resides (self-reported), by assigning each state a value based on the state-level voting patterns in the last four national elections (yielding five-point scale from 100% republican to 100% democratic).

For our analyses, we run a generalized linear model regressing the RoT categories on all z-scored demographic variables, and report the β

	RoT Agreement	Action Agreement	Cultural Pressure	Social Judgment
Gender (M: 0, F: 1)	0.070***	0.104***	*n.s.*	*n.s.*
Urbanness	0.065***	0.085***	*n.s.*	*n.s.*
Education	0.022**	0.037***	*n.s.*	0.025***
Politics (rep: 0, dem: 1)	0.052***	0.075***	0.023**	*n.s.*
Household size	0.059***	0.080***	*n.s.*	*n.s.*
Social class	*n.s.*	*n.s.*	*n.s.*	*n.s.*
Income	-0.027*	*n.s.*	*n.s.*	*n.s.*
Age	*n.s.*	*n.s.*	*n.s.*	*n.s.*

Table 5: Correlations between worker demographics and categorical RoT annotations, Bonferroni corrected for multiple comparisons ($p < 0.0001$: ***, $p < 0.001$: **, $p < 0.01$: *).

coefficients from that model. In our action moral judgment analyses, we control for actions; for action agreement, we control for the action and the moral judgement; for the RoT agreement and action pressure, we control for individual RoTs. Our results for categorical RoT annotations are shown in Table 5.

Agreement (RoT and Action) The projection of how many people agree with the judgement is correlated with various demographic characteristics. Specifically, judgments of actions, being a woman and living in an urban setting was most strongly correlated with ascribing high agreement to the judgment. Other associations include higher education, household size, and inferred political leaning based on state of residency.

For RoT agreement, we find similar but weaker associations. Additionally, we find a small correlation between income and social class and ascribing higher agreement.

Cultural Pressure The only variable correlated with feeling culturally pressured is the political leaning of the state where workers are located, though the effect is small.

Social Judgment Similar to action agreement. Effects are somewhat weaker, but workers being women, highly educated, or younger are associated with selecting higher (better) judgment to actions.

B Experimental details

Generative Models We use the Transformers package (Wolf et al., 2019) to implement our models. We train all the models for a single epoch with a batch size of 64, with the random seed 42. Each input and output sequence is prefixed with a special token indicating its type (e.g. `[attrs]`, `[rot]`, `[action]`). We also define a special token for each attribute value (e.g. `<morality-ethics>`, `<bad>`, `<all>`, `<against>`). We initialize the special token embeddings with the embedding of their corresponding words, taking the average for multiword expressions. For example, $\vec{v}_{\text{<bad>}} = \vec{v}_{\text{bad}}$, $\vec{v}_{\text{<morality-ethics>}} = (\vec{v}_{\text{morality}} + \vec{v}_{\text{ethics}})/2$.

Event Extraction by Answering (Almost) Natural Questions

Xinya Du and **Claire Cardie**
Department of Computer Science
Cornell University
Ithaca, NY, USA
`{xdu, cardie}@cs.cornell.edu`

Abstract

The problem of event extraction requires detecting the event trigger and extracting its corresponding arguments. Existing work in event argument extraction typically relies heavily on entity recognition as a preprocessing/concurrent step, causing the well-known problem of error propagation. To avoid this issue, we introduce a new paradigm for event extraction by formulating it as a question answering (QA) task that extracts the event arguments in an end-to-end manner. Empirical results demonstrate that our framework outperforms prior methods substantially; in addition, it is capable of extracting event arguments for roles not seen at training time (i.e., in a zero-shot learning setting).[1]

1 Introduction

Event extraction is a long-studied and challenging task in Information Extraction (IE) (Sundheim, 1992; Grishman and Sundheim, 1996; Riloff, 1996). Its goal is to extract structured information — "what is happening" and the persons/objects that are involved — from unstructured text. The task is illustrated via an example in Figure 1, which depicts an ownership transfer event (the *event type*), triggered by the word "sale" (the event *trigger*) and accompanied by its extracted *arguments* — text spans denoting entities that fill a set of (semantic) *roles* associated with the event type (e.g., BUYER, SELLER and ARTIFACT for ownership transfer events).

Recent successful approaches to event extraction have benefited from dense features extracted by neural models (Chen et al., 2015; Nguyen et al., 2016; Liu et al., 2018) as well as contextualized lexical representations from pretrained language models (Zhang et al., 2019b; Wadden et al., 2019).

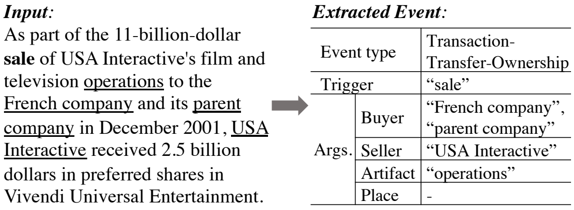

Figure 1: Event extraction example from the ACE 2005 corpus (Doddington et al., 2004).

The approaches, however, exhibit two key weaknesses. First, they rely heavily on entity information for argument extraction. In particular, event argument extraction generally consists of two steps – first identifying entities and their general semantic class with trained models (Wadden et al., 2019) or a parser (Sha et al., 2018), then assigning argument roles (or no role) to each entity. Although joint models (Yang and Mitchell, 2016; Nguyen and Nguyen, 2019; Zhang et al., 2019a; Lin et al., 2020) have been proposed to mitigate this issue, error propagation (Li et al., 2013) still occurs during event argument extraction.

A second weakness of neural approaches to event extraction is their inability to exploit the similarities of related argument roles across event types. For example, the ACE 2005 (Doddington et al., 2004) CONFLICT.ATTACK events and JUSTICE.EXECUTE events have TARGET and PERSON argument roles, respectively. Both roles, however, refer to a *human being (who) is affected* by an action. Ignoring the similarity can hurt performance, especially for argument roles with few/no examples at training time (e.g., similar to the zero-shot setting in Levy et al. (2017)).

In this paper, we propose a new paradigm for the event extraction task – formulating it as a question answering (QA)/machine reading comprehension (MRC) task (**Contribution 1**). The general framework is illustrated in Figure 2. Using BERT (Devlin

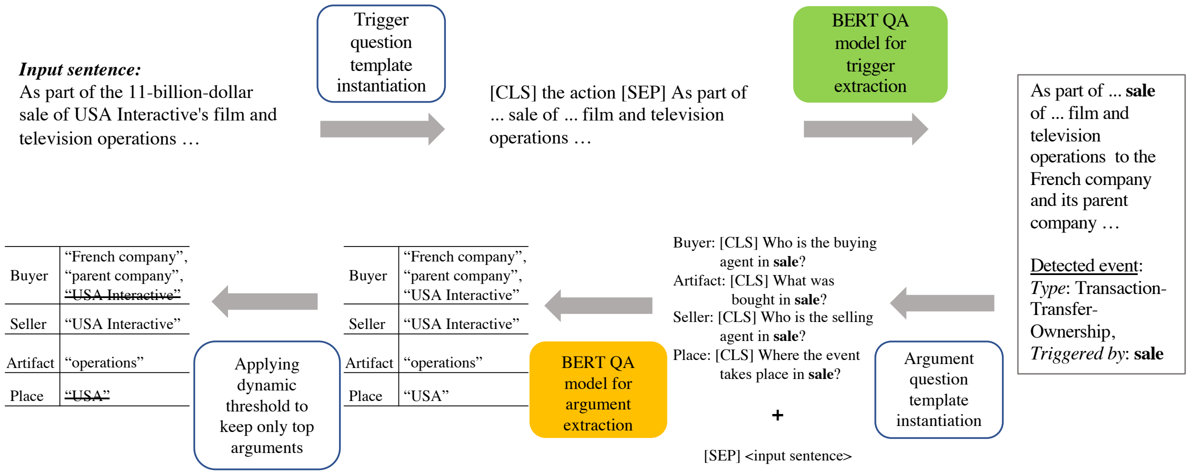

Figure 2: Our framework for event extraction.

et al., 2019) as the base model for obtaining contextualized representations from the input sequences, we develop two BERT-based QA models – one for event trigger detection and the other for argument extraction. For each, we design one or more Question Templates that map the input sentence into the standard BERT input format. Thus, trigger detection becomes a request to identify "the action" or the "verb" in the input sentence and determine its event type; and argument extraction becomes a sequence of requests to identify the event's arguments, each of which is a text span in the input sentence. Details will be explained in Section 2. To the best of our knowledge, this is the first attempt to cast event extraction as a QA task.

Treating event extraction as QA overcomes the weaknesses in existing methods identified above (**Contribution 2**): (1) Our approach requires *no entity annotation* (gold or predicted entity information) and no entity recognition pre-step; event argument extraction is performed as an end-to-end task; (2) The question answering paradigm naturally permits the transfer of argument extraction knowledge across semantically related argument roles. We propose rule-based question generation strategies (including incorporating descriptions in annotation guidelines) for templates creation, and conduct extensive experiments to evaluate our framework on the Automatic Content Extraction (ACE) event extraction task and show empirically that the performance on both trigger and argument extraction outperform prior methods (Section 3.2). Finally, we show that our framework extends to the zero-shot setting – it is able to extract event arguments for unseen roles (**Contribution 3**).

2 Methodology

In this section, we first provide an overview for the framework (Figure 2), then go deeper into details of its components: question generation strategies for template creation, as well as training and inference of QA models.

2.1 Framework Overview

Our QA framework for event extraction relies on two sets of Question Templates that map an input sentence to a suitable input *sequence* for two instances of a standard pre-trained bidirectional transformer (BERT (Devlin et al., 2019)). The first of these, BERT_QA_Trigger (green box in Figure 2), extracts from the input sentence the event trigger which is a single token, and its type (one of a fixed set of pre-defined event types). The second QA model, BERT_QA_Arg (orange box in Figure 2), is applied to the input sequence, the extracted event trigger and its event type to iteratively identify candidate event arguments (spans of text) in the input sentence. Finally, a dynamic threshold is applied to the extracted candidate arguments, and only the arguments with probability above the threshold are retained.

The input sequences for the two QA models share a standard BERT-style format:

[CLS] <question> [SEP] <sentence> [SEP]

where [CLS] is BERT's special classification token, [SEP] is the special token to denote separation, and <sentence> is the tokenized input sentence. We provide details on how to obtain the **<question>** in Section 2.2. Details on the QA models and the inference process will be explained in Section 2.3.

Argument	Template 1 (Role name)	Template 2 (Type + Role question)	Template 3 (Annotation guideline question)
Artifact	artifact	What is the artifact?	What is being transported?
Agent	agent	Who is the agent?	Who is responsible for the transport event?
Vehicle	vehicle	What is the vehicle?	What is the vehicle used?
Origin	origin	What is the origination?	Where the transporting originated?
Destination	destination	What is the destination?	Where the transporting is directed?

Table 1: Arguments (of event type MOVEMENT.TRANSPORT) and corresponding questions from three templates. "in <trigger>" is not added to the questions in this example.

2.2 Question Generation Strategies

For our QA-based framework for event extraction to be easily moved from one domain to the other, we concentrated on developing question generation strategies that not only worked well for the task, but can be quickly and easily implemented. For event trigger detection, we experiment with a set of four fixed templates – "what is the trigger", "trigger", "action", "verb". Basically, we use the fixed literal phrase as the question. For example, if we choose the "action" template, the input sequence for the example sentence in Figures 1 and 2 is instantiated as:

> [CLS] action [SEP] As part of the 11-billion-dollar sale ... [SEP]

As for event argument extraction, we design three templates with argument role name, basic argument based question and annotation guideline based question, respectively:

- **Template 1 (Role Name)** For this template, <question> is simply instantiated with the argument role name (e.g., artifact, agent, place).

- **Template 2 (Type + Role)** Instead of directly using the argument role name (<role name>) as the question, we first determine the argument role's general semantic type — one of person, place, other; and construct the associated "WH" word question – *who* for person, *where* for place and *what* for all other cases, of the following form:

  <WH_word> is the <role name> ?

  Examples are shown in Table 1 for the arguments of event type MOVEMENT.TRANSPORT. By adding the WH word, more semantic information is included as compared to Template 1.

- **Template 3 (Incorporating Annotation Guidelines)** To incorporate even more semantic information and make the question more natural sounding, we utilize the descriptions of each argument role provided in the ACE annotation guidelines for events (Linguistic Data Consortium, 2005) for generating the questions.

- **+ "in <trigger>"** Finally, for each template type, it is possible to encode the trigger information by adding "in <trigger>" at the end of the question (where <trigger> is instantiated with the real trigger token obtained from the trigger detection phase). For example, the Template 2 question incorporating trigger information would be:

  <WH_word> is the <argument> in <trigger>?

To help better understand all the strategies above, Table 1 presents an example for argument roles of event type MOVEMENT.TRANSPORT. We see that the annotation guideline based questions are more natural and encode more semantics about a given argument role, than the simple Type + Role question "what is the artifact?".

2.3 Question Answering Models

We use BERT (Devlin et al., 2019) as the base model for getting contextualized representations for the input sequences for both BERT_QA_Trigger and BERT_QA_Arg. After the instantiation with question templates the sequences are of format [CLS] <question> [SEP] <sentence> [SEP].

Then we get the contextualized representations of each token for trigger detection and argument extraction with $\texttt{BERT}_{Tr}$ and $\texttt{BERT}_{Arg}$, respectively. For the input sequence $(e_1, e_2, ..., e_N)$ prepared for trigger detection, we have:

$$\mathbf{E} = [\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_N]$$
$$\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_N = \texttt{BERT}_{Tr}(e_1, e_2, ..., e_N)$$

For the input sequence $(a_1, a_2, ..., a_M)$ prepared for argument span extraction, we have:

$$\mathbf{A} = [\mathbf{a}_1, \mathbf{a}_2, ..., \mathbf{a}_M]$$
$$\mathbf{a}_1, \mathbf{a}_2, ..., \mathbf{a}_M = \texttt{BERT}_{Arg}(a_1, a_2, ..., a_M)$$

The output layer of each QA model, however, differs: BERT_QA_Trigger predicts the event type for each token in sentence (or None if it is not an event trigger), while BERT_QA_Arg predicts the start and end offsets for the argument span with a different decoding strategy.

More specifically, for **trigger prediction**, we introduce a new parameter matrix $\mathbf{W}_{tr} \in \mathbb{R}^{H \times T}$, where H is the hidden size of the transformer and T is the number of event types plus one (for non-trigger tokens). softmax normalization is applied across the T types to produce P_{tr}, the probability distribution across the event types:

$$P_{tr} = \texttt{softmax}(\mathbf{E}\mathbf{W}_{tr}) \in \mathbb{R}^T \times N$$

At test time, for trigger detection, to obtain the type for each token $e_1, e_2, ..., e_N$, we simply apply argmax to P_{tr}.

For **argument span prediction**, we introduce two new parameter matrices $\mathbf{W}_s \in \mathbb{R}^{H \times 1}$ and $\mathbf{W}_e \in \mathbb{R}^{H \times 1}$; softmax normalization is then applied across the input tokens $a_1, a_2, ..., a_M$ to produce the probability of each token being selected as the start/end of the argument span:

$$P_s(i) = \texttt{softmax}(\mathbf{a}_i \mathbf{W}_s)$$
$$P_e(i) = \texttt{softmax}(\mathbf{a}_i \mathbf{W}_e)$$

To train the models (BERT_QA_Trigger and BERT_QA_Arg), we minimize the negative log-likelihood loss for both models, parameters are updated during the training process. In particular, the loss for the argument extraction model is the sum of two parts: the start token loss and end end token loss. For the training examples with no argument span (no answer case), we minimize the start and end probability of the first token of the sequence ([CLS]).

$$\mathcal{L}_{arg} = \mathcal{L}_{arg\_start} + \mathcal{L}_{arg\_end}$$

Inference with Dynamic Threshold for Argument Spans At test time, predicting the argument spans is more complex – for each argument role, there can be *several* or *no* spans to be extracted. After the output layer, we have the probability of each token $a_i \in (a_1, a_2, ..., a_M)$ being the start ($P_s(i)$) and end ($P_e(i)$) of the argument span.

Algorithm 1: Harvesting Argument Spans Candidates

```
Input  : $P_s(i)$, where $i \in \{1, ..., M\}$,
         $P_e(i)$, where $i \in \{1, ..., M\}$
Output : valid candidate spans for the argument role
for $start \leftarrow 1$ to $M$ do
    for $end \leftarrow 1$ to $M$ do
        if $start$ or $end$ not in the input sentence then continue;
        if $end - start + 1 >$ MaxSpanLength then continue;
        if $P_s(start) < P_s([CLS])$ or $P_e(end) < P_e([CLS])$ then continue;
        // add the valid candidate span to the set
        $score \leftarrow P_s(start) + P_e(end)$;
        $no\_ans\_score \leftarrow P_s(1) + P_e(1) - score$;
        $candidates$.add($[start, end, no\_ans\_score]$)
    end
end
```

Algorithm 2: Automatic Filtering on Argument Candidates

```
Input  : $dev\_candidates(i), i \in \{1, ..., dev\_n\}$,
         $test\_candidates(i), i \in \{1, ..., test\_n\}$.
Output : A set of top arguments from test_candidates
// get the best dynamic threshold
sort($dev\_candidates, key = no\_ans\_score$);
$best\_thresh \longleftarrow 0$;
$best\_res \longleftarrow 0$;
for $i \leftarrow 1$ to $dev\_n$ do
    $thresh \leftarrow dev\_candidates(i).no\_ans\_score$;
    $result \leftarrow$ eval($dev\_candidates$ with
      $no\_ans\_score <= thresh$);
    if $result > best\_res$ then
      $best\_thresh \leftarrow thresh$;
      $best\_res \leftarrow result$;
end
// apply the best threshold
$final\_arguments \longleftarrow \{\}$;
for $i \leftarrow 1$ to $test\_n$ do
    if $test\_candidates(i).no\_ans\_score <=$
      $best\_thresh$ then
      $final\_arguments$.add($test\_candidates(i)$);
end
```

Firstly, we run an algorithm to harvest all valid argument spans candidates for each argument role (Algorithm 1). Basically, we:

1. Enumerate all the possible combinations of

start offset ($start$) and end offset (end) of the argument spans (line 1–2);

2. Eliminate the spans not satisfying the constraints: start and end token must be within the sentence; the length of the span should be shorter than a maximum length constraint; Argument spans should have larger probability than the probability of "no argument" (which is stored at the [CLS] token) (line 3–5);

3. Calculate the relative no answer score (no_ans_score) for the candidate span and add the candidate to list (line 6–8).

Then we run another algorithm to filter out candidate arguments that should not be included (Algorithm 2). More specifically, we obtain a probability threshold ($best\_thresh$) that helps achieve best evaluation results on the dev set (line 1–9) and keep only those arguments with no_ans_score smaller than the threshold (line 10–13). With the dynamic threshold for determining the number of arguments to be extracted for each role, we avoid adding a (hard) hyperparameter for this purpose.

Another easier way to get final argument predictions is to directly include all the candidates with $no\_ans\_score < 0$, which does not require tuning the dynamic threshold $best\_thresh$.

3 Experiments

3.1 Dataset and Evaluation Metric

We conduct experiments on the ACE 2005 corpus (Doddington et al., 2004), it contains documents crawled between year 2003 and 2005 from a variety of areas such as newswire (nw), weblogs (wl), broadcast conversations (bc) and broadcast news (bn). The part that we use for evaluation is fully annotated with 5,272 event triggers and 9,612 arguments. We use the same data split and preprocessing step as in the prior works (Zhang et al., 2019b; Wadden et al., 2019).

As for evaluation, we adopt the same criteria defined in Li et al. (2013): An event trigger is correctly identified (ID) if its offsets match those of a gold-standard trigger; and it is correctly classified if its event type (33 in total) also match the type of the gold-standard trigger. An event argument is correctly identified (ID) if its offsets and event type match those of any of the reference argument mentions in the document; and it is correctly classified if its semantic role (22 in total) is also correct. Though our framework does not involve the trigger/argument identification step and tackles the identification + classification in an end-to-end way. We still report the trigger/argument identification's results to compare to prior work. It could be seen as a more lenient eval metric, as compared to the final trigger detection and argument extraction metric (ID + Classification), which requires both the offsets and the type to be correct. All the aforementioned elements are evaluated using precision (denoted as P), recall (denoted as R) and F1 scores (denoted as F1).

3.2 Results

Evaluation on ACE Event Extraction We compare our framework's performance to a number of prior competitive models: **dbRNN** (Sha et al., 2018) is an LSTM-based framework that leverages the dependency graph information to extract event triggers and argument roles. **Joint3EE** (Nguyen and Nguyen, 2019) is a multi-task model that performs entity recognition, trigger detection and argument role assignment by shared BiGRU hidden representations. **GAIL** (Zhang et al., 2019b) is an ELMo-based model that utilizes generative adversarial network to help the model focus on harder-to-detect events. **DYGIE++** (Wadden et al., 2019) is a BERT-based framework that models text spans and captures within-sentence and cross-sentence context. **OneIE** (Lin et al., 2020) is a joint neural model for extraction with global features.[2]

In Table 2, we present the comparison of models' performance on trigger detection. We also implement a BERT fine-tuning baseline and it reaches nearly same performance as its counterpart in the DYGIE++. We observe that our BERT_QA_Trigger model with best trigger questioning strategy reaches comparable (better) performance with the baseline models.[3]

Table 3 shows the comparison between our model and baseline systems on argument extraction. Notice that the performance of argument extraction is directly affected by trigger detection. Because argument extraction correctness requires the trigger to which the argument refers to be correctly identified and classified. We observe, (1)

---

[2] Slightly different from our and Wadden et al. (2019)'s data pre-processing, OneIE skips lines before the <text> tag (e.g., headline, datetime).

[3] Note that OneIE is concurrent to our work and reports better performance. On trigger detection, it reaches 74.7 F1 as compare to our 72.39. On argument extraction (affected by trigger detection), it reaches 56.8 as compared to our 53.31.

	Trigger Identification			Trigger ID + Classification

Table 3: Argument extraction results. * indicates statistical significance ($p < 0.05$).

Our BERT_QA_Arg model with best argument question generation strategy (annotation guideline based questions) outperforms prior work significantly, although it uses no entity recognition resources; (2) Drop of F1 performance from argument identification (correct offset) to argument ID + classification (both correct offset and argument role) is only around 1%, while the gap is around 3% for prior models which rely on entity recognition and a multi-step process for argument extraction. This once again demonstrates the benefit of our new formulation for the task as question answering.

To better understand how the dynamic threshold is affecting our framework's performance. We conduct an ablation study on this (Table 3) and find that the threshold increases the precision and the general F1 substantially. The last row in the table shows the test time ensemble performance of the predictions from BERT_QA_Arg trained with template 2 question, and another BERT_QA_Arg trained with template 3 question. The ensemble system outperforms the non-ensemble system in both precision and recall, demonstrating the benefit from both templates.

Table 4: Evaluation on unseen argument roles.

Evaluation on Unseen Argument Roles To verify how our formulation provides advantages for extracting arguments with unseen argument roles (similar to the zero-shot relation extraction setting in Levy et al. (2017)), we conduct another experiment, where we keep 80% of the argument roles (16 roles) seen at training time, and 20% (6 roles) only seen at test time. Specifically, the unseen roles are "Vehicle, Artifact, Target, Victim, Recipient, Buyer".

Table 4 presents the results. **Random NE** is our random baseline that selects a named entity in the sentence, it comes with a reasonable performance of near 25%. Prior model such as **GAIL** is not capable of handling the unseen roles. **ZSTE** (Huang et al., 2018) is a framework for zero-shot transfer learning of event extraction with AMR. It maps each parsed candidate span to a specific type in a

Table 5: Influence of question generation strategies on argument extraction.

target event ontology. This framework's argument extraction's results are affected by the AMR results and their reported F1 is around 20-30% in their evaluation setting.

Using our QA-based framework, as we leverage more semantic information and naturalness into the question (from question template 1 to 2, to 3), both the precision and recall increase substantially.

4 Further Analysis

4.1 Influence of Question Templates

To investigate how the question generation strategies affect the performance of event extraction, we perform experiments on trigger and argument extractions with different strategies, respectively.

In Table 6, we try different fixed questions for trigger detection. By "leaving empty", we mean instantiating the **question** with empty string.[4] There's no substantial gap between different alternatives. By using "verb" as the question, our BERT_QA_Trigger model achieves best performance (measured by F1 score). The QA model also encodes the semantic *interactions* between the fixed question ("verb") and the sentence, this explains why BERT_QA_Trigger is better than BERT FineTune in trigger detection.

	Trigger ID + Classification		
	P	R	F1
leaving empty	67.15	73.20	70.04
"what is the trigger"	70.15	69.98	70.06
"What happened"	70.53	69.48	70.00
"trigger"	69.73	71.46	70.59
"action"	72.25	71.71	71.98
"verb"	71.12	73.70	**72.39**

Table 6: Effect of different questions on trigger detection.

The comparison between different question generation strategies for argument extraction is even more interesting. In Table 5, we present the results in two settings: event argument extraction with predicted triggers (the same setting as in Table 3), and with gold triggers. In summary, we finds that:

- *Adding "in <trigger>" afterwards the question consistently improve the performance.* It serves as an indicator for what/where the trigger is in the input sentence. Without adding the "in <trigger>", for each template (1, 2 & 3), the F1 of models' predictions drop around 3 percent when given predicted triggers, and more when given gold triggers.
- *Our template 3 questioning strategy which is most natural achieves the best performance.* As we mentioned earlier, template 3 questions are based on descriptions for argument roles in the annotation guideline, thus encoding more semantic information about the role name. And this corresponds to the accuracy of models' predictions – template 3 outperforms template 1&2 in both with "in <trigger>" and without "in <trigger>" setting. What's more, we observe that template 2 (adding a WH_word to form the questions) achieves better performance than the template 1 (directly using argument role name).

4.2 Error Analysis

We further conduct error analysis and provide a number of representative examples. Table 7 summarizes error statistics for trigger detection and argument extraction.

For event triggers, the majority of the errors relates to missing or spurious predictions, and only 8.29% involves misclassified event types (e.g., a ELECT event is mistaken for a START-POSITION

---

[4] In this case, the model degrades to a token classification model. It matches our BERT FineTune baseline's performance.

Missing	Spurious	Wrong Type
46.08%	45.62%	8.29%

same number		more	less
exact match	not exact match		
14.48%	17.21%	13.93%	54.37%

Table 7: Trigger errors (upper table) and argument errors (lower table).

event). For event arguments, on the sentences that comes with at least one event in gold data, our framework extracts more argument spans only around 14% of the cases. Most of the time (54.37%), our framework extracts less argument spans, this corresponds to the results in Table 3, where the precision of our models are higher. In around 30% of the cases, our framework extracts same number of argument spans as in the gold data, half of them match exactly the gold arguments.

After examining the example predictions, we find that reasons for errors can be mainly divided into the following categories:

- More complex sentence structures. In the following example, where the input sentence has multiple clauses, each with trigger and arguments (such as when triggers are partial or elided). Our model is capable of also extracting "Tom" as another ENTITY of the CONTACT.MEET event.

  > [She]$_{\text{ENTITY}}$ **visited** the store and [Tom]$_{\text{ENTITY}}$ did too.

  But in the second example, when there is a higher-order event expressed spanning events in nested clauses:

  > Canadian authorities arrested two Vancouver-area men on Friday and charged them in the **deaths** of [329 passengers and crew members of an Air-India Boeing 747 that blew up over the Irish Sea in 1985, en route from Canada to London]$_{\text{VICTIM}}$.

  Our model did not extract the entire VICTIM correctly, which proves the difficulty of handling complex clauses structures.
- Lack of reasoning with document-level context. In sentence "MCI must now seize additional assets owned by Ebbers, to secure the **loan**." There is a TRANSFER-MONEY event triggered by loan, with MCI being the GIVER and Ebbers being the RECIPIENT. In the previous paragraph, it's mentioned that "Ebbers failed to make repayment of certain amount of money on the loan from MCI." Without this context, it is hard to determine that Ebbers should be the recipient of the loan.
- Lack of knowledge for obtaining exact boundary for the argument span. For example, in "Negotiations between Washington and Pyongyang on their nuclear dispute have been set for April 23 in Beijing ...", for the ENTITY role, two argument spans should be extracted ("Washington" and "Pyongyang"). While our framework predicts the entire "Washington and Pyongyang" as the argument span. Although there's an overlap between the prediction and gold-data, the model gets no credit for it.
- Data and lexical sparsity. In the following two examples, our model fails to detect the triggers of type END-POSITION. "Minister Tony Blair said **ousting** Saddam Hussein now was key to solving similar crises." "There's no indication if Erdogan would **purge** officials who opposed letting in the troops." It's partially due to they were not seen during training as trigger words. "ousting" a rare word and is not in the tokenizers' vocabulary. Purely inferring from the sentence context is hard for the purpose.

5 Related Work

Event Extraction Most event extraction research has focused on the 2005 Automatic Content Extraction (ACE) sentence-level event task (Walker et al., 2006). In recent years, continuous representations from convolutional neural network (Nguyen and Grishman, 2015; Chen et al., 2015) and recurrent neural network (Nguyen et al., 2016) have been proved to help substantially for the pipeline classifiers. To mitigate the effect of error propagation, joint models have been proposed for event extraction, Yang and Mitchell (2016) consider structural dependencies between events and entities. It requires heavy feature engineering to capture discriminative information. Nguyen and Nguyen (2019) propose a multitask model that performs entity recognition, trigger detection and argument role prediction by sharing BiGRU hidden representations. Zhang et al. (2019a) utilizes a neural transition-based extraction framework (Zhang and Clark, 2011), which requires specially designed transition actions, which still requires recognizing entities during decoding, though entity recognition and argument role prediction are done jointly.

These methods generally perform **trigger detection** → **entity recognition** → **argument role assignment** during decoding. Different from the works above, our framework completely bypasses the entity recognition stage (thus no annotation resources for NER needed), and directly tackles event argument extraction. Also related to our work includes Wadden et al. (2019), they model the entity/argument spans (with start and end offset) instead of labeling with BIO scheme. Different from our work, their learned span representations are later used to predict the entity/argument type. While our QA model directly extract the spans for certain argument role type. Contextualized representations produced by pre-trained language models (Peters et al., 2018; Devlin et al., 2019) have been proved to be helpful for event extraction (Zhang et al., 2019b; Wadden et al., 2019) and question answering (Rajpurkar et al., 2016). The attention mechanism helps capture relationships between tokens in question and input sequence. We use BERT in our framework for capturing semantic relationship between question and input sentence.

Machine Reading Comprehension (MRC) Span-based MRC tasks involve extracting a span from a paragraph (Rajpurkar et al., 2016) or multiple paragraphs (Joshi et al., 2017; Kwiatkowski et al., 2019). Recently, there have been explorations on formulating NLP tasks as a question answering problem. McCann et al. (2018) propose natural language decathlon challenge (decaNLP), which consists of ten tasks (e.g., machine translation, summarization, question answering, etc.) They cast all tasks as question answering over a context and propose a general model for this. In the information extraction literature, Levy et al. (2017) propose the zero-shot relation extraction task and reduce the task to answering crowd-sourced reading comprehension questions. Li et al. (2019) casts entity-relation extraction as a multi-turn question answering task. Their questions lack diversity and naturalness. For example for the PART-WHOLE relation, the template questions is “find Y that belongs to X”, where X is instantiated with the pre-given entity. The follow-up work from Li et al. (2020) propose better query strategies incorporating synonyms and examples for named entity recognition. Different from the works above, we focus on the more complex event extraction task, which involves both trigger detection and argument extraction. Our generated questions for extracting event arguments are more natural (incorporating descriptions from annotation guidelines) and leverage trigger information.

Question Generation To generate question templates 2&3 (Type + Role question and annotation guideline based question) which are more natural, we draw insights from literature of automatic rule-based question generation (Heilman and Smith, 2010). Heilman (2011) propose to use linguistically motivated rules for WH word (question phrase) selection. In their more general case of question generation from sentences, answer phrases can be noun phrases, prepositional phrases, or subordinate clauses. Complicated rules are designed with help from superTagger (Ciaramita and Altun, 2006). In our case, event arguments are mostly noun phrases and the rules are simpler – “who” for person, “where” for place and “what” for all other types of entities. We sample around 10 examples from the development set to determine the entity type of each argument role.

In the future, it is interesting to investigate how to utilize machine learning-based question generation method (Du et al., 2017), which would be more beneficial for schema/ontology containing a large number of event argument types.

6 Conclusion

In this paper, we introduce a new paradigm for event extraction based on question answering. We investigate how the question generation strategies affect the performance of our framework on both trigger detection and argument span extraction, and find that more natural questions lead to better performance. Our framework outperforms prior works on the ACE 2005 benchmark, and is capable of extracting event arguments of roles not seen at training time. For future work, it would be interesting to try incorporating broader context (e.g., paragraph/document-level context (Ji and Grishman, 2008; Huang and Riloff, 2011; Du and Cardie, 2020) in our methods to improve the accuracy of the predictions.

Abstract

Event schemas can guide our understanding and ability to make predictions with respect to what might happen next. We propose a new *Event Graph Schema*, where two event types are connected through multiple paths involving entities that fill important roles in a coherent story. We then introduce *Path Language Model*, an auto-regressive language model trained on event-event paths, and select salient and coherent paths to probabilistically construct these graph schemas. We design two evaluation metrics, *instance coverage* and *instance coherence*, to evaluate the quality of graph schema induction, by checking when coherent event instances are covered by the schema graph. Intrinsic evaluations show that our approach is highly effective at inducing salient and coherent schemas. Extrinsic evaluations show the induced schema repository provides significant improvement to downstream end-to-end Information Extraction over a state-of-the-art joint neural extraction model, when used as additional global features to unfold instance graphs.[1]

1 Introduction

Existing approaches to automated event extraction retain the overly simplistic assumption that events are atomic occurrences. Understanding events requires knowledge in the form of a repository of abstracted event schemas (complex event templates). Scripts (Schank and Abelson, 1977) encode frequently recurring event sequences, where events are ordered by temporal relation (Chambers and Jurafsky, 2009), causal relation (Mostafazadeh et al., 2016b), or narrative order (Jans et al., 2012). Event schemas have become increasingly important for natural language understanding tasks such as story ending prediction (Mostafazadeh et al., 2016a) and reading comprehension (Kočiský et al., 2018; Ostermann et al., 2019).

Previous schema induction methods mostly ignore uncertainty, re-occurring events and multiple hypotheses, with limited attention to capture complex relations among events, other than temporal or causal relations. Temporal relations exist between almost all events, even those that are not semantically related; while research in identifying causal relations has been hobbled by low inter-annotator agreement (Hong et al., 2016).

In this paper, we hypothesize that two events are connected when their entity arguments are coreferential or semantically related. For example, in Figure 1, (a) and (b) refer to very different event instances, but they both illustrate a typical scenario where a group of people moved from one place to another and then attacked the destination. From many such event instance pairs, we can induce multiple paths connecting a movement event to a related attack event: the person being moved became the attacker, and the weapon or vehicle being moved became the instrument of the attack. Low-level primitive components of event schemas are abundant, and can be part of multiple, sparsely occurring, higher-level graph schemas. We thus propose a new schema representation, *Event Graph Schema*, where *two* event types are connected by such paths containing entity-entity relations. Each node represents an entity type or event type, and each edge represents an entity-entity relation type or the argument role of an entity played in an event.

However, between two event types, there may also be noisy paths that should be excluded from graph schemas. We define the following criteria to select good paths in a graph schema: (1). **Salience**: A good path should appear frequently between two event types; (2). **Coherence**: Multiple paths between the same pair of event types should tell a

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 684–695,
November 16–20, 2020.

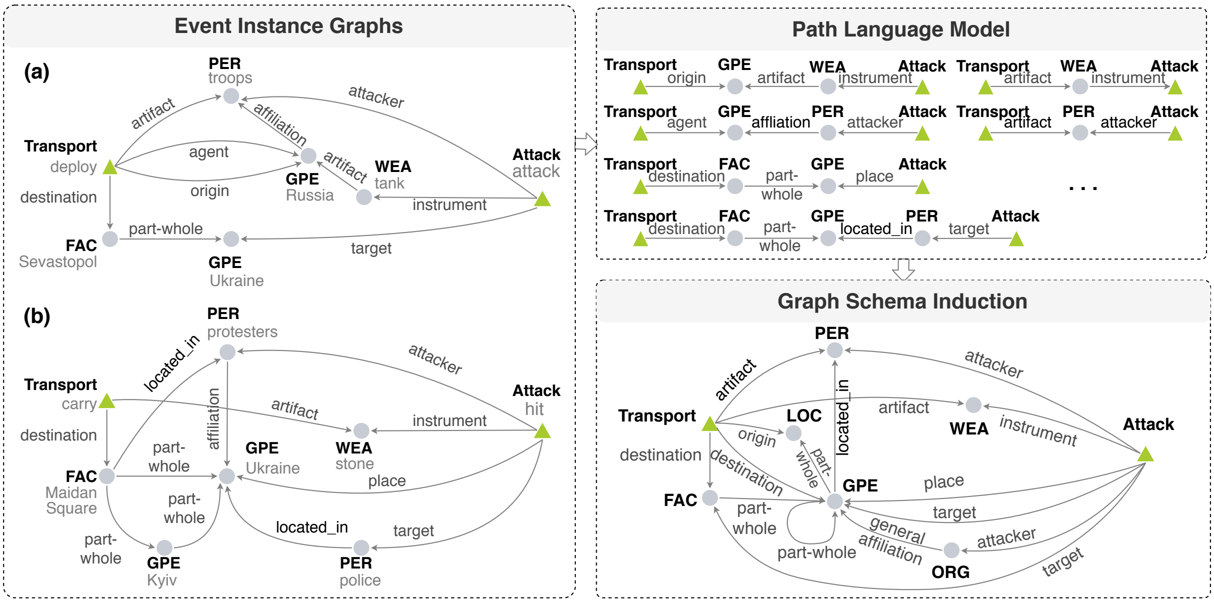

Figure 1: The framework of event graph schema induction. Given a news article, we construct an instance graph for every two event instances from information extraction (IE) results. In this example, instance graph (a) tells the story about Russia deploying troops to attack Ukraine using tanks from Russia; instance graph (b) is about Ukrainian protesters hit police using stones that are being carried to Maidan Square. We learn a path language model to select salient and coherent paths between two event types and merge them into a graph schema. The graph schema between ATTACK and TRANSPORT is an example output containing the top 20% ranked paths.

coherent story, namely they should co-occur frequently in the same discourse (e.g., the same document). Table 1 shows some examples of good paths and bad paths.

As the first attempt to extract such schemas, we propose a path language model to select paths which clearly indicate how two events are connected through their shared entity arguments or the entity-entity relations between their arguments. For example, in Figure 1 (b), Maidan Square and Ukraine connect events TRANSPORT and ATTACK through the path $\text{TRANSPORT} \xrightarrow{\text{DESTINATION}} \text{FAC} \xrightarrow{\text{PART-WHOLE}} \text{GPE} \xrightarrow{\text{PLACE}^{-1}} \text{ATTACK}$. We train the path language model on two tasks: learning an auto-regressive language model (Ponte and Croft, 1998; Dai and Le, 2015; Peters et al., 2018; Radford et al.; Yang et al., 2019) to predict an edge or a node, given previous edges and nodes in a path, and a neighboring path classification task to predict how likely two paths co-occur. The path language model is trained from all the paths between two event instances from the same document, based on the assumption that events from the same document (especially news document) tell a coherent story.

We propose two intrinsic evaluation metrics, *instance coverage* and *instance coherence*, to assess when event instance graphs are covered by each graph schema, and when different schemas appear in the same document. Intrinsic evaluation on held-out documents demonstrates that our approach can produce highly salient and coherent schemas.

Such event graph schemas can also be exploited to enhance the performance of Information Extraction (IE) tasks, such as entity extraction, relation extraction, event extraction and argument role labeling, because most of the existing methods ignore such inter-event dependencies. For example, from the following sentence *"Following the trail of Mohammed A. Salameh, the first suspect arrested in the bombing, investigators discovered a jumble of chemicals, chemistry implements and detonating materials..."*, the state-of-the-art IE system (Lin et al., 2020) successfully extracts the ARRESTJAIL event but fails to extract the INVESTIGATECRIME triggered by *"discovered"* and its DEFENDANT argument *"Mohammed A. Salameh"*. Event graph scehmas can inform the model that a person who is arrested was usually investigated, our IE system can fix this missing error. Therefore we also conduct extrinsic evaluations and show the effectiveness of the induced schema repository in enhancing downstream end-to-end IE tasks.

In summary, we make the following novel contributions:

- A novel semantic schema induction framework for the new event schema representation, *Event Graph Schema*, that encodes rich event structures and event-event connections, and two new evaluation metrics to assess graph schemas for coverage and coherence.
- A *Path Language Model* to select salient and coherent event-event paths and construct an event graph schema repository that is probabilistic and semantically coherent.
- The first work to show how to apply event schema to enhance end-to-end IE.

2 Problem Formulation

Given an input document, we extract instances of entities, relations, and events. The type set of entities and events is Φ, and the type set of entity-entity relations and event argument roles is Ψ. For every two event instances, we construct an event instance graph $g = (V, E, \varphi) \in \mathcal{G}$ with all paths connecting the two, as in Figure 1 (a) and (b). V and E are the node and edge sets, and $\varphi : \{V, E\} \rightarrow \{\Phi, \Psi\}$ is a mapping function to obtain the type of each node or edge. Each node $v_i = \langle w_i, \varphi(v_i) \rangle \in V$ represents an entity or an event with text mention w_i, and $\varphi(v_i) \in \Phi$ denotes its node type. Each set of coreferential entities or events is mapped to one single node. Each edge $e_{ij} = \langle v_i, \varphi(e_{ij}), v_j \rangle \in E$ represents an event-argument role or an entity-entity relation, where i and j denote the involved nodes. $\varphi(e_{ij}) \in \Psi$ indicates the edge type. Figure 1 shows two example instance graphs.

Event graph schema induction aims to generate a set of recurring graph schemas $\mathcal{S}$ from instance graphs $\mathcal{G}$. For every event type pair, we induce an event graph schema $s = (U, H) \in \mathcal{S}$, where U and H are the node and edge sets. Each node $u_i = \langle \phi_i \rangle \in U$ is a node type $\phi_i \in \Phi$ in instance graphs $\mathcal{G}$, and each edge $h_{ij} = \langle \phi_i, \psi_{ij}, \phi_j \rangle \in H$ represents an edge type $\psi_{ij} \in \Psi$ in instance graphs $\mathcal{G}$, where ϕ_i and ϕ_j denote the involved node types. Figure 1 shows an example of an induced graph schema between TRANSPORT and ATTACK.

3 Path Language Model based Graph Schema Induction

3.1 Overview

As shown in Table 1, a graph schema for two event types consists of **salient** and **coherent** paths between them. A salient path reveals knowledge of recurring event-event connection patterns. For example, the frequent path in Table 1 shows that the attacker is a member of the government conducting a deployment, which repeatedly appears in the story about attackers sending weapons and people to attack a target place. However, the attacker is unlikely to be affiliated with a target place, so the infrequent path in Table 1 should be excluded from the schema.

In addition, a good path is semantically coherent. For example, the coherent path in Table 1 shows that the origin of transportation is a subarea of the attacker's country, which captures the hierarchical part-whole relation between two places. However, in the bad path example, a person is affiliated with both the origin and destination of the transportation, which is a weakly coherent situation.

Furthermore, multiple paths in a good schema should be semantically consistent, namely they should co-occur frequently in the same scenario. For example, in Table 1, the destination of transportation is the attack's target, and meanwhile, is the location of the transported people. The co-occurrence of these two paths represents a repetitive pattern to connect TRANSPORT and ATTACK. However, the incoherent example in Table 1 indicates that the attack place is both the destination and the origin of the transportation, where two paths rarely co-occur.

To induce such salient and coherent graph schemas, we start by applying Information Extraction (IE) to construct instance graphs between event instances in each document (Section 3.2). We consider a path sequence as a text sequence, and learn an auto-regressive path language model to score each path (Section 3.3). To capture the coherence between paths, we learn a neighbor path classifier to predict whether two paths co-occur (Section 3.4). The path language model is trained jointly on these two tasks (Section 3.5), which enables us to score and rank paths between event type pairs, and merge salient and coherent paths into graph schemas (Section 3.6).

3.2 Instance Graph Construction

Starting with entities, entity-entity relations, events and their arguments extracted from an input document by IE systems or manual annotation, we construct an event instance graph g for two event instances v and v', that includes all *instance paths*

Criteria			**Examples**	**Frequency**
Single Path	**Salience**	**High**	$\textsc{Transport} \xrightarrow{\text{AGENT}} \text{GPE} \xrightarrow{\text{AFFILIATION}^{-1}} \text{PER} \xrightarrow{\text{ATTACKER}^{-1}} \textsc{Attack}$	31
		Low	$\textsc{Transport} \xrightarrow{\text{DESTINATION}} \text{GPE} \xrightarrow{\text{AFFILIATION}^{-1}} \text{PER} \xrightarrow{\text{ATTACKER}^{-1}} \textsc{Attack}$	2

Table 1: The criteria of path ranking to construct event schema graph. Frequency is computed based on ACE 2005 annotations. We use '-1' to indicate the reversed edge direction.

between them. Each instance path

$$p^{\mathbb{I}} = \left[v, e_{0;1}, v_1, \dots, e_{n-1;n}, v'\right]$$

is a sequence of nodes $v, v_1, \ldots, v' \in V$ and edges $e_{0;1}, \ldots, e_{n-1;n} \in E$, such as the instance path *attack* $\xrightarrow{\text{INSTRUMENT}}$ *tank* $\xrightarrow{\text{ARTIFACT}}$ *Russia* $\xrightarrow{\text{AGENT}^{-1}}$ *deploy* in Figure 1 (a). The node instances in each path are distinct to avoid cycles. An event-event path is a sequence of types of nodes and edges,

$$p = \left[\varphi(v), \varphi(e_{0;1}), \varphi(v_1), \dots, \varphi(e_{n-1;n}), \varphi(v')\right].$$

For example, the path abstracted from the instance path above is $\textsc{Attack} \xrightarrow{\text{INSTRUMENT}} \text{WEA} \xrightarrow{\text{ARTIFACT}} \text{GPE} \xrightarrow{\text{AGENT}^{-1}} \textsc{Transport}$. We consider paths in both directions, namely that reversed paths are valid.

3.3 Autoregressive Path Language Model

To score and select salient and semantically coherent path sequences, we take a language modeling approach, inspired by node representation learning (Grover and Leskovec, 2016; Goikoetxea et al., 2015) using language model over paths. Autoregressive language model (Ponte and Croft, 1998; Dai and Le, 2015; Peters et al., 2018; Radford et al.; Yang et al., 2019) learns the probability of text sequences as the probability distribution of each word, given its context factorizing the likelihood of prior words into a forward product or, for context in the other direction, a backward product. Similarly, for a path instance $p^{\mathbb{I}}$, we estimate the probability distribution of a node type $\varphi(v_i)$ (or edge type $\varphi(e_{j;j+1})$), given the sequence of previously observed nodes and edges $[\varphi(v), \varphi(e_{0;1}), \varphi(v_1), \ldots, \varphi(e_{i-1;i})]$, (or $[\varphi(v), \varphi(e_{0;1}), \varphi(v_1), \ldots, \varphi(v_i)]$), i.e.,

$$\mathcal{L}_{LM} = \sum_{p^{\mathbb{I}}} \Big[\sum_{v_i \in p^{\mathbb{I}}} \log P(\varphi(v_i) | \varphi(v), \ldots, \varphi(e_{i-1;i})) + \sum_{e_{j;j+1} \in p^{\mathbb{I}}} \log P(\varphi(e_{j;j+1}) | \varphi(v), \varphi(e_{0;1}), \ldots, \varphi(v_i)) \Big].$$

Following (Yang et al., 2019), we apply the Transformer (Vaswani et al., 2017) to learn the probability distribution, with permutation operation (Yang et al., 2019) to capture bidirectional contexts. Unlike in text sequences, we have nodes and edges that alternate within path sequences. As shown in Figure 2, to distinguish nodes and edges, we add type embedding $\boldsymbol{E_T} = [1, 2, 1, \ldots, 2, 1]$ into the token representation, where 1 stands for nodes, 2 for edges, and 0 for special tokens such as [CLS].

We hypothesize that event instances from the same discourse (e.g., a news document) describe a coherent story, and so we use the paths between them as training paths.

3.4 Neighbor Path Classification

To capture the consistency between paths, we train a binary neighbor path classifier to learn the occurrence probability of two paths. For each path $p_i \in \mathcal{P}_{\langle v,v' \rangle}$ between two event instances v and v', we obtain its *neighbor path* set as its co-occuring paths between the same event instances v and v',

$$\mathcal{N}_{p_i} = \{p_j | p_j \in \mathcal{P}_{\langle v,v' \rangle}, v, v' \in V\}.$$

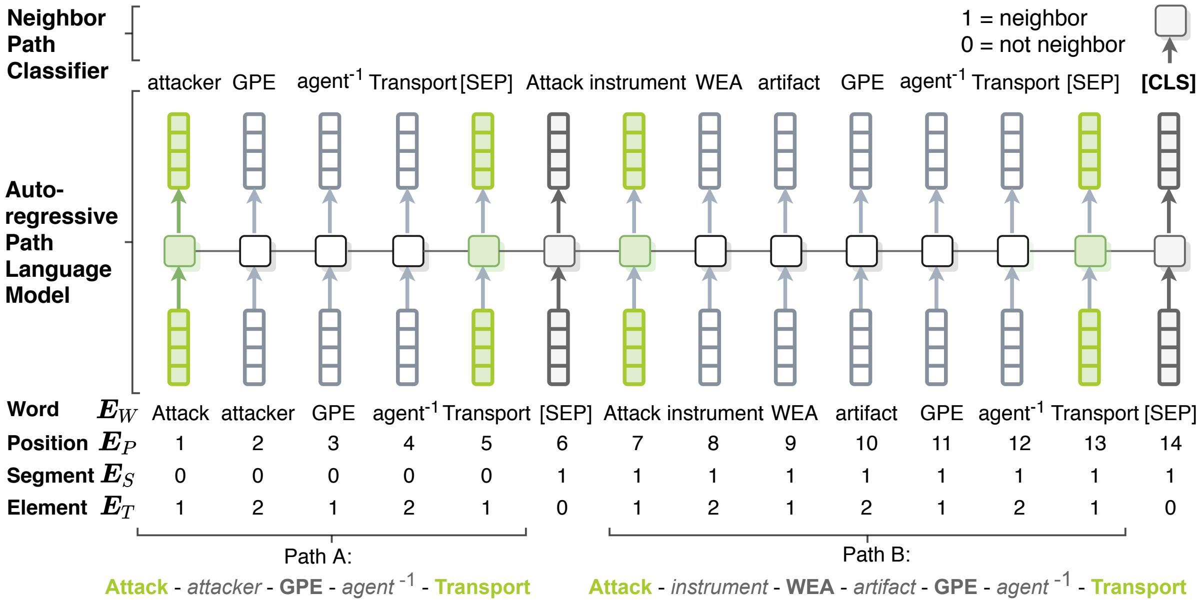

Figure 2: Autoregressive path language model with neighbor path classification.

We sample negative neighbor paths from paths that appear between the same event types $\varphi(v)$ and $\varphi(v')$, but never occur with p_i in the corpus.

$$\mathcal{N}'_{p_i} = \{p_j | p_j \in \mathcal{P}_{\langle\varphi(v),\varphi(v')\rangle}, p_j \notin \mathcal{N}_{p_i}\}.$$

We also swap each path pair to improve the consistency of the neighbor path classification. The neighbor path classifier (top of Figure 2) is a linear layer with the classification token $\boldsymbol{x}_{[\mathrm{CLS}]}$ as input,

$$P(p_j \in \mathcal{N}_{p_i}) = \mathrm{sigmoid}\left(\boldsymbol{W}\boldsymbol{x}_{[\mathrm{CLS}]} + \boldsymbol{b}\right).$$

We balance the positive and negative path pairs during training, and optimize cross-entropy loss,

$$\mathcal{L}_{NP} = \sum_{p_i}\Big[\sum_{p_j \in \mathcal{N}_{p_i}} \log P(p_j \in \mathcal{N}_{p_i}) + \sum_{p_j \in \mathcal{N}'_{p_i}} \log(1 - P(p_j \in \mathcal{N}_{p_i}))\Big].$$

3.5 Joint Training

We jointly optimize autoregressive language model loss and neighbor path classifier loss,

$$\mathcal{L} = \mathcal{L}_{LM} + \lambda\mathcal{L}_{NP}.$$

3.6 Graph Schema Construction

Given two event types ϕ and ϕ', we construct a graph schema s by merging the top k percent ranked paths. Paths in $\mathcal{P}_{\langle\phi,\phi'\rangle}$ are ranked in terms of a score function $f(p)$,

$$f(p_i) = f_{\mathrm{LM}}(p_i) + \alpha f_{\mathrm{NP}}(p_i),$$

where $f_{\mathrm{LM}}(p)$ captures salience and coherence of a single path,

$$f_{\mathrm{LM}}(p_i) = \log P([\phi, \psi_{0;1}, \phi_1, \psi_{1;2}, ..., \phi']),$$

and where $f_{\mathrm{NP}}(p)$ scores a path p_i by its average probability of co-occuring with other paths $p_j \in \mathcal{P}_{\langle\phi,\phi'\rangle}$ between the given event types ϕ and ϕ',

$$f_{\mathrm{NP}}(p_i) = \frac{1}{|\mathcal{P}_{\langle\phi,\phi'\rangle}|}\sum_{p_j \in \mathcal{P}_{\langle\phi,\phi'\rangle}} \log P(p_j \in \mathcal{N}_{p_i}).$$

We merge instance paths into a graph schema s by mapping nodes of the same type into a single node. We allow some self-loops in the graph, such as GPE $\xrightarrow{\text{PART-WHOLE}}$ GPE. Each path in the schema has a probability,

$$P(p_i) = \frac{\exp(f(p_i))}{\sum_{p_j \in s}\exp(f(p_j))}.$$

Each edge and node is assigned a salience score by aggregating the scores of paths passing through it,

$$f(\psi_{i;j}) = \sum_{p \in \{p|\psi_{i;j} \in p, p \in s\}} P(p), \quad f(\phi_i) = \sum_{p \in \{p|\phi_i \in p, p \in s\}} P(p).$$

4 Evaluation Benchmark

4.1 Dataset

We use Automatic Content Extraction (ACE) 2005 dataset[2], the widely used dataset with annotated

---

[2] https://www.ldc.upenn.edu/collaborations/past-projects/ace

instances of 7 entity types, 6 relation types, 33 event types, and 22 argument roles. We follow our recent work on ACE IE (Lin et al., 2020) to split the data. We consider the training set as historical data to train the LM, and the test set as our target data to induce schema for target scenarios. The instance graphs of the target data set are constructed from manual annotations. For historical data, we construct event instance graphs from both manual annotations (Historical$_{\text{ann}}$) and system extraction results (Historical$_{\text{sys}}$) from the state-of-the-art IE model (Lin et al., 2020). We perform cross-document entity coreference resolution by applying an entity linker (Pan et al., 2017) for both annotated and system generated instance graphs. Table 2 shows the data statistics.

Split	#Docs	#Entities	#Rels	#Events	#Args
Historical$_{\text{ann}}$	529	47,525	7,152	4,419	7,888
Historical$_{\text{sys}}$	529	48,664	7,018	4,426	6,614
Validation	40	3,422	728	468	938
Target	30	3,673	802	424	897

Table 2: Data statistics.

4.2 Instance Coverage

A salient schema can serve as a skeleton to recover instance graphs. Therefore, we use each graph schema $s \in \mathcal{S}$ to match back to each ground-truth instance graph $g \in \mathcal{G}$ and evaluate their intersection $g \cap s$ in terms of Precision and Recall.

Intersection is obtained by searching instance graphs with each graph schema as a query. Since instance graphs can be regarded as *partially* instantiated graph schema, we employ the substructures of the schema graph, i.e., paths of different lengths, as queries. For example, a path of length $l = 3$ is a triple in graph schema $\langle \phi_i, \psi_{ij}, \phi_j \rangle \in s$. We consider an instance triple $\langle v_m, e_{mn}, v_n \rangle \in g$ matched if instance types match, i.e., $\varphi(v_m){=}\phi_i$, $\varphi(e_{mn}){=}\psi_{ij}$, $\varphi(v_n){=}\phi_j$. Let $|\cdot|_{\mathbb{I}}$ denote the number of instance substructures matched, and $|\cdot|_{\mathbb{S}}$ is the number of schema substructures matched, i.e.,

$$|g \cap s|_{\mathbb{I}} = \sum_{\langle \phi_i, \psi_{ij}, \phi_j \rangle \in s} \text{count}(\langle v_m, e_{mn}, v_n \rangle),$$
$$|g \cap s|_{\mathbb{S}} = \sum_{\langle v_m, e_{mn}, v_n \rangle \in g} \text{count}(\langle \phi_i, \psi_{ij}, \phi_j \rangle).$$

The cardinality for an instance graph and a schema will be the number of substructures in each, i.e.,

$$|g|_{\mathbb{I}} = \sum_{\langle v_m, e_{mn}, v_n \rangle \in g} \text{count}(\langle v_m, e_{mn}, v_n \rangle),$$
$$|s|_{\mathbb{S}} = \sum_{\langle \phi_i, \psi_{ij}, \phi_j \rangle \in s} \text{count}(\langle \phi_i, \psi_{ij}, \phi_j \rangle).$$

By extension, each path of length $l{=}5$ in a graph schema $[\phi_i, \psi_{ij}, \phi_j, \psi_{jk}, \phi_k]$ contains two consecutive triples $\langle \phi_i, \psi_{ij}, \phi_j \rangle, \langle \phi_j, \psi_{jk}, \phi_k \rangle \in s$, and a matched instance path contains two consecutive instance triples $\langle v_m, e_{mn}, v_n \rangle, \langle v_n, e_{no}, v_o \rangle \in g$, where $\varphi(v_m){=}\phi_i$, $\varphi(e_{mn}){=}\psi_{ij}$, $\varphi(v_n){=}\phi_j$, $\varphi(e_{no}){=}\psi_{jk}$, $\varphi(v_o){=}\phi_k$. Similarly, a path of length $l{=}7$ contains three consecutive triples. Then we compute:

$$\text{Precision} = \frac{\sum_{s \in \mathcal{S}} \sum_{g \in \mathcal{G}} |g \cap s|_{\mathbb{S}}}{\sum_{s \in \mathcal{S}} |s|_{\mathbb{S}}},$$
$$\text{Recall} = \frac{\sum_{s \in \mathcal{S}} \sum_{g \in \mathcal{G}} |g \cap s|_{\mathbb{I}}}{\sum_{g \in \mathcal{G}} |g|_{\mathbb{I}}}.$$

4.3 Instance Coherence

For an instance graph between two events v and v', we hypothesize that the graph is coherent if v and v' are from the same discourse (document). We carefully select 24 documents with each document talking about a unique complex event such as *Iraq War* or *North Korea Nuclear Test*. A coherent schema should have the maximal number of matched instance graphs $g \cap s$ from a single document, but the minimal number of matched graphs connecting two event instances from different documents. We define **Instance Coherence** as the proportion of event-event path instances in graphs within one document.

$$\text{Coherence} = \frac{\sum_{s \in \mathcal{S}} \sum_{g \in \mathcal{G}} \sum_{p \in g \cap s} f(p) \cdot \mathbb{I}_g}{\sum_{s \in \mathcal{S}} \sum_{g \in \mathcal{G}} \sum_{p \in g \cap s} f(p)},$$

where $\mathbb{I}_g$ is an indicator function taking value 1 when g is between event instances from the same document, and value 0 otherwise.

4.4 Schema-Guided Information Extraction

As a case study for extrinsic evaluation, we evaluate the impact of our induced schema[3] on end-to-end Information Extraction (IE). We choose our state-of-the-art IE system OneIE (Lin et al., 2020) [4]

---

[3] The schema is induced from annotated instance graphs of historical data, which is the training data of IE system.

[4] Code is public available at `http://blender.cs.illinois.edu/software/oneie/`

as our baseline for two reasons: (1) it achieves state-of-the-art performance on all IE components; (2) it can easily incorporate global features during decoding converting each input sentence into an instance graph.

Given an input sentence, ONEIE generates a set of candidate IE graphs at each decoding step, as shown in Figure 3. The candidate IE graphs are ranked by type prediction scores $s'(G)$ of each entity, relation and event in each graph G. We consider schemas as global features and use them as an additional scoring mechanism for ONEIE [5]. The schemas are induced from the training data of our IE system. If a path p_i in the schema appears n_i times in a candidate graph, we add $n_i * w_i$ to obtain the global score of this graph,

$$s(G) = s'(G) + \sum_{p_i \in s, s \in \mathcal{S}} n_i * w_i,$$

where w_i is a learnable weight. The candidate graphs are then ranked in terms of their global scores. In this way, the model can promote candidate graphs containing positive global features, even if the graphs may have lower local type prediction scores.

5 Experiments

5.1 Settings

Baselines. As the first to induce event graph schema, we compare our method to various path ranking methods: (1) **Frequency Ranking Model** ranks paths between every two event types by the number of associated instance paths in the historical and target data. (2) **Unigram, Bigram, and Trigram Language Models** assign probabilities to path sequences by estimating the probability of each node (or edge) from the unigram, bigram, and trigram frequency counts, respectively. We also include a variant of PathLM by removing the neighbor path classifier ($\mathrm{CLS}_{\mathrm{NP}}$) as an ablation study.

Schema@K. To compare the ranking of paths with baselines, we evaluate graph schemas containing top k % ranked paths.

Implementation Details. We use the same hyperparameters as in XLNet-base-cased (Yang et al., 2019), with dropout = 0.5. $\lambda = 0.1$, and $\alpha = 0.3$. Detailed parameter settings are in Appendix.

5.2 Results and Analysis

We induce 124 and 197 graph schemas for Schema@10 and Schema@20 respectively. Figure 1 shows an output graph schema.[6] According to Table 3 and Table 4, PathLM achieves significant improvement on both instance coverage and instance coherence. T-test shows that the gains achieved by PathLM are all statistically significant over baselines (Frequency, UnigramLM, BigramLM, TrigramLM), with a P value less than 0.01. We make the following observations:

(1) PathLM achieves larger gains compared to baselines on Schema@10 than Schema@20 in Table 3, demonstrating the effectiveness of our ranking approach, especially on top ranked ones.

(2) The improvement relative to baselines on longer path queries (e.g. l = 7) is greater than shorter paths (e.g., l = 3) in Table 3, showing that our approach is able to capture complex graph structures involving long distance between related events. In the l=3 setting, the performance of PathLM is close to baselines. The reason is that l=3 setting evaluates a single overlapped triple, which is exactly the objective of TrigramLM. We conduct t-test, and the gain is statistically significant (P value less than 0.01).

(3) The neighbor path classification proves to be effective in enhancing the salience (see 'w/o $\mathrm{CLS}_{\mathrm{NP}}$' in Table 3) and coherence (see 'w/o $\mathrm{CLS}_{\mathrm{NP}}$' in Table 4) of the induced schemas, showing that salient substructures can be better captured by frequently co-occurring paths. The model outputs consistent neighbor path classification results for the swapped path pairs. 96.17% swapped path pairs yield the same results as original pairs.

(4) The schemas induced from $\mathrm{Historical}_{\mathrm{sys}}$ and $\mathrm{Historical}_{\mathrm{ann}}$ have comparable performance. This proves our approach is robust to extraction noise and effective even with lower quality input.

As shown in Table 5, our event graph schemas have provided significant improvement on relation extraction and event extraction which require knowledge of complex connections among events and entities. Our approach achieves dramatic improvement on relation extraction, because existing methods mainly rely on local contexts between two entities, which are typically short and ambiguous. In contrast, the paths in our graph schemas can capture the global context between two events, and thus event-related information captures deeper

---

[5] To show the effectiveness of schema, we remove the original human-designed global features in ONEIE.

[6] Visualization of schema repository is in `http://blender.cs.illinois.edu/software/pathlm`.

contextual features, yielding a big boost in performance. For example, when decoding candidate IE graph in Figure 3, the LOCATED_IN relation is extracted by promoting the structures matching paths in the graph schema.

5.3 Remaining Challenges

A major challenge in schema induction is to automatically decide the type granularity. For example, if two events happen on the same *street*, it is likely that they are related; if it is a *country* that connects to two events through place arguments, they can be independent. In this case, the fine-grained type information of shared place argument is required in schemas. However, to induce schemas about *war*, geopolitical entities of different granularities should be generalized as GPE.

6 Related Work

Atomic Event Schema Induction. Atomic event schema induction methods (Chambers, 2013; Cheung et al., 2013; Nguyen et al., 2015; Huang et al., 2016; Sha et al., 2016; Yuan et al., 2018) focus on discovering event types and argument roles of individual atomic events.

Narrative Event Schema Induction. Previous work (Chambers and Jurafsky, 2008, 2009, 2010; Jans et al., 2012; Balasubramanian et al., 2013; Pichotta and Mooney, 2014, 2016; Rudinger et al., 2015; Granroth-Wilding and Clark, 2016; Modi, 2016; Mostafazadeh et al., 2016a; Peng et al., 2019) focuses on inducing *narrative schemas* as partially ordered sets of events (represented as verbs) sharing a common argument. The event order is further extended to include causality (Mostafazadeh et al., 2016b; Kalm et al., 2019), and *temporal script graph* is proposed where events and arguments are abstracted as event types and participant types (Modi et al., 2017; Wanzare et al., 2017; Zhai et al., 2019). In our work, we propose a new event graph schema representation to capture more complex connections between events, and use event types instead of verbs as in previous work for more abstraction power.

Path-based Language Model. Language models (LMs) (Ponte and Croft, 1998) achieve great advances on contextualizing LMs in the last few years (Peters et al., 2018; Devlin et al., 2019; Yang et al., 2019). LM has been used over paths to learn node representations in a network (Goikoetxea et al., 2015; Grover and Leskovec, 2016; Dong et al., 2017). To the best of our knowledge, there has not been an effort to incorporate latent linguistic structures into language models based on typed event-event paths. This is also the first work to demonstrate how to leverage event schemas to enhance the performance of an IE system.

Graph Pattern Mining. Motif finding on heterogeneous networks (Prakash et al., 2004; Carranza et al., 2018; Rossi et al., 2019; Hu et al., 2019) discovers highly recurrent instance graph patterns, but fails in abstracting schema graphs to the type level. Previous work applies graph summarization to discover frequent subgraph patterns for heterogeneous networks (Cook and Holder, 1993; Buehrer and Chellapilla, 2008; Li and Lin, 2009; Zhang et al., 2010; Koutra et al., 2014; Wu et al., 2014; Song et al., 2018; Bariatti et al., 2020), but ignores semantic coherence among multiple patterns.

7 Conclusions and Future Work

We propose Event Graph Schema induction as a new step towards semantic understanding of inter-event connections. We develope a path language model based method to construct graph schemas containing salient and semantically coherent event-event paths, which also effectively enhances end-to-end Information Extraction. In the future, we aim to extend graph schemas to encode hierarchical and temporal relations, as well as rich ontologies in open domain. We will also assemble our graph schemas to represent more complex scenarios involving multiple events, so they can be applied to more downstream applications including event graph completion and event prediction.

Abstract

Understanding natural language involves recognizing how multiple event mentions structurally and temporally interact with each other. In this process, one can induce event complexes that organize multi-granular events with temporal order and membership relations interweaving among them. Due to the lack of jointly labeled data for these relational phenomena and the restriction on the structures they articulate, we propose a joint constrained learning framework for modeling event-event relations. Specifically, the framework enforces logical constraints within and across multiple temporal and subevent relations by converting these constraints into differentiable learning objectives. We show that our joint constrained learning approach effectively compensates for the lack of jointly labeled data, and outperforms SOTA methods on benchmarks for both temporal relation extraction and event hierarchy construction, replacing a commonly used but more expensive global inference process. We also present a promising case study showing the effectiveness of our approach in inducing event complexes on an external corpus.[1]

1 Introduction

Human languages evolve to communicate about real-world events. Therefore, understanding events plays a critical role in natural language understanding (NLU). A key challenge to this mission lies in the fact that events are not just simple, standalone predicates. Rather, they are often described at different granularities and may form complex structures. Consider the example in Figure 1, where the description of a storm (e_1) involves more fine-grained event mentions about people killed (e_2), flights canceled (e_3) and passengers affected (e_4). Some of those mentions also follow strict temporal order (e_3, e_4 and e_5). Our goal is to induce such an *event complex* that recognizes the membership of multi-granular events described in the text, as well as their temporal order. This is not only at the core of text understanding, but is also beneficial to various applications such as question answering (Khashabi et al., 2018), narrative prediction (Chaturvedi et al., 2017), timeline construction (Do et al., 2012a) and summarization (Daumé III and Marcu, 2006).

On Tuesday, there was a typhoon-strength (e_1:***storm***) in Japan. One man got (e_2:***killed***) and thousands of people were left stranded. Police said an 81-year-old man (e_3:***died***) in central Toyama when the wind blew over a shed, trapping him underneath. Later this afternoon, with the agency warning of possible tornadoes, Japan Airlines (e_4:***canceled***) 230 domestic flights, (e_5:***affecting***) 31,600 passengers.

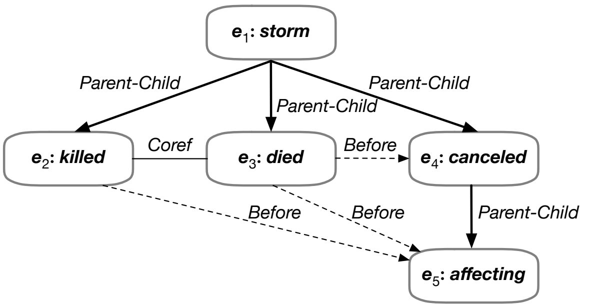

Figure 1: An example of an event complex described in the document. Bold arrows denote PARENT-CHILD relation; dotted arrows represent BEFORE relation; solid line represents two events are COREF to each other. For clarity, not all event mentions are shown in the figure.

Recently, significant research effort has been devoted to several event-event relation extraction tasks, such as event temporal relation (TempRel) extraction (Ning et al., 2018a, 2019) and subevent

---

relation extraction (Liu et al., 2018; Aldawsari and Finlayson, 2019). Addressing such challenging tasks requires a model to recognize the inherent connection between event mentions as well as their contexts in the documents. Accordingly, a few previous methods apply statistical learning methods to characterize the grounded events in the documents (Glavaš et al., 2014; Ning et al., 2017b, 2018c). Such methods often require designing various features to characterize the structural, discourse and narrative aspects of the events, which are costly to produce and are often specific to a certain task or dataset. More recent works attempted to use data-driven methods based on neural relation extraction models (Dligach et al., 2017; Ning et al., 2019; Han et al., 2019a,b) which refrain from feature engineering and offer competent performances.

While data-driven methods provide a general and tractable way for event-event relation extraction, their performance is restricted by the limited annotated resources available (Glavaš et al., 2014; Ning et al., 2018b). For example, the largest temporal relation extraction dataset MATRES (Ning et al., 2018b) only has 275 articles, which is far from enough for training a well-performing supervised model. The observation that relations and, in particular, event-event relations should be constrained by their logical properties (Roth and Yih, 2004; Chambers and Jurafsky, 2008), led to employing global inference to comply with transitivity and symmetry consistency, specifically on TempRel (Do et al., 2012b; Ning et al., 2017b; Han et al., 2019a). However, in an event complex, the logical constraints may globally apply to different task-specific relations, and form more complex conjunctive constraints. Consider the example in Figure 1: given that ***e2:died*** is BEFORE ***e3:canceled*** and ***e3:canceled*** is a PARENT event of ***e4:affecting***, the learning process should enforce ***e2:died*** BEFORE ***e4:affecting*** by considering the conjunctive constraints on both TempRel and subevent relations. While previous works focus on preserving logical consistency through (post-learning) inference or structured learning (Ning et al., 2017a), there was no effective way to endow neural models with the sense of global logical consistency during training. This is key to bridging the learning processes of TempRel and subevent relations, which is a research focus of this paper.

The *first* contribution of this work is proposing a joint constrained learning model for multi-faceted event-event relation extraction. The joint constrained learning framework seeks to regularize the model towards consistency with the logical constraints across both temporal and subevent relations, for which three types of consistency requirements are considered: *annotation consistency*, *symmetry consistency* and *conjunction consistency*. Such consistency requirements comprehensively define the interdependencies among those relations, essentially unifying the ordered nature of time and the topological nature of multi-granular subevents based on a set of declarative logic rules. Motivated by the logic-driven framework proposed by Li et al. (2019), the declarative logical constraints are converted into differentiable functions that can be incorporated into the learning objective for relation extraction tasks. Enforcing logical constraints across temporal and subevent relations is also a natural way to combine the supervision signals coming from two different datasets, one for each of the relation extraction tasks with a shared learning objective. Despite the scarce annotation for both tasks, the proposed method surpasses the SOTA TempRel extraction method on MATRES by relatively 3.27% in F_1; it also offers promising performance on the HiEve dataset for subevent relation extraction, relatively surpassing previous methods by at least 3.12% in F_1.

From the NLU perspective, the *second* contribution of this work lies in providing a general method for inducing an event complex that comprehensively represents the relational structure of several related event mentions. This is supported by the memberships vertically identified between multi-granular events, as well as the horizontal temporal reasoning within the event complex. As far as we know, this is different from all previous works that only formulated relations along a single axis. Our model further demonstrates the potent capability of inducing event complexes when evaluated on the RED dataset (O'Gorman et al., 2016).

2 Related Work

Various approaches have been proposed to extract event TempRels. Early effort focused on characterizing event pairs based on various types of semantic and linguistic features, and utilizing statistical learning methods, such as logistic regression (Mani et al., 2006; Verhagen and Pustejovsky, 2008) and SVM (Mirza and Tonelli, 2014), to capture the relations. Those methods typically require extensive feature engineering, and do not comprehensively consider the contextual information and global constraints among event-event relations. Recently, data-driven methods have been developed for TempRel extraction, and have offered promising performance. Ning et al. (2019) addressed this problem using a system combining an LSTM document encoder and a Siamese multi-layer perceptron (MLP) encoder for temporal commonsense knowledge from TEMPROB (Ning et al., 2018a). Han et al. (2019a) proposed a bidirectional LSTM (BiLSTM) with structured prediction to extract TempRels. Both of these works incorporated global inference to facilitate constraints on TempRels.

Besides TempRels, a couple of efforts have focused on event hierarchy construction, a.k.a. subevent relation extraction. This task seeks to extract the hierarchy where each parent event contains child events that are described in the same document. To cope with this task, both Araki et al. (2014) and Glavaš and Šnajder (2014) introduced a variety of features and employed logistic regression models for classifying event pairs into subevent relations (PARENT-CHILD and CHILD-PARENT, coreference (COREF), and no relation (NOREL). Aldawsari and Finlayson (2019) further extended the characterization with more features on the discourse and narrative aspects. Zhou et al. (2020a) presented a data-driven method by fine-tuning a time duration-aware BERT (Devlin et al., 2019) on corpora of time mentions, and used the estimation of time duration to predict subevent relations.

Though previous efforts have been devoted to preserving logical consistency through inference or structured learning (Roth and Yih, 2004; Roth and tau Yih, 2007; Chang et al., 2008), this is difficult to do in the context of neural networks. Moreover, while it is a common strategy to combine multiple training data in multi-task learning (Lin et al., 2020), our work is distinguished by enhancing the learning process by pushing the model towards a coherent output that satisfies logical constraints across separate tasks.

3 Methods

In this section, we present the joint learning framework for event-event relation extraction. We start with the problem formulation (§3.1), followed by the techniques for event pair characterization (§3.2), constrained learning (§3.3) and inference (§3.4).

3.1 Preliminaries

A document D is represented as a sequence of tokens $D = [t_1, \cdots, e_1, \cdots, e_2, \cdots, t_n]$. Some of the tokens belong to the set of annotated event triggers, i.e., $\mathcal{E}_D = \{e_1, e_2, \cdots, e_k\}$, whereas the rest are other lexemes. The goal is to induce event complexes from the document, which is through extracting the multi-faceted event-event relations. Particularly, we are interested in two subtasks of relation extraction, corresponding to the label set $\mathcal{R} = \mathcal{R}_T \cup \mathcal{R}_H$. $\mathcal{R}_T$ thereof denotes the set of temporal relations defined in the literature (Ning et al., 2017b, 2018b, 2019; Han et al., 2019b), which contains BEFORE, AFTER, EQUAL, and VAGUE. To be consistent with previous studies (Ning et al., 2018b, 2019), the temporal ordering relations between two events are decided by the order of their starting time, without constraining on their ending time. $\mathcal{R}_H$ thereof denotes the set of relation labels defined in the subevent relation extraction task (Hovy et al., 2013; Glavaš et al., 2014), i.e., PARENT-CHILD, CHILD-PARENT, COREF and NOREL. Following the definitions by Hovy et al. (2013), an event e_1 is said to have a child event e_2 if e_1 is a collector event that contains a sequence of activities, where e_2 is one of these activities, and e_2 is spatially and temporally contained within e_1. Note that each pair of events can be annotated with one relation from each of $\mathcal{R}_H$ and $\mathcal{R}_T$ respectively, as the labels within each task-specific relation set are mutually exclusive.

Our learning framework first obtains the event pair representation that combines contextualized and syntactic features along with commonsense knowledge, and then use an MLP to get confidence scores for each relation in $\mathcal{R}$. The joint learning objective seeks to enforce the logical consistency of outputs for both TempRel and subevent relations. The overall architecture is shown in Figure 2.

3.2 Event Pair Representation

To characterize the event pairs in the document, we employ a neural encoder architecture which provides event representations from two groups of features. Specifically, the representation here incorporates the contextualized representations of the event triggers along with statistical commonsense knowledge from several knowledge bases. On top of the features that characterize an event pair (e_1, e_2), we use an MLP with $|\mathcal{R}|$ outputs to estimate the confidence score for each relation r,

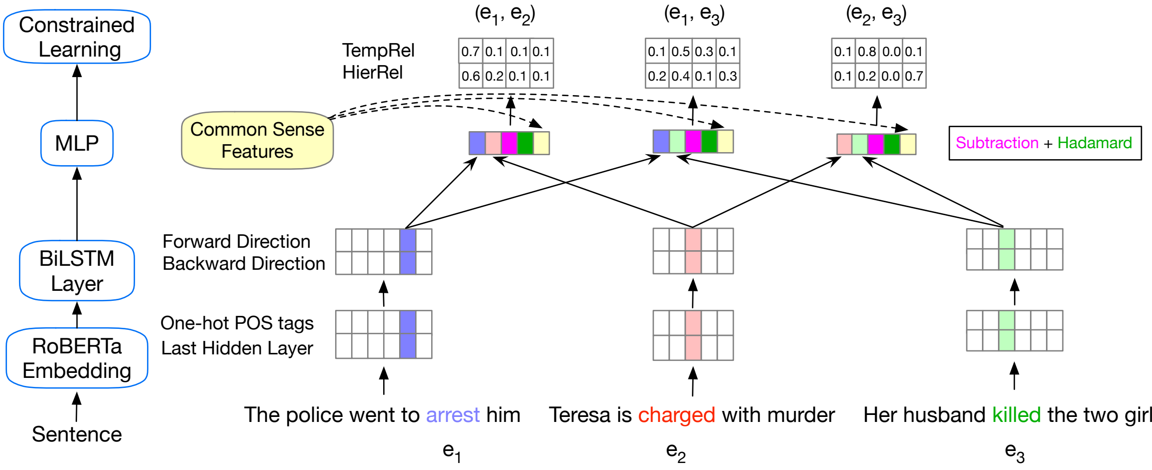

Figure 2: Model architecture. The model incorporates contextual features and commonsense knowledge to represent event pairs (§3.2). The joint learning enforces logical consistency on TempRel and subevent relations (§3.3).

denoted as $r_{(e_1,e_2)}$. Two separate softmax functions are then added to normalize the outputs for two task-specific label sets $\mathcal{R}_T$ and $\mathcal{R}_H$.

3.2.1 Contextualized Event Trigger Encoding

Given a document, we first use a pre-trained language model, RoBERTa (Liu et al., 2019), to produce the contextualized embeddings for all tokens of the entire document. The token embeddings are further concatenated with the one-hot vectors of POS (part-of-speech) tags, and fed into a BiLSTM. The hidden state of the last BiLSTM layer that is stacked on top of each event trigger e is therefore treated as the embedding representation of the event, denoted as h_e. For each event pair (e_1, e_2), the contextualized features are obtained as the concatenation of h_{e_1} and h_{e_2}, along with their element-wise Hadamard product and subtraction. This is shown to be a comprehensive way to model embedding interactions (Zhou et al., 2020b).

3.2.2 Commonsense Knowledge

We also incorporate the following sources of commonsense knowledge to characterize event pairs. Specifically, we first extract relevant knowledge from ConceptNet (Speer et al., 2017), which is a large-scale commonsense knowledge graph for commonsense concepts, entities, events and relations. A portion of the relations in ConceptNet that are relevant to our tasks include “HasSubevent”, “HasFirstSubevent” and “HasLastSubevent” relations. From ConceptNet we extract around 30k pairs of event concepts labeled with the aforementioned relations, along with 30k randomly corrupted negative samples. We also incorporate commonsense knowledge from TEMPROB (Ning et al., 2018a). This provides prior knowledge of the temporal order that some events usually follow.

We use the event pairs from those knowledge bases to train two MLP encoders. Each takes the concatenated token embeddings of two event triggers as inputs, and is trained with *contrastive loss* to estimate the likelihood that if a relation holds. For subevent and temporal related commonsense knowledge, two MLPs are separately trained. After the encoders are well-trained, we fix their parameters and combine them as a black box that corresponds to “Common Sense Features” in Figure 2.

3.3 Joint Constrained Learning

Given the characterization of grounded event pairs from the document, we now define the learning objectives for relation prediction. The goal of learning is to let the model capture the data annotation, meanwhile regularizing the model towards consistency on logic constraints. Inspired by the logic-driven framework for consistency of neural models (Li et al., 2019), we specify three types of consistency requirements, i.e. *annotation consistency*, *symmetry consistency* and *conjunction consistency*. We hereby define the requirements with declarative logic rules, and show how we transform them into differentiable loss functions.

Annotation Consistency For labeled cases, we expect the model to predict what annotations specify. That is to say, if an event pair is annotated with

α \ β	PC	CP	CR	NR	BF	AF	EQ	VG

Table 1: The induction table for conjunctive constraints on temporal and subevent relations. Given the relations $\alpha(e_1, e_2)$ in the left-most column and $\beta(e_2, e_3)$ in the top row, each entry in the table includes all the relations and negations that can be deduced from their conjunction for e_1 and e_3, i.e. $\text{De}(\alpha, \beta)$. The abbreviations PC, CP, CR, NR, BF, AF, EQ and VG denote PARENT-CHILD, CHILD-PARENT, COREF, NOREL, BEFORE, AFTER, EQUAL and VAGUE, respectively. Vertical relations are in black, and TempRel are in blue. "–" denotes no constraints.

relation r, then the model should predict so:

$$\bigwedge_{e_1, e_2 \in \mathcal{E}_D} \top \rightarrow r(e_1, e_2).$$

To obtain the learning objective that preserves the annotation consistency, we use the product t-norm to get the learning objective of maximizing the probability of the true labels, by transforming to the negative log space to capture the inconsistency with the product t-norm. Accordingly, the annotation loss is equivalently defined as the cross entropy

$$L_A = \sum_{e_1, e_2 \in \mathcal{E}_D} -w_r \log r_{(e_1, e_2)},$$

in which w_r is the label weight that seeks to balance the loss for training cases of each relation r.

Symmetry Consistency Given any event pair (e_1, e_2), the grounds for a model to predict a relation $\alpha(e_1, e_2)$ to hold between them should also implies the hold of the converse relation $\bar{\alpha}(e_2, e_1)$. The logical formula is accordingly written as

$$\bigwedge_{e_1, e_2 \in \mathcal{E}_D,\, \alpha \in \mathcal{R}_S} \alpha(e_1, e_2) \leftrightarrow \bar{\alpha}(e_2, e_1),$$

where the $\mathcal{R}_S$ is the set of relations enforcing the symmetry constraint. Particularly for the TempRel extraction task, $\mathcal{R}_S$ contains a pair of reciprocal relations BEFORE and AFTER, as well as two reflexive ones EQUAL and VAGUE. Similarly, the subevent relation extraction task adds reciprocal relations PARENT-CHILD and CHILD-PARENT as well as reflexive ones COREF and NOREL.

Using the product t-norm and transformation to the negative log space as before, we have the symmetry loss:

$$L_S = \sum_{e_1, e_2 \in \mathcal{E}, \alpha \in \mathcal{R}_S} |\log \alpha_{(e_1, e_2)} - \log \bar{\alpha}_{(e_2, e_1)}|.$$

Conjunction Consistency This set of constraints are applicable to any three related events e_1, e_2 and e_3. If we group the events into three pairs, namely $(e_1, e_2), (e_2, e_3)$ and (e_1, e_3), the relation definitions mandate that not all of the possible assignments to these three pairs are allowed. More specifically, if two relations $\alpha(e_1, e_2)$ and $\beta(e_2, e_3)$ apply to the first two pairs of events, then the conjunction consistency may enforce the following two conjunctive rules.

In the first rule, the conjunction of the first two relations infers the hold of another relation γ between the third event pair (e_1, e_3), namely

$$\bigwedge_{\substack{e_1, e_2, e_3 \in \mathcal{E}_D \\ \alpha, \beta \in \mathcal{R},\ \gamma \in \text{De}(\alpha, \beta)}} \alpha(e_1, e_2) \wedge \beta(e_2, e_3) \rightarrow \gamma(e_1, e_3).$$

$\text{De}(\alpha, \beta)$ thereof is a set composed of all relations from $\mathcal{R}$ that do not conflict with α and β, which is a subset of the deductive closure (Stine, 1976) of the conjunctive clause for these two relations. A special case that the above formula expresses is a (task-specific) transitivity constraint, where $\alpha = \beta = \gamma$ present the same transitive relation.

Another condition could also hold, where the former two relations always infer the negation of a certain relation δ on (e_1, e_3), for which we have

$$\bigwedge_{\substack{e_1, e_2, e_3 \in \mathcal{E}_D \\ \alpha, \beta \in \mathcal{R},\ \delta \notin \text{De}(\alpha, \beta)}} \alpha(e_1, e_2) \wedge \beta(e_2, e_3) \rightarrow \neg\delta(e_1, e_3).$$

Table 1 is an induction table that describes all the conjunctive rules for relations in $\mathcal{R}$. To illustrate the conjunction consistency requirement (see the orange cell in Table 1), assume that (e_1, e_2) and (e_2, e_3) are respectively annotated with BEFORE and PARENT-CHILD. Then the two conjunctive formulae defined above infer that we have the relation

BEFORE hold on (e_1, e_3), whereas we should not have CHILD-PARENT hold.

Similar to the other consistency requirements, the loss function dedicated to the conjunction consistency is derived as follows:

$$L_C = \sum_{\substack{e_1,e_2,e_3 \in \mathcal{E}_D, \\ \alpha,\beta \in \mathcal{R}, \gamma \in \mathrm{De}(\alpha,\beta)}} |L_{t_1}| + \sum_{\substack{e_1,e_2,e_3 \in \mathcal{E}_D, \\ \alpha,\beta \in \mathcal{R}, \delta \notin \mathrm{De}(\alpha,\beta)}} |L_{t_2}|,$$

where the two terms of triple losses are defined as

$$L_{t_1} = \log \alpha_{(e_1,e_2)} + \log \beta_{(e_2,e_3)} - \log \gamma_{(e_1,e_3)}$$
$$L_{t_2} = \log \alpha_{(e_1,e_2)} + \log \beta_{(e_2,e_3)} - \log(1 - \delta_{(e_1,e_3)})$$

It is noteworthy that modeling the conjunctive consistency is key to the combination of two different event-event relation extraction tasks, as this general consistency requirement can be enforced between both TempRels and subevent relations.

Joint Learning Objective After expressing the logical consistency requirements with different terms of cross-entropy loss, we combine all of those into the following joint learning objective loss

$$L = L_A + \lambda_S L_S + \lambda_C L_C.$$

The λ's are non-negative coefficients to control the influence of each loss term. Note that since the consistency requirements are defined on both temporal and subevent relations, the model therefore seamlessly incorporates both event-event relation extraction tasks with a shared learning objective. In this case, the learning process seeks to unify the ordered nature of time and the topological nature of subevents, therefore supporting the model to comprehensively understand the event complex.

3.4 Inference

To support task-specific relation extraction, i.e. extracting either a TempRel or a subevent relation, our framework selects the relation r with highest confident score $r_{(e_1,e_2)}$ from either of $\mathcal{R}_T$ and $\mathcal{R}_H$. When it comes to extracting event complexes with both types of relations, the prediction of subevent relations has higher priority. The reason lies in the fact that a relation in $\mathcal{R}_H$, except for NOREL, always implies a TempRel, yet there is not a single TempRel that necessitates a subevent relation.

We also incorporate ILP in the inference phase to further ensure the logical consistency in predicted results. Nevertheless, we show in experiments that a well-trained constrained learning model may not additionally require global inference (§4.5).

4 Experiments

In this section, we present the experiments on event-event relation extraction. Specifically, we conduct evaluation for TempRel and subevent relation extraction based on two benchmark datasets (§4.1-§4.4). To help understand the significance of each model component in the framework, we also give a detailed ablation study (§4.5). Finally, a case study on the RED dataset is described to demonstrate the capability of inducing event complexes (§4.6).

4.1 Datasets

Since there is not a large-scale dataset that amply annotates for both TempRel and subevent relations, we evaluate the joint training and prediction of both categories of relations on two separate datasets. Specifically, we use MATRES (Ning et al., 2018b) for TempRel extraction and HiEve (Glavaš et al., 2014) for subevent relation extraction.

MATRES is a new benchmark dataset for TempRel extraction, which is developed from TempEval3 (UzZaman et al., 2013). It annotates on top of 275 documents with TempRels BEFORE, AFTER, EQUAL, and VAGUE. Particularly, the annotation process of MATRES has defined four axes for the actions of events, i.e. *main*, *intention*, *opinion*, and *hypothetical* axes. The TempRels are considered for all event pairs on the same axis and within a context of two adjacent sentences. The labels are decided by comparing the starting points of the events. The multi-axis annotation helped MATRES to achieve a high IAA of 0.84 in Cohen's Kappa.

The HiEve corpus is a news corpus that contains 100 articles. Within each article, annotations are given for both subevent and coreference relations. The HiEve adopted the IAA measurement proposed for TempRels by (UzZaman and Allen, 2011), resulting in 0.69 F_1.

In addition to these two datasets, we also present a case study on an updated version of the RED dataset (O'Gorman et al., 2016). This dataset contains 35 news articles with annotations for event complexes that contain both membership relations and TempRels. Since small dataset is not sufficient for training, we use it only to demonstrate our method's capability of inducing event complexes on data that are external to training.

We briefly summarize the data statistics for HiEve, MATRES, and RED dataset in Table 3.

Model	P	R	F_1
CogCompTime (Ning et al., 2018c)	0.616	0.725	0.666
Perceptron (Ning et al., 2018b)	0.660	0.723	0.690
BiLSTM+MAP (Han et al., 2019b)	-	-	0.755
LSTM+CSE+ILP (Ning et al., 2019)	0.713	0.821	0.763
Joint Constrained Learning (ours)	**0.734**	**0.850**	**0.788**

Table 2: TempRel extraction results on MATRES. Precision and recall are not reported by (Han et al., 2019b).

	HiEve	MATRES	RED

Test	7093	827	1718

Table 3: Data statistics of HiEve, MATRES, and RED.

4.2 Baselines and Evaluation Protocols

On MATRES, we compare with four baseline methods. Ning et al. (2018b) present a baseline method based on a set of linguistic features and an averaged perceptron classifier (Perceptron). Han et al. (2019b) introduce a BiLSTM model that incorporates MAP inference (BiLSTM+MAP). Ning et al. (2019) present the SOTA data-driven method incorporating ILP and commonsense knowledge from TempProb with LSTM (LSTM+CSE+ILP). We also compare with the CogCompTime system (Ning et al., 2018c). On HiEvewe compare with a structured logistic regression model (StructLR, Glavaš and Šnajder 2014) and a recent data-driven method based on fined-tuning a time duration-aware BERT on large time-related web corpora (TacoLM, Zhou et al. 2020a).

MATRES comes with splits of 183, 72 and 20 documents respectively used for training, development and testing. Following the settings in previous work (Ning et al., 2019; Han et al., 2019b), we report the micro-average of precision, recall and F1 scores on test cases. On HiEve, we use the same evaluation setting as Glavaš and Šnajder (2014) and Zhou et al. (2020a), leaving 20% of the documents out for testing. The results in terms of F_1 of Parent-Child and Child-Parent and the micro-average of them are reported. Note that in the previous setting by Glavaš and Šnajder (2014), the relations are only considered for event pairs (e_1, e_2) where e_1 appears before e_2 in the document. We also follow Glavaš and Šnajder (2014) to populate the annotations by computing the transitive closure of CoRef and subevent relations.

Model	F_1 score PC	CP	Avg.
StructLR (Glavaš et al., 2014)	0.522	**0.634**	0.577
TacoLM (Zhou et al., 2020a)	0.485	0.494	0.489
Joint Constrained Learning (ours)	**0.625**	0.564	**0.595**

Table 4: Subevent relation extraction results on HiEve. PC, CP and Avg. respectively denote Parent-Child, Child-Parent and their micro-average.

4.3 Experimental Setup

To encode the tokens of each document, we employ the officially released 768 dimensional RoBERTa (Liu et al., 2019), which is concatenated with 18 dimensional one-hot vectors representing the tokens' POS tags. On top of those embeddings, the hidden states of the trainable BiLSTM are 768 dimensional, and we only apply one layer of BiLSTM. Since the TempRel extraction and subevent relation extraction tasks are considered with two separate sets of labels, we use two separate softmax functions for normalizing the outputs for each label set from the single MLP. For all the MLPs we employ one hidden layer each, whose dimensionality is set to the average of the input and output space following convention (Chen et al., 2018).

We use AMSGrad (Reddi et al., 2018) to optimize the parameters, with the learning rate set to 0.001. Label weights in the annotation loss L_A is set to balance among training cases for different relations. The coefficients λ_S and λ_D in the learning objective function are both fixed to 0.2. Training is limited to 80 epochs, which is sufficient to converge.

4.4 Results

In Table 2 we report the TempRel extraction results on MATRES. Among the baseline methods, Ning et al. (2019) offer the best performance in terms of F_1 by incorporating an LSTM with global inference and commonsense knowledge. In contrast, the proposed joint constrained learning framework surpasses the best baseline method by a relative gain of 3.27% in F_1, and excels in terms of both precision and recall. While both methods ensure logical constraints in learning or inference phases, the improvement by the proposed method is largely due to the joint constraints combining both TempRel and subevent relations. Learning to capture

Model	SUBEVENT P	SUBEVENT R	SUBEVENT F_1	TEMPREL P	TEMPREL R	TEMPREL F_1
Single-task Training	32.5	**73.1**	45.0	67.7	80.3	73.5
Joint Training	50.4	43.1	46.5	68.4	82.0	74.6

+ Global inference (ILP)	**57.4**	61.7	**59.5**	**73.4**	**85.0**	**78.8**
All but constrained learning	54.2	41.8	47.2	72.1	80.8	76.2

Table 5: Ablation study results (§4.5). The results on HiEve are the micro-average of PARENT-CHILD and CHILD-PARENT. Results in the middle group are achieved by incrementally adding the corresponding model components. The gray-scaled row shows the results of the complete model.

subevent relations from an extrinsic resource simultanously offer auxiliary supervision signals to improve the comprehension on TempRel, even though the resources dedicated to the later is limited.

The results in Table 4 for subevent relation extraction exhibit similar observation. Due to scarcer annotated data, the pure data-driven baseline method (TACOLM) falls behind the statistical learning one (i.e. StructLR) with comprehensively designed features. However, our model successfully complements the insufficient supervision signals, partly by incorporating linguistic and commonsense knowledge. More importantly, while our model is able to infer TempRel decently, the global consistency ensured by cross-task constraints naturally makes up for the originally weak supervision signals for subevent relations. This fact leads to promising results, drastically surpassing TACOLM with a relative gain of 21.4% in micro-average F_1, and outperforming StructLR by $\sim$3% relatively.

In general, the experiments here show that the proposed joint constrained learning approach effectively combines the scarce supervision signals for both tasks. Understanding the event complex by unifying the ordered nature of time and the topological nature of multi-granular subevents, assists the comprehension on both TempRel and memberships among multi-granular events.

Original labels in RED	Mapped labels

SIMULTANEOUS	EQUAL
OVERLAP, REINITIATES	VAGUE
CONTAINS, CONTAINS-SUBEVENT	PARENT-CHILD & BEFORE
BEGINS-ON	AFTER

Table 6: Mapping from relations annotated in the RED dataset to the relations studied in this work.

4.5 Ablation Study

To help understand the model components, we conduct an ablation study and report the results in Table 5. Starting from the vanilla single-task BiLSTM model with only RoBERTa features, changing to joint training both tasks with only annotation brings along 1.1-1.5% of absolute gain in F_1. Incorporating task-specific constraints to learning for relations only in $\mathcal{R}_T$ or $\mathcal{R}_H$ notably brings up the F_1 2.0-8.9%, whereas the cross-task constraints bring along an improvement of 1.0-2.6% in F_1. This indicates that the global consistency ensured within and across TempRel and subevent relations is important for enhancing the comprehension for both categories of relations. The commonsense knowledge leads to another 0.8-1.2% of improvement. Lastly, global inference does not contribute much to the performance in our setting, which indicates that the rest model components are already sufficient to preserve global consistency through joint constrained learning.

To compare both ways of ensuring logical consistency, we also report a set of results in the last row of Table 5, where constrained learning is removed and only global inference is used to cope with consistency requirements in prediction. As expected, this leads to significant performance drop of 2.6-12.3% in F_1. This fact implies that ensuring the logical consistency in the learning phase is essential, in terms of both complementing task-specific training and enhancing the comprehension of event complex components.

4.6 Case Study on the RED Dataset

We use the RED dataset (2019 updated version) to further evaluate our model trained on MATRES

A (***e1:convoy***) of 280 Russian trucks (***e2:headed***) for Ukraine, which Moscow says is (***e3:carrying***) relief goods for war-weary civilians, has suddenly (***e4:changed***) course, according to a Ukrainian state news agency.

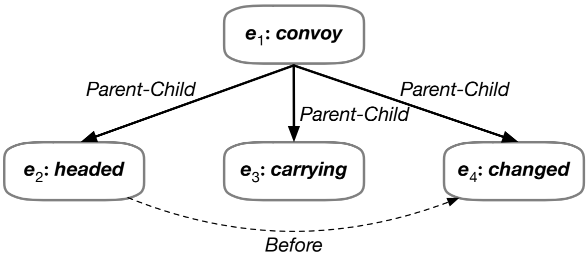

Figure 3: An example of an event complex extracted from a document in RED. Bold arrows denote the PARENT-CHILD relation, and dotted arrows represent the BEFORE relation.

and HiEve for inducing complete event complexes, as well as to show the model's generalizability to an external validation set. Since the labels of RED are defined differently from those in the datasets we train the model on, Table 6 shows the details about how some RED lables are mapped to MATRES and HiEve labels. Other event-event relations in RED are mapped to VAGUE or NOREL according to their relation types, and the relations annotated between entities are discarded. To obtain the event complexes, as stated in §3.4, prediction of subevent relations is given higher priority than that of TempRels. In this way, our model achieves 0.72 F_1 on TempRel extraction and 0.54 F_1 on subevent relation extraction.

Here we give an example of an event complex extracted from the RED dataset in Figure 3, using our joint constrained learning method.

5 Conclusion

We propose a joint constrained learning framework for extracting event complexes from documents. The proposed framework bridges TempRel and subevent relation extraction tasks with a comprehensive set of logical constraints, which are enforced during learning by converting them into differentiable objective functions. On two benchmark datasets, the proposed method outperforms SOTA statistical learning methods and data-driven methods for each task, without using data that is jointly annotated with the two classes of relations. It also presents promising event complex extraction results on RED that is external to training. Thus, our work shows that the global consistency of the event complex significantly helps understanding both temporal order and event membership. For future work, we plan to extend the framework towards an end-to-end system with event extraction. We also seek to extend the conjunctive constraints along with event argument relations.

Abstract

Conventional approaches to event detection usually require a fixed set of pre-defined event types. Such a requirement is often challenged in real-world applications, as new events continually occur. Due to huge computation cost and storage budge, it is infeasible to store all previous data and re-train the model with all previous data and new data, every time new events arrive. We formulate such challenging scenarios as incremental event detection, which requires a model to learn new classes incrementally without performance degradation on previous classes. However, existing incremental learning methods cannot handle semantic ambiguity and training data imbalance problems between old and new classes in the task of incremental event detection. In this paper, we propose a **K**nowledge **C**onsolidation **N**etwork (**KCN**) to address the above issues. Specifically, we devise two components, *prototype enhanced retrospection* and *hierarchical distillation*, to mitigate the adverse effects of semantic ambiguity and class imbalance, respectively. Experimental results demonstrate the effectiveness of the proposed method, outperforming the state-of-the-art model by 19% and 13.4% of whole F1 score on ACE benchmark and TAC KBP benchmark, respectively.

1 Introduction

Event detection (ED) is an important task of information extraction, which aims to identify event triggers and classify them into specific types (Ahn, 2006; Chen et al., 2015). For instance, in the sentence "*A man died when a tank fired on the hotel*", an ED model should be able to recognize two events: a *Die* event triggered by the word "*died*" and an *Attack* event triggered by the word "*fired*".

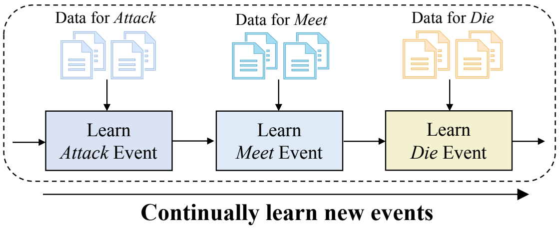

Figure 1: Incremental event detection: a model continually learns new event classes, when data for them becomes available. At any time, the model is able to perform prediction for all event classes observed so far.

Existing ED methods can only handle a fixed number of event classes (also called event types) and perform once-and-for-all training on a fixed dataset. Although the evaluation of this setting is straightforward, it clearly limits the usage of these methods in practical applications, as new events continually emerge in the real world. A practical ED system should be able to incrementally learn new classes, instead of requiring a fixed set of pre-defined event classes. Therefore, we consider a more realistic *incremental learning* setting (also called continual learning or lifelong learning) (Ring, 1994; Thrun, 1998), where a learning system learns from class-incremental data streams in which examples of different event classes arrive at different times, which can be shown in Figure 1. In such scenarios, it is often infeasible to combine the new data with all previous data to re-train the model, due to various issues such as huge computation cost, storage budget and data privacy (McMahan et al., 2017).

Alternatively, a natural approach to incremental event detection is to simply finetune a pre-trained model on new data. However, this approach faces a serious challenge – *catastrophic forgetting* (McCloskey and Cohen, 1989; French, 1999). To be more specific, a learned system usually suffers from significant performance drop on old classes when it adapts to new classes. For example in Figure 2, after finetuning on the training data of new class (i.e., *Attack*), the updated model can recog-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 707–717,
November 16–20, 2020. ©2020 Association for Computational Linguistics

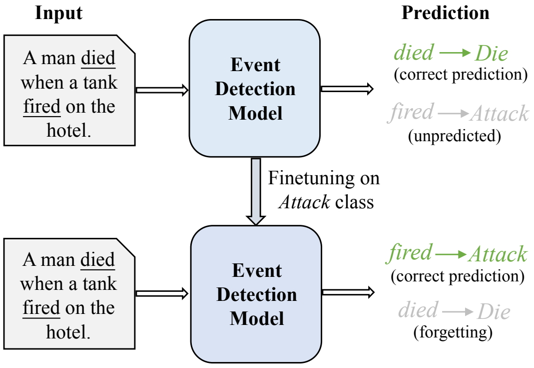

Figure 2: Catastrophic forgetting in incremental event detection. Top: An event detection model originally trained for *Die* class, successfully recognizes the *Die* event, and cannot predict *Attack* event, due to no training on *Attack* class. Bottom: After finetuning on *Attack* class, the updated model can recognize the *Attack* event, but fails to recognize the *Die* event, due to forgetting previous knowledge.

nize the *Attack* event, but fails to detect the *Die* event, which it was capable of originally.

Great efforts have been devoted to overcoming the catastrophic forgetting on the image classification task, which can be mainly divided into parameter-based methods which try to identify and preserve significant parameters of the original model (i.e., the model learned on old classes) (Kirkpatrick et al., 2017; Aljundi et al., 2018), and replay-based methods which reserve a small amount of data from each old class. When new classes arrive, the stored data and new data are combined to re-train the model (Rebuffi et al., 2017; Hou et al., 2018, 2019). Since replay-based methods are very simple and effective, such methods have dominated the research.

However, when applying replay-based methods to incremental event detection, we find two challenges: 1) *Semantic Ambiguity* problem and 2) *Class Imbalance* problem. ***Semantic Ambiguity***: Compared with simple image classification task, event detection has more serious ambiguity problem (Chen et al., 2018). For example, in the sentence "*He left the company*", the word "*left*" can not only trigger *End-Position* event, but also trigger *Transport* event. By contrast, the example "*He resigned his position as manager*" can more accurately express *End-Position* event and is more representative for the *End-Position* class. The ambiguous examples could confuse the classifier, affecting the generalization ability (Liu et al., 2014). It indicates that re-training the model with ambiguous old examples isn't conducive to retaining previous knowledge. Therefore, to alleviate semantic ambiguity, we need to reserve the most representative examples for each class. ***Class Imbalance***: Since only a small number of old data is stored while the number of new classes data is usually large, there is a serious training data imbalance between old and new classes. Under this circumstance, the focus of the training process is significantly biased towards new classes (He and Garcia, 2009; Wu et al., 2019), which severely misleads the classifier. It is a crucial cause of catastrophic forgetting.

In response to the above problems, we propose a **K**nowledge **C**onsolidation **N**etwork (**KCN**) for preserving previous knowledge. Specifically, to address the semantic ambiguity issue, we devise a *prototype enhanced retrospection* module to reserve the most representative examples for each old class. To reduce the adverse effect of class imbalance, we propose a *hierarchical distillation* module which makes the current model mimic the behaviors of the original model in feature level and event class prediction level, respectively. Experimental results demonstrate that our method outperforms previous state-of-the-art models. In summary, the contributions of this paper are listed as follows:

- To our best knowledge, we are the first to introduce the incremental event detection task and we construct two incremental event detection benchmarks by using two widely used ED datasets, ACE 2005 and TAC KBP 2017.
- We propose a knowledge consolidation network for incremental event detection task, which can efficiently alleviate catastrophic forgetting problem via prototype enhanced retrospection and hierarchical distillation.
- Experimental results show that our method outperforms previous state-of-the-art models, achieving 19% and 13.4% improvements of whole F1 score on the ACE benchmark and TAC KBP benchmark, respectively. The source code of this paper is available at `https://github.com/CPF-NLPR/IncrementalED`.

2 Problem Definition

Event detection (ED) is a subtask of event extraction (EE). We first introduce some Automatic Content Extraction (ACE) terminologies to facilitate the understanding of ED task: **Event trigger** refers

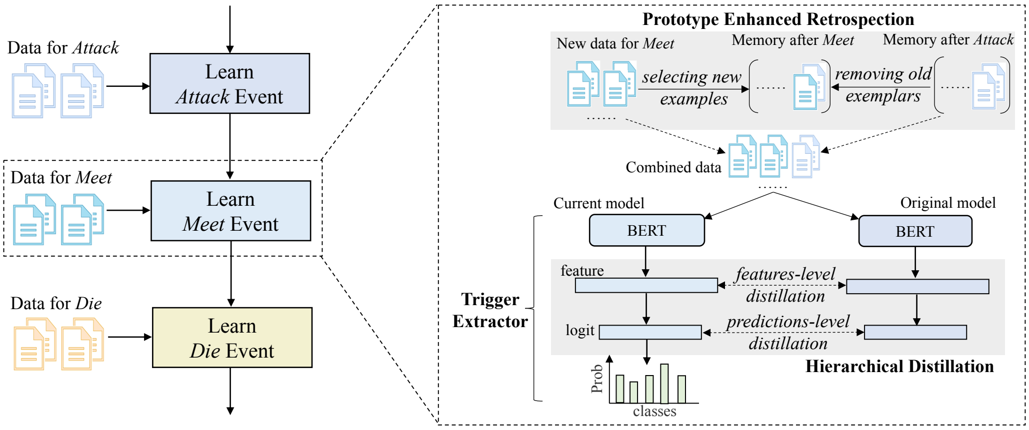

Figure 3: Illustration of **K**nowledge **C**onsolidation **N**etwork (**KCN**). When learning *Meet* event, the model is first updated with the combination of training data for *Meet* event and stored data in memory (i.e., memory after *Attack*). Then the model selects the representative examples to reserve. Since the size of memory is limited, the memory need to remove some reserved exemplars of old classes to allocate space for *Meet* event. Note that there is only one memory. For better understanding, we show the memory states after learning *Attack* and *Meet*, respectively.

to a word that most clearly expresses the occurrence of an event. **Event arguments** are participants of the event. **Event mention** refers to a phrase or sentence within which an event is described.

Given a sentence or document, an ED system aims to locate event triggers and categorize their types. For example, in the sentence "*A man died in the hospital*", an ED system is expected to detect a *Die* event along with the trigger word "*died*". Following previous work (Chen et al., 2015; Nguyen et al., 2016; Liu et al., 2018a), we formulate ED as a token-level multi-class classification task. Namely, given a sentence, we treat every token in it as a trigger candidate, and we aim to classify each candidate into pre-defined event classes.

In real world, new event classes continually occur. Therefore, a practical ED system should enable to incrementally learn new event classes. We introduce a new problem, *incremental event detection*. Suppose that there a class-incremental data stream, denoted as $\{\mathcal{X}^{(1)}, \mathcal{X}^{(2)}, \ldots, \mathcal{X}^{(M)}\}$. Each $\mathcal{X}^{(k)}$[1] contains training/validation/testing data $(\mathcal{X}^{(k)}_{\text{train}}, \mathcal{X}^{(k)}_{\text{valid}}, \mathcal{X}^{(k)}_{\text{test}})$ and its own event class set $\mathcal{C}^{(k)}$. Any two event class sets are disjoint (i.e., $\mathcal{C}^{(i)} \bigcap \mathcal{C}^{(j)} = \emptyset$, $i \neq j$). At step k, the event detection model optimizes its parameters using the training data $\mathcal{X}^{(k)}_{\text{train}}$ and the updated model should still perform well on all previous observed classes. That is to say, during testing stage at step k, we evaluate the updated model on the testing data of all observed classes (i.e., $\bigcup_{i=1}^{k} \mathcal{X}^{(i)}_{\text{test}}$). Given an input from $\mathcal{X}^{(j)}$ $(j \leq k)$, the model ought to give a prediction from $\bigcup_{i=1}^{k} \mathcal{C}^{(i)}$, instead of $\mathcal{C}^{(j)}$.

To alleviate catastrophic forgetting, a bounded memory is allowed to store a small amount of old classes data. Therefore, every time new classes arrive, the event detection model exploits the reserved old classes data and the training data of new classes to update parameters.

3 Method

We propose a **K**nowledge **C**onsolidation **N**etwork (**KCN**) for incremental event detection, which is illustrated in Figure 3. The model consists of three important components: 1) *Trigger Extractor*, 2) *Prototype Enhanced Retrospection* and 3) *Hierarchical Distillation*. When new classes occur, the proposed KCN model updates the parameters with the combination of reserved old classes data and training data of new arriving classes. The prototype enhanced retrospection retains previous knowledge via reserving the most representative examples. The hierarchical distillation transfers the previous knowledge from the original model to the current model. We will detail these three components.

3.1 Trigger Extractor

Our trigger extractor is based on the Transformer architecture (Vaswani et al., 2017). We use the state-of-the-art text encoder BERT (Devlin et al., 2019) to encode the input sentence. BERT is a multi-layer bidirectional Transformer, pre-trained on a large-scale unlabeled corpus, which has achieved the state-of-the-art performance for event detection

---

[1] In general, $\mathcal{X}^{(k)}$ can contain one or more new classes.

(Wang et al., 2019b; Yang et al., 2019).

When new classes $\mathcal{C}^{(k)}$ arrive, the training data of the new classes is denoted as $\mathcal{X}^{(k)}_{\text{train}} = \{(X_i, Y_i), 1 \leq i \leq K\}$, where K is the number of training examples, X_i is the sentence and Y_i denotes the label of each token in the sentence X_i. The memory reserves the representative examples for old m classes (i.e., $m = |\bigcup_{i=1}^{k-1} \mathcal{C}^{(i)}|$), denoted as $\mathcal{P} = \{\mathcal{P}^{(1)}, \ldots, \mathcal{P}^{(m)}\}$, where $\mathcal{P}^{(i)}$ is the set of stored examples for i-th class. We combine the stored old data and training data of new classes data, denoted as $\mathcal{N} = \mathcal{P} \bigcup \mathcal{X}^{(k)}_{\text{train}}$, to train the current model. The target label set contains all observed event types, denoted as $\mathcal{C}^o = \bigcup_{i=1}^{k} \mathcal{C}^{(i)}$. The token [CLS] and [SEP][2] are placed at the start and end of the sentence, respectively. We first leverage BERT to obtain the contextual representation for each token. Then a multi-classifier (i.e., softmax classifier) is added on BERT to predict event types. As general, we adopt cross entropy as the loss function to train the event detection model:

$$\mathcal{L}_{ce} = -\frac{1}{|\mathcal{N}|} \sum_{X \in \mathcal{N}} \sum_{x \in X} \boldsymbol{y} \cdot \log(\boldsymbol{p}) \qquad (1)$$

where $\boldsymbol{y}$ is the one-hot ground-truth label for token x and $\boldsymbol{p}$ is the corresponding class probabilities obtained by softmax. The size of them is the number of all observed classes, i.e., $|\mathcal{C}^o|$.

Since event detection has serious ambiguity problems and the capacity of memory is bounded, we need to reserve the most representative examples for old classes. We devise a prototype enhanced retrospection to achieve the objective.

3.2 Prototype Enhanced Retrospection

In our model, all classes are treated equally, i.e., when m classes have been learned so far and B is the total number of examples that can be reserved in a memory, our model will store $n = B/m$ examples for each class. Since the size of memory is limited, when new classes arrive, the memory unit performs two operations: one to select representative examples to reserve for new classes and one to remove some stored examples of old classes to allocate space for new classes.

3.2.1 Selecting Representative Examples

At step k, when the training data of new classes $\mathcal{C}^{(k)}$ is added to the model, we compute the *prototype* for each class in $\mathcal{C}^{(k)}$:

$$\boldsymbol{\mu}_c = \frac{1}{N_c} \sum_{i=1}^{N_c} \boldsymbol{z}_i \qquad (2)$$

where N_c is the number of training samples for class $c \in \mathcal{C}^{(k)}$ and $\boldsymbol{z}_i$ is representation of sentence X_i belonging to class c. Expressing an event usually requires the whole of information of a sentence, therefore, we use the representation of [CLS] token as the sentence representation. We refer to $\boldsymbol{\mu}_c$ as the *prototype* of class c.

Inspired by the recent works about prototype learning (Snell et al., 2017; Yang et al., 2018) which refer to the prototype as the class representative point in feature space, we devise a prototype-based selection algorithm. For each class, the algorithm computes the distance between each training example and the corresponding prototype, and then produces a sorted list of samples of one class based on the distance to the prototype of that class. Intuitively, the closer the example to the prototype, the more representative the example is for the class. Based on the sorted list of examples, the first n examples of the list are selected as exemplars to store in a bounded memory.

3.2.2 Removing Reserved Exemplars

Since the storage size of memory is constant, when new classes arrive, the memory needs to remove some reserved examples of old classes to allocate space for the examples from new classes. Suppose the number of old and new classes is m and t ($t = |\mathcal{C}^{(k)}|$), respectively. The memory needs to remove $B/m - B/(m+t)$ stored examples of each old class. We adopt a data-independent removal strategy. For each old class, we remove examples that are far from prototype according to the sorted list of examples. In this way, the most representative examples of old classes are still reserved.

3.3 Hierarchical Distillation

Although storing a small number of old data is very useful to improve performance, the number of training samples between old and new classes is very imbalanced, which makes the model have a bias towards the new classes, resulting in severely forgetting previous knowledge (Wu et al., 2019; Hou et al., 2019).

Since the original model isn't trained on the new classes data, it is less biased towards the new classes compared with the current model. Therefore, if the knowledge of the original model is well

---

[2] [CLS] and [SEP] are special tokens of BERT.

preserved, the adverse effects of the imbalance will be efficiently mitigated. Knowledge distillation is an effective way to transfer knowledge from one network to another (Hinton et al., 2015). Inspired by it, we propose a hierarchical distillation to learn the previous knowledge from the original model. The core idea is as follows: for the same input, if the current model can extract similar features, and give similar prediction distributions with the original model on previous classes, it can be assumed that the current model can efficiently preserve the previous knowledge.

3.3.1 Features-level Distillation

We use the BERT as feature extractor, denoted as $f(\cdot)$. For the input x, the extracted features of original model and current model are $f^*(x)$ and $f(x)$, respectively. To enforce extracted features not to bias towards new classes, we propose a features-level distillation loss function:

$$\mathcal{L}_{fd} = \frac{1}{|\mathcal{N}|} \sum_{X \in \mathcal{N}} \sum_{x \in X} 1 - \langle \bar{f}^*(x), \bar{f}(x) \rangle \tag{3}$$

where $\bar{f}^*(x)$ and $\bar{f}(x)$ are l_2-normalized features extracted by the original model and current model, respectively. $\langle \bar{f}^*(x), \bar{f}(x) \rangle = \bar{f}^*(x)^T \bar{f}(x)$ measures the cosine similarity between two normalized feature vectors. The features-level distillation loss is computed for all samples from the new classes and reserved exemplars.

If the extracted features of the current model don't greatly deviate from the ones of the original model, the feature extractor can effectively preserve previous knowledge.

3.3.2 Predictions-level Distillation

Besides features-level distillation loss, we also propose a predictions-level distillation loss, which preserves the previous knowledge of classifier by encouraging the current predictions on old classes to match the soft labels by the original model. At step k, t ($t = |\mathcal{C}^{(k)}|$) new classes arrive, and the model has observed m old classes. For token x, the output logits (i.e., the results before softmax) of the original and current model are $\boldsymbol{o}^* = [o_1^*, o_2^*, \ldots, o_m^*]$ and $\boldsymbol{o} = [o_1, o_2, \ldots, o_{m+1}, \ldots, o_{m+t}]$, respectively. The predictions-level distillation loss is formulated as follows:

$$\begin{aligned} \mathcal{L}_{pd} &= -\frac{1}{|\mathcal{N}|} \sum_{X \in \mathcal{N}} \sum_{x \in X} \sum_{i=1}^{m} \tau_i^* \log(\tau_i), \\ \tau_i^* &= \frac{e^{o_i^*/T}}{\sum_{j=1}^{m} e^{o_j^*/T}}, \quad \tau_i = \frac{e^{o_i/T}}{\sum_{j=1}^{m} e^{o_j/T}} \end{aligned} \tag{4}$$

where T is the temperature scalar, which is usually set to be greater than 1 (e.g., $T = 2$ in our experiments) to increase the weights of small values. The predictions-level distillation loss is also computed for all samples from the new classes and reserved exemplars from the old classes.

Algorithm 1 Training Procedures of KCN

```
Input: training data $\mathcal{X}^{(k)}_{\text{train}}$ at step $k$, the number of new classes $t = |\mathcal{C}^{(k)}|$
Require: memory capacity $B$
Require: current model parameters $\Theta$
Require: current reserved exemplar sets $\mathcal{P} = (\mathcal{P}^{(1)}, \ldots, \mathcal{P}^{(m)})$, $m$ classes occured
Form combined training set: $\mathcal{X}^{(k)}_{\text{train}} \bigcup \mathcal{P}$
Update the model parameters $\Theta$ with loss function $\mathcal{L} = \mathcal{L}_{ce} + \alpha\mathcal{L}_{fd} + \beta\mathcal{L}_{pd}$
Compute the number of exemplars per class: $n \leftarrow B/(m+t)$
for $c = 1, \ldots, m$ do
    Remove some reserved exemplars for old class $c$ until the number of exmplars is $n$
end for
for $c = m+1, \ldots, m+t$ do
    Compute the prototype for new class $c$ via Equation (2)
    Select the examples to store in a memory according to the distance to prototype
end for
```

3.4 Training

Our approach addresses the catastrophic forgetting problem by storing the most representative examples for each class and reducing the impact of class imbalance. Combining the losses presented above, we reach a total loss comprised of three terms, given as:

$$\mathcal{L} = \mathcal{L}_{ce} + \alpha\mathcal{L}_{fd} + \beta\mathcal{L}_{pd} \tag{5}$$

where α and β are adjustment coefficients. If α and β are very large, the model will place more emphasis on the old classes, hurting the performance on new classes. The coefficients are used to balance the performance on old classes and new classes.

The overall training procedures is outlined in Algorithm 1.

4 Experiments

4.1 Incremental Event Detection Benchmarks

So far, there is no benchmark for evaluating incremental event detection models. Therefore, we propose the following construction method: for a given event detection dataset, the classes are arranged in a fixed order. Each method is then trained in a class-incremental way on the available training data. Based on two widely used datasets, ACE 2005[3] and TAC KBP 2017[4], we introduce two instantiations of the above construction method. 1) *ACE benchmark*: We use the dataset split of ACE dataset as suggested in (Li et al., 2013; Chen et al., 2015; Lu et al., 2019; Liu et al., 2019). Since the ACE dataset has long-tail frequency distribution, we exploit the data of the top 10 most frequent classes. 2) *TAC KBP benchmark*: We exploit the official training and testing data of TAC KBP. Same as the ACE benchmark, we also use the data of the top 10 most frequent classes. For both of two benchmarks, one new class is available for the model at each time.

4.2 Evaluation Metrics and Implementation Details

For conventional event detection, Precision (P), Recall (R) and F1 score are used as evaluation metrics. For incremental event detection, every time the model finishes training on the new classes data, we report the F1 score on the test data of all observed classes. For example, after time step k, the result is denoted as $F1_k$. Therefore, these results can be plotted as a curve. In addition, if a single number is preferable, we report the ***Average F1*** which is the average of these F1 scores (i.e., $\frac{1}{k}\sum_{i=1}^{k} F1_i$), and ***Whole F1*** which is the F1 score on the whole testing data of all classes.

Our method uses the HuggingFace's Transformers library[5] to implement BERT base model. The learning rate is set to 2e-5. The batch size is 16. The adjustment coefficients α and β are both 0.5. For the two benchmarks, the capacity of memory is 100 and 500, respectively.

4.3 Baselines

We compare our approach KCN with the following baselines:

EWC (Kirkpatrick et al., 2017). The method is proposed to keep the network parameters close to the optimal parameters for the previous classes while training new classes data. It is the representative work of parameter-based methods.

EMR (Wang et al., 2019a). The method alleviates the impact of catastrophic forgetting via randomly storing some samples of old classes, which is the representative work of replay-based methods.

LwF (Li and Hoiem, 2017). The method aims to match the softmax output of the network of previous models for old classes, which is also a widely used incremental learning method.

Finetune. A straightforward method which simply finetunes the pre-trained model on new arriving data. We exploit the state-of-the-art model (i.e., BERT) for finetuning.

UpperBound. A model is trained using all training samples from all observed classes, which can provide the upper bound of the benchmark.

4.4 Compared with State-of-the-art Methods

We conduct experiments on ACE benchmark and KBP benchmark to compare our proposed methods with the above baselines. The F1 scores over all observed classes during the whole incremental learning process are presented in Figure 4. We also list the results at the last step in Table 1. From the results, we can observe that:

(1) Our method outperforms all the baselines by a large margin. For example, compared with the state-of-the-art model EMR, our method achieves 19% and 13.4% improvements of whole F1 score on the ACE benchmark and TAC KBP benchmark, respectively. It indicates that our proposed method KCN is very effective for the incremental event detection task.

(2) EMR and LwF can achieve competitive performance at the beginning. However, the gap between the two baselines and our method KCN becomes wider as more new classes arrive. The reason is that data imbalance becomes more serious as the incremental step increases, since the total capacity of memory is bounded. It demonstrates

LwF	47.7	11.2	33.1	17.4
EMR	55.3	36.1	35.5	21.5
KCN(Ours)	**65.9**	**55.1**	**44.3**	**34.9**

Table 1: The average F1 (%) on all observed classes ("Avg" column), and whole F1 (%) on the whole testing data ("Whole" column) after the last time step.

Models	ACE		TAC KBP	
	Avg	Whole	Avg	Whole
KCN	**65.9**	**55.1**	**44.3**	**34.9**
w/o PS	62.1	51.6	41.8	32.2
w/o FD	64.1	53.2	42.4	32.7
w/o PD	59.7	50.6	38.2	27.4
w/o HD	58.2	44.3	36.8	24.0
w/o PS and HD	55.3	36.1	35.5	21.5

Table 2: Ablation studies by removing the main components, where "w/o" indicates without. "PS", "FD", "PD" and "HD" refer to "prototype-based selection", "features-level distillation", "predictions-level distillation" and "hierarchical distillation", respectively. Actually, "HD" is the combination of "FD" and "PD".

that data imbalance between old and new classes are well handled in our approach.

(3) Finetuning always achieves the worst results on the two benchmarks, confirming that catastrophic forgetting is indeed a major problem in incremental event detection. In addition, the gap between these incremental learning methods and the UpperBound model indicates that incremental event detection is a very challenging task.

4.5 Ablation Experiment

To investigate the effectiveness of the prototype enhanced retrospection and hierarchical distillation, we conduct the ablation studies. The experimental results are listed in Table 2. Overall, we can observe that:

(1) Effectiveness of Prototype Enhanced Retrospection. Compared with the model removed prototype-based selection (PS), i.e., randomly selecting examples, our model KCN improves the average F1 score from 62.1% to 65.9% on the ACE benchmark. It indicates the prototype enhanced retrospection is able to effectively select the most representative examples for each class.

(2) Effectiveness of Hierarchical Distillation. We can see that removing any submodule of hierarchical distillation (features-level distillation (FD) or predictions-level distillation (PD)) brings performance degradation. If we remove the entire hierarchical distillation module (HD), the performance further declines. It demonstrates the hierarchical distillation is very effective to alleviate the class imbalance problem.

(3) Effectiveness of Prototype Enhanced Retrospection and Hierarchical Distillation. When we remove the prototype-based selection and hierarchical distillation, the performance drops significantly. The whole F1 score drops from 34.9% to 21.5% on the TAC KBP benchmark. It indicates simultaneously exploiting the prototype enhanced retrospection and hierarchical distillation is also

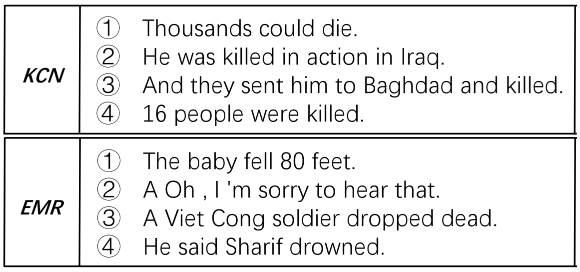
60	**69.1**	**60.8**	**65.2**	**53.4**

Table 3: The effect of the number of reserved samples. We compare our method KCN with the replay-based method EMR on the ACE benchmark.



KCN	① Thousands could die. ② He was killed in action in Iraq. ③ And they sent him to Baghdad and killed. ④ 16 people were killed.
EMR	① The baby fell 80 feet. ② A Oh , I 'm sorry to hear that. ③ A Viet Cong soldier dropped dead. ④ He said Sharif drowned.

Figure 5: Sampling some reserved examples of *Die* class for case study to qualitatively illustrate the effectiveness of our method.

very effective.

4.6 Discussion

4.6.1 The effect of the number of reserved samples

To reserve a few samples has proven much helpful to maintain the performance on old classes (Rebuffi et al., 2017; Wang et al., 2019a). Table 3 shows the comparison of our approach with EMR reserving different number of samples per class. From the results, we can observe that:

(1) The more samples reserved, the better performance for both EMR and our approach KCN. While in each case, the results of our approach are superior to those of EMR. It demonstrates the effectiveness of our proposed method.

(2) Even reserved fewer samples, our method still achieves better performance than EMR, which indicates that the prototype enhanced retrospection can select the most representative examples and hierarchical distillation enables to reduce the impact of class imbalance.

4.6.2 Case Study

We sample some reserved examples of *Die* event type of our approach and EMR during training to conduct a case study for qualitatively analyzing the effects of our method. It is shown in Figure 5. Although the reserved sentence "*A Oh, I 'm sorry to hear that*" of EMR may express the *Die* event, it is very obscure and implicit. By contrast, the reserved examples of our method can more accurately express the type and are more representative. The example qualitatively demonstrates our method is able to select the most representative examples.

5 Related Work

In this section, we briefly review two related topics: event detection and incremental learning.

5.1 Event Detection

Event detection (ED) is a very important task in information extraction. The proposed models can be divided into feature-based methods (Ahn, 2006; Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013; Li and Ji, 2014) and neural network-based methods (Chen et al., 2015; Nguyen and Grishman, 2015; Liu et al., 2017, 2018a,b; Lu et al., 2019; Ding et al., 2019).

In feature-based methods, a diverse set of features is exploited to predict event. Ahn (2006) leverage lexical features, syntactic features and external knowledge features to extract the event. Hong et al. (2011) propose a cross-event and cross-entity inference method to capture more clues. However, feature-based methods rely heavily on handcrafted features, limiting the scalability and robustness. In recent years, neural network-based methods have dominated the research. Chen et al. (2015) exploit the convolutional neural network for event extraction. Nguyen et al. (2016) leverage the recurrent neural network to model the dependency of triggers and arguments. Wang et al. (2019b) and Yang et al. (2019) exploit the BERT for event detection.

Despite the vast progress that event detection has made in recent years, these existing methods cannot address incremental event detection task.

5.2 Incremental Learning

Incremental learning has been a long standing problem in machine learning (Cauwenberghs and Poggio, 2001; Kuzborskij et al., 2013). Existing methods can be divided into two categories, parameter-based methods (Kirkpatrick et al., 2017; Aljundi et al., 2018) and replay-based methods (Rebuffi et al., 2017; Hou et al., 2019; Wang et al., 2019a).

In parameter-based methods, these methods try to identify and preserve significant parameters of the original model (Kirkpatrick et al., 2017; Zenke et al., 2017; Aljundi et al., 2018). However, it is difficult to design a reasonable metric to evaluate all the parameters. In replay-based methods, these methods preserve the previous knowledge via storing a small number of old data (Castro et al., 2018; Wang et al., 2019a; Han et al., 2020). Wang et al. (2019a) propose an episodic memory replay (EMR) method which randomly selects examples to reserve in a memory.

Despite the effectiveness of these methods on image classification tasks, these methods cannot handle semantic ambiguity problem and class imbalance problem in incremental event detection.

6 Conclusion

In this paper, we introduce incremental learning into event detection and propose a knowledge consolidation network to preserve previously learned knowledge. To alleviate semantic ambiguity, we devise the prototype enhanced retrospection to reserve the most representative examples. Moreover, to mitigate the adverse effect of class imbalance, we propose the hierarchical distillation to learn the previous knowledge from the original model. Experimental results demonstrate that our model outperforms previous state-of-the-art methods.

Semi-supervised New Event Type Induction and Event Detection

Lifu Huang and Heng Ji
Computer Science Department
University of Illinois at Urbana-Champaign
`{lifuh2,hengji}@illinois.edu`

Abstract

Most previous event extraction studies assume a set of target event types and corresponding event annotations are given, which could be very expensive. In this paper, we work on a new task of semi-supervised event type induction, aiming to automatically discover a set of unseen types from a given corpus by leveraging annotations available for a few seen types. We design a Semi-Supervised Vector Quantized Variational Autoencoder framework to automatically learn a discrete latent type representation for each seen and unseen type and optimize them using seen type event annotations. A variational autoencoder is further introduced to enforce the reconstruction of each event mention conditioned on its latent type distribution. Experiments show that our approach can not only achieve state-of-the-art performance on supervised event detection but also discover high-quality new event types. [1]

1 Introduction

Event extraction is a task of automatically identifying and typing event trigger words (Event Detection), and extracting participants for each trigger (Argument Extraction) from natural language text. Traditional event extraction studies (Ji and Grishman, 2008; McClosky et al., 2011; Li et al., 2013; Chen et al., 2015; Yang and Mitchell, 2016; Liu et al., 2018; Nguyen and Nguyen, 2019; Lin et al., 2020; Li et al., 2020) usually assume there exists a set of predefined event types and argument roles, so that supervised machine learning models, e.g., deep neural networks, can be employed to extract events for each type based on human annotations. However, in practice, it is usually very expensive and time-consuming to manually craft an event schema, which defines the types and complex templates of the expected events. Moreover, the coverage of manually crafted schemas is often very low, making them fail to generalize to new scenarios.

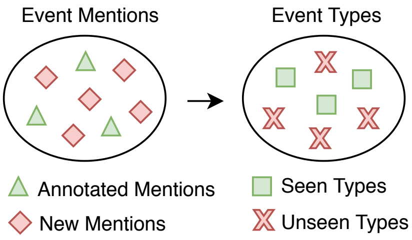

Figure 1: Semi-supervised new event type induction: discovering a set of new event types and their event mentions given the annotations for a few seen types.

Recent studies have shown that it's possible to automatically induce an event schema from raw text. Some researchers explore probabilistic generative methods (Chambers, 2013; Nguyen et al., 2015; Yuan et al., 2018; Liu et al., 2019) or ad-hoc clustering-based algorithms (Huang et al., 2016) to discover a set of event types and argument roles. Several studies (Huang et al., 2018; Lai and Nguyen, 2019) also explore zero-shot and few-shot learning approaches to leverage available resources and extend event extraction to new types. Generally, event schema induction can be divided into two steps: event type induction, aiming to discover a set of new event types for the given scenario, and argument role induction which discovers a set of argument roles for each type. In this work, we focus on tackling the first problem only.

We propose a task of semi-supervised event type induction, which is shown in Figure 1 and aims to leverage available event annotations for a few types, which are called as *seen* types, and automatically discover a set of new *unseen* types, as well as their corresponding event mentions. As a solution, we design a new Semi-supervised Vector Quantized Variational Autoeocoder framework (short as **SS-VQ-VAE**) which first assigns a discrete latent type

---

November 16–20, 2020. ©2020 Association for Computational Linguistics

representation for each seen and unseen type, and optimizes them during the process of projecting each candidate trigger into a particular seen or unseen type. The candidate triggers are discovered with a heuristic approach.

Experiments under the setting of both supervised event detection and new event type induction demonstrate that our approach can not only detect event mentions for seen types with high precision, but also discover high-quality new unseen types.

2 Approach

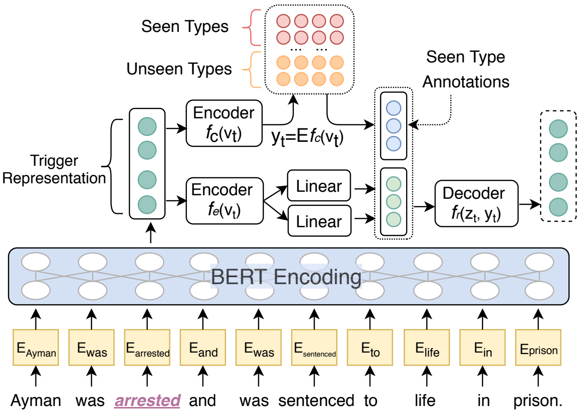

Figure 2: Architecture Overview.

As Figure 2 shows, given an input sentence, we first automatically discover all candidate triggers and encode each trigger with a contextual vector using a pre-trained BERT (Devlin et al., 2019) encoder. Then, we predict the type of each candidate trigger by looking up a dictionary of discrete latent representations of all seen and unseen types. Meanwhile, to avoid the type prediction to be over-fitted to seen types, we apply a variational autoencoder (VAE) as a regularizer to first project each trigger into a latent variational embedding and then reconstruct the trigger conditioned on its type distribution.

2.1 Event Trigger Identification

Similar to (Huang et al., 2016), we identify all candidate triggers based on word sense induction. Specifically, for each word, we disambiguate its senses and link each sense to OntoNotes (Hovy et al., 2006) using a word sense disambiguation system — IMS (Zhong and Ng, 2010) [2]. We consider all noun and verb concepts that can be mapped to OntoNotes senses as candidate triggers. In addition, the concepts that can be matched with verbs or nominal lexical units in FrameNet (Baker et al., 1998) are also considered as candidate triggers.

2.2 Trigger Representation Learning

Given a sentence $s = [w_1, ..., w_n]$, where we assume w_i is identified as a candidate trigger, we use a pre-trained BERT encoder to encode the whole sentence and get a contextual representation for w_i. If w_i can be split into multiple subwords or words, we use the average of all subword vectors as the final trigger representation.

2.3 Event Type Prediction with Vector Quantization

To predict a type for a candidate trigger, an intuitive approach is to learn a classifier using the event annotations of seen types. However, as we also aim to discover a set of unseen types, without any annotations, the classifier for the unseen types cannot be optimized.

To solve this problem, we employ a Vector Quantization (Gersho and Gray, 2012) strategy. We first define a discrete latent event type embedding space $\boldsymbol{E} \in \mathrm{R}^{k \times d}$, where k is the number of candidate event types, and d is the dimensionality of each type embedding $\boldsymbol{e}_i$. Each $\boldsymbol{e}_i$ can be viewed as the *centroid* of the triggers belonging to the corresponding event type. For each seen type, we initialize $\boldsymbol{e}$ with the contextual vector of a trigger which is randomly selected from the corresponding annotations. For each unseen type, we initialize $\boldsymbol{e}$ with the contextual vector of another trigger which is randomly picked from all unannotated event mentions. Assuming there are m seen types, we arbitrarily assign $\boldsymbol{E}^{[1:m]}$ as their type representations.

Given a candidate trigger t and its contextual vector $\boldsymbol{v}_t$, we first apply a linear encoder $f_c(\boldsymbol{v}_t) \in \mathrm{R}^d$ to extract type-specific features. Then, we compute a type distribution $\boldsymbol{y}$ based on $f_c(\boldsymbol{v}_t)$ by looking up all the discrete latent event type embeddings with inner-product operation

$$\boldsymbol{y}_t = \mathrm{Softmax}(\boldsymbol{E}^{[1:k]} \cdot f_c(\boldsymbol{v}_t)) \tag{1}$$

The feature encoder $f_c(.)$ is optimized using all event annotations for seen types (the cross-entropy term in Equation 2) and event mentions for unseen types (the second term in Equation 2 [3]). The intuition of the second term in Equation 2 is that, for each new event mention, we don't know the correct type but we know that the type must be from

---

[2] We use the OntoNotes based IMS word sense disambiguator (`https://github.com/c-amr/camr`)

[3] We only apply this term when we know the new event mentions do not belong to any seen types

a set of unseen types, so we maximize the margin between the probability of the most likely unseen type and the highest probability of the incorrect seen type.

$$\mathcal{L}_c = \sum_{(t,\tilde{y}_t)\in D_s} -\tilde{\boldsymbol{y}}_t \log(\boldsymbol{y}_t) + \sum_{t\in D_u} \max(\boldsymbol{y}_t^{[1:m]}) - \max(\boldsymbol{y}_t^{[m:k]}) \tag{2}$$

where $-\tilde{y}_t$ is the ground truth label. D_s and D_u denote the set of annotated event mentions for seen types and new event mentions for unseen types. $\boldsymbol{y}_t^{[1:m]}$ and $\boldsymbol{y}_t^{[m:k]}$ are the type prediction scores for seen and unseen types respectively.

To optimize the type embeddings $\boldsymbol{E}$, we follow the VQ objective (van den Oord et al., 2017) and use l_2 error to move the type vector $\boldsymbol{e}_i$ towards the type-specific feature $f_c(\boldsymbol{v}_t)$ (the first term in Equation 3) while $\boldsymbol{e}_i$ of t is determined by $\boldsymbol{y}_t$. To make sure $f_c(.)$ commits to an embedding, we add a commitment loss (the second term in Equation 3)

$$\mathcal{L}_{vq} = ||\mathrm{sg}(f_c(\boldsymbol{v}_t)) - \boldsymbol{e}_i||^2 + ||f_c(\boldsymbol{v}_t) - \mathrm{sg}(\boldsymbol{e}_i)||^2 \tag{3}$$

where sg stands for the stop gradient operator to make its operand to be a non-updated constant. The output of sg is the same as the input in the forward pass, and it is zero when computing gradients in the training process.

2.4 Variational Autoencoder as Regularizer

To avoid the type prediction to be over-fitted to the seen types, we employ a semi-supervised variational autoencoder as a regularizer. The intuition is that each event mention can be generated conditioned on a latent variational embedding $\boldsymbol{z}$ and its corresponding type distribution $\boldsymbol{y}$, which is predicted by the approach described in Section 2.3.

We first describe the semi-supervised variational inference process. It consists of an inference network $q(z|t)$ which is a posterior of the learning of a latent variable z given the trigger t, and a generative network $p(t|z, y)$ to reconstruct the candidate trigger t from the latent variable z and type information y. For each candidate trigger t with human annotated label y, the likelihood $p(t, y)$ can be approximated to a variational lower bound

$$\log p(t, y) \geq \log p(t|y, z) - KL(q(z|t)||p(z)) = -\mathcal{L}(t, y)$$

where $\log p(t|z, y)$ is the expectation of reconstruction of t conditioned on z and y, $p(z)$ is the prior Gaussian distribution. For each unlabeled candidate trigger t, the likelihood $p(t)$ approximates to another variational lower bound

$$\log p(t) \geq \sum_y q(y|t)(-\mathcal{L}(t, y)) - q(y|t)\log q(y|t) = -\mathcal{L}(t)$$

where $q(y|t)$ is obtained from Equation 1.

As for model implementation, given a candidate trigger t and its contextual embedding $\boldsymbol{v}_t$, we first pass it through an encoder $f_e(\boldsymbol{v}_t)$ to extract features. As we assume the latent variational embedding $\boldsymbol{z}_t$ follows Gaussian distribution $\boldsymbol{z}_t \sim \boldsymbol{N}(\boldsymbol{\mu}_t, \boldsymbol{\sigma}_t)$, we apply two linear functions to obtain the mean vector $\boldsymbol{\mu}_t = f_\mu(f_e(\boldsymbol{v}_t))$ and a variance vector $\boldsymbol{\sigma}_t = f_\sigma(f_e(\boldsymbol{v}_t))$. For decoding, we employ another linear function to reconstruct $\boldsymbol{v}_t$ from the concatenation of $\boldsymbol{z}_t$ and $\boldsymbol{y}_t$: $\boldsymbol{v}_t' = f_r([\boldsymbol{z}_t : \boldsymbol{y}_t])$. We optimize the following objective for the semi-supervised VAE

$$\mathcal{L}_v = \sum_{t\in D_u} \mathcal{L}(t) + \sum_{(t,y)\in D_s} \mathcal{L}(t, y) \tag{4}$$

The overall loss function for optimizing the whole **SS-VQ-VAE** framework is

$$\mathcal{L} = \alpha\mathcal{L}_c + \beta\mathcal{L}_{vq} + \gamma\mathcal{L}_v \tag{5}$$

where α, β and γ are hyper-parameters to balance these three objectives.

3 Experiments and Results

3.1 Dataset

We perform experiments on Automatic Content Extraction (ACE) 2005 dataset and evaluate our approach under two settings: (1) supervised event extraction, where the target types include 33 ACE predefined types and *other*, thus k is set as 34. Giving all candidate triggers, the goal is to correctly identify all ACE event mentions and classify them into corresponding types. We follow the same data split with prior work (Li et al., 2013; Nguyen et al., 2016) in which 529/30/40 newswire documents are used for training/dev/test set. (2) new event type induction, where we follow a previous study (Huang et al., 2018) and use top-10 most popular event types from ACE05 data as seen and the remaining 23 types as unseen. Given all ACE annotated event mentions, the goal of this task is to test whether the approach can automatically discover the remaining 23 unseen ACE types and categorize each candidate trigger into a particular seen or unseen type. In this experiment, k is set as 500.

In terms of implementation details, we use the pre-trained bert-large-cased [4] model for fine-tuning,

and optimize our model with BertAdam. we optimize the parameters with grid search: training epoch 15, learning rate $l \in \{1e-5, 2e-5, 3e-5, 5e-5\}$, gradient accumulation steps $g \in \{1, 2, 3\}$, training batch size $b \in \{5g, 8g, 10g\}$, the hyper-parameters for the overall loss function $\alpha \in \{1.0, 5.0, 10.0\}$, $\beta \in \{0.1, 0.5, 1.0\}$, $\gamma \in \{0.1, 0.5, 1.0\}$. The dimensionality of type embedding as well as latent variational embedding, and the hidden states of $f_c(.)$ are all 500 while the hidden states of $f_e(.)$, $f_\mu(.)$, $f_\sigma(.)$ are all 1024.

3.2 Supervised Event Detection

Table 1 compares our approach with several baselines. We conduct ablation study to testify the impact of the VQ and VAE components: **SS-VQ-VAE w/o VQ-VAE** is only optimized with the classification loss (Equation 2) while **SS-VQ-VAE w/o VAE** is optimized with the classification loss (Equation 2) and the VQ objective (Equation 3).

As we can see, BERT based approaches generally outperform the methods using CNN, RNN or GRU. Our approach achieves the state-of-the-art among all methods. In particular, the recall of our approach is much higher than other methods, which demonstrate the effectiveness of the trigger identification step. It can narrow the learning space of the model. The ablation studies also prove the effectiveness of the VQ and VAE components.

3.3 New Event Type Induction

For new event type induction, we compare our approach with another intuitive baseline, **BERT-C-Kmeans**, which takes in the BERT based trigger representations and group all candidate triggers into clusters with a Constrained K-means (Wagstaff et al., 2001), a semi-supervised clustering algorithm which enforces all trigger candidates annotated with the same seen type to belong to the same cluster. Table 2 shows the performance with several clustering metrics (Chen and Ji, 2010), which measure the agreement between the ground truth class assignment and system based unseen type prediction.

Normalized Mutual Info is a normalization of the Mutual Information (MI) score and scales the MI score to be between 0 and 1.

$$NMI(Y, C) = \frac{2 \times I(Y; C)}{[H(Y) + H(C)]}$$

where Y denotes the ground truth class labels, C denotes the cluster labels, $H(.)$ denotes the entropy function and $I(Y; C)$ is the mutual information between Y and C.

Fowlkes Mallows (Fowlkes and Mallows, 1983) is to evaluate the similarity between the clusters obtained from our approach and ground-truth labels of the data.

$$FM(Y, C) = \frac{TP}{\sqrt{((TP + FP) \times (TP + FN))}}$$

where TP means True Positive, which is calculated as the number of data point pairs that are in the same cluster in Y and in C. FP refers to False Positive and it is calculated as the number of data point pairs that are in the same cluster in Y but not in C. FN is False Negative and it is calculated as the number of pair of data points that are not in the same cluster in Y but are in the same cluster in C.

Completeness : A clustering result satisfies completeness if all members of a given class are assigned to the same cluster.

$$C(Y, C) = 1 - \frac{H(C|Y)}{H(C)}$$

where $H(C|Y)$ is the conditional entropy of the clustering output given the class labels.

Homogeneity : A clustering result satisfies completeness if all of its clusters contain only data points which are members of a single class.

$$C(Y, C) = 1 - \frac{H(Y|C)}{H(Y)}$$

V-Measure (Rosenberg and Hirschberg, 2007) is the weighted harmonic mean between homogeneity score and completeness score.

$$V(Y, C) = \frac{(1 + \beta) \cdot h \cdot c)}{(\beta \cdot h) + c}$$

where h denotes the homogeneity score and c refers to the completeness score.

As qualitative analysis, we further pick 6 unseen ACE types and randomly select at most 100 event mentions for each type. We visualize their type distribution $\boldsymbol{y}$ using TSNE [5]. As Figure 3 shows, most of the event mentions that are annotated with the same ACE type tends to be predicted to the same new unseen type.

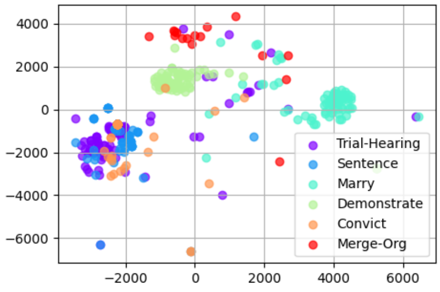

Figure 3: Type Distribution of 6 Unseen Types of Event Mentions.

4 Related Work

Traditional event extraction studies (Ji and Grishman, 2008; McClosky et al., 2011; Li et al., 2013; Chen et al., 2015; Yang and Mitchell, 2016; Feng et al., 2016; Liu et al., 2018; Nguyen and Nguyen, 2019; Lin et al., 2020; Li et al., 2020) assume all the target event types and annotations are given. They can extract high-quality event mentions for the given types, but cannot extract mentions for any new types. Recent studies (Huang et al., 2018; Chan et al., 2019; Ferguson et al., 2018) leverage annotations for a few seen event types or several keywords provided for the new types to extract mentions for new types. However, all these studies assume all the target types are given, which is very costly when moving to a new scenario.

Recent studies have explored probabilistic generative methods (Chambers, 2013; Nguyen et al., 2015; Yuan et al., 2018; Liu et al., 2019) or ad-hoc clustering based algorithms (Huang et al., 2016) to automatically discover a set of event types as well as argument roles. Most of these studies are completely unsupervised and mainly rely on statistical patterns or semantic matching, while our work tries to leverage the knowledge learned from available annotations to discover new event types.

5 Conclusion and Future Work

We have designed a semi-supervised vector quantized variational autoencoder approach which automatically learns a discrete representations for each seen and unseen type and predict a type for each candidate trigger. Experiments show that our approach achieves the state-of-the-art on supervised event extraction and discovers a set of high-quality unseen types. In the future, we will extend this approach to argument role induction to discover complete event schemas.

Abstract

Despite the success of generative pre-trained language models on a series of text generation tasks, they still suffer in cases where reasoning over underlying commonsense knowledge is required during generation. Existing approaches that integrate commonsense knowledge into generative pre-trained language models simply transfer relational knowledge by post-training on individual knowledge triples while ignoring rich connections within the knowledge graph. We argue that exploiting both the structural and semantic information of the knowledge graph facilitates commonsense-aware text generation. In this paper, we propose *Generation with Multi-Hop Reasoning Flow* (GRF) that enables pre-trained models with dynamic multi-hop reasoning on multi-relational paths extracted from the external commonsense knowledge graph. We empirically show that our model outperforms existing baselines on three text generation tasks that require reasoning over commonsense knowledge. We also demonstrate the effectiveness of the dynamic multi-hop reasoning module with reasoning paths inferred by the model that provide rationale to the generation.[1]

1 Introduction

Despite the recent success of pre-trained language models such as GPT-2 (Radford et al., 2019) on various language generation tasks, these models are still struggling on generation tasks that require reasoning over commonsense knowledge that is not *explicitly* stated in the context. For example, Figure 1 illustrates an example in the story ending generation task, where external commonsense knowledge in the form of relational paths can guide the generation of the key concepts "substance" and "lava" in the story ending by providing background knowledge such as (`volcano`, `MadeOf`, `lava`) besides the story context. Although pre-trained models have been demonstrated to possess commonsense reasoning ability (Trinh and Le, 2018) by *implicitly* learning some relational patterns from large-scale corpora, they do not fully utilize the commonsense knowledge bases that provide more explicit knowledge grounding.

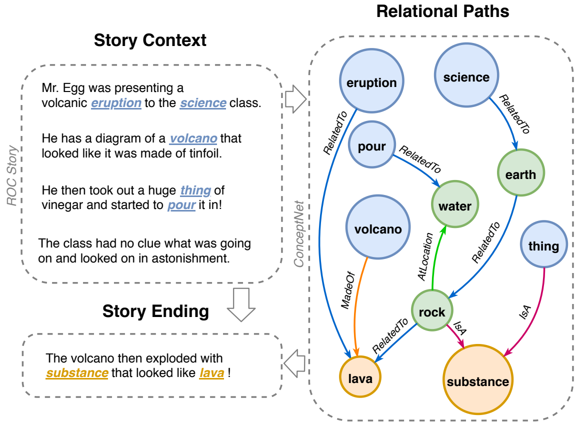

Figure 1: An example of using structural relational knowledge as commonsense grounding in story ending generation. Blue nodes correspond to the concepts in the context, orange nodes correspond to those in the story ending and gree nodes are intermediate concepts that connect the evidence chain.

To address this defect, incorporating external commonsense knowledge to enhance models' reasoning ability has been widely explored (Lin et al., 2019; Ye et al., 2019; Lv et al., 2019). In language generation, previous work (Bhagavatula et al., 2020; Guan et al., 2020) transfers commonsense knowledge into pre-trained language models by utilizing triple information in commonsense knowledge bases such as ConceptNet (Speer and Havasi, 2012) and ATOMIC (Sap et al., 2019).

However, this approach has two drawbacks.

November 16–20, 2020.

First, recovering knowledge triples at the post-training stage (Guan et al., 2020) hardly enables the model to utilize the encoded knowledge in fine-tuning generation tasks which requires reasoning over underlying commonsense knowledge. Second, it ignores the abundant structural relational relevance of the concepts in the knowledge graph (Guan et al., 2020; Bhagavatula et al., 2020) that may provide multiple plausible evidence for complex reasoning. Thus a richer and more explicit way of utilizing external commonsense knowledge is to exploit both *structural* and *semantic* information of the knowledge graph and reason over multi-hop relational paths where multiple connected triples provide chains of evidence for grounded text generation.

In this paper, we propose *Generation with Multi-Hop Reasoning Flow* (GRF), a generation model that performs multi-hop reasoning on the external knowledge graph for knowledge-enriched language generation. The model operates on the sub-graph extended from the concepts in the input text as commonsense knowledge grounding. It first encodes the multi-relational graph with compositional operation to obtain graph-aware representations for the concepts and the relations (§3.2.1). Then, the multi-hop reasoning module performs dynamic reasoning via aggregating triple evidence along multiple relational paths to generate the salient concept under the context (§3.2.3). Finally, the generation distribution combines the probability of copying concepts from the knowledge graph and that of choosing a word from the standard vocabulary with a gate control (§3.2.4). The overall model architecture is shown in Figure 2. We conduct experiments on three commonsense-aware text generation tasks including story ending generation (Mostafazadeh et al., 2016), abductive natural language generation (Bhagavatula et al., 2020), and explanation generation for sense making (Wang et al., 2019). Results show that our model outperforms strong baselines on these tasks, thereby demonstrating the benefit of multi-hop commonsense reasoning in language generation.

Our contributions can be summarized as follows: 1) We propose GRF, a novel generation model that utilizes external structural commonsense knowledge to facilitate explicit commonsense reasoning in text generation. 2) We propose the dynamic multi-hop reasoning module that aggregates evidence along relational paths for grounded generation of some critical concepts. 3) We conduct extensive experiments including automatic and human evaluation on three commonsense-aware text generation tasks and show that our model outperforms various selective baselines. We also visualize reasoning paths inferred by the model to demonstrate the effectiveness of the multi-hop reasoning module.

2 Related Work

2.1 Commonsense-Aware Neural Text Generation

Incorporating commonsense knowledge is essential for text generation to augment the limited textual information. In dialogue generation, Zhou et al. (2018) enriched the context representations of the post with neighbouring concepts on ConceptNet using graph attention. In story ending generation, Guan et al. (2019) proposed incremental encoding with multi-source attention to incorporate one-hop knowledge graph for concepts in the story context. In topic-to-essay generation, Yang et al. (2019) augmented the generator with a concept memory that updated dynamically with gate mechanism. Recently, some work also attempted to integrate external commonsense knowledge into generative pretrained language models such as GPT-2 (Radford et al., 2019). Guan et al. (2020) conducted post-training on sythetic data constructed from commonsense knowledge bases by translating triplets into natural language texts using templates. Bhagavatula et al. (2020) transferred embeddings of COMeT (Bosselut et al., 2019), a GPT-2 model fine-tuned to generate the tail entity of a triple in commonsense knowledge graph, into another GPT-2 model for text generation. In comparison, our model utilizes both structural and semantic information of the commonsense knowledge graph during generation and does not suffers from the catastrophic forgetting problem (Kirkpatrick et al., 2016) caused by implicit knowledge transferring.

2.2 Multi-Hop Reasoning on Graph Structure

Performing explicit multi-hop reasoning on graph structure has been demonstrated to be an effective approach for query answering over incomplete knowledge graphs (Das et al., 2018; Chen et al., 2018; Lin et al., 2018), multi-hop question answering (Bauer et al., 2018; Cao et al., 2019; Qiu et al., 2019) and dialogue generation (Tuan et al.,

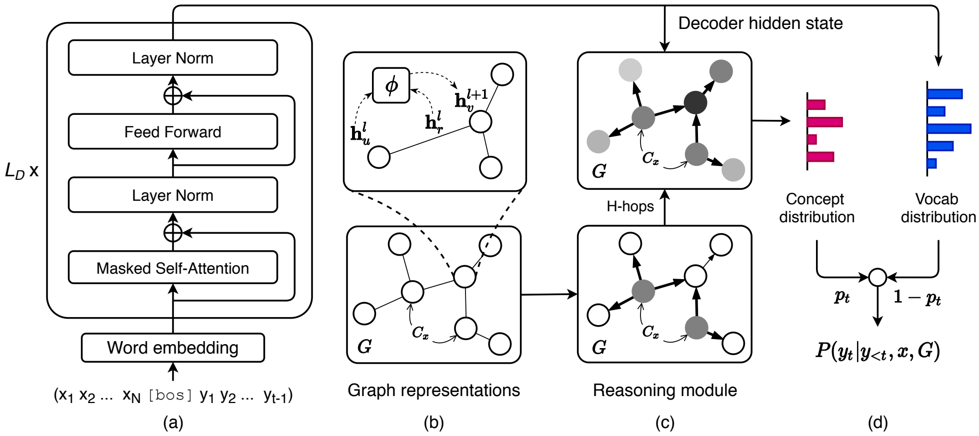

Figure 2: Model architecture. (a) Context modeling with pre-trained transformer (§3.2.2). (b) The model encodes the multi-relational graph with non-parametric operation $\phi(\cdot)$ to combine relations and concepts (§3.2.1). (c) The multi-hop reasoning module aggregates evidence from source concepts $C_{\boldsymbol{x}}$ along structural paths to all nodes where shade indicates the node score (§3.2.3). (d) The final generation distribution with gate control (§3.2.4).

2019; Moon et al., 2019; Liu et al., 2019). Particularly, reasoning on knowledge graphs to answer relational query typically adopts REINFORCE to learn concrete policies to search for entities or relations. In multi-hop question answering tasks, the reasoning process is augmented with entity graph (Cao et al., 2019; Qiu et al., 2019) or concept paths (Bauer et al., 2018) to enhance semantic connections among document segments. In dialogue generation, Tuan et al. (2019) modeled multiple hops on relationship graphs with a Markov transition matrix. Liu et al. (2019) proposed a two-stage architecture that selected information from a knowledge graph for further generating the response. Compared with these generation models that operate on knowledge graphs within a specific domain, our focus is to utilize general commonsense knowledge to supply evidence for text generation.

3 Methodology

3.1 Problem Formulation

In this paper, we focus on text generation tasks where reasoning over external commonsense knowledge is required. Without loss of generality, the input source is a text sequence $\boldsymbol{x} = (x_1, x_2, \cdots, x_N)$ which may consist of several sentences. The output target is another text sequence $\boldsymbol{y} = (y_1, y_2, \cdots, y_M)$. To facilitate the reasoning process, we resort to an external commonsense knowledge graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V}$ denotes the concept set and $\mathcal{E}$ denotes the relations connecting these concepts. Since direct reasoning on the complete graph is intractable, we extract a sub-graph $G = (V, E)$ given the input text where $V \subset \mathcal{V}$ and $E \subset \mathcal{E}$. The sub-graph consists of inter-connected H-hop paths starting from the source concepts $C_{\boldsymbol{x}}$ extracted from the input text. We only consider concepts with 1-gram surface texts. The task is then formulated as generating the best hypothesis $\hat{\boldsymbol{y}}$ which maximizes the following conditional probability:

$$\hat{\boldsymbol{y}} = \mathrm{argmax}_{\boldsymbol{y}} P(\boldsymbol{y}|\boldsymbol{x}, G). \tag{1}$$

We leave the detailed sub-graph extraction process in §4.2 and describe our proposed model in the next section.

3.2 Generation with Multi-Hop Reasoning Flow

3.2.1 Static Multi-Relational Graph Encoding

Graph Neural Network (GNN) frameworks, such as graph convolution network (GCN) (Kipf and Welling, 2017) and graph attention network (GAT) (Velickovic et al., 2018), have been shown effective at encoding graph-structured data by aggregating node information from local neighbours. To model the relational information in the knowledge graph, R-GCN (Schlichtkrull et al., 2018) generalizes GCN with relation-specific weight matrices but is reported to be over-parameterized (Marcheggiani and Titov, 2017; Schlichtkrull et al., 2018). We follow Vashishth et al. (2020) and use a non-parametric compositional operation $\phi(\cdot)$ to combine the node embedding and the relation embedding. Specifically, given the input graph $G = (V, E)$ and a GCN with L_G layer, for each node $v \in V$ we update the node embedding at the $l + 1$-th layer by aggregating information from its local neighbours $\mathcal{N}(v)$ which consist of pairs of node u and the connected relation r.

$$\boldsymbol{o}_v^l = \frac{1}{|\mathcal{N}(v)|} \sum_{(u,r)\in\mathcal{N}(v)} \mathbf{W}_N^l \phi(\boldsymbol{h}_u^l, \boldsymbol{h}_r^l), \quad (2)$$

$$\boldsymbol{h}_v^{l+1} = \text{ReLU}\Big(\boldsymbol{o}_v^l + \mathbf{W}_S^l \boldsymbol{h}_v^l\Big), \quad (3)$$

where $\boldsymbol{h}_v^0$ is initialized by looking up the word embedding and $\boldsymbol{h}_r^0$ by the relation-type embedding. $\mathbf{W}_N^l$ and $\mathbf{W}_S^l$ are two learnable weight matrices specific to the l-th layer. We define the compositional operation as $\phi(\boldsymbol{h}_u, \boldsymbol{h}_r) = \boldsymbol{h}_u - \boldsymbol{h}_r$ inspired by the TransE model (Bordes et al., 2013).

The relation embedding is also updated via another linear transformation.

$$\boldsymbol{h}_r^{l+1} = \mathbf{W}_R^l \boldsymbol{h}_r^l. \quad (4)$$

Finally, we obtain node embeddings $\boldsymbol{h}_v^{L_G}$ and relation embeddings $\boldsymbol{h}_r^{L_G}$ that encode the static graph context for dynamic reasoning during decoding.

3.2.2 Context Modeling with Pre-Trained Transformer

We adopt the GPT-2 model (Radford et al., 2019), a pre-trained multi-layer transformer decoder to model the contextual dependency of the text sequence. The input to the model is the concatenation of the source and the target sequence: $\boldsymbol{s} = (x_1, \cdots, x_N, [\texttt{bos}], y_1, \cdots, y_M)$.

$$\boldsymbol{h}_t^0 = \boldsymbol{e}_t + \boldsymbol{p}_t, \quad (5)$$

$$\boldsymbol{h}_t^l = \texttt{T\_block}(\mathbf{H}_{\le t}^{l-1}), l \in [1, L_D] \quad (6)$$

$$P(s_t|\boldsymbol{s}_{<t}) = \text{softmax}(\mathbf{W}_{LM}\boldsymbol{h}_t^{L_D} + \boldsymbol{b}) \quad (7)$$

where $\boldsymbol{e}_t$ and $\boldsymbol{p}_t$ are the token embedding vector and the positional embedding vector. `T_block` is the transformer block with masked self-attention. The final hidden state at the t-th time step $\boldsymbol{h}_t^{L_D}$ which encodes the context information is used as the input to the multi-hop reasoning module.

3.2.3 Dynamic Multi-Hop Reasoning Flow

To perform explicit reasoning on the graph structure during generation, we devise a dynamic reasoning module that utilizes both structural patterns of the knowledge graph and contextual information to propagate evidence along relational paths at each decoding step.

Specifically, the module broadcasts information on G by updating the score of outer nodes with their visited neighbours for multiple hops until all the nodes on G are visited. Initially, nodes correspond to the concepts in $C_{\boldsymbol{x}}$ are given a score of 1 while other unvisited nodes are assigned with 0.

For the unvisited node $v \in V$, its node score $ns(v)$ is computed by aggregating evidence from $\mathcal{N}_{in}(v)$ which denotes the set of visited node u and its edge r that directly connects v.

$$ns(v) = \underset{(u,r)\in\mathcal{N}_{in}(v)}{f}\Big(\gamma \cdot ns(u) + R(u, r, v)\Big), \quad (8)$$

where γ is a discount factor that controls the intensity of the information flow from the previous hops. $f(\cdot)$ is the aggregator that assembles scores from connected nodes. We consider two forms of aggregators: $\texttt{max}(\cdot)$ and $\texttt{mean}(\cdot)$. We use $\texttt{max}(\cdot)$ for the main results and present the results with $\texttt{mean}(\cdot)$ in the ablation study.

$R(u, r, v)$ is the triple relevance that reflects the relevancy of the evidence given by the triplet (u, r, v) under the current context. We compute the triple relevance as follows:

$$R(u, r, v) = \sigma(\boldsymbol{h}_{u,r,v}^{\mathrm{T}} \mathbf{W}_{sim} \boldsymbol{h}_t^{L_D}), \quad (9)$$

$$\boldsymbol{h}_{u,r,v} = [\boldsymbol{h}_u^{L_G}; \boldsymbol{h}_r^{L_G}; \boldsymbol{h}_v^{L_G}]. \quad (10)$$

After H hops, the final distribution over the nodes is obtained by a normalization.

$$P(c_t|\boldsymbol{s}_{<t}, G) = \text{softmax}_{v\in V}(ns(v)), \quad (11)$$

where c_t is the concept of the selected node at the t-th time step.

Intuitively, the reasoning module learns to dynamically distribute along the paths by considering the triple evidence according to the current decoder state.

3.2.4 Generation Distribution with Gate Control

The final generation distribution combines the distribution over the concepts (Eq. 11) and the distribution over the standard vocabulary (Eq. 7). We use a soft gate probability g_t which denotes whether to copy a concept in the generation to control the weight of the two distributions similar to the copy mechanism (Gu et al., 2016; See et al., 2017).

$$g_t = \sigma\Big(\mathbf{W}_{gate}\boldsymbol{h}_t^{L_D}\Big). \quad (12)$$

The final output distribution is the linear combination of the two distributions weighted by g_t and $1 - g_t$ respectively.

$$P(y_t|\boldsymbol{y}_{<t}, \boldsymbol{x}, G) = g_{t+N} \cdot P(c_{t+N}|\boldsymbol{s}_{<t+N}, G) \\ + (1 - g_{t+N}) \cdot P(s_{t+N}|\boldsymbol{s}_{<t+N}), \tag{13}$$

where N is the length of the input text sequence.

3.3 Training and Inference

To train the proposed model, we minimize the negative log-likelihood of generating the ground truth target sequence $\boldsymbol{y}^{\text{gold}} = (y_1, y_2 \cdots, y_M, [\text{eos}])$.

$$\mathcal{L}_{gen} = \sum_{t=1}^{M+1} -\log P(y_t^{\text{gold}}|\boldsymbol{y}_{<t}^{\text{gold}}, \boldsymbol{x}, G). \tag{14}$$

We add an auxiliary gate loss $\mathcal{L}_{gate}$ to supervise the probability of selecting a concept or a generic word. We additionally introduce a weak supervision $\mathcal{L}_{weak}$ to induce the predicted triple relevances to match the heuristic labels of edges obtained by breadth-first search from the source concepts to the concepts in $\boldsymbol{y}^{\text{gold}}$ on the graph. Both loss functions take the form of binary cross-entropy. We observe that both loss terms encourage the model to learn multi-hop reasoning on the graph more effectively.

The final loss to be optimized is the linear combination $\mathcal{L}_{gen} + \alpha\mathcal{L}_{gate} + \beta\mathcal{L}_{weak}$.

During the inference stage, the input to the model is $(x_1, \cdots, x_N, [\text{bos}])$. The model generates a token at a time and concatenates it to the input sequence to generate the next token. The generation process terminates when the special ending symbol [eos] is generated.

4 Experiments

4.1 Datasets and Metrics

The statistics of the datasets are shown in Table 1.
Story Ending Generation (SEG) is to generate a reasonable ending given a four-sentence story context. The stories come from ROCStories corpus (Mostafazadeh et al., 2016). We use the same data split as Guan et al. (2019).
Abductive NLG (αNLG) is to generate an explanatory hypothesis given two observations: O_1 as the cause and O_2 as the consequence. We use the official data split[2] from Bhagavatula et al. (2020).
Explanation Generation (EG) is to generate an explanation given a counter-factual statement for sense-making (Wang et al., 2019). We randomly split 85% of the data as the training set, 10% as the test set, and the latter as the development set.

For automatic evaluation, we use metrics including BLEU-4 (Papineni et al., 2002), CIDEr (Vedantam et al., 2015), ROUGE-L (Lin, 2004) and METEOR (Banerjee and Lavie, 2005) to evaluate the abductive NLG and the explanation generation tasks. We follow common practice in story generation (Guan et al., 2019, 2020) and use BLEU-1/2 to evaluate the generated endings. We also adopt Distinct-n (Li et al., 2016) to measure the diversity of the generated endings.

4.2 Extracting Sub-Graphs as Knowledge Grounding

To supply knowledge grounding for language generation, we use ConceptNet (Speer and Havasi, 2012) as the commonsense knowledge base. Each triple (h, r, t) in ConceptNet denotes that the head concept h has a relation r with the tail concept t. To condense the knowledge graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ we group the original 42 relation types into 17 following Lin et al. (2019) and add reversed links (t, r^{-1}, h) to the graph (Lin et al., 2018; Das et al., 2018).

We extract a sub-graph $G = (V, E)$ from $\mathcal{G}$ which consists of multiple inter-connected paths starting from the source concepts $C_{\boldsymbol{x}}$ in the input sequence. To recognize concepts from the input text sequence, we perform fuzzy matching with the lemmatized form of the surface texts using Spacy[3] and filter out stop words. Following Guan et al. (2019), we only consider verbs and nouns as our candidate concepts since we find the extracted graph is much noisier with all the matched concepts.

Specifically, we iterate the following process for H hops: starting from the nodes in the current sub-graph (initialized by $C_{\boldsymbol{x}}$) and search for the direct neighbours of each node and preserve top-B nodes with the connected edges to enlarge the sub-graph. For each candidate node, the selection is based on its incoming degree of this node. The incoming degree of a candidate node v is defined as the number of nodes in the current sub-graph that directly connect v. Intuitively, we keep those salient concepts that are commonly visited nodes and support information flow on the graph.

4.3 Implementation Details

Graph statistics	EG	αNLG	SEG
Avg. # Concepts	193.1	201.6	208.5
Avg. # Triples	1094.3	1324.6	1148.6

Table 2: Statistics of the extracted subgraphs on the training sets of three datasets, including the average number of concepts and triples for each subgraph.

Our model employs the small version of GPT-2 model[4] with 12 layers, 768-dimensional hidden states, and 12 attention heads for contextual modeling and a 2-layer GCN model. We choose the $\mathtt{max}(\cdot)$ aggregator for the main results since it yields better performance. During sub-graph extraction, we set the maximum number of hops $H = 2$ and preserve top-$B = 100$ nodes per hop. We find this setting balances the coverage and noise of the knowledge graph. Detailed statistics of the extracted sub-graphs are presented in Table 2. To train the model, we use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.999, \varepsilon = 1 \times 10^{-8}$ and linearly decrease the learning rate to zero with no warmup. We search the best hyper-parameters according to BLEU-4 on the development set of each task. At the inference stage, we adopt beam search decoding with a beam size of 3 for our model and all the baselines we produce. We conduct all the experiments using the PyTorch framework (Paszke et al., 2017).

4.4 Compared Baselines

We produce the following baselines on three generation tasks to compare with our model:

Seq2Seq is a sequence-to-sequence model based on gated recurrent unit (GRU) with attention mechanism. We also utilize the copying mechanism (Gu et al., 2016) for the model to generate out-of-vocabulary words.

GPT2-FT is a GPT-2 model fine-tuned on the task-specific dataset with its model initialization from Radford et al. (2019).

GPT2-OMCS-FT is a commonsense-enhanced GPT-2 model first post-trained on the Open Mind Common Sense (OMCS) corpus[5] from which the ConceptNet is constructed. The model is then fine-tuned on the task-specific dataset.

We also compare our model with baseline models designated to each specific task. For story ending generation, we compare to **IE+GA** which is based on incremental encoding and graph attention (Guan et al., 2019) and **WriterForcing** that forces the attention to focus on important keyphrases and avoid generating generic words.

For abductive NLG, we compare with two baselines introduced by Bhagavatula et al. (2020): **COMeT-Txt-GPT2** which uses the output texts generated by COMeT as prefix texts to the GPT-2 model while fine-tuning, and **COMeT-Emb-GPT2** which integrates the embeddings of the outputs generated by COMeT into the GPT-2 model during fine-tuning.

4.5 Automatic Evaluation

We present the automatic evaluation results on the test sets of the explanation generation and the abductive NLG tasks in Table 3. We have the following observations:

I. Our model outperforms all the baselines that utilize pre-trained language models or incorporate external commonsense knowledge in terms of all evaluation metrics indicating that incorporating rich structural information of commonsense knowledge graphs can enhance the overall generation quality.

II. Simply post-training on commonsense knowledge source degrades the performance on these two tasks. This is possibly due to the fact that the triple-level post-trained corpus cannot provide rich semantics for the model to generalize on tasks that emphasize reasoning and explaining.

For story ending generation, we present the evaluation results in Table 4. Our model outperforms all the baselines in BLEU and distinct metrics. We also observe that post-training on external commonsense data improves the generation diversity of the pre-trained language model, which accords with the findings of Guan et al. (2020). We suspect that post-training on the commonsense data enables

the model to generate concepts related to the story context, which improves the text diversity.

4.6 Human Evaluation

To evaluate the fluency and the reasonability of the generated texts under the specific task settings, we conduct pair-wise comparison with **COMeT-Emb-GPT2** on αNLG, **IE+GA** on SEG, and with two fine-tuned GPT-2 models on all the three tasks. For human evaluation, we randomly sample 100 sentences from the test set for each pair of models and obtain 1,100 sentences from five models. We recruit three annotators to make a preference among *win*, *tie* and *lose* given the input context and two outputs generated by our model and a baseline respectively according to two criteria: fluency and reasonability.

For fluency, we require the annotators to focus only on the grammatical correctness and readability of the generated results disregarding the input context. When evaluating reasonability, the annotators are required to assess whether the generated sentence is reasonable under the given context in each task. In SEG and αNLG, annotators are asked to focus on evaluating the causal and temporal relevance of the generated results and the contexts. While on EG, annotators are mainly asked to check whether the generated results explain the counterfactual points in the statements properly.

The human evaluation results are presented in Table 6 where our model significantly outperforms compared baselines in terms of both criteria on all the datasets. Specifically, incorporating structural commonsense knowledge yields significant improvement in generating reasonable texts given the context. Table 7 shows the inter-rater agreement where five out of six annotations show moderate ($0.4 \leq \kappa < 0.6$) or good agreement ($0.6 \leq \kappa < 0.8$). We check the annotation results and find that the GPT-2 baselines also generate story endings with good grammar, which makes it hard for the annotators to reach a high consensus when evaluating the fluency criterion of the story ending generation task ($\kappa = 0.315$).

4.7 Ablation Study

We conduct ablation study to verify the effect of different model components. As shown in Table 5, all the components contribute to the final performance. Removing the dynamic reasoning module (w/o DMRF) results in the largest performance drop, thereby indicating that dynamic multi-hop reasoning plays a major role in this task. Ablating the graph representation module (w/o SMGE) also degrades the performance since it encodes the graph structure with relational information that benefits concept selection. We also show the results of our reasoning module with `mean`$(\cdot)$ aggregator and observe some performance drop comparing with `max`$(\cdot)$.

Models	EG				αNLG				SEG			
	Fluency		Reasonability		Fluency		Reasonability		Fluency		Reasonability	
	W	L	W	L	W	L	W	L	W	L	W	L
vs. IE+GA	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	0.62**	0.07	0.72**	0.11
vs. COMeT-Emb-GPT2	N/A	N/A	N/A	N/A	0.31**	0.14	0.55**	0.25**	N/A	N/A	N/A	N/A
vs. GPT2-FT	0.24**	0.09	0.54**	0.21	0.15*	0.10	0.56**	0.20	0.21**	0.12	0.45**	0.19
vs. GPT2-OMCS-FT	0.18**	0.09	0.58**	0.18	0.12	0.09	0.50**	0.20	0.17*	0.11	0.40**	0.15

Table 6: Human evaluation results on three datasets. Scores indicate the percentage of *Win* (**W**) and *Lose* (**L**) when comparing our model with a baseline in terms of *fluency* and *reasonability*. Scores marked with * mean p-value < 0.05 and ** indicates p-value < 0.01 in sign test. Entries with N/A mean the baseline is not designated for this task.

Criteria	EG	αNLG	SEG
Fluency	0.615	0.543	0.315
Reasonability	0.551	0.677	0.595

Table 7: Annotator agreement. Scores denotes Fleiss' kappa (Fleiss, 1971) which evaluates the agreement from multiple annotators in terms of *fluency* and *reasonability*.

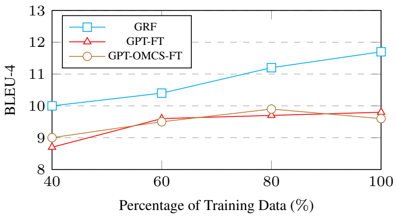

Figure 3: Performance with different amount of training data on the test set of αNLG.

4.8 Impact of the Size of Training Data

To demonstrate the complementary performance gain of utilizing relational paths besides textual modeling, we sample different fractions of training data of αNLG for training and evaluate on the original test set. We compare our method with knowledge-agnostic finetuning of the GPT-2 model and the commonsense-enhanced GPT-2 post-trained on OMCS. As shown in Figure 3, our model achieves consistent performance gains against the chosen baselines with different amount of training data, which demonstrates the generalization ability of the proposed model with the aid of structural relation knowledge.

4.9 Effectiveness of Dynamic Multi-Hop Reasoning

We demonstrate the effectiveness of the multi-hop reasoning module through both quantitative and qualitative analysis.

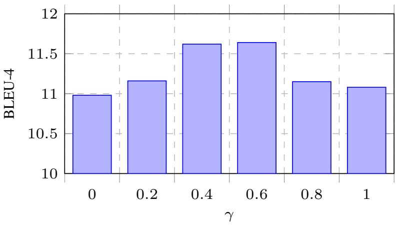

Figure 4: Effect of γ in DMRF. Performance with different value of discount factor γ on the test set of αNLG.

We investigate the impact of the hyper-parameter γ that controls the information flow in the multi-hop reasoning module. As shown in Figure 4, the maximum performance is obtained when γ is around 0.4 and 0.6. When $\gamma \to 0$, the multi-hop reasoning module reduces to local scoring of each concept and ignores evidence accumulated on the paths. While $\gamma \to 1$, the node score increases monotonically along the paths which also hinders the model's ability to select the correct concept. Therefore, we set $\gamma = 0.5$ for all the main results of our model.

To qualitatively assess the ability of the dynamic reasoning module, we visualize a test case on αNLG with top-ranked concepts and scored reasoning paths. As shown in Figure 5, at the first hop the reasoning module starts from the source concepts "*adopt*" and "*puppy*" and assigns higher scores to neighbouring concepts which are verbs considering the generated context. At the second hop the module utilizes more plausible evidences along 2-hop reasoning paths and selects "*play*" ($g_t = 0.64$) which is more reasonable given both the observations.

4.10 Case Study

We provide some test cases on three datasets in Table 8 and observe that: **I.** Baseline models tend to generate general cases while the GRF is able to generate more specific concepts by exploring the plau-

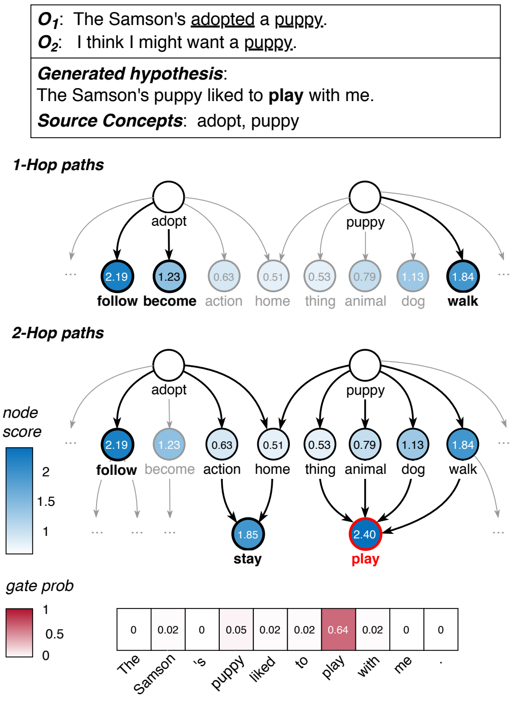

Figure 5: Visualization of a test case with inferred reasoning paths by our model. We highlight top-3 concepts with reasoning paths at **1-Hop** and **2-Hop** reasoning step respectively.

sible relations between concepts. For example in the first case, the GRF generates “expensive” which is the antonym of “cheap” under the story context. **II.** Baseline models sometimes fail to identify the transition of the narrative as shown in the third case where the GRF generates “seasick” as a plausible explanation for the transition from “cruise” to “beach”. **III.** The GRF generates proper attributes of the source concepts in the input context with the aid of external commonsense knowledge as shown in the last two cases of explanation generation.

5 Conclusion

We present Generation with Multi-Hop Reasoning Flow that reasons over structured commonsense knowledge during text generation. The proposed method leverages both the structural and semantic information of the external knowledge base by performing dynamic multi-hop reasoning on the relational paths. We conduct extensive experiments and empirically show that our method outperforms existing approaches that integrate commonsense knowledge to pre-trained language models on three text generation tasks. We also demonstrate the interpretability of our method with inferred reasoning paths that provide rationale to the generated results.

	Story Ending Generation
Story Context	*I wanted a simple bike for commuting.* *So I bought a* ***cheap*** *one on sale.* *But it didn’t fit me properly.* *And it was uncomfortable to ride.*
IE+GA	So I decided to buy a new one.
GPT2-FT	So I decided to buy a new bike.
GPT2-OMCS-FT	So I decided to buy a bike from a bike shop instead.
GRF	So I decided to get a more **expensive** bike.
Story Context	*Ava made shakes for her kids on a* ***hot*** *summer day.* *She called them in from play, but they dallied.* *By time they came in, the shakes were almost* ***melted****.* *Ava blended in more* ***ice*** *cubes and refreshed them.*
IE+GA	Then she went home and ate them.
GPT2-FT	Ava was proud of her kids for being so good at cooking.
GPT2-OMCS-FT	She was proud of her kids for being so thoughtful!
GRF	Her kids thanked her profusely for helping them **cool** off.
	Abductive NLG
Observation 1	*The Smith family went on a* ***cruise*** *for their summer vacation.*
Observation 2	*From then on, the Smiths went to the* ***beach*** *each summer instead.*
GPT2-FT	The Smith family had a great time on the beach.
GPT2-OMCS-FT	The Smith family went to the beach.
COMeT-Emb-GPT2	They didn’t have a nice vacation.
GRF	The Smith family got **seasick** on the cruise.
Observation 1	*Nancy bought her dog a squeaky stuffed animal.*
Observation 2	*The dog had* ***ripped*** *the toy to shreds.*
GPT2-FT	Nancy found a toy that looked like a toy.
GPT2-OMCS-FT	Nancy found a toy that looked like a toy.
COMeT-Emb-GPT2	The squeaky stuffed animal was the first to come in.
GRF	Nancy’s dog **scratched** the stuffed animal.
	Explanation Generation
Statement	***Coke*** *is made of* ***alcohol****.*
GPT2-FT	Coke is a drink.
GPT2-OMCS-FT	Coke is not a liquid.
GRF	Coke is made from **corn**.
Statement	*She* ***cut*** *up a* ***blanket****.*
GPT2-FT	A blanket is not sharp enough to cut.
GPT2-OMCS-FT	A blanket is too small to be cut.
GRF	Blankets are too **soft** to be cut.

Table 8: Case study on the test set of three datasets. Words in blue denote source concepts in the input contexts while words in orange are the associated concepts generated by the GRF.

Abstract

Modern NLP defines the task of *style transfer* as modifying the style of a given sentence without appreciably changing its semantics, which implies that the outputs of style transfer systems should be paraphrases of their inputs. However, many existing systems purportedly designed for style transfer inherently warp the input's meaning through *attribute transfer*, which changes semantic properties such as sentiment. In this paper, we reformulate unsupervised style transfer as a paraphrase generation problem, and present a simple methodology based on fine-tuning pretrained language models on automatically generated paraphrase data. Despite its simplicity, our method significantly outperforms state-of-the-art style transfer systems on both human and automatic evaluations. We also survey 23 style transfer papers and discover that existing automatic metrics can be easily gamed and propose fixed variants. Finally, we pivot to a more real-world style transfer setting by collecting a large dataset of 15M sentences in 11 diverse styles, which we use for an in-depth analysis of our system.

1 Introduction

The task of *style transfer* on text data involves changing the style of a given sentence while preserving its semantics.[1] Recent work in this area conflates style transfer with the related task of *attribute transfer* (Subramanian et al., 2019; He et al., 2020), in which modifications to attribute-specific content words (e.g., those that carry sentiment) warp both stylistic *and* semantic properties of a sentence (Preotiuc-Pietro et al., 2016). Attribute transfer has been criticized for its limited real-world applications: Pang (2019) argue that semantic preservation is critical for author obfuscation (Shetty et al., 2018), data augmentation (Xie et al., 2019; Kaushik et al., 2020), text simplification (Xu et al., 2015), writing assistance (Heidorn, 2000). Moreover, semantic preservation (via paraphrases) has several applications like better translation evaluation (Sellam et al., 2020; Freitag et al., 2020) and adversarial defenses (Iyyer et al., 2018).

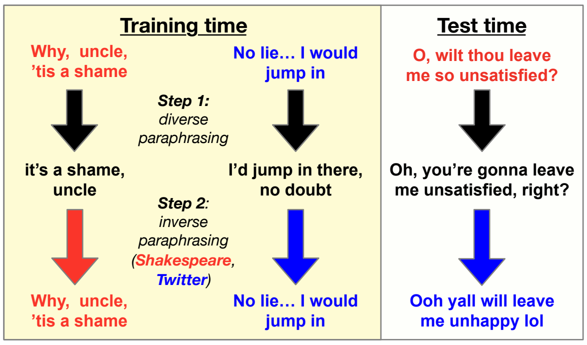

Figure 1: During training, STRAP applies a diverse paraphraser to an input sentence and passes the result through a style-specific *inverse paraphraser* to reconstruct the input. At test time, we perform style transfer by swapping out different inverse paraphrase models (Shakespeare → Twitter shown here). All generated sentences shown here are **actual outputs from STRAP**.

We propose to improve semantic preservation in style transfer by modeling the task as a controlled paraphrase generation problem. Our unsupervised method (**St**yle **Tra**nsfer via **P**araphrasing, or STRAP) requires no parallel data between different styles and proceeds in three simple stages:

1. Create pseudo-parallel data by feeding sentences from different styles through a diverse paraphrase model (Figure 1, left).
2. Train style-specific *inverse* paraphrase models that convert these paraphrased sentences back into the original stylized sentences.
3. Use the inverse paraphraser for a desired style to perform style transfer (Figure 1, right).

---

[1] We use the *quasi-paraphrase* definition of semantic equivalence from Bhagat and Hovy (2013) throughout this paper. We loosely define *style* as patterns in lexical and syntactic choice within the space of quasi-paraphrases.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 737–762,
November 16–20, 2020.

Our approach requires none of the finicky[2] modeling paradigms popular in style transfer research — no reinforcement learning (Luo et al., 2019), variational inference (He et al., 2020), or autoregressive sampling during training (Subramanian et al., 2019). Instead, we implement the first two stages of our pipeline by simply fine-tuning a pretrained GPT-2 language model (Radford et al., 2019).

Despite its simplicity, STRAP significantly outperforms the state of the art on formality transfer and Shakespeare author imitation datasets by **2-3x** on automatic evaluations and **4-5x** on human evaluations. We further show that only 3 out of 23 prior style transfer papers properly evaluate their models: in fact, a naïve baseline that randomly chooses to either copy its input or retrieve a random sentence written in the target style *outperforms* prior work on poorly-designed metrics.

Finally, we take a step towards real-world style transfer by collecting a large dataset CDS (**C**orpus of **D**iverse **S**tyles) of 15M English sentences spanning **11 diverse styles**, including the works of James Joyce, romantic poetry, tweets, and conversational speech. CDS is orders of magnitude larger and more complex than prior benchmarks, which generally focus on transferring between just two styles. We analyze STRAP's abilities on CDS, and will release it as a benchmark for future research.

In summary, **our contributions** are:

(1) a simple approach to perform lexically and syntactically diverse paraphrasing with pretrained language models;

(2) a simple unsupervised style transfer method that models semantic preservation with our paraphraser and significantly outperforms prior work;

(3) a critique of existing style transfer evaluation based on a naïve baseline that performs on par with prior work on poorly designed metrics;

(4) a new benchmark dataset that contains 15M sentences from 11 diverse styles.

2 Style Transfer via Paraphrasing

We loosely define *style* as common patterns of lexical choice and syntactic constructions that are distinct from the content of a sentence, following prior work (Hovy, 1987; DiMarco and Hirst, 1993; Green and DiMarco, 1993; Kabbara and Cheung, 2016). While we acknowledge this distinction is not universally accepted,[3] this treatment is critical to unlock several real-world applications of style transfer (as argued in Section 1). Unfortunately, many modern style transfer systems do not respect this definition: a human evaluation (Table 2) shows that **fewer than 25% of style-transferred sentences** from two state-of-the-art systems (Subramanian et al., 2019; He et al., 2020) on formality transfer were rated as paraphrases of their inputs.

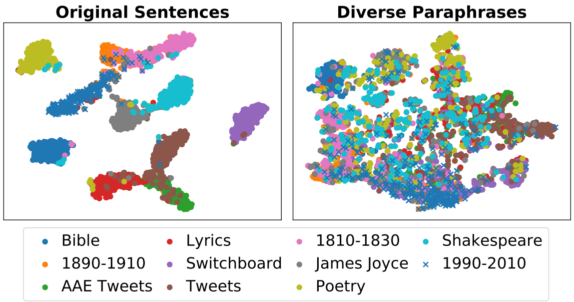

Figure 2: **Diverse paraphrasing normalizes sentences by removing stylistic identifiers.** We cluster validation sentences from our CDS dataset by applying t-SNE to `[CLS]` vectors from a RoBERTa style classifier. The original sentences (left) form distinct clusters, while the paraphrased sentences (right) do not, showing the stylized text has been normalized.

Motivated by this result, we reformulate style transfer as a controlled paraphrase generation task. We call our method **STRAP**, or **S**tyle **Tr**ansfer via **P**araphrasing. STRAP operates within an unsupervised setting: we have raw text from distinct target styles, but no access to parallel sentences paraphrased into different styles. To get around this lack of data, we create *pseudo-parallel* sentence pairs using a paraphrase model (Section 2.1) trained to maximize output diversity (Section 2.4). Intuitively, this paraphrasing step normalizes the input sentence by stripping away information that is predictive of its original style (Figure 2). The normalization effect allows us to train an *inverse paraphrase* model specific to the original style, which attempts to generate the original sentence given its normalized version (Section 2.2). Through this process, the model learns to identify and produce salient features of the original style without unduly warping the input semantics.

2.1 Creating pseudo-parallel training data

The first stage of our approach involves normalizing input sentences by feeding them through a

---

[2] For example, reproducing deep RL methods is challenging (Henderson et al., 2018), vanilla adversarial training is unstable (Arjovsky et al., 2017), and VAEs suffer from posterior collapse (Bowman et al., 2016).

[3] For example, Eckert (2008) considers style and semantics to be inseparable; while Meyerhoff (2015) considers style to be intra-speaker variation in different social contexts

diverse paraphrase model. Consider a corpus of sentences from multiple styles, where the set of all sentences from style i is denoted by $\mathbf{X}^i$. We first generate a paraphrase $\mathbf{z}$ for every sentence $\mathbf{x} \in \mathbf{X}^i$ using a pretrained paraphrase model f_{para},

$$\mathbf{z} = f_{\text{para}}(\mathbf{x}) \text{ where } \mathbf{x} \in \mathbf{X}^i.$$

This process results in a dataset $\mathbf{Z}^i$ of normalized sentences and allows us to form a pseudo-parallel corpus $(\mathbf{X}^i, \mathbf{Z}^i)$ between each original sentence and its paraphrased version. Figure 2 shows that this paraphrasing process has a powerful style normalization effect for our instantiation of f_{para}.

2.2 Style transfer via inverse paraphrasing

We use this pseudo-parallel corpus to train a style-specific model that attempts to reconstruct the original sentence $\mathbf{x}$ given its paraphrase $\mathbf{z}$. Since f_{para} removes style identifiers from its input, the intuition behind this *inverse* paraphrase model is that it learns to insert stylistic features through the reconstruction process. Formally, the inverse paraphrase model f^i_{inv} for style i learns to reconstruct[4] the original corpus $\mathbf{X}^i$ using the standard language modeling objective with cross-entropy loss $\mathcal{L}_{\text{CE}}$,

$$\begin{aligned} \bar{\mathbf{x}} &= f^i_{\text{inv}}(\mathbf{z}) \text{ where } \mathbf{z} \in \mathbf{Z}^i \\ \text{loss} &= \sum_{\mathbf{x} \in \mathbf{X}^i} \mathcal{L}_{\text{CE}}(\mathbf{x}, \bar{\mathbf{x}}) \end{aligned}$$

During inference, given an arbitrary sentence $\mathbf{s}$ (in any particular style), we convert it to a sentence $\bar{\mathbf{s}}^j$ in target style j using a two-step process of style normalization with f_{para} followed by stylization with the inverse paraphraser f^j_{inv}, as in

$$\bar{\mathbf{s}}^j = f^j_{\text{inv}}(f_{\text{para}}(\mathbf{s})).$$

2.3 Paraphraser implementation with GPT-2

We fine-tune the large-scale pretrained GPT2-large language model (Radford et al., 2019) to implement both the paraphraser f_{para} and inverse paraphrasers f^i_{inv} for each style.[5] Starting from a pretrained LM improves both output fluency and generalization to small style-specific datasets (Section 5). We use the encoder-free seq2seq modeling approach described in Wolf et al. (2018), where input and output sequences are concatenated together with a separator token. We use Hugging Face's Transformers library (Wolf et al., 2019) to implement our models; see Appendix A.2 for more details about the architecture & hyperparameters.

2.4 Promoting diversity by filtering data

The final piece to our approach is how we choose training data for the paraphrase model f_{para}. We discover that maximizing lexical and syntactic diversity of the output paraphrases is crucial for effective style normalization (Section 5, 6). We promote output diversity by training f_{para} on an aggressively-filtered subset of PARANMT-50M (Wieting and Gimpel, 2018), a large corpus of backtranslated text. Specifically, we apply three filters: (1) removing sentence pairs with more than 50% trigram or unigram overlap to maximize lexical diversity and discourage copying; (2) removing pairs with lower than 50% reordering of shared words, measured by Kendall's tau (Kendall, 1938), to promote syntactic diversity; and (3) removing pairs with low semantic similarity, measured by the SIM model from Wieting et al. (2019).[6] After applying these filters, our training data size shrinks from 50M to 75K sentence pairs, which are used to fine-tune GPT-2; see Appendix A.1 for more details about the filtering process and its effect on corpus size.

3 Evaluating style transfer

Providing a meaningful comparison of our approach to existing style transfer systems is difficult because of (1) poorly-defined automatic and human methods for measuring style transfer quality (Pang, 2019; Mir et al., 2019; Tikhonov et al., 2019), and (2) misleading (or absent) methods of aggregating three individual metrics (transfer accuracy, semantic similarity and fluency) into a single number. In this section, we describe the flaws in existing metrics and their aggregation (the latter illustrated through a naïve baseline), and we propose a new evaluation methodology to fix these issues.

3.1 Current state of style transfer evaluation

We conduct a survey of **23** previously-published style transfer papers (more details in Appendix A.9), which reveals three common

---

[4] This process resembles **denoising autoencoders** (Vincent et al., 2008; Lample et al., 2018, DAE): f_{para} acts as a semantic preserving noise function; f^i_{inv} reconstructs the input.

[5] We fine-tune a separate GPT-2 model f^i_{inv} per style. Section 5 shows that this outperforms a single inverse paraphraser shared across all styles with style input.

[6] This model achieves strong performance on semantic textual similarity (STS) SemEval benchmarks (Agirre et al., 2016). We remove all pairs with a score lower than 0.7.

properties on which style transfer systems are evaluated. Here, we discuss how prior work implements evaluations for each of these properties and propose improved implementations to address some of their downsides.

Transfer accuracy (ACC): Given an output sentence $\bar{\mathbf{s}}^j$ and a target style j, a common way of measuring transfer success is to train a classifier to identify the style of a transferred sentence and report its accuracy ACC on generated sentences (i.e., whether $\bar{\mathbf{s}}^j$ has a predicted style of j). 14 of 23 surveyed papers implement this style classifier with a 1-layer CNN (Kim, 2014). However, recent large Transformers like BERT (Devlin et al., 2019) significantly outperform CNNs on most NLP tasks, including style classification. Thus, we build our style classifier by fine-tuning RoBERTa-large (Liu et al., 2019) on all our datasets, leading to significantly more reliable ACC evaluation.[7]

Semantic similarity (SIM): A style transfer system can achieve high ACC scores without maintaining the semantics of the input sentence, which motivates also measuring how much a transferred sentence deviates in meaning from the input. 15 / 23 surveyed papers use n-gram metrics like BLEU (Papineni et al., 2002) against reference sentences, often along with self-BLEU with the input, to evaluate semantic similarity. Using BLEU in this way has many problems, including (1) unreliable correlations between n-gram overlap and human evaluations of semantic similarity (Callison-Burch et al., 2006), (2) discouraging output diversity (Wieting et al., 2019), and (3) not upweighting important semantic words over other words (Wieting et al., 2019; Wang et al., 2020). These issues motivate us to measure semantic similarity using the subword embedding-based SIM model of Wieting et al. (2019), which performs well on semantic textual similarity (STS) benchmarks in SemEval workshops (Agirre et al., 2016).[8]

Fluency (FL): A system that produces ungrammatical outputs can still achieve high scores on both ACC and SIM, motivating a separate measure for fluency. Only 10 out of 23 surveyed papers did a fluency evaluation; 9 of which used language model perplexity, which is a poor measure because (1) it is unbounded and (2) unnatural sentences with common words tend to have low perplexity (Mir et al., 2019; Pang, 2019). To tackle this we replace perplexity with the accuracy of a RoBERTa-large classifier trained on the CoLA corpus (Warstadt et al., 2019), which contains sentences paired with grammatical acceptability judgments. In Table 1, we show that our classifier marks most reference sentences as fluent, confirming its validity.[9]

Human evaluation: As automatic evaluations are insufficient for evaluating text generation (Liu et al., 2016; Novikova et al., 2017), 17 out of 23 surveyed style transfer papers also conduct human evaluation. In our work, we evaluate SIM and FL using human evaluations.[10] As we treat style transfer as a paraphrase generation task, we borrow the three-point scale used previously to evaluate paraphrases (Kok and Brockett, 2010; Iyyer et al., 2018), which jointly captures SIM and FL. Given the original sentence and the transferred sentence, annotators on Amazon Mechanical Turk can choose one of three options: **0** for no paraphrase relationship; **1** for an ungrammatical paraphrase; and **2** for a grammatical paraphrase. A total of 150 sentence pairs were annotated per model, with three annotators per pair. More details on our setup, payment & agreement are provided in Appendix A.10.

3.2 Aggregation of Metrics

So far, we have focused on individual implementations of ACC, SIM, and FL. After computing these metrics, it is useful to aggregate them into a single number to compare the overall style transfer quality across systems (Pang, 2019). However, only 5 out of the 23 papers aggregate these metrics, either at the corpus level (Xu et al., 2018; Pang and Gimpel, 2019) or sentence level (Li et al., 2018). Even worse, the corpus-level aggregation scheme can be easily gamed. Here, we describe a naïve system that outperforms state-of-the-art style transfer systems when evaluated using corpus-level aggregation, and we present a new sentence-level aggregation metric that fixes the issue.

The issue with corpus-level aggregation: Aggregating ACC, SIM, and FL is inherently difficult

---

[7] The RoBERTa style classifier, built with `fairseq` (Ott et al., 2019), achieves a test accuracy of 90.4% on the Shakespeare data(vs 83.5% for CNN) and 94.8% on the Formality data (vs 92.4%). The datasets are introduced in Section 4.1.

[8] For reference, we evaluate with BLEU in Appendix A.5.

[9] Mir et al. (2019) also recommended a similar method to evaluate fluency instead of perplexity, where they train classifiers to distinguish between machine / human sentences.

[10] We do not conduct human evaluations for ACC since style classification is difficult for an untrained crowdsourced worker unfamiliar with the set of target styles.

because they are inversely correlated with each other (Pang, 2019). Prior work has combined these three scores into a single number using geometric averaging (Xu et al., 2018) or learned weights (Pang and Gimpel, 2019). However, the aggregation is computed *after* averaging each metric independently across the test set (*corpus-level aggregation*), which is problematic since systems might generate sentences that optimize only a subset of metrics. For example, a Shakespeare style transfer system could output *Wherefore art thou Romeo?* regardless of its input and score high on ACC and FL, while a model that always copies its input would score well on SIM and FL (Pang, 2019).

A Naïve Style Transfer System: To concretely illustrate the problem, we design a naïve baseline that exactly copies its input with probability p and chooses a random sentence from the target style corpus for the remaining inputs, where p is tuned on the validation set.[11] When evaluated using geometric mean corpus-level aggregation (GM column of Table 1) this system *outperforms* state of the art methods (UNMT, DSLM) on the Formality dataset despite not doing any style transfer at all!

Proposed Metric: A good style transfer system should **jointly** optimize all metrics. The strong performance of the naïve baseline with corpus-level aggregation indicates that metrics should be combined at the sentence level *before* averaging them across the test set (*sentence aggregation*). Unfortunately, **only 3** out of 23 surveyed papers measure absolute performance after *sentence-level aggregation*, and all of them use the setup of Li et al. (2018), which is specific to human evaluation with Likert scales. We propose a more general alternative,

$$J(\text{ACC}, \text{SIM}, \text{FL}) = \sum_{x \in \mathbf{X}} \frac{\text{ACC}(x) \cdot \text{SIM}(x) \cdot \text{FL}(x)}{|\mathbf{X}|}$$

where x is a sentence from a test corpus $\mathbf{X}$. We treat ACC and FL at a sentence level as a binary judgement, ensuring incorrectly classified or disfluent sentences are automatically assigned a score of 0. As a sanity check, our naïve system performs extremely poorly on this new metric (Table 1), as input copying will almost always yield an ACC of zero, while random retrieval results in low SIM.

4 Experiments & Results

We evaluate our method (STRAP) on two existing style transfer datasets, using the evaluation methodology proposed in Section 3. Our system significantly outperforms state of the art methods and the naïve baseline discussed in Section 3.2.

4.1 Datasets

We focus exclusively on semantics-preserving style transfer tasks, which means that we do not evaluate on *attribute transfer* datasets such as sentiment, gender, and political transfer. Specifically, we use two standard benchmark datasets for Shakespeare author imitation and formality transfer to compare STRAP against prior work. While both datasets contain parallel data, we only use it to automatically evaluate our model outputs; for training, we follow prior work by using the non-parallel train-validation-test splits from He et al. (2020).

The **Shakespeare author imitation** dataset (Xu et al., 2012) contains 37k training sentences from two styles — William Shakespeare's original plays, and their modernized versions. Shakespeare's plays are written in Early Modern English, which has a significantly different lexical (e.g., *thou* instead of *you*) and syntactic distribution compared to modern English. Our second dataset is **Formality transfer** (Rao and Tetreault, 2018), which contains 105k sentences, also from two styles. Sentences are written either in formal or informal modern English. Unlike formal sentences, informal sentences tend to have more misspellings, short forms (*u* instead of *you*), and non-standard usage of punctuation.

4.2 Comparisons against prior work

We compare STRAP on the Shakespeare / Formality datasets against the following baselines:

- COPY: a lower bound that simply copies its input, which has been previously used in prior work (Subramanian et al., 2019; Pang, 2019)
- NAÏVE: our method from Section 3.2 that randomly either copies its input or retrieves a sentence from the target style
- REF: an upper bound computed by evaluating reference sentences using our metrics
- UNMT: unsupervised neural machine translation from Subramanian et al. (2019)
- DLSM: the deep latent sequence model from

---

[11] p = 0.4 / 0.5 for Formality / Shakespeare datasets.

Model	Formality (GYAFC)					Shakespeare

	$p = 0.0$	70.7	**79.3**	**56.0**	**47.3**
	$p = 0.9$	**74.7**	54.0	38.0	24.7

Table 2: Human evaluation of STRAP with greedy decoding ($p = 0.0$) and nucleus sampling ($p = 0.9$) shows large improvements (**4-5x**) on both the Formality (Form.) and Shakespeare (Shak.) datasets. Details on metric calculations are provided in Appendix A.10.

He et al. (2020), which is currently state-of-the-art on both datasets.[12]

STRAP significantly outperforms the prior state of the art (DLSM) on automatic metrics (Table 1) with a $J(\cdot)$ score of 45.5 (vs 18.6) on Formality and 34.7 (vs 16.3) on Shakespeare. The improvements are even larger when SIM and FL are measured through human evaluations (Table 2): in this setting, STRAP achieves 41.3 (vs 10.0) on Formality and 47.3 (vs 9.3) on Shakespeare. Across the board, STRAP significantly improves in SIM and FL while maintaining similar ACC. Finally, the large gap between REF and STRAP on automatic metrics provides exciting avenues for future research.[13]

Dataset	Model	ACC	SIM	FL	J(A,S,F)
Form.	STRAP	67.7	72.5	90.4	45.5
	– Inf. PP	27.5	78.5	88.2	20.7
	– Mult. PP	63.1	72.0	90.8	42.3
	– Div. PP	61.2	79.5	88.7	43.8
	– GPT2	84.6	43.8	61.7	23.1
	GPT2-md	71.0	70.7	88.6	45.8
	GPT2-sm	69.1	68.6	87.6	42.9
Shak.	STRAP	71.7	56.4	85.2	34.7
	– Inf. PP	40.1	66.1	76.3	23.3
	– Mult. PP	45.9	56.5	91.1	24.8
	– Div. PP	49.7	64.4	82.9	28.2
	– GPT2	75.6	26.7	66.9	13.6
	GPT2-md	73.4	54.0	86.4	34.3
	GPT2-sm	68.0	53.2	84.6	31.5

Table 3: Ablation study using automatic metrics on the Formality (Form.) and Shakespeare (Shak.) datasets.

5 Ablation studies

In this section, we perform several ablations on STRAP to understand which of its components contribute most to its improvements over baselines. Overall, these ablations validate the importance of both paraphrasing and pretraining for style transfer.

Paraphrase diversity improves ACC: How critical is diversity in the paraphrase generation step? While our implementation of f_{para} is trained on data that is heavily-filtered to promote diversity, we also build a non-diverse paraphrase model by removing this diversity filtering of PARANMT-50M but keeping all other experimental settings identical. In Table 3, the *–Div. PP* rows show a drop in ACC across both datasets as well as higher SIM, which in both cases results in a lower $J(\cdot)$ score. A qualitative inspection reveals that the decreased ACC and increased SIM are both due to a greater degree of input copying, which motivates the importance of diversity.

Paraphrasing during inference improves ACC:

---

[12] We use the implementations of both UNMT and DLSM made publicly available by He et al. (2020), and we verify that their UNMT model performs on par with reported sentiment transfer numbers in Subramanian et al. (2019). The original code of Subramanian et al. (2019) has not been open-sourced.

[13] Results with other metrics such as BLEU, as well as comparisons against several other baselines like Li et al. (2018); Prabhumoye et al. (2018); Luo et al. (2019); Dai et al. (2019); Sudhakar et al. (2019) are provided in Appendix A.5. STRAP significantly outperforms all prior work.

The diverse paraphraser f_{para} is obviously crucial to train our model, as it creates pseudo-parallel data for training f^i_{inv}, but is it necessary during inference? We try directly feeding in the original sentence (without the initial paraphrasing step) to the inverse paraphrase model f^i_{inv} during inference, shown in the *–Inf. PP* row of Table 3. While SIM and FL are largely unaffected, there is a large drop in ACC, bringing down the overall score (45.5 to 20.7 in Formality, 34.7 to 23.3 in Shakespeare). This supports our hypothesis that the paraphrasing step is useful for normalizing the input.

LM pretraining is crucial for SIM and FL: As we mainly observe improvements on FL and SIM compared to prior work, a natural question is how well does STRAP perform without large-scale LM pretraining? We run an ablation study by replacing the GPT-2 implementations of f_{para} and f^i_{inv} with LSTM seq2seq models, which are trained with global attention (Luong et al., 2015) using OpenNMT (Klein et al., 2017) with mostly default hyperparameters.[14] As seen in the *– GPT2* row of Table 3, this model performs competitively with the UNMT / DLSM models on J(ACC,SIM,FL), which obtain 20.0 / 18.6 on Formality (Table 1), respectively. However, it is significantly worse than STRAP, with large drops in SIM and FL.[15] This result shows the merit of both our algorithm and the boost that LM pretraining provides.[16]

Nucleus sampling trades off ACC for SIM: While our best performing system uses a greedy decoding strategy, we experiment with nucleus sampling (Holtzman et al., 2020) by varying the nucleus p value in both Table 1 and Table 2. As expected, higher p improves diversity and trades off increased ACC for lowered SIM. We find that $p = 0.6$ is similar to greedy decoding on $J(\cdot)$ metrics, but higher p values degrade performance.

Multiple inverse paraphrasers perform better than a single style-conditional model: Finally, we explore a more parameter-efficient alternative to training a separate inverse paraphrase model per style. Prior work in conditioned language models feed style-specific tokens as input to a single model to control the output style (Johnson et al., 2017; Keskar et al., 2019). We adopt this strategy by feeding in the average RoBERTa-large `[CLS]` vectors (by running the pretrained classifier on the training data) as style indicators to a single f^i_{inv}. We present results in Table 3 as *–Mult. PP*. This strategy is not as effective as training a different paraphrase model per style, primarily due to drop in ACC. We hypothesize this is due to a conflict between different style distributions in a single model.

	1810-1830	1890-1910	1990-2010	AAE Tweets	Bible	Tweets	James Joyce	Lyrics	Poetry	Shakespeare	Switchboard
1810-1830	34	24	9	2	7	4	7	3	3	7	0

Figure 3: **Classifier confusion after style transfer**. Every row shows the classifier label distribution on sentences *transferred to* the target style (the row label). The off-diagonal elements show mis-classifications with intuitive domain similarities, such as (Lyrics, Poetry); (AAE, Tweets); (Joyce, Shakespeare).

6 Towards Real-World Style Transfer

All of our experiments and ablations thus far have been on the Shakespeare and Formality datasets, which contain just two styles each. To explore the ability of our system to perform style transfer between many diverse styles, we create the **C**orpus of **D**iverse **S**tyles (CDS), a new non-parallel style transfer benchmark dataset with 11 diverse styles (15M tokens), and use it to evaluate STRAP.

Corpus of Diverse Styles: To create CDS, we obtain data (Table 5) from existing academic research datasets (Godfrey et al., 1992; Blodgett et al., 2016) and public APIs or online collections like Project Gutenberg (Hart, 1992). We choose styles that are easy for human readers to identify at a sentence level (e.g., Tweets or Biblical text), and the left side of Figure 2 confirms that machines also cluster CDS into eleven distinct styles. While prior benchmarks involve a transfer between two styles, CDS has 110 potential transfer directions.

---

[14] The only hyperparameter we tune is the learning rate schedule. More details in Appendix A.4.

[15] A qualitative inspection of outputs confirms the LSTM struggles to maintain semantics. We suspect this is due to lack of training data (< 75K pairs) to learn a powerful paraphraser.

[16] Additionally, we note that weaker pretrained language models like GPT2-medium (*GPT2-md*) perform similarly to GPT2-large, while GPT2-small (*GPT2-sm*) is notably worse.

Direction	Input	Output
Tweet → Shak.	yall kissing before marriage?	And you kiss'd before your nuptial?
Lyrics → AAE	It's a good thing you don't have bus fare	It's a good thing u aint gettin no ticket
Tweet → Poetry	Its so disrespectful I hate itttttt	For 'tis so rude, I have a sick regard,
Shak. → Tweet	Need you my help?	Are yall okay? Like do you need my help??
AAE → Shak.	Aint got nooooo holiday spirit frfr	No spirit of this holiday, gentle man.
Poetry → Bible	For the foul thief is just at your gate.	the wicked thief art at thy door.
1990. → Tweet	Now I can't talk to him about it.	I dont wanna talk to him abt that
1990. → Poetry	I don't know why, but I sensed there was something wrong.	Something felt wrong; I knew not why,
Tweet → Bible	when ur going thru an episode and cant cope anymore	when thou art in an episode, and cannot stand it any more;
1890. → AAE	I was just thinking the same thing that you have expressed.	u said the same thing i thought lol
1990. → 1810.	He was being terrorized into making a statement by the same means as the other so-called "witnesses."	Terror had been employed in the same manner with the other witnesses, to compel him to make a declaration.
AAE → Shak.	If I got a dollar every time one of my friends told me they hate me, I'd be rich	I would have been rich, had I but a dollar for every friend that hath said they hate me.
Joyce → Bible	I appeal for clemency in the name of the most sacred word our vocal organs have ever been called upon	I beseech thee in the name of the most holy word which is in our lips, forgive us our trespasses.

Table 4: Example outputs from STRAP trained on our CDS dataset (more generations in Appendix A.11).

Style	Size	Style	Size
Shakespeare	27.5K	Lyrics	5.1M
James Joyce	41.2K	1810-1830	216.0K
English Tweets	5.2M	1890-1910	1.3M
AAE Tweets	732.3K	1990-2010	2.0M
Romantic Poetry	29.8K	Bible	34.8K
Switchboard	148.8K		

Table 5: List of styles in our dataset along with the their total sizes. The year periods (like "1810-1830") refer to sentences from the Corpus of Historical American English (Davies, 2012). "AAE Tweets" refers to African American English Tweets corpus from Blodgett et al. (2016). "Switchboard" is a collection of conversational speech transcripts from Godfrey et al. (1992). Details of the collection and examples are in Appendix A.6.

We present dataset examples, details on collection and style similarity analysis in Appendix A.6.

Diverse paraphrasing normalizes stylized text With eleven styles, we can better validate the effectiveness of our diverse paraphraser at normalizing input sentences. After training an 11-way style classifier on CDS using RoBERTa-large, we observe an accuracy of **88.9%** on the original validation set. After paraphrasing the validation set with f_{para}, this classifier only correctly classifies **42.5%** sentences, indicating a significant decrease in recognizable stylistic features. Figure 2 further demonstrates this normalization effect. Finally, the magnitude of normalization is lower with the non-diverse paraphraser (from Section 5), with a smaller accuracy drop to **51.5%** after paraphrasing;[17] qualitatively, the diverse model exhibits more lexical swaps and syntactic diversity.[18]

Shakespeare ↔ English Tweets, CDS				
Model	ACC	SIM	FL	J(A,S,F)
COPY	0.1	100.0	69.2	0.0
UNMT (2019)	76.7	20.6	37.7	4.4
DLSM (2020)	64.2	19.6	33.1	2.0
STRAP ($p = 0.0$)	20.3	65.0	81.1	8.7
STRAP ($p = 0.6$)	31.1	58.1	75.0	10.8
STRAP ($p = 0.9$)	43.2	54.5	68.3	**13.9**

Table 6: A controlled comparison between models on 2 styles from CDS using automatic evaluation. ACC is calculated using our **11-way** CDS classifier and SIM is with input. STRAP greatly outperforms prior work.

Style Transfer on CDS: We measure STRAP's performance on CDS using Section 3's evaluation methodology. We sample 1K sentences from each style and use STRAP to transfer these sentences to each of the 10 other styles. Despite having to deal with many more styles than before, our system achieves **48.4%** transfer accuracy (on a 11-way RoBERTa-large classifier), a paraphrase similarity score of **63.5**, and **71.1%** fluent generations, yielding a J(ACC,SIM,FL) score of 20.7. A break-

---

[17] Even if we retrain the classifiers on a paraphrased version of the training set (to model the distribution better), the performance is only 65.8% for the diverse model and 72.3% for the non-diverse model, indicating a loss in style signal.

[18] On average, the diverse model has 51% unigram F1 word overlap and 27% word shuffling measured by Kendall's τ_B, compared to 28% unigram F1 and 6% shuffling for the non-diverse model; Appendix A.7 has a style-wise breakdown.

Direction	Input → Paraphrase → Output	Analysis
Shak. → Bible	Have you importuned him by any means? → did you ever try to import him? → hast thou ever tried to import him?	Misunderstanding the word "importune" — the model believes it refers to *import* rather than *harass / bother*.
1990. → Tweet.	The machine itself is made of little straws of carbon. → the machine is made of straw. → Machine made of straw.	Dropping of important semantic words during diverse paraphrasing ("carbon") significantly warps the meaning of sentences
Swit. → Shak.	well they offer classes out at uh Ray Hubbard → they're offering a course at Ray Hubbard's. → They do offer a course at the house of the Dukedom.	Hallucination of tokens irrelevant to the input ("house of the dukedom") to better reflect style distribution.
Tweet → Swit.	Knoxville aint for me → I'm not in Knoxville. → i don't know Knoxville	Subtle modifications in semantics since the models fail to understand their inputs.

Table 7: Representative examples showing the common failure modes of STRAP when evaluated on CDS.

down of style-specific performance is provided in Appendix A.8. An error analysis shows that the classifier misclassifies some generations as styles sharing properties with the target style (Figure 3).

Controlled comparisons: To ground our CDS results in prior work, we compare STRAP with baselines from Section 4.2. We sample equal number of training sentences from two challenging styles in CDS (Shakespeare, English Tweets) and train all three models (UNMT, DLSM, STRAP) on this subset of CDS.[19] As seen in Table 6, STRAP greatly outperforms prior work, especially in SIM and FL. Qualitative inspection shows that baseline models often output arbitrary style-specific features, completely ignoring input semantics (explaining poor SIM but high ACC).

Qualitative Examples: Table 4 contains several outputs from STRAP; see Appendix A.11 for more examples. We also add more qualitative analysis of the common failures of our system in Table 7. Our model makes mistakes similar to contemporary text generation systems — poor understanding of rare words, dropping / modification of semantic content, hallucination to better reflect training distribution.

7 Related Work

Unsupervised style transfer is often modeled by disentangling style & content using attribute classifiers (Hu et al., 2017; Shen et al., 2017), policy gradient training (Xu et al., 2018; Luo et al., 2019) or retrieval-based approaches (Li et al., 2018). Recently, backtranslation has emerged as a method to model semantic preservation (Prabhumoye et al., 2018), but this method can also warp semantics as seen in Subramanian et al. (2019); as such, we only use it to build our paraphraser's training data after heavy filtering. Our work relates to recent efforts that use Transformers in style transfer (Sudhakar et al., 2019; Dai et al., 2019). Closely related to our work is Gröndahl and Asokan (2019), who over-generate paraphrases using a complex hand-crafted pipeline and filter them using proximity to a target style corpus. Instead, we *automatically learn* style-specific paraphrasers and do not need over-generation at inference. Relatedly, Preotiuc-Pietro et al. (2016) present qualitative style transfer results with statistical MT paraphrasers. Other, less closely related work on control & diversity in text generation is discussed in Appendix A.12.

8 Conclusion

In this work we model style transfer as a controlled paraphrase generation task and present a simple unsupervised style transfer method using diverse paraphrasing. We critique current style transfer evaluation using a survey of 23 papers and propose fixes to common shortcomings. Finally, we collect a new dataset containing 15M sentences from 11 diverse styles. Possible future work includes (1) exploring other applications of diverse paraphrasing, such as data augmentation; (2) performing style transfer at a paragraph level; (3) performing style transfer for styles unseen during training, using few exemplars provided during inference.

A Appendices for "Reformulating Unsupervised Style Transfer as Paraphrase Generation"

A.1 PARANMT-50M Filtering Details

We train our paraphrase model in a seq2seq fashion using the PARANMT-50M corpus (Wieting and Gimpel, 2018), which was constructed by back-translating (Sennrich et al., 2016) the Czech side of the CzEng parallel corpus (Bojar et al., 2016). This corpus is large and noisy and we aggressively filter it to encourage content preservation and diversity maximization. We use the following filtering,

Content Filtering: We remove all sentence pairs which score lower than 0.5 on a strong paraphrase similarity model from Wieting et al. (2019).[20] We filter sentence pairs by length, allowing a maximum length difference of 5 words between paired sentences. Finally, we remove very short and long sentences by only keeping sentence pairs with an average token length between 7 and 25.

Lexical Diversity Filtering: We only preserve backtranslated pairs with sufficient unigram distribution difference. We filter all pairs where more than 50% of words in the backtranslated sentence can be found in the source sentence. This is computed using the SQuAD evaluation scripts (Rajpurkar et al., 2016). Additionally, we remove sentences with more than 70% trigram overlap.

Syntactic Diversity Filtering: We discard all paraphrases which have a similar word ordering. We compare the relative ordering of the words shared between the input and backtranslated sentence by measuring the Kendall tau distance (Kendall, 1938) or the "bubble-sort" distance. We keep all backtranslated pairs which are at least 50% shuffled.[21]

LangID Filtering: Finally, we discard all sentences where both the input and backtranslated sentence are classified as non-English using `langdetect`.[22]

Effect of each filter: We adopt a pipelined approach to filtering. The PARANMT-50M corpus size after each stage of filtering is shown in Table 8.

	Filter Stage	Corpus Size
0.	Original	51.41M
1.	Content Similarity	30.49M
2.	Trigram Diversity	9.03M
3.	Unigram Diversity	1.96M
4.	Kendall-Tau Diversity	112.01K
5.	Length Difference	82.64K
6.	LangID	74.55K

Table 8: Steps of filtering conducted on PARANMT-50M along with its effect on corpus size.

A.2 Generative Model Details

This section provides details of our seq2seq model used for both paraphrase model and style-specific inverse paraphrase model. Recent work (Radford et al., 2019) has shown that GPT2, a massive transformer trained on a large corpus of unlabeled text using the language modeling objective, is very effective in performing more human-like text generation. We leverage the publicly available GPT2-large checkpoints by finetuning it on our custom datasets with a small learning rate. However, GPT2 is an unconditional language model having only a decoder network, and traditional seq2seq setups use separate encoder and decoder neural network (Sutskever et al., 2014) with attention (Bahdanau et al., 2014). To avoid training an encoder network from scratch, we use the encoder-free seq2seq modeling approach described in Wolf et al. (2018). where both input and output sequences are fed to the decoder network separated with a special token, and use separate segment embeddings. Our model is implemented using the `transformers` library[23] (Wolf et al., 2019). We use encoder-free seq2seq modeling (Wolf et al., 2018) which feeds the input into the decoder neural network, separating it with segment embeddings. We fine-tune GPT2-large to perform encoder-free seq2seq modeling.

Architecture: Let $\mathbf{x} = (x_1, ..., x_n)$ represent the tokens in the input sequence and let $\mathbf{y} = (y_{bos}, y_1, ..., y_m, y_{eos})$ represent the tokens of the output sequence, where y_{bos} and y_{eos} corresponds to special beginning and end of sentence tokens. We feed the sequence $(x_1, ..., x_n, y_{bos}, y_1, ..., y_m)$ as input to GPT2 and train it on the next-word prediction objective for the tokens $y_1, ..., y_m, y_{eos}$

---

[20] We use the SIM model from Wieting et al. (2019), which achieves a strong performance on the SemEval semantic text similarity (STS) benchmarks (Agirre et al., 2016)

[21] An identical ordering of words is 0% shuffled whereas a reverse ordering is 100% shuffled.

[22] This is using the Python port of Nakatani (2010), `https://github.com/Mimino666/langdetect`.

[23] `https://github.com/huggingface/transformers`

using the cross-entropy loss. During inference, the sequence $(x_1, ..., x_n, y_{bos})$ is fed as input and the tokens are generated in an autoregressive manner (Vaswani et al., 2017) until y_{eos} is generated.

Every token in $\mathbf{x}$ and $\mathbf{y}$ is passed through a shared input embedding layer to obtain a vector representation of every token. To encode positional and segment information, learnable positional and segment embeddings are added to the input embedding consistent with the GPT2 architecture. Segment embeddings are used to denote whether a token belongs to sequence $\mathbf{x}$ or $\mathbf{y}$.

Other seq2seq alternatives: Note that our unsupervised style transfer algorithm is agnostic to the specific choice of seq2seq modeling. We wanted to perform transfer learning from massive left-to-right language models like GPT2, and found the encoder-free seq2seq approach simple and effective. Future work includes finetuning more recent models like T5 (Raffel et al., 2019) or BART (Lewis et al., 2019). These models use the standard seq2seq setup of separate encoder / decoder networks and pretrain them jointly using denoising autoencoding objectives based on language modeling.

Hyperparameter Details: We finetune GPT2-large using NVIDIA TESLA M40 GPUs for 2 epochs using early stopping based on validation set perplexity. The models are finetuned using a small learning rate of 5e-5 and converge to a good solution fairly quickly as noticed by recent work (Li et al., 2020; Kaplan et al., 2020). Specifically, each experiment completed within a day of training on a single GPU, and many experiments with small datasets took a lot less time. We use a minibatch size of 10 sentence pairs and truncate sequences which are longer than 50 subwords in the input or output space. We use the Adam optimizer (Kingma and Ba, 2015) with the weight decay fix and using a linear learning rate decay schedule, as implemented in the `transformers` library. Finally, we left-pad the input sequence to get a total input length of 50 subwords and right-pad output sequence to get a total output length of 50 subwords. This special batching is necessary to use minibatches during inference time. Special symbols are used to pad the sequences and they are not considered in the cross-entropy loss. Our model has 774M trainable parameters, identical to the original GPT2-large.

A.3 Classifier Model Details

We fine-tune RoBERTa-large to build our classifier, using the official implementation in `fairseq`. We use a learning rate of 1e-5 for all experiments with a minibatch size of 32. All models were trained on a single NVIDIA RTX 2080ti GPU, with gradient accumulation to allow larger batch sizes. We train models for 10 epochs and use early stopping on the validation split accuracy. We use the Adam optimizer (Kingma and Ba, 2015) with modifications suggested in the RoBERTa paper (Liu et al., 2019). Consistent with the suggested hyperparameters, we use a learning rate warm-up for the first 6% of the updates and then decay the learning rate.

A.4 OpenNMT Model Details

We train sequence-to-sequence models with attention based on LSTMs using OpenNMT (Klein et al., 2017) using their PyTorch port.[24] We mostly used the default hyperparameter settings of `OpenNMT-py`. The only hyperparameter we modified was the learning rate schedule, since our datasets were small and overfit quickly. For the paraphrase model, we started decay after 11000 steps and halved the learning rate every 1000 steps. For Shakespeare, we started the decay after 3000 steps and halved the learning rate every 500 steps. For Formality, we started the decay after 6000 steps and halved the learning rate every 1000 steps. These modifications only slightly improved validation perplexity (by 3-4 points in each case).

We used early stopping on validation perplexity and checkpoint the model every 500 optimization steps. The other hyperparameters are the default `OpenNMT-py` settings — SGD optimization using learning rate 1.0, LSTM seq2seq model with global attention (Luong et al., 2015), 500 hidden units and embedding dimensions and 2 layers each in the encoder and decoder.

A.5 More Comparisons with Prior Work

Please refer to Table 12 for an equivalent of Table 1 using BLEU scores.

We present more comparisons with prior work in Table 13. We use the generated outputs for the Formality test set available in the public repository of Luo et al. (2019) (including outputs from the algorithms described in Prabhumoye et al., 2018 and Li et al., 2018) and run them on our evaluation pipeline. We compare the results

---

[24] `https://github.com/OpenNMT/OpenNMT-py`

with our formality transfer model used in Table 1 and Table 2. We note significant performance improvements, especially in the fluency of the generated text. Note that there is a domain shift for our model, since we trained our model using the splits of He et al. (2020) which use the Entertainment & Music splits of the Formality corpus. The outputs in the repository of Luo et al. (2019) use the Family & Relationships split. It is unclear in the paper of Luo et al. (2019) whether the models were trained on the Family & Relationships training split or not.

Other Comparisons: We tried to compare against other recent work in style transfer based on Transformers, such as Dai et al. (2019) and Sudhakar et al. (2019). Both papers do not evaluate their models on the datasets we use (Shakespeare and Formality), where parallel sentences preserve semantics.

The only datasets used in Dai et al. (2019) were sentiment transfer benchmarks, which modify semantic properties of the sentence. We attempted to train the models in Dai et al. (2019) using their codebase on the Shakespeare dataset, but faced three major issues 1) missing number of epochs / iterations. The early stopping criteria is not implemented or specified, and metrics were being computed on the *test set* every 25 training iterations, which is invalid practice for choosing the optimal checkpoint; 2) specificity of the codebase to the Yelp sentiment transfer dataset in terms of maximum sequence length and evaluation, making it non-trivial to use for any other dataset; 3) despite our best efforts we could not get the model to converge to a good minima which would produce fluent text (besides word-by-word copying) when trained on the Shakespeare dataset.

Similarly, the datasets used in Sudhakar et al. (2019) modify semantic properties (sentiment, political slant etc.). On running their codebase on the Shakespeare dataset using the default hyperparameters, we achieved a poor performance of 53.1% ACC, 55.2 SIM and 56.5% FL, aggregating to a J(A,S,F) score of 18.4. Similarly on the Formality dataset, performance was poor with 41.7% ACC, 67.8 SIM and 67.7% FL, aggregating to J(A,S,F) score of 18.1. A qualitatively inspection showed very little abstraction and nearly word-by-word copying from the input (due to the delete & generate nature of the approach), which explains the higher SIM score but lower ACC score (just like COPY baseline in Table 1). Fluency was low despite GPT pretraining, perhaps due to the token deletion step in the algorithm.

A.6 Details of our Dataset, CDS

We provide details of our sources, the sizes of individual style corpora and examples from our new benchmark dataset CDS in Table 14. We individually preprocessed each corpus to remove very short and long sentences, boilerplate text (common in Project Gutenberg articles) and section headings. We have added some representative examples from each style in Table 14. More representative examples (along with our entire dataset) will be provided in the project page `http://style.cs.umass.edu`.

Style Similarity: In Figure 4 we plot the cosine similarity between styles using the averaged `[CLS]` vector of the trained RoBERTa-large classifier (inference over validation set). The off-diagonal elements show intuitive domain similarities, such as (Lyrics, Poetry); (AAE, Tweets); (Joyce, Shakespeare) or among classes from the Corpus of Historical American English.

A.7 Diverse Paraphrasing on CDS

We compare the quality and diversity of the paraphrases generated by our diverse and non-diverse paraphrasers on our dataset CDS in Table 16. Note that this is the pseudo parallel training data for the inverse paraphrase model (described in Section 2.1 and Section 2.4) and not the actual style transferred sentences. Overall, the diverse paraphraser achieves high diversity, with 51% unigram change and 27% word shuffling,[25] compared to 28% unigram and 6% shuffling for non-diverse paraphraser, while maintaining good semantic similarity (SIM= 72.5 vs 83.9 for non-diverse) even in complex stylistic settings.

A.8 Style Transfer Performance on CDS

We provide a detailed breakdown of performance in different styles of CDS in Table 15. For each of the 11 target styles, we style transferred 1,000 sentences from every other style and jointly evaluated the 10,000 generations. Some styles are more successfully transferred than others, such as Switchboard, Lyrics and James Joyce. While wearing the

---

[25] The "unigram change" and "word shuffling" refer to the unigram F1 word overlap and Kendall's τ_B scores.

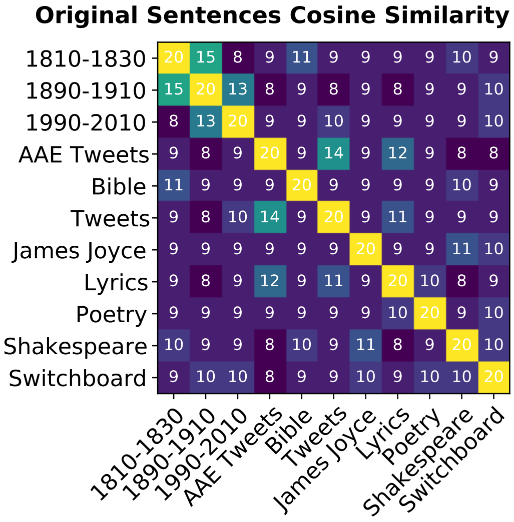

Figure 4: Cosine similarities between styles in CDS using the `[CLS]` vectors of the RoBERTa-large classifier (normalized to $[0, 20]$). The off-diagonal elements show intuitive domain similarities, such as (Lyrics, Poetry); (AAE, Tweets); (Joyce, Shakespeare) or among classes from the COHA corpus.

p value for nucleus sampling, we notice a trend similar to the **Nucleus sampling trades off ACC for SIM** experiment in Section 5. Increasing the p value improves ACC at the cost of SIM. However unlike the Shakespeare and Formality dataset, we find $p = 0.6$ the optimal value for the best ACC-SIM tradeoff.

Note that Fluency scores on this dataset could be misleading since even the original sentences from some styles are often classified as disfluent (Orig. FL). Qualitatively, this seems to happen for styles with rich lexical and syntactic diversity (like Romantic Poetry, James Joyce). These styles tend to be out-of-distribution for the fluency classifier trained on the CoLA dataset (Warstadt et al., 2019).

A.9 A Survey of Evaluation Methods

We present a detailed breakdown of evaluation metrics used in prior work in Table 10 and the implementations of the metrics in Table 11. Notably, only 3 out of 23 prior works use an absolute sentence-level aggregation evaluation. Other works either perform "overall A/B" testing, flawed corpus-level aggregation or don't perform any aggregation at all. Note that while "overall A/B" testing cannot be gamed like corpus-aggregation, it has a few issues — (1) it is a *relative* evaluation and does not provided an *absolute* performance score for future reference; (2) "A/B" testing requires human evaluation, which is expensive and noisy; (3) evaluating overall performance will require human annotators to be familiar with the styles and style transfer task setup; (4) Kahneman (2011) has shown that asking humans to give a single number for "overall score" is biased when compared to an aggregation of *independent* scores on different metrics. Luckily, the sentence-level aggregation in Li et al. (2018) does the latter and is the closest equivalent to our proposed $J(\cdot)$ metric.

A.10 Details on Human Evaluation

We conduct experiments of Amazon Mechanical Turk, annotating the paraphrase similarity of 150 sentences with 3 annotators each. We report the label chosen by two or more annotators, and collect additional annotations in the case of total disagreement. We pay workers 5 cents per sentence pair ($10-15 / hr). We only hire workers from USA, UK and Australia with a 95% or higher approval rating and at least 1000 approved HITs. Sentences where the input was exactly copied (after lower-casing and removing punctuation) are automatically assigned the option **2** paraphrase and grammatical. Even though these sentences are clearly not style transferred, we expect them to be penalized in $J(\text{ACC,SIM,FL})$ by poor ACC. We found that every experiment had a Fleiss kappa (Fleiss, 1971) of at least 0.13 and up to 0.45 (slight to moderate agreement according to (Landis and Koch, 1977)). A qualitative inspection showed that crowdworkers found it easier to judge sentence pairs in the Formality dataset than Shakespeare, presumably due to greater familiarity with modern English. We also note that crowdworkers had higher agreement for sentences which were clearly not paraphrases (like the UNMT / DLSM generations on the Formality dataset).

Calculating Metrics in Table 2: To calculate SIM, we count the percentage of sentences which humans assigned a label **1** (ungrammatical paraphrase) or **2** (grammatical paraphrase). This is used as a binary value to calculate $J(\text{ACC, SIM})$. To calculate $J(\text{ACC, SIM, FL})$, we count sentences which are correctly classified as well as humans assigned a label of **2** (grammatical paraphrase). We cannot calculate FL alone using the popular 3-way evaluation, since the fluent sentences which are not paraphrases are not recorded.

A.11 More Example Generations

More examples are provided in Table 9. All of our style transferred outputs on CDS will be available in the project page of this work, `http://style.cs.umass.edu`.

A.12 More Related Work

Our inverse paraphrase model is a style-**controlled text generator** which automatically learns lexical and syntactic properties prevalent in the style's corpus. Explicit syntactically-controlled text generation has been studied previously using labels such as constituency parse templates (Iyyer et al., 2018; Akoury et al., 2019) or learned discrete latent templates (Wiseman et al., 2018). Syntax can also be controlled using an exemplar sentence (Chen et al., 2019; Guu et al., 2018; Peng et al., 2019). While style transfer requires the underlying content to be provided as input, another direction explores attribute-controlled *unconditional* text generation (Dathathri et al., 2020; Keskar et al., 2019; Zeng et al., 2020; Ziegler et al., 2019).

Diversity in text generation is often encouraged during inference time via heuristic modifications to beam search (Li et al., 2016; Vijayakumar et al., 2018), nucleus sampling (Holtzman et al., 2020) or submodular optimization (Kumar et al., 2019); in contrast, we simply filter our training data to increase diversity. Other algorithms learn to condition generation on latent variables during training (Bowman et al., 2016), which are sampled from at inference time to encourage diversity (Jain et al., 2017; Gupta et al., 2018; Park et al., 2019). Relatedly, Goyal and Durrett (2020) promote syntactic diversity of paraphrases by conditioning over possible syntactic rearrangements of the input.

Direction	Input	Output
1810. → Swit.	She forgot her gold pieces lying on the table in front of her.	and uh she forgot the gold pieces on the desk
1810. → AAE	This story is not well devised, my lord.	Lord this story ain't no good

Bible → Tweet	This persuasion cometh not of him that calleth you.	Its not him who comes from. Its who you call
Swit. → AAE	um yeah just a second	yea just a lil bit
Joyce → Shak.	Smell of burn.	This is the smoke of a burning.
1990. → Joyce	The Second World War, son, " he answered.	SECOND WORLD WAR, son, says he.
1990. → AAE	no, I implore you not to consider this option.	Naw I asked u not to think bout that option
Tweet → Joyce	i wanted to sleep but now i cant	sleep is my preferred repose.
1990. → 1810.	She ninety-three and she can't hear too good.	She is 93 years of age and cannot hear well yet.
AAE → Poetry	y'all play? we spray	And weel weel, we'll spray a' that.
Joyce → Poetry	Now, don't tell a big fib!	And say not so big a lie!
1810. → Bible	without first veiling that, I could not sin.	And I could not sin without veil.
1890. → Shak.	When did we ever find Gaston de Marignac objectionable?	When was 't that we found Gaston de Marignac's foul faults?
Shak. → 1990.	O, much I fear some ill unlucky thing.	I was afraid of a lot of misadventures.
Shak. → 1810.	By Jesu, a very good blade!	The very knife of heaven, Jesu!
Lyrics → 1890	For a thing to explode	Oh, oh, oh, for something to blow up!
Lyrics → Bible	You are the sun that lights my world	Thou art the sun that lighteth mine earth: thou art my righteousness.
Lyrics → Joyce	But now it shouldn't have to be this way	But oughtn't to be like that.
Swit. → 1810.	oh that poor child	(sighing) the poor dear little thing.
Swit. → Lyrics	you know Karen i wonder if we are recording	Karen, I wonder if we're tapein'
Tweet → Bible	Ok will get back to you ASAP!	And he said, All right; I will return.
Tweet → Shak.	Movies are always funnier in the cinema.	It always is more humorous in the theatre.
Lyrics → Poetry	You know I still fear the bomb	I was yet a-fear'd at the bomb,
Joyce → 1890.	Just missed that by a hair.	It was a hair-spitting thing I missed.
Joyce → 1810.	Me seemeth a dragon man.	Hark ye, I'm a dragon man, Me.
Poetry → Bible	Of deities or mortals, or of both,	Of the gods, and of the people, or of the both of them together.
Poetry → Lyrics	Makes countless thousands mourn!	Gonna be a lot of people mourning!
Poetry → Bible	My helpless lambs, I trust them wi' him.	Surely he will feed my lambs in safety.
1890. → Poetry	Stark was sentenced to ten years' imprisonment, Gibbon to five.	Stark was sentence'd ten yeares, Gibbon five;
1890. → Swit.	I want no pursuit when I do my work.	i don't want to chase after when i'm at work
Tweet → Bible	The way this is set up has me dying	This death cometh because of this.
Tweet → Swit.	Yay! Ill order them then! I dont have patience to wait on them!	now i'm gonna order those
Lyrics → Joyce	And all the guns is in Kesha's name	All your gunsees belong to Kesha.
AAE → 1810.	boredom gonna be the death of me one day	I shall die, one day, of the insupportable want of amusement.
AAE → 1890.	That's just what I needed to see.... Thank Ya Lord	Thank you, Lord; that is just what I was expecting.
AAE → Swit.	okay ii will see you later	yeah see you later bye
Poetry → Tweet	Fam'd heroes! had their royal home:	royal bloods heroes:
Tweet → Bible	Check out this new painting that I uploaded to!	Look upon my new picture that I have set before thee!
Swit. → Shak.	so uh what do you wear to work	And what dost thou wear for thy work?
Tweet → Poetry	Now I gotta delete it	O now, must I part? And can I now erase
Tweet → 1810.	#India is now producing the worlds cheapest solar power #energy	Now is India's solar power cheapest of all the world.
Poetry → Joyce	Away, away, or I shall dearly rue	O offside, away, or do I am rather sad.
Tweet → Swit.	Oh shit ima be a senior	so uh i got to the senior level of the business

Table 9: More example outputs from our model STRAP trained on our dataset CDS. Our project page will provide all 110k style transferred outputs generated by STRAP on CDS.

Table 10: Survey of evaluation methods used in 23 prior papers. We check whether prior work evaluate their algorithm on transfer accuracy (ACC), semantic similarity (SIM), fluency (FL), corpus-level aggregation (CA) and sentence-level aggregation (SA). We use the "A/B" to denote relative comparisons via A/B testing between generations from the baseline and the proposed system, rather than absolute performance numbers. Specific implementations of the metrics have been provided in Table 11. We do not include Pang (2019) since it's a survey of existing evaluation methods.

Table 13: More comparisons against prior work on the Formality dataset (Rao and Tetreault, 2018) using the outputs provided in the publicly available codebase of Luo et al. (2019) using both BLEU score (BL) and paraphrase similarity (PP). This model uses the Family & Relationships split of the Formality dataset whereas (He et al., 2020) used the Entertainment & Music split. Hence, we have retrained our RoBERTa-large classifiers to reflect the new distribution. ***Note**: While our system significantly outperforms prior work, we re-use the formality system used in Table 1 and Table 2 for these results, which was trained on Entertainment & Music (consistent with He et al. (2020)). There could be a training dataset mismatch between our model and the models from Luo et al. (2019), since the Formality dataset has two domains. This is not clarified in Luo et al. (2019) to the best of our knowledge.

Style	Train	Dev	Test	Source	Examples
Shakespeare	24,852	1,313	1,293	Shakespeare split of Xu et al. (2012).	1. *Why, Romeo, art thou mad?* 2. *I beseech you, follow straight.*
English Tweets	5,164,874	39,662	39,690	A random sample of English tweets collected on 8th-9th July, 2019 using Twitter APIs.	1. *Lol figures why I dont wanna talk to anyone rn* 2. *omg no problem i felt bad holding it! i love youuuu*
Bible	31,404	1,714	1,714	The English Bible collected from Project Gutenberg (Hart, 1992) (link).	1. *Jesus saith unto her, Woman, what have I to do with thee?* 2. *Wherefore it is lawful to do well on the sabbath days.*
Romantic Poetry	26,880	1,464	1,470	The Romantic section of the Poetry bookshelf on Project Gutenberg (link).	1. *There in that forest did his great love cease;* 2. *But, oh! for Hogarth's magic pow'r!*
Switchboard	145,823	1,487	1,488	Conversational speech transcripts (link) from the Switchboard speech recognition corpus (Godfrey et al., 1992).	1. *uh-huh well we're not all like that um* 2. *well yes i i well i- i don't think i have the time to really become a student in every article*
AAE (African American English) Tweets	717,634	7,316	7,315	Using the geo-located tweet corpus collected by Blodgett et al. (2016).	1. *ay yall everything good we did dat...* 2. *I know data right, it don't get more real than that.*
James Joyce	37,082	2,054	2,043	Two novels (Ulysses, Finnegans) of James Joyce from Project Gutenberg (link) and the Internet Archive (link).	1. *At last she spotted a weeny weeshy one miles away.* 2. *chees of all chades at the same time as he wags an antomine art of being rude like the boor.*
Lyrics	4,588,522	252,368	252,397	Music lyrics dataset from MetroLyrics, used in a Kaggle competition (link).	1. *I gotta get my mind off you,* 2. *This is it, we are, baby, we are one of a kind*
1810-1830 historical English	205,286	5,340	5,338	1810-1830 in the Corpus of Historical American English (Davies, 2012) using fiction, non-fiction and magazine domains (link).	1. *The fulness of my fancy renders my eye vacant and inactive.* 2. *What then do you come hither for at such an hour?*
1890-1910 historical English	1,210,687	32,024	32,018	1890-1910 in the Corpus of Historical American English using fiction, non-fiction and magazine domains (link).	1. *Nor shall I reveal the name of my friend; I do not wish to expose him to a torrent of abuse.* 2. *You know olive oil don't give the brightest illumination.*
1990-2010 historical English	1,865,687	48,985	48,982	1990-2010 in the Corpus of Historical American English using fiction, non-fiction and magazine domains (link).	1. *They were, in fact, tears of genuine relief.* 2. *I don't know why, but I sensed there was something wrong.*
Total	14,018,731	393,727	393,748		

Table 14: Details of our new benchmark dataset CDS along with representative examples. Our dataset contains eleven lexically and syntactically diverse styles and has a total of nearly 15M sentences, an order of magnitude larger than previous datasets. We will provide more representative examples along with our entire dataset in the project page `http://style.cs.umass.edu`.

Table 15: A detailed performance breakup when transferring **to** each style in CDS from the other 10 styles. We test three nucleus sampling (Holtzman et al., 2020) strategies with our trained model by varying the p value between 0.0 (greedy) and 1.0 (full sampling). For reference, the classification accuracy (Orig. ACC) and fluency (Orig. FL) of original sentences in the target style corpus are provided.

Split	Diverse Paraphraser Similarity (↑)	Lexical (↓)	Syntactic (↓)	Non-Diverse Paraphraser Similarity (↑)	Lexical (↓)	Syntactic (↓)
AAE Tweets	65.1	44.7	0.43	74.3	66.4	0.82
Bible	74.6	48.5	0.55	88.3	73.5	0.92
COHA 1810s-1820s	74.0	50.6	0.51	86.3	71.8	0.92
COHA 1890s-1900s	75.3	52.0	0.50	88.2	75.3	0.93
COHA 1990s-2000s	77.6	57.4	0.53	89.9	80.7	0.95
English Tweets	73.1	52.4	0.50	82.8	75.7	0.91
James Joyce	71.5	47.8	0.35	82.4	69.8	0.82
Lyrics	74.5	52.8	0.52	86.7	78.6	0.92
Romantic Poetry	72.3	46.3	0.44	81.3	67.1	0.86
Shakespeare	67.9	38.7	0.23	81.4	63.4	0.75
Switchboard	71.6	50.1	0.55	81.1	72.4	0.90
Overall	72.5	49.2	0.46	83.9	72.3	0.88

Table 16: A detailed style-wise breakup of the **diverse paraphrase quality** in CDS (the training data for the inverse paraphrase model, described in Section 2.1 and Section 2.4). The ideal paraphraser should score lower on "Lexical" and "Syntactic" overlap and high on "Similiarity". Overall, our method achieves high diversity (51% unigram change and 27% word shuffling, compared to 28% unigram and 6% shuffling for non-diverse), while maintaining good semantic similarity (SIM= 72.5 vs 83.9 for non-diverse) even in complex stylistic settings. We measure lexical overlap in terms of unigram F1 overlap using the evaluation scripts from Rajpurkar et al. (2016). Syntactic overlap is measured using Kendall's τ_B (Kendall, 1938) of shared vocabulary. A $\tau_B = 1.0$ indicates no shuffling whereas a value of $\tau_B = -1.0$ indicates 100% shuffling (complete reversal). Finally, the SIM model from Wieting et al. (2019) is used for measuring similarity.

Abstract

Court's view generation is a novel but essential task for legal AI, aiming at improving the interpretability of judgment prediction results and enabling automatic legal document generation. While prior text-to-text natural language generation (NLG) approaches can be used to address this problem, neglecting the confounding bias from the data generation mechanism can limit the model performance, and the bias may pollute the learning outcomes. In this paper, we propose a novel Attentional and Counterfactual based Natural Language Generation (AC-NLG) method, consisting of an attentional encoder and a pair of innovative counterfactual decoders. The attentional encoder leverages the plaintiff's claim and fact description as input to learn a claim-aware encoder from which the claim-related information in fact description can be emphasized. The counterfactual decoders are employed to eliminate the confounding bias in data and generate judgment-discriminative court's views (both supportive and non-supportive views) by incorporating with a synergistic judgment predictive model. Comprehensive experiments show the effectiveness of our method under both quantitative and qualitative evaluation metrics.

1 Introduction

Owing to the prosperity of machine learning, especially the natural language processing (NLP) techniques, many legal assistant systems have been proposed to improve the effectiveness and efficiency of a judge from different aspects, such as relevant case retrieval (Chen et al., 2013), applicable law articles recommendation (Chen et al., 2019), controversy focus mining (Duan et al., 2019), and judgment prediction (Lin et al., 2012; Zhong et al., 2018; Hu et al., 2018; Jiang et al., 2018; Chalkidis et al., 2019). Court's view can be regarded as the interpretation for the sentence of a case. Being an important portion of verdict, court's view is difficult to generate due to its logic reasoning in the content. Therefore court's view generation is regarded as one of the most critical functions in a legal assistant system. Court's view consists of two main parts, including the judgment and the rationales, where the judgment is a response to the plaintiff's claims in civil cases or charges in criminal cases, and the rationales are summarized from the fact description to derive and explain the judgment.

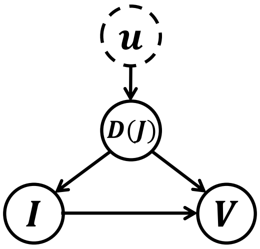

Figure 1: Confounding bias from the data generation mechanism. u refers to the unobserved mechanism (i.e., plaintiffs sue when they have a high probability to be supported) that causes the judgment in dataset $D(J)$ to be imbalanced. $D(J) \to I$ denotes that the imbalanced data $D(J)$ has a causal effect on the representation of input I (i.e., plaintiff's claim and fact description), and $D(J) \to V$ denotes that $D(J)$ has a causal effect on the representation of court's view V. Such imbalance in $D(J)$ leads to the confounding bias that the representations of I and V tend to be supportive, and blind the conventional training on $P(V|I)$.

Recently, Ye et al. (2018) investigated the problem of court's view generation for the criminal cases, but it focused on the generation of rationales in the court's view based on the given criminal charge and fact description of a case. Such an experimental scenario is not applicable to the practical situation since the rationales should be concluded before reaching the final judgment. Moreover, dif-

PLAINTIFF'S CLAIM	The plaintiff A claimed that the defendant B should return the loan of \$29,500 $^{\textit{Principle Claim}}$ and the corresponding interest $^{\textit{Interest Claim}}$.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: The defendant B borrowed \$29,500 from the plaintiff A, and agreed to return after one month. After the loan expired, the defendant failed to return $^{\textit{Fact}}$.
COURT'S VIEW	The court concluded that the loan relationship between the plaintiff A and the defendant B is valid. The defendant failed to return the money on time $^{\textit{Rationale}}$. Therefore, the plaintiff's claim on principle was supported $^{\textit{Acceptance}}$ according to law. The court did not support the plaintiff's claim on interest $^{\textit{Rejection}}$ because the evidence was insufficient $^{\textit{Rationale}}$.

Figure 2: An example of plaintiff's claim, fact description, and court's view from a legal document in a civil case. The judgment is non-support since there exists a rejection on one of the plaintiff's claims in the court's view.

ferent from the criminal cases, in civil cases, the judgment depends not only on the facts recognized but also on the claims that the plaintiff declared.

In this paper, we focus on the problem of automatically generating the court's view in civil cases by injecting the plaintiff's claim and fact description, as shown in Fig. 2. In such a context, the problem of the court's view generation can be formulated as a text-to-text natural language generation (NLG) problem, where the input is the plaintiff's claim and the fact description, and the output is the corresponding court's view that contains the judgment and the rationales[1]. Although classical text generative models (e.g., sequence-to-sequence model Sutskever et al., 2014, attention-based model, and pointer-generator networks See et al., 2017) have been applied to many text generation tasks, yet, in the task of the court's view generation, such techniques cannot be simply applied for the following reasons: (1) **There exists "no claim, no trial" principle in civil legal systems**: The judgment in the real court's view is the response to the claims declared by the plaintiff, where its rationales summarize the corresponding facts. In other words, there exists a correspondence relationship between the input (claims and facts) and the generated text (court's view). For example, the plaintiff's claims shown in Fig. 2 mentioned the principal and the interest, respectively. Hence, the court's view of this case would and might only focus on the facts about the principal and the interest. (2) **The imbalance of judgment in civil cases**: The distribution of judgment results of civil cases is very imbalanced. For example, over 76% of cases were supported in private lending, which is the most frequent category in civil cases. Such an imbalance of judgment would blind the training of the model by focusing on the supported cases while ignoring the non-supported cases, leading to incorrect judgment generation of court's view.

From the perspective of causality (Pearl, 2009; Kuang et al., 2020), the imbalance of judgment reveals the confounding bias induced by the data generation mechanism that plaintiffs sue when they have a high probability to be supported. Such imbalanced data would cause the learned representation of both inputs (claims and recognized facts) and output (court's view) to be supported, leading to confounding bias between inputs and output, and blinding the training process of conventional NLG models as we demonstrated in Fig. 1.

To address these challenges, we propose an Attentional and Counterfactual based Natural Language Generation (AC-NLG) method by jointly optimizing a claim-aware encoder, a pair of counterfactual decoders to generate judgment-discriminative court's views (both supportive and non-supportive views) and a synergistic judgment predictive model. Specifically, the claim-aware encoder is designed to represent the fact description which emphasizes on the declared claims. The counterfactual decoder is inspired by the backdoor adjustment in causal inference (Pearl et al., 2016; Kuang et al., 2020) to address the confounding bias and the imbalance problem in judgment. To determine the judgment result of each case, a judgment predictive model is jointly learned with the two decoders and decides which output to be selected as the final generated court's view. We validate the effectiveness of our AC-NLG method with extensive experiments on real legal documents. Comprehensive experiments show the effectiveness of our method under both quantitative and qualitative evaluation metrics.

Since legal AI is a sensitive field, we make ethical discussion in the penultimate section(Sec. 6).

The main contributions of this paper can be sum-

---

[1] Since the claims are various, for simplification, the judgment of a civil case is defined as supported if all its claims are accepted, otherwise, defined as non-supported.

marized as follows:

- We investigate the problem of de-biased court's view generation in civil cases from a causal perspective, considering the issue of confounding bias from judgment imbalance.
- We propose a novel AC-NLG model to jointly optimize a claim-aware encoder and a pair of counterfactual decoders for generating a judgment-discriminative court's view by incorporating with a judgment predictive model.
- We construct a dataset based on raw civil legal documents, where each case is objectively split into three parts: plaintiff's claim, fact description, and court's view with human annotation on the judgment. To motivate other scholars to investigate this novel but important problem, we make the experiment dataset publicly available[2].
- We validate the superior performance of the proposed method with extensive experiments. Our method can be applied to other natural language generation tasks with confounding bias or data imbalance.

2 Related Work

2.1 Legal Assistant

In recent years, many researchers from both law and computer science fields have been exploring the potential and methods to perform judicial decisions and auxiliary tasks, aiming at helping lawyers and lower court judges. In recent work, judicial intelligence is also applied to various tasks of natural language processing. Since most of the legal documents appear in textual form, many NLP technologies have been brought into the legal field to improve the efficiency of legal work. Charge prediction is a common task of judgment prediction, considered as a text classification problem (Lin et al., 2012; Zhong et al., 2018; Hu et al., 2018; Jiang et al., 2018; Chalkidis et al., 2019). Besides, there are also works on legal questions classification (Xiao et al., 2017), law articles recommendation (Chen et al., 2019), controversy focus mining (Duan et al., 2019) and relevant case retrieval (Chen et al., 2013). Ye et al. (2018) explored the court's view generation in criminal cases, where the input is only fact description, and the court's view generation is conditioned on the known judgment results, which is not applicable in real cases.

2.2 Natural Language Generation

Our task aims at generating the court's view based on the plaintiff's claim and the fact description, which can be regarded as a NLG task. NLG has been widely studied and applied to many tasks, such as machine translation (Wu et al., 2016), question answering (McCann et al., 2018; Bagchi and Wynter, 2013) and text summarization (Rush et al., 2015). The recent success of sequence-to-sequence models (Sutskever et al., 2014), in which recurrent neural networks (RNNs) reading and generating text simultaneously, has made the generation task feasible. Bahdanau et al. (2014) firstly applied the attention mechanism into the NLG task. See et al. (2017) proposed a Pointer-Generator Networks (PGN) , which can effectively solve the Out-Of-Vocabulary (OOV) problem. Although the previous work on NLG can produce fluent sentences, they are struggling to be directly applied to our task since a good court's view considers not only the text fluency but also the logical correctness.

2.3 Causal Inference

Causal Inference (Pearl, 2009; Kuang et al., 2020) is a powerful statistical modeling tool for explanatory analysis by removing confounding bias in data. That bias might bring a spurious correlation or confounding effect among variables. Recently, many methods have been proposed to remove confounding bias in the literature of causal inference, including do-operation based on structure causal model (Pearl, 2009) and counterfactual outcome prediction based on potential outcome framework (Imbens and Rubin, 2015). With do-operation, the backdoor adjustment (Pearl et al., 2016) have been proposed for data de-bias. In this paper, we sketch the causal structure model of our problem, as shown in Fig. 1, and adopt backdoor for confounding bias reduction.

3 Problem Formulation

In this work, we focus on the problem of the court's view generation in civil cases, where the input is the plaintiff's claim and the fact description, and the output is the corresponding court's view. We formulate our problem with the definition of the plaintiff's claim, the fact description, and the court's view, as shown in Fig. 2.

Plaintiff's claim (C) is a descriptive sentence that depicts the claims from the plaintiff. In a civil case, it often appears multiple claims from the

---

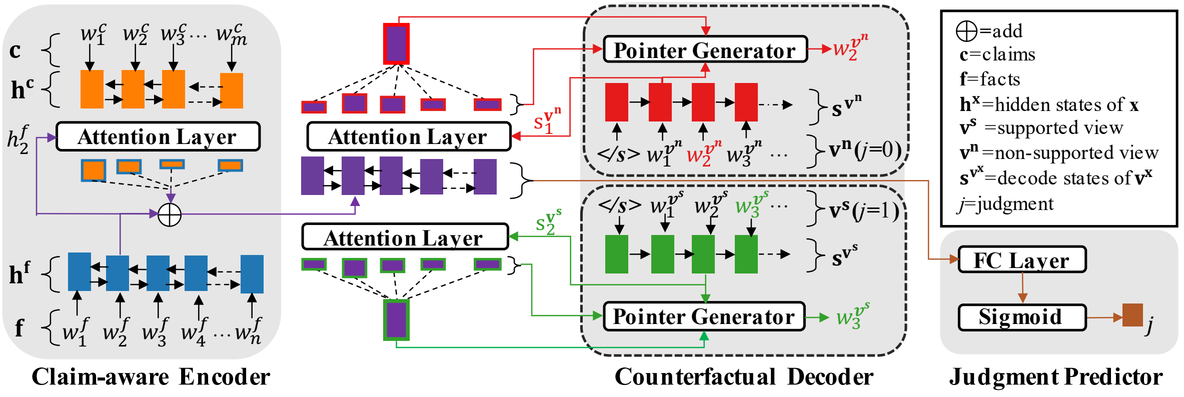

Figure 3: The architecture of AC-NLG, which consists of a claim-aware encoder, a pair of counterfactual decoders, and a judgment predictor.

plaintiff. For example, the plaintiff's claim demonstrated in Fig. 2 contains the principal claim and the interest claim. Here, we denote the plaintiff's claim in a case as a sentence form $\mathbf{c} = \{w_t^c\}_{t=1}^m$, where w_t^c represents one word, and m is the number of words in plaintiff's claim.

Fact description (**F**) is also a descriptive sentence, which describes the identified facts (relevant events that have happened) in a case, as Fig. 2 shows. Here, we denote the fact description in a case as $\mathbf{f} = \{w_t^f\}_{t=1}^n$, where n is the length.

Court's view (**V**) contains two main components, judgment and rationales, where the judgment is to respond the plaintiff's claims, and the rationales are the claim-related summarization on the fact description to determine and interpret the judgment. Here, we denote the court's view as $\mathbf{v} = \{w_t^v\}_{t=1}^l$, where l is the length. Moreover, we use a variable j to denote the judgment in the court's view. For simplicity, we set $j = 1$ to denote supported judgment (all the claims are judged to be accepted), and $j = 0$ to denote non-supported judgment.

Then, the problem of court's view generation can be denoted as follow:

Problem 1 (Court's View Generation)**.** *Given the plaintiff's claim* $\mathbf{c} = \{w_t^c\}_{t=1}^m$ *and the fact description* $\mathbf{f} = \{w_t^f\}_{t=1}^n$*, our task is to generate the court's view* $\mathbf{v} = \{w_t^v\}_{t=1}^l$.

4 Method

In this section, we first introduce the effect of mechanism confounding bias on the court's view generation and propose a backdoor-inspired method to eliminate that bias. Then, we describe our Attentional and Counterfactual based Natural Language Generation (AC-NLG) model in detail. Fig. 3 shows the overall framework.

4.1 Backdoor Adjustment

As shown in Fig. 1, the confounding bias from the data generation mechanism would blind the conventional training on $P(V|I)$, and current sequence-to-sequence models struggle to solve this problem. Here, we see through why these models fail mathematically. For a certain case, given the input $I = (\mathbf{c}, \mathbf{f})$, using Bayes rule, we would train the model to generate the court's view V as follow:

$$P(V|I) = \sum_j P(V|I,j)P(j|I) \qquad (1)$$

If the supported cases dominate our training data, e.g., $P(j = 1|I) \approx 1$. Thus, $P(V|I)$ degrades to $P(V|I, j = 1)$, which would ignore the representation of non-supported cases, leading to the learned representations of inputs I and output V tend to be supported. Thus, the model tends to build a strong connection between inputs and the supported court's view, even for the cases that are non-supported. In this way, the representation of input I is contaminated by the confounding bias from $I \leftarrow D(J) \rightarrow V$.

Backdoor adjustment is a main de-confounding technique in causal inference (Pearl et al., 2016; Pearl, 2009). De-confounding seeks the exact causal effect of one variable on another, which appeals for our court's view generation task since the court's view should be faithful only to the content of the plaintiff's claims and fact descriptions.

The backdoor adjustment makes a do-operation on I, which promotes the posterior probability from passive observation to active intervention.

The backdoor adjustment addresses the confounding bias by computing the interventional posterior $P(V|do(I))$ and controlling the confounder as:

$$P(V|do(I)) = \sum_j P(V|I,j)P(j) \tag{2}$$

In our problem, the variable j is a binary variable (support or non-support), hence,

$$\begin{aligned} P(V|do(I)) &= P(V|I,j=0)P(j=0) \\ &+ P(V|I,j=1)P(j=1) \end{aligned} \tag{3}$$

The main difference between traditional posterior in Eq. 1 and interventional posterior in Eq. 2 is that $P(j|I)$ is changed to $P(j)$. Since the backdooor adjustment help to cut the dependence between $D(J)$ and I, we can eliminate the confounding bias from data generation mechanism and learn a interventional model for de-biased court's view generation.

4.2 Backdoor In Implementation

As shown in Fig. 3, to optimize Eq. 3, we use a pair of counterfactual decoders to learn the likelihood $P(V|I,j)$ for each j. At inference, we propose to use a predictor to approximate $P(j)$. Note that our implementation on backdoor-adjustment can be easily applied for multi-valued confounding with multiple counterfactual decoders.

4.3 Model Architecture

Our model is conducted in a multi-task learning manner which consists of a shared encoder, a predictor, and a pair of counterfactual decoders. The predictor and the decoders take the output of the encoder as input. Our model looks like SHAPED(Zhang et al., 2018) (several decoders with a classifier), but the motivations and mechanisms behind the model are different.

Claim-aware Encoder Intuitively, the plaintiff's claim $\mathbf{c}$ and the fact description $\mathbf{f}$ are sequences of words. Therefore, the encoder firstly transforms the words to embeddings. Then the embedding sequences are fed to the Bi-LSTM, producing two sequences of hidden states $\mathbf{h^c}$, $\mathbf{h^f}$ corresponding to the plaintiff's claim and the fact description respectively.

After that, we use a claim-aware attention mechanism to fuse $\mathbf{h^c}$ and $\mathbf{h^f}$. For each hidden state h_i^f in $\mathbf{h^f}$, e_k^i is its attention weight on h_k^c, and the attention distribution q^i is calculated as follow:

$$e_k^i = v^T tanh(W_c h_k^c + W_f h_i^f + b_{attn}) \tag{4}$$

$$q^i = softmax(e^i) \tag{5}$$

where v, W_c, W_f, b_{attn} are learnable parameters. The attention distribution can be regarded as the importance of each word in the plaintiff's claim for a word in fact description. Next, the new representation of fact description is produced as follows:

$$h_i^{f*} = h_i^f + \sum_k q_k^i h_k^c \tag{6}$$

After feeding to another Bi-LSTM layer, we get the claim-aware representation of fact $\mathbf{h}$.

Judgment Predictor Given the claim-aware representation of fact $\mathbf{h}$, the judgment predictor produces the probability of support P_{sup} through a fully connected layer and a sigmoid operation. The prediction result j is obtained as follow:

$$j = \begin{cases} 1 & P_{sup} > 0.5 \\ 0 & P_{sup} <= 0.5 \end{cases} \tag{7}$$

where 1 means support, and 0 means non-support.

Counterfactual Decoder To eliminate the effect of data bias, here we use a pair of counterfactual decoders, which contains two decoders, one is for supported cases, and the other is for non-supported cases. The two decoders have the same structure but aim to generate the court's view with different judgments. We name them as counterfactual decoders because every time there is only one of the two generated court's views correct. Still, we apply the attention-mechanism. At each step t, given the encoder's output $\mathbf{h}$, and the decode state s_t, the attention distribution a^t is calculated the same way as q^i in Eq. 5, but with different parameters. The context vector h_t^* is then a weighted sum of $\mathbf{h}$:

$$h_t^* = \sum_i a_i^t h_i \tag{8}$$

The context vector h_t^*, which can be regarded as a representation of the input for this step, is concatenated with the decode state s_t and fed to linear layers to produce the vocabulary distribution p_{vocab}:

$$p_{vocab} = softmax(V'(V[s_t, h_t^*]) + b) + b') \tag{9}$$

where V, V', b, b' are all learnable parameters. Then we add a generation probability (See et al., 2017) to solve the OOV problem. Given the context

h_t^*, the decode state s_t and the decoder's input (the word embedding of the previous word) x_t, the generation probability p_{gen} can be calculated:

$$P_{gen} = \sigma(w_{h^*}^T h_t^* + w_s^T s_t + w_x^T x_t + b_{ptr}) \quad (10)$$

where w_{h^*}, w_s, w_x and b_{ptr} are learnable, and σ is the sigmoid function. The final probability for a word w in time step is obtained:

$$P(w) = P_{gen} * p_{vocab}(w) + (1 - P_{gen}) \sum_{i:w_i=w} a_i^t \quad (11)$$

We introduce how to alienate the two decoders in the training part.

Training For predictor, we use cross-entropy as the loss function:

$$\mathcal{L}_{pred} = -\hat{j} log(P_{sup}) - (1 - \hat{j}) log(1 - P_{sup}) \quad (12)$$

where $\hat{j}$ is the real judgment.

For decoders, the previous word in training is the word in real court's view, and the loss for timestep t is the negative log-likelihood of the target word w_t^*:

$$\mathcal{L}_t = -logP(w_t^*) \quad (13)$$

and the overall generation loss is:

$$\mathcal{L}_{gen} = \frac{1}{T} \sum_{t=0}^{T} \mathcal{L}_t \quad (14)$$

where T is the length of real court's view. Since we aim to make the two decoders generate two different court's views, we take a mask operation when calculating the loss of each decoder. The exact loss for the support decoder is:

$$\mathcal{L}_{sup} = \begin{cases} \mathcal{L}_{gen} & \hat{j} = 1 \\ 0 & \hat{j} = 0 \end{cases} \quad (15)$$

the loss for the non-support decoder $\mathcal{L}_{nsup}$ is obtained by the opposite way. Thus, the total loss is:

$$\mathcal{L}_{total} = \mathcal{L}_{sup} + \mathcal{L}_{nsup} + \lambda \mathcal{L}_{pred} \quad (16)$$

where we set λ to 0.1 in our model.

Inference In inference, the counterfactual decoders apply beam search to generate two court's views, and one of them will be selected as the final output, depending on the result of the predictor j.

Table 1: Statistics of private lending dataset

Type	Result
# Supported case	51087(76%)
# Non-supported case	15817(24%)
Avg. # tokens in claim	77.9
Avg. # tokens in fact	158.0
Avg. # tokens in court's view	194.4

5 Experiments

5.1 Data Construction

Since there is no publicly available court's view generation dataset in civil cases, we build a dataset based on raw civil legal documents[3]. Specifically, we choose private lending, which is the most frequent category in civil cases, to construct the dataset. We process the legal documents as following steps: 1) Split legal documents into three parts: plaintiff's claim, facts description, and court's view, which can be objectively split by keywords (subtitles). 2) Human annotation. We employ experts with legal backgrounds to annotate the judgment (defined in Sec. 3) on the court's view. 3) Annotation verification. We use random sampling test to ensure that the annotation accuracy is over 95%.

After that, we get the dataset as shown in Tab. 1. We randomly separate the dataset into a training set, a validation set, and a test set according to a ratio of 8: 1: 1, the ratio of supported cases is about 76% in each set.

5.2 Baselines

We implement the following baselines for comparison:

- **S2S** Sequence-to-sequence model (Sutskever et al., 2014) is a classic model for NLG task. We concatenate the plaintiff claims and facts descriptions as input.
- **PGN** Pointer Generator Networks (See et al., 2017) utilizes a pointer network to solve the out-of-vocabulary (OOV) problem, which is essential for the court's view generation since many nouns occur there.

Oversampling is a common method to alleviate data imbalance. We oversample the non-supported cases so that the ratio between supported cases and non-supported cases become 1 : 1.

- **S2SwS** Apply oversampling to S2S.

- **PGNwS** Apply oversampling to PGN.
- **AC-NLGwS** Apply oversampling to AC-NLG.

We do ablation experiments as follows:

- **AC-NLGw/oD** We remove the decoder and train the remaining model (encoder and predictor) as a classification task for judgment prediction.
- **AC-NLGw/oBA** We remove the backdoor adjustment by replacing the pair of counterfactual decoders and predictor with a single decoder, but keep the claim-aware attention mechanism.
- **AC-NLGw/oCA** We remove the claim-aware attention, and concatenate the claims and the facts instead.

5.3 Metrics

ROUGE[4] is a set of metrics used in the NLP task. We keep the results of ROUGE-1, ROUGE-2, and ROUGE-L. ROUGE-1 and ROUGE-2 refer to the overlap of unigram and bigram between the generated and reference documents, respectively. ROUGE-L is a Longest Common Subsequence (LCS) based statistics.

BLEU[5] (Papineni et al., 2002) is a method of automatic text-generation evaluation that highly correlates with human evaluation. We use BLEU-1, BLEU-2 to evaluate from the perspectives of unigram, bigram. BLEU-N is an average of BLEU-1, BLEU2, BLEU-3, BLEU-4.

BERT SCORE[6] (Zhang et al., 2019) computes a similarity score by using contextual embedding of the tokens. We calculate the $precision$ (p), $recall$ (r) and f_1-score to evaluate the information matching degree.

Accuracy of judgment prediction To evaluate the performance of the predictor, we calculate the $precision$ (p), $recall$ (r) and, f_1-score of supported and non-supported cases, respectively.

Human Evaluation We conduct a human evaluation to better analyze the quality of the generated court's view. First, we randomly sample 500 test cases, where the ratio of the supported and non-supported cases are 1:1. For each case, we present the generated court's views from each method[7] with the ground truth to 5 human annotators with legal backgrounds. The evaluation is conducted following three perspectives: (1) **Judgment level**. Annotators are asked to give a score (1-5) on the judgment in the generated court's view. 1 for totally wrong and 5 for totally correct. (2) **Rational level**. Annotators are asked to give a score (1-5) on the rationals in the generated court's view. 1 for the worst and 5 for the best. (3) **Fluency level**. Annotators are asked to give a score (1-5) on the fluency of the generated court's view. 1 for the worst and 5 for the best.

5.4 Experimental Results

Tab. 2 demonstrates the results of court's view generation with ROUGE, BLEU, and BERT SCORE.

Also, we report the results on the judgment prediction of our predictor component with $precision$

PLAINTIFF’S CLAIM	The defendant B return the loan of $495,000. The defendant C return the loan together.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: From November 20, 2010 to March 23, 2011, the defendant B successively borrowed a total of $495,000 from the plaintiff A and issued four separate borrowings. The defendant B has not repaid the above loan.
PGN	The court concluded that: The private lending relationship between Plaintiff A and Defendant B, where the subject was appropriate, the content was legitimate, and the meaning was true, should be confirmed to be legal and valid. The two sides did not agreed in writing on a loan period, so the defendant should return the plaintiff's loan in a timely manner within a reasonable period after the plaintiff urged. The defendant’s failure to return the loan timely constituted a breach of contract and should bear corresponding civil liabilities. Therefore, the plaintiff 's claim was reasonable and legal, and the court supported it $^{\textit{Acceptance}}$.
AC-NLG	The court concluded that the subject of the private lending relationship between Plaintiff A and Defendant B was qualified, the content was legal, and the meaning was true. It should be deemed valid. The two sides did not agreed in writing on a loan period, the defendant shall return the loan within a reasonable period after the plaintiff urged. The plaintiff ’s claim requesting the defendant to return the loan of $495,000 was in compliance with the law and the court supported it $^{\textit{Acceptance}}$. However, the court did not support the claim requesting the defendant C to bear the guarantee liability because the evidence was insufficient $^{\textit{Rejection}}$.
REAL	The court concluded that: The subject of the private lending relationship between Plaintiff A and Defendant B was qualified, the content was legal, and the meaning was true. It should be deemed valid. Defendant should repay the plaintiff's loan within a reasonable period after the plaintiff urged. Therefore, Defendant B should bear the civil liability of returning the plaintiff's loan of $495,000 and paying overdue interest $^{\textit{Acceptance}}$. The court did not support the plaintiff’s claim requesting the defendant C to return the loan together because the evidence was insufficient $^{\textit{Rejection}}$. Defendant B failed to appear in court after being legally summoned by the court.

Figure 4: Case study.

(p), $recall$ (r), and f_1-score (f1) in Tab. 3.

To demonstrate that our method is de-biased on judgment generation, we report the result of human evaluation in Tab. 4.

Results of court’s view generation: From Tab. 2, we can conclude that: (1) **S2S** tends to repeat words, which makes it get high BLEU but low BERT SCORE. (2) Oversampling strategy doesn’t benefit the models, hence, it cannot address the confounding bias. (3) With claim-aware encoder and backdoor-inspired counterfactual decoders, our **AC-NLG** achieves better performance on court’s view generation compared with baselines. (4) The performance gap between **AC-NLGw/oCA** and **AC-NLG** demonstrates the effectiveness of our proposed claim-aware encoder, and the gap between **AC-NLGw/oBA** and **AC-NLG** illustrates the superiority of our counterfactual decoders.

Results of judgment prediction: From Tab. 3, we have the following observations: (1) The counterfactual decoders in our model can significantly eliminate the confounding bias, hence, achieve remarkable improvement on the non-supported cases, for example boosting $f1$ from 49.8% to 76.9%. (2) The proposed claim-aware encoder has a limited effect on judgment prediction since it’s designed for improving the quality of generation as shown in Tab. 2. (3) Still, oversampling brings no improvement to the model.

Results of human evaluation: From Tab. 4, we have the following observations: (1) due to the confounding bias in data, the performance of judgment generation in **PGN** is poor for non-supported cases, and its performance gap between supported and non-supported cases is huge (1.56). (2) By debiasing with backdoor-inspired counterfactual decoders, our AC-NLG significantly improves the performance of judgment generation, especially for non-supported cases, and achieves a smaller performance gap (only 0.28) between the supported and non-supported cases. (3) With a claim-aware encoder, our **AC-NLG** also achieves better performance on the generation of rational and generated court’s view fluency. (4) Kappa coefficient κ is more than 0.8 between any two judges, which proves the validation of human evaluation.

Overall, thanks to the proposed claim-aware encoder, counterfactual decoders, and a synergistic judgment predictor, our model achieves better performance than single-task baselines on the task of judgment prediction, judgment generation in court’s view and court’s view generation.

5.5 Experiment Details

We use Gensim (Řehůřek and Sojka, 2010) with a large-scale generic corpus to train a language model as the pre-trained model, then use it to initialize the word embeddings, which is in the dimension of 300.[8]

5.6 Case Study

Figure 4 shows three court’s views for a certain case: the court’s view generated by PGN, by the proposed AC-NLG method, and the real court’s view. We find that the one generated by PGN accepts the claim for principal, but ignores other claims such as issue related to guarantee. Compared with the real court’s view, our model accu-

[8] Source code, data, more experiment details and results can be found in supplementary materials.

rately responds to both claims and produces the correct judgment.

6 Ethical Discussion

While AI is gaining adoption in legal justice(Lin et al., 2012; Zhong et al., 2018; Hu et al., 2018; Jiang et al., 2018; Chalkidis et al., 2019), any subtle statistical miscalculation may trigger serious consequences. From a fairness perspective, prior studies suggested that global (statistical) optimization $\neq$ individual (demographic) fairness (Zemel et al., 2013), and this ethical concern should be further investigated. In this section, we explore the following ethical issues.

Target User: According to the report of statistics, a typical active trial judge closed around 250 cases in a year. Trial judges suffering from 'daunting workload' is becoming an critical issue(Duan et al., 2019). The proposed algorithm is designed for generating the court's view draft for assisting the trial judges for decision making. This work is an algorithmic investigation, but such algorithm should never 'replace' human judges. Human knowledge/judgment should be the final safeguard to protect social justice and individual fairness.

Potential Error: The potential error would be as follows: a) generating a wrong judgment and b) generating a wrong rationale. The goal of our algorithm is to generate a draft of court's view for trail judge as a reference, and judges need to proofread the content generated from algorithm.

Demographic Bias: In this paper, we focus on addressing the bias problem from the data generation by treating the variable of data generation as confounder in back-door adjustment. The model adoption can face potential demographic bias/unfairness challenges, such as gender and race bias in the training data. To further ensure the model fairness, in the future, algorithm adoption should be empowered with de-biased legal content pretraining, which could avoid potential demographic bias. For instance, in order to remove gender/race bias, system could use (Bolukbasi et al., 2016) algorithm to debias the sensitive gender/race information, e.g., replace 'he/she' and 'asian/hispanic' with gender/race neutral words for pretraining, which can be vital for legal domain.

7 Conclusion and Future Work

In this paper, we propose a novel Attentional and Counterfactual based Natural Language Generation (AC-NLG) method to solve the task of court's view generation in civil cases and ensure the fairness of the judgment. We design a claim-aware encoder to represent the fact description which emphasizes on the plaintiff's claim, as well as a pair of backdoor-inspired counterfactual decoders to generate judgment-discriminative court's views (both supportive and non-supportive views) and to eliminate the bias that arose from the data generation mechanism by connecting with a synergistic judgment predictive model. The experimental results show the effectiveness of our method.

Based on the AC-NLG method, in the future, we can explore the following directions: (1) Improve the accuracy of judgment on a claim-level. (2) Add external knowledge (e.g. a logic graph) to the predictor for the interpretability of the model.

Acknowledgments

PLAINTIFF'S CLAIM	1.The defendant B shall return the plaintiff's loan of $30,000 and pay the overdue interest at the interest rate of 2.4% per month from the date of prosecution to the date of repayment. 2. The defendant B shall pay the litigation costs of this case.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: On December 11, 2013, the defendant B borrowed $30,000 from the plaintiff A. The defendant B received the loan and gave a receipt of this loan. Note: I have borrowed $30,000 from A today.
PGN	The court concluded that: The facts that defendant B borrowed $30,000 from the plaintiff A are clear. The private lending relationship between Plaintiff A and Defendant B is legitimate and valid, it shall be protected by the law. The plaintiff now demands that the defendant repay the loan of $30,000. This demand is justified and should be supported ^{Acceptance}. Defendant B refused to appear in court without justification after being legally summoned by the court.
AC-NLG	The court concluded that: The legitimate private lending relationships are protected by law. The act of borrowing between the plaintiff A and the defendant B did not violate the prohibitive provisions of state laws and regulations, so it should be valid. The fact that the defendant B owed the plaintiff A a loan of $30,000 is clear, and the evidence is sufficient. The defendant was supposed to repay the loan in time, and his failure to repay in time constituted a breach of contract, and he shall assume corresponding civil liabilities according to law ^{Acceptance}. The receipt of this loan provided by the plaintiff A does not have agreed interest, as not to pay interest. So the court does not support the claim that the plaintiff A asked the defendant B to calculate the interest from the date of the loan ^{Rejection}. The defendant was summoned by the court and refused to appear in court without justification.
REAL	The court concluded that: the lending agreement between the plaintiff A and the defendant B contains the true meaning and does not violate the prohibitive provisions of state laws and regulations, it is legal and valid. Although the plaintiff and the defendant did not specifically agree on the time for repayment, after the defendant received the loan, it shall be returned within a reasonable period after being appealed by the plaintiff. If the defendant fails to return it within a reasonable period after being called, the defendant shall be responsible to pay the overdue interest from the date of prosecution ^{Acceptance}. For the calculation standard for overdue interest, the plaintiff claimed that the monthly interest rate was 2.4%, but it did not provide a corresponding evidence. Therefore, the court does not support this claim of overdue interest ^{Rejection}. With reference to the loan interest rate announced by the People's Bank of China for the same period, the court determined that overdue interest is calculated at an annual interest rate of 5.6%. The fact that the defendant has not returned the loan of $30,000 is clear. So the court supports the reasonable part of the plaintiff 's claim requesting the defendant to return the loan and pay the overdue interest. Defendant B refused to appear in court without justification after being legally summoned by the court.

Figure 5: Show case 1.

PLAINTIFF'S CLAIM	The two defendants B and C return the loan principal of $2,000,000 and interest (The interest will be calculated as four times the interest rate of similar loans of the bank from February 28, 2014 to the date when the judgment is confirmed, it is $40,000 temporarily calculated to the date of prosecution).
FACT DESCRIPTION	After the hearing, the court held the facts as follows: The two defendants B and C have spousal relationship. On February 28, 2014, the defendant B borrowed $2,000,000 from the plaintiff A and signed a loan contract, stipulating that the defendant borrowed 2 million ($2,000,000.00) from the plaintiff, and the loan period is from the date of signing to March 27, 2014, the interest is calculated at four times the interest rate of similar loans of the People 's Bank of China over the same period. The loan period has expired and the defendant refused to return the loan. For this reason, the plaintiff A claimed in court.
PGN	The court concluded that: The legal loan relationship is protected by law. The fact that the defendant B borrowed $2,000,000 from the plaintiff A is clear, and the evidence is indeed sufficient. The defendant B did not return the loan in time according to the contract, which was a breach of contract and should assume the corresponding liabilities for breach of contract according to law. The plaintiff 's claim was accepted and the court supports it^{Acceptance}. The defendants failed to appear in court after being legally summoned by the court. The court can judge the case in absentia according to law.
AC-NLG	The court concluded that: The civil loan relationship formed by the defendant B borrowing money from the plaintiff A and the act of giving a receipt of this loan are based on the true intention of them, they did not violate the mandatory provisions of the laws and regulations, it is legal and valid, and it should be protected by law. The defendant B did not repay the plaintiff's loan of $2 million, which constituted a breach of contract, and he should assume the civil liabilities for returning the loan and paying interest. The defendant B and C have spousal relationship. The debt in this case occurred during the marriage, so it should be treated as joint debts and paid by the two defendants together. In summary, the plaintiff 's claim is supported by law, and the court supports it^{Acceptance}. The defendants B and C was legally summoned by the court and refused to appear in court without justifiable reasons.
REAL	The court concluded that: The defendant B has not repaid the loan of $2 million from the plaintiff A, and should return it in time and pay interest according to the agreed time limit. The debt occurred during the marriage of the defendants B and C, so it should be treated as joint debts, the two defendants should jointly take the responsibility for repayment. The plaintiff A's claim is legal, and the court supports it^{Acceptance}. The defendants B and C were legally summoned by the court and refused to appear in court without justifiable reasons.

Figure 6: Show case 2.

PLAINTIFF’S CLAIM	1. The defendant B shall return the principal of $50,000. 2.The defendant B is ordered to pay the plaintiff A an overdue interest of $12,000 (from June 28, 2013 to March 31, 2014, the actual calculation until the date when the judgment is confirmed, calculated at 2% monthly interest), and it is $62,000 in total.3. The litigation costs in this case are paid by the defendant B.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: On June 28, 2013, the defendant B gave a receipt of loan. The defendant needed a loan of $50,000. The loan period was from June 28, 2013 to July 27, 2013. There was no agreed interest on the loan. After the due date, the defendant agreed to calculate the interest on the unrefunded principal at four times the bank ’s loan interest during the same period. On the same day, the plaintiff A made a payment of $50,000 from his bank account to the defendant B's bank account. Then the defendant B issued a receipt confirming that the loan of $50,000 was received. However, the defendant B has not returned the loan principal and interest.
PGN	The court concluded that: The loan relationship between the plaintiff and the defendant does not violate the compulsory provisions of state laws and administrative regulations, and should be deemed as legal and effective. The defendant B failed to repay the interest according to the receipt, and the plaintiff ’s claim to return the principal and pay the overdue interest should be supported according to law $^{\textit{Acceptance}}$. Defendant B refused to appear in court without justification after being legally summoned by the court, and is deemed to have waived his right to litigation. The court can judge the case in absentia according to law.
AC-NLG	The court concluded that: The loan relationship between the plaintiff A and the defendant B is legal and effective. After the defendant borrowed money, he should take the responsibility to return the loan and pay legal interest. If the borrower and the lender have not agreed on the interest on the loan, it shall be deemed as non-payment of interest $^{\textit{Acceptance}}$. However, the plaintiff has the right to claim the interest to be calculated from the benchmark interest rate of the same grade of loans issued by the People ’s Bank of China at the same period when the loan occurred since the date of the prosecution $^{\textit{Rejection}}$.
REAL	The court concluded that: The loan between the plaintiff A and the defendant B did not violate the legal provisions, and was based on the true intentions of them, and this case has the loan agreement, receipt and bank statement issued by the defendant. The loan relationship is legal and valid. The plaintiff requested the defendant to return the loan principal of $50,000 in compliance with the law, and the court will support it. $^{\textit{Acceptance}}$. In this case, the interest was not agreed during the loan period, the court does not support the interest during the loan period in the plaintiff’s claim $^{\textit{Rejection}}$. But the court supports the calculation of the overdue interest from July 28, 2013 to March 31, 2014 based on the four times bank ’s loan interest rate during the same period.

Figure 7: Show case 3.

PLAINTIFF’S CLAIM	1. The defendants B and C jointly repaid the loan principal of $20,000 and the interest loss (calculated from the bank ’s loan interest rate at the same period from the date of prosecution to the date when the judgment is confirmed). 2.The litigation costs in this case are paid by the two defendants.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: On November 3, 2011, the defendant B borrowed $20,000 from the plaintiff A, and the defendant B issued a receipt for this loan of $20,000 to the plaintiff. The loan receipt did not specify the loan interest and repayment date. The plaintiff stated in court that the defendant B paid about $500 but less than $1,000. It was also found that the defendant B and the defendant C registered their marriage on September 1, 2006.
PGN	The court concluded that: The legal loan relationship is protected by law. The defendant B borrowed $20,000 from the plaintiff A. This case has the evidence of the loan receipt and the plaintiff ’s statement in court. The facts were clear and the evidence was true and sufficient. The legal loan relationship is protected by law, and the loan principal and interest should be repaid $^{\textit{Acceptance}}$.
AC-NLG	The court concluded that: The legal loan relationship is protected by law. The fact that the defendant B owed the plaintiff A a loan of $20,000 was based on a loan receipt and the plaintiff ’s statement in court. The facts are clear and the evidence is true and sufficient. The loan repayment period does not stipulate the repayment period, the plaintiff can urge the defendant to repay within a reasonable period. Now the plaintiff claims that the defendants repay the loan principal of $20,000, it complies with the law and the court supports it. The defendant B and the defendant C have spousal relationship. In this case, the debt in this case occurred during the marriage, so it should be treated as joint debts and paid by the two defendants together $^{\textit{Acceptance}}$.
REAL	The court concluded that: The legal loan relationship is protected by law. The fact that the defendant B borrowed money from the plaintiff A was based on a loan receipt and the plaintiff ’s statement. The facts are clear, and the evidence is true and sufficient. The loan interest rate is not agreed on the receipt, it shall be deemed as non-payment of interest. The plaintiff‘s opinion that the amount paid by the defendant B is interest has no factual basis and the court will not approve it. Because the plaintiff could not determine the specific amount paid by the defendant B, the court determined the amount paid by the defendant B as $500 at his discretion, and the $500 should be deducted from the loan principal. If the loan does not agree on the repayment period, the debtor shall return the loan if the creditor requests it to be returned according to trading habits. The defendant B and the defendant C registered their marriage on September 1, 2006. The debt in this case occurred during their marriage, so it is the joint debt of the two defendants and should be repaid together $^{\textit{Acceptance}}$. The defendants B and C were legally summoned by the court and refused to appear in court without justifiable reasons.

Figure 8: Show case 4.

PLAINTIFF’S CLAIM	The defendant B should return to the defendant $20,000 and pay litigation costs of this case, and the defendant C shall undertake joint and several liability.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: Plaintiff A supported the facts of his claim and provided the court with a receipt of the loan issued by the defendant B on September 22, 2008. Although the evidence was not cross-examined by the two defendants in court, it was considered by the court that the evidence was legal, true and relevant to the facts of this case, so the validity of the evidence was confirmed. The facts confirmed by the court are consistent with the facts claimed by the plaintiff A.
PGN	The court concluded that: The loan relationship between the plaintiff and the defendant is legal and effective, it should be protected by law. The defendant did not return the loan within the agreed time limit, which constituted a breach of contract and should bear the corresponding liability. The plaintiff is now claiming the defendant to return the loan of $20,000, which complies with the law and the court will support it $^{\textit{Acceptance}}$. The defendant was legally summoned by the court and failed to appear in court without justifiable reasons.
AC-NLG	The court concluded that: The loan relationship between the plaintiff and the defendant is legal and valid. The defendant still owes the plaintiff a loan of $20,000 and has not returned. The plaintiff ’s request for the defendant to return the money complies with the law and the court supports it $^{\textit{Acceptance}}$. The defendant B was legally summoned by the court and failed to appear in court without justifiable reasons. It was deemed to have waived his right to defend the facts and claims by the plaintiff.
REAL	The court concluded that: The guaranteed loan relationship between the plaintiff and the defendant is legal and effective. The defendant B still owes the plaintiff a loan of $20,000 and has not returned. The plaintiff ’s claim for the defendant B to return the loan complies with the law and the court supports it $^{\textit{Acceptance}}$. Defendant C voluntarily provided guarantee for this loan and did not stipulate the guarantee method and period. According to law, he should bear joint and several liability for the above debt within six months from the date of maturity of the main debt. The main contract in this case did not stipulate the time limit for the performance of the main debt, and the guarantee period should be calculated from the date when the plaintiff claimed the rights. The plaintiff's claim that the defendant C bears joint and several liability for the settlement of the above debts complies with the law, and the court also supports it $^{\textit{Acceptance}}$. The two defendants were legally summoned by the court and failed to appear in court without justifiable reasons. It was deemed to have waived his right to defend the facts and claims by the plaintiff.

Figure 9: Show case 5.

PLAINTIFF'S CLAIM	The two defendants B and C are required to return the loan of \$180,000 and pay the overdue interest of the loan of \$100,000 (from March 9, 2013, the monthly interest rate is calculated at 1.87% to the date that the judgment is confirmed)
FACT DESCRIPTION	After the hearing, the court held the facts as follows: In support of the facts claimed by the plaintiff, the following evidence materials were provided to this court within the proof period: 1. Two loan agreements to prove the fact that the defendant B borrowed \$180,000 from the plaintiff. 2. One piece of marriage registration information, to prove that the loan in the case occurred during the marriage of the two defendants, and should be the joint debts of the two defendants. Although the evidence provided by the plaintiff has not been cross-examined by the two defendants, the court found that the content of the above-mentioned evidence was objective and clear, the source form was legal, and was related to the facts of the case, so it was accepted. Based on the evidence adopted above and the court investigation, the facts confirmed by the court are consistent with the facts claimed by the plaintiff.
PGN	The court concluded that: The private lending relationship between the plaintiff and the defendant B is established and legally valid. As the borrower, the defendant B failed to repay the loan, which constituted a breach of contract and should bear corresponding civil liabilities. The plaintiff 's claim has sufficient evidence and complies with the law, and the court supports it $^{\textit{Acceptance}}$. The two defendants were legally summoned by the court and failed to appear in court without justifiable reasons. It was deemed to have waived his right to defend the facts and claims by the plaintiff.
AC-NLG	The court concluded that: The private lending relationship between the plaintiff and the defendant B is established and legally valid. As the borrower, the defendant B failed to perform the repayment obligations in time and should bear corresponding civil liabilities. The plaintiff 's changed claim has sufficient evidence and complies with the law, and the court will support it $^{\textit{Acceptance}}$. The two defendants were legally summon by the court and failed to appear in court without justifiable reasons. It was deemed to have waived his right to defend the facts and claims by the plaintiff.
REAL	The court concluded that: The civil lending relationship between the plaintiff A and the defendant B was established and legally valid. As the borrower, the defendant B failed to fully perform the repayment obligations as agreed, which constituted a breach of contract and should bear corresponding civil liabilities. Because the loan in this case was formed during the marriage of the two defendants, in view of the fact that the defendant C did not respond to the claim and did not appear in court to participate in the litigation, the debt owned by the defendant B personally should be regarded as the joint debts of the defendant B and C. The plaintiff 's changed claim has sufficient evidence and complies with the law, and the court will support it $^{\textit{Acceptance}}$. The two defendants were legally summon by the court and failed to appear in court without justifiable reasons. It was deemed to have waived his right to defend the facts and claims by the plaintiff.

Figure 10: Show case 6.

PLAINTIFF'S CLAIM	1. The defendant B shall pay $28,000 and interest $2560. Payment of interest is calculated from the date of prosecution to the actual settlement date, based on the base rate of the People's Bank of China of the same period at the amount of $28,000. 2. The litigation costs in this case shall be paid by the defendant.
FACT DESCRIPTION	After the hearing, the court held the facts as follows: On September 30, 2013 and August 25, 2014, the defendant B borrowed $10,000 each time from the plaintiff A. The defendant issued a loan receipt to the plaintiff for each of the two loans. There was no written agreement on the interest and loan period. Later, the defendant did not return the loan, then it caused a dispute. The above facts are proved by two receipts of the loan provided by the plaintiff and the plaintiff's statement in the court.
PGN	The court concluded that: The private lending relationship between the plaintiff and the defendant is established according to law, and is effective from the date the plaintiff provides the defendant with the loan. After the plaintiff provided the loan to the defendant, the defendant failed to return the loan as agreed, it was obviously a breach of contract. Therefore, the plaintiff's claim requesting the defendant to return the loan principal of $28,000 was justified, and the court supports it ^{Acceptance}. The defendant was legally summoned by the court and refused to appear in court without justifiable reasons to participate in the proceedings.
AC-NLG	The court concluded that: The private lending relationship between the plaintiff and defendant is established according to law and should be protected by law. The defendant borrowed $10,000 from the plaintiff. The facts were clear and the evidence was sufficient. The plaintiff now requires the defendant to repay the loan of $10,000. The reasons are justified, and the court supports it ^{Acceptance}. But the court does not support the plaintiff 's claim requesting the defendant to pay interest on the loan because the plaintiff failed to provide evidence to prove the fact that both of them agreed on the interest of the loan ^{Rejection}. The defendant was legally summoned by this court and refused to appear in court without justifiable reasons to participate in the proceedings.
REAL	The court concluded that: The private lending relationship between the plaintiff and the defendant is established and effective, and shall be protected according to law. The defendant should repay the loan after receiving it, but now he did not repay, it is obviously a breach of contract. Therefore, this court supports the claim of the plaintiff that the defendant should return the loan of $20,000 and the corresponding loss of interest ^{Acceptance}. The plaintiff claimed that the defendant should pay interest, but did not provide evidence to prove that both of them clearly agreed on the interest, so the court does not support the plaintiff's claim for interest ^{Rejection}. The plaintiff withdrew some of the claims in the court hearing, and this court permitted it.

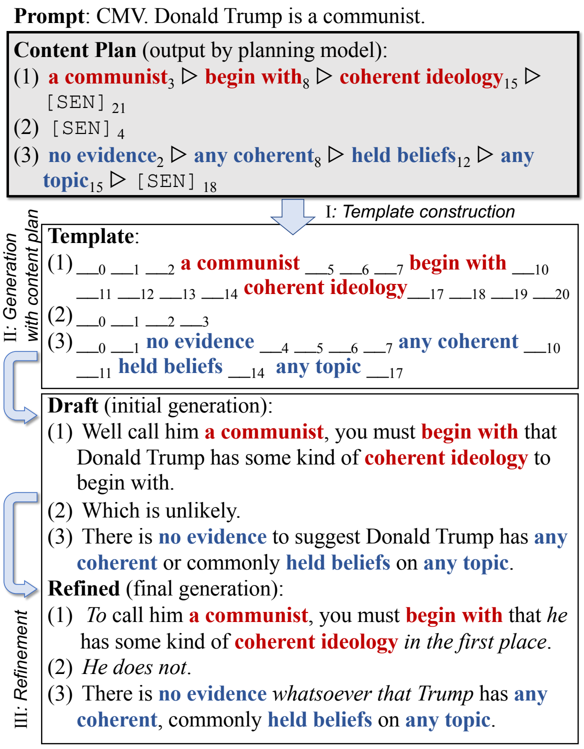
Abstract

Pre-trained Transformers have enabled impressive breakthroughs in generating long and fluent text, yet their outputs are often "rambling" without coherently arranged content. In this work, we present a novel content-controlled text generation framework, **PAIR**, with planning and iterative refinement, which is built upon a large model, BART. We first adapt the BERT model to automatically construct the content plans, consisting of keyphrase assignments and their corresponding sentence-level positions. The BART model is employed for generation without modifying its structure. We then propose a refinement algorithm to gradually enhance the generation quality within the sequence-to-sequence framework. Evaluation with automatic metrics shows that adding planning consistently improves the generation quality on three distinct domains, with an average of 20 BLEU points and 12 METEOR points improvements. In addition, human judges rate our system outputs to be more relevant and coherent than comparisons without planning.

1 Introduction

Large pre-trained language models are the cornerstone of many state-of-the-art models in various natural language understanding and generation tasks (Devlin et al., 2019; Liu et al., 2019; Lewis et al., 2020), yet they are far from perfect. In generation tasks, although models like GPT-2 (Radford et al., 2019) are able to produce plausible text, their spontaneous nature limits their utility in actual applications, e.g., users cannot specify what contents to include, and in what order.

To make large models more useful in practice, and to improve their generation quality, we believe it is critical to inform them of *when to say what*, which is addressed as *content planning* in traditional generation systems (Duboue and McKeown, 2001; Stent et al., 2004). Specially designed control codes and auxiliary planning modules have been integrated into neural models (Keskar et al., 2019; Moryossef et al., 2019; Hua and Wang, 2019), yet those solutions require model architecture modification or retraining, making text generation with large models a very costly endeavor.



Prompt: CMV. Donald Trump is a communist.

Content Plan (output by planning model):
(1) **a communist**$_3$ ▷ **begin with**$_8$ ▷ **coherent ideology**$_{15}$ ▷ `[SEN]` $_{21}$
(2) `[SEN]` $_4$
(3) **no evidence**$_2$ ▷ **any coherent**$_8$ ▷ **held beliefs**$_{12}$ ▷ **any topic**$_{15}$ ▷ `[SEN]` $_{18}$

Template:
(1) ___$_0$ ___$_1$ ___$_2$ **a communist** ___$_5$ ___$_6$ ___$_7$ **begin with** ___$_{10}$ ___$_{11}$ ___$_{12}$ ___$_{13}$ ___$_{14}$ **coherent ideology** ___$_{17}$ ___$_{18}$ ___$_{19}$ ___$_{20}$
(2) ___$_0$ ___$_1$ ___$_2$ ___$_3$
(3) ___$_0$ ___$_1$ **no evidence** ___$_4$ ___$_5$ ___$_6$ ___$_7$ **any coherent** ___$_{10}$ ___$_{11}$ **held beliefs** ___$_{14}$ **any topic** ___$_{17}$

Draft (initial generation):
(1) Well call him **a communist**, you must **begin with** that Donald Trump has some kind of **coherent ideology** to begin with.
(2) Which is unlikely.
(3) There is **no evidence** to suggest Donald Trump has **any coherent** or commonly **held beliefs** on **any topic**.

Refined (final generation):
(1) *To* call him **a communist**, you must **begin with** that *he* has some kind of **coherent ideology** *in the first place*.
(2) *He does not*.
(3) There is **no evidence** *whatsoever that Trump* has **any coherent**, commonly **held beliefs** on **any topic**.

Figure 1: An argument generation example using Reddit ChangeMyView. [Top] Partial output by our planner with keyphrase assignment and positions (in subscripts) for each sentence, segmented by special token `[SEN]`, from which a template is constructed. [Bottom] A draft is first produced and then refined, with updated words highlighted in *italics*.

To this end, this work aims to bring new insights into *how to effectively incorporate content plans into large models to generate more rele-*

vant and coherent text. We first study *a planning model trained from BERT* (Devlin et al., 2019) to produce the initial content plan, which assigns keyphrases to different sentences and predicts their positions. Next, we propose a *content-controlled text generation framework*, built upon the pre-trained sequence-to-sequence (seq2seq) Transformer model BART (Lewis et al., 2020). As shown in Figure 1, our generation model takes in a content plan consisting of *keyphrase assignments* and their corresponding *positions* for each sentence. The plan is encoded as a template, with `[MASK]` tokens added at positions where no content is specified. Our model then outputs a fluent and coherent multi-sentence text (draft) to reflect the plan. This is done by fine-tuning BART without modifying its architecture.

Furthermore, we present an *iterative refinement algorithm* to improve the generation in multiple passes, within the seq2seq framework. At each iteration, tokens with low generation confidence are replaced with `[MASK]` to compose a new template, from which a new output is produced. Unlike prior refinement algorithms that only permit editing in place, our solution offers more flexibility. Figure 1 exemplifies the refinement outcome.

We call our system **PAIR** (Planning And Iterative Refinement).[1] It is experimented on three distinct domains: counter-argument generation with Reddit ChangeMyView data, opinion article writing with the New York Times (NYT) corpus[2] (Sandhaus, 2008), and news report production on NYT. Automatic evaluation with BLEU, ROUGE, and METEOR shows that, by informing the generation model with sentence-level content plans, our model significantly outperforms a BART model fine-tuned with the same set of keyphrases as input (§ 5.1). Human judges also rate our system outputs as more relevant and coherent (§ 5.2). Additionally, our iterative refinement strategy consistently improves the generation quality according to both automatic scores and human evaluation. Finally, our model achieves better content control by reflecting the specified keyphrases in the content plan, whose outputs are preferred by human to another version with weaker control.

To summarize, our major contributions include:

- We propose a novel content planner built upon BERT to facilitate long-form text generation.
- We present a novel template mask-and-fill method to incorporate content planning into generation models based on BART.
- We devise an iterative refinement algorithm that works within the seq2seq framework to flexibly improve the generation quality.

2 Related Work

Content Planning as a Generation Component. Despite the impressive progress made in many generation tasks, neural systems are known to produce low-quality content (Wiseman et al., 2017; Rohrbach et al., 2018), often with low relevance (Li et al., 2016) and poor discourse structure (Zhao et al., 2017; Xu et al., 2020). Consequently, planning modules are designed and added into neural systems to enhance content relevance (Wiseman et al., 2018; Moryossef et al., 2019; Yao et al., 2019; Hua and Wang, 2019). However, it is still an open question to include content plans in large models, given the additional and expensive model retraining required. This work innovates by adding content plans as masked templates and designing refinement strategy to further boost generation performance, without architectural change.

Controlled Text Generation. Our work is also in line with the study of controllability of neural text generation models. This includes manipulating the syntax (Dušek and Jurčíček, 2016; Goyal and Durrett, 2020) and semantics (Wen et al., 2015; Chen et al., 2019) of the output. Specific applications encourage the model to cover a given topic (Wang et al., 2017; See et al., 2019), mention specified entities (Fan et al., 2018), or display a certain attribute (Hu et al., 2017; Luo et al., 2019; Balakrishnan et al., 2019). However, most existing work relies on model engineering, limiting the generalizability to new domains and adaptability to large pre-trained Transformers. One exception is the Plug and Play model (Dathathri et al., 2020), which directly modifies the key and value states of GPT-2 (Radford et al., 2019). However, since the signal is derived from the whole generated text, it is too coarse to provide precise sentence-level content control. Here, we instead gain fine-grained controllability through keyphrase assignment and positioning per sentence, which can be adapted to any off-the-shelf pre-trained Transformer generators.

Iterative Refinement has been studied in machine translation (Lee et al., 2018; Freitag et al., 2019;

---

[1] Code and data are available at: `http://xinyuhua.github.io/Resources/emnlp20/`

[2] `https://catalog.ldc.upenn.edu/LDC2008T19`

Mansimov et al., 2019; Kasai et al., 2020) to gradually improve translation quality. Refinement is also used with masked language models to improve fluency of non-autoregressive generation outputs (Ghazvininejad et al., 2019; Lawrence et al., 2019). Our work uses BART (Lewis et al., 2020), a state-of-the-art seq2seq model that offers better generalizability and stronger capacity for long text generation. Our proposed strategy substantially differs from prior solutions that rely on in-place word substitutions (Novak et al., 2016; Xia et al., 2017; Weston et al., 2018), as we leverage the seq2seq architecture to offer more flexible edits.

3 Content-controlled Text Generation with PAIR

Task Description. Our input consists of (1) a sentence-level prompt $\boldsymbol{x}$, such as a news headline, or a proposition in an argument, and (2) a set of keyphrases $\boldsymbol{m}$ that are relevant to the prompt. The system aims to generate $\boldsymbol{y}$ that contains multiple sentences, as in a news report or an argument, by reflecting the keyphrases in a coherent way.

In this section, we first introduce content planning built upon BERT, that assigns keyphrases into sentences and predicts their positions (§ 3.1). Then we propose a seq2seq generation framework with BART fine-tuning that includes a given content plan derived from keyphrases $\boldsymbol{m}$ (§ 3.2). Finally, § 3.3 discusses improving generation quality by iteratively masking the less confident predictions and regenerating within our framework.

3.1 Content Planning with BERT

Our content planner is trained from BERT to assign keyphrases to different sentences and predict their corresponding positions. As shown in Figure 2, the concatenation of prompt $\boldsymbol{x}$ and unordered keyphrases $\boldsymbol{m}$ is encoded with bidirectional self-attentions. Keyphrase assignments are produced autoregressively as a sequence of tokens $\boldsymbol{m}' = \{w_j\}$, with their positions in the sentence $\boldsymbol{s} = \{s_j\}$ predicted as a sequence tagging task.

We choose BERT because it has been shown to be effective at both language modeling and sequence tagging. Moreover, we leverage its segment embedding to distinguish the input and output sequences. Specifically, we reuse its pre-trained language model output layer for keyphrase assignment. We further design a separate keyphrase positioning layer to predict token position s_j as the relative distance from each sentence's beginning:

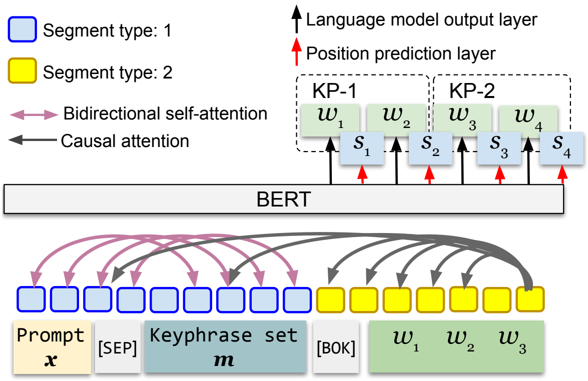

Figure 2: Content planning with BERT. We use bidirectional self-attentions for input encoding, and apply causal self-attentions for keyphrase assignment and position prediction. The input ($\boldsymbol{x}$, $\boldsymbol{m}$) and output keyphrase assignments ($\boldsymbol{m}'$) are distinguished by different segment embeddings.

$$p(s_j|\boldsymbol{w}_{\leq j}) = \text{softmax}(\boldsymbol{H}^L \boldsymbol{W}_s) \qquad (1)$$

where $\boldsymbol{H}^L$ is the last layer hidden states of the Transformer, and $\boldsymbol{W}_s$ are the newly added keyphrase positioning parameters learned during BERT fine-tuning. The range of allowed positions is from 0 to 127.

Noticeably, as our prediction is done autoregressively, attentions should only consider the generated tokens, but not the future tokens. However, BERT relies on bidirectional self-attentions to attend to both left and right. To resolve this discrepancy, we apply causal attention masks (Dong et al., 2019) over $\boldsymbol{m}'$ to disallow attending to the future (gray arrows in Figure 2).

Training the Planner. We extract keyphrases and acquire their ground-truth positions from human-written references, and fine-tune BERT with cross-entropy losses for both assignment and positioning, with a scaling factor 0.1 over the positioning loss.

Inference. A `[BOK]` token signals the beginning of keyphrase assignment generation. We employ a greedy decoding algorithm, and limit the output vocabulary to tokens in $\boldsymbol{m}$ and ensure each keyphrase is generated at most once. To allow sentence-level content planning, a special `[SEN]` token is generated to represent the sentence boundary, with its predicted position indicating the length. The planning process terminates when `[EOS]` is produced.

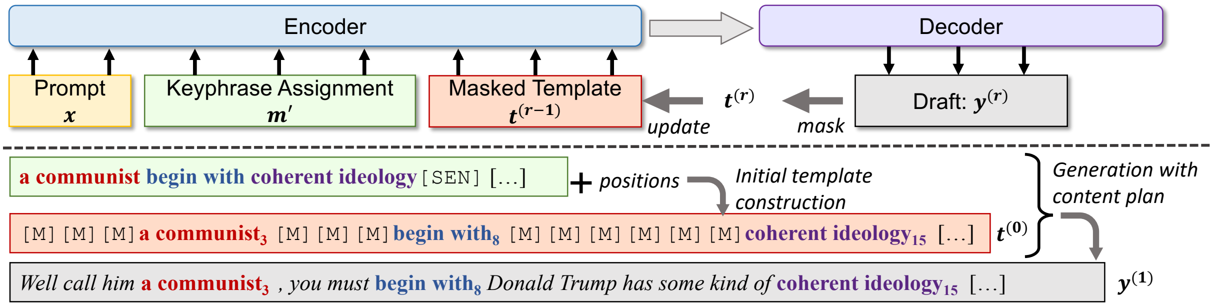

Figure 3: Our content-controlled text generation framework, PAIR, which is built on BART. Decoding is executed iteratively. At each iteration, the encoder consumes the input prompt x, the keyphrase assignments m', as well as a partially masked template ($t^{(r-1)}$ for the r-th iteration, `[M]` for masks). The autoregressive decoder produces a complete sequence $y^{(r)}$, a subset of which is further masked, to serve as the next iteration's template $t^{(r)}$.

3.2 Adding Content Plan with a Template Mask-and-Fill Procedure

Given a content planning model, we invoke it to output keyphrase assignments to different sentences (m'), their corresponding positions s, along with each sentence's length (based on the prediction of `[SEN]`). We first employ a post-processing step to convert between different tokenizers, and correct erroneous position predictions that violate the assignment ordering or break the consecutivity of the phrase (Appendix A). We then convert the plan into a **template** $t^{(0)}$ as follows: For each sentence, the assigned keyphrases are placed at their predicted positions, and empty slots are filled with `[MASK]` symbols. Figure 3 illustrates the template construction process and our seq2seq generation model. In Appendix B, we show statistics on the constructed templates.

The input prompt x, keyphrase assignments m', and template $t^{(0)}$ are concatenated as the input to the encoder. The decoder then generates an output $y^{(1)}$ according to the model's estimation of $p(y^{(1)}|x, m', t^{(0)})$. $y^{(1)}$ is treated as a draft, to be further refined as described in the next section.

Our method is substantially different from prior work that uses constrained decoding to enforce words to appear at specific positions (Hokamp and Liu, 2017; Post and Vilar, 2018; Hu et al., 2019), which is highly biased by the surrounding few words and suffers from disfluency. Since BART is trained to denoise the masked input with contextual understanding, it naturally benefits our method.

Decoding. We employ the nucleus sampling strategy (Holtzman et al., 2019), which is shown to yield superior output quality in long text generation. In addition to the standard top-k sampling from tokens with the highest probabilities, nucleus sampling further limits possible choices based on a cumulative probability threshold (set to 0.9 in all experiments below). We also require the *keyphrases to be generated at or nearby their predicted positions*. Concretely, for positions that match any keyphrase token, we force the decoder to copy the keyphrase unless it has already been generated in the previous five tokens. We sample three times to choose the one with the lowest perplexity, as estimated by GPT-2$_{\text{base}}$ (Radford et al., 2019).

3.3 Iterative Refinement

Outputs generated in a single pass may suffer from incorrectness and incoherence (see Figure 1), therefore we propose an iterative refinement procedure to improve the quality. In each pass, tokens with low generation confidence are masked (Algorithm 1). This is inspired by iterative decoding designed for inference acceleration in *non-autoregressive* generation (Lee et al., 2018; Lawrence et al., 2019), though their refinement mostly focuses on word substitution and lacks the flexibility for other operations. Moreover, our goal is to improve fluency while ensuring the generation of given keyphrases.

At each iteration, the n least confident tokens are replaced with `[MASK]`. Similar as the mask-predict algorithm (Ghazvininejad et al., 2019), we gradually reduce the number of masks. In our experiments, each sample is refined for 5 iterations, with n decaying linearly from 80% of $|y^{(r)}|$ to 0.

Training the Generator. Our training scheme is similar to masked language model pre-training. Given the training corpus $\mathcal{D} = \{(x_i, m'_i, y_i)\}$, we consider two approaches that add noise to the target y_i by randomly masking a subset of (1) any tokens, or (2) tokens that are not within the span

Algorithm 1: Iteratively refinement via template mask-and-fill. The sample with the lowest perplexity (thus with better fluency) is selected for each iteration.

```
Data: prompt $x$, keyphrase assignments $m'$,
      keyphrase positions $s$, $R$ refinement
      iterations, $\rho$ nucleus sampling runs
Result: final output $y^{(R)}$
Construct template $t^{(0)}$ based on $m'$ and $s$ ;
for $r = 1$ to $R$ do
    Run encoder over $x \oplus m' \oplus t^{(r-1)}$ ;
    $\mathcal{Y} \leftarrow \varnothing$ ;
    for $i = 1$ to $\rho$ do
        Run nucleus sampling to generate $y_i$
          with keyphrase position
          enforcement;
        Append $y_i$ to $\mathcal{Y}$;
    $y^{(r)} \leftarrow \text{argmin}_{y_i \in \mathcal{Y}}$ GPT2-PPL($y_i$);
    $n \leftarrow |y^{(r)}| \times (1 - r/R)$;
    Mask $n$ tokens with the lowest
      probabilities to create new template
      $t^{(r)}$;
```

of any keyphrase. The latter is better aligned with our decoding objective, since keyphrases are never masked. We concatenate x_i, m'_i, and the corrupted target $\widetilde{y}_i$ as input, and fine-tine BART to reconstruct the original y_i with a cross-entropy loss.

4 Experiment Setups

4.1 Tasks and Datasets

We evaluate our generation and planning models on datasets from three distinct domains for multi-paragraph-level text generation: (1) argument generation (**ArgGen**) (Hua et al., 2019), to produce a counter-argument to refute a given proposition; (2) writing opinionated articles (**Opinion**), e.g., editorials and op-eds, to show idea exchange on a given subject; and (3) composing news reports (**News**) to describe events. The three domains are selected with diverse levels of subjectivity and various communicative goals (persuading vs. informing), with statistics shown in Table 1.

Task 1: Argument Generation. We first evaluate our models on persuasive argument generation, based on a dataset collected from Reddit `r/ChangeMyView` (CMV) in our prior work (Hua et al., 2019). This dataset contains pairs of original post (OP) statement on a controversial issue about politics and filtered high-quality counter-arguments, covering 14,833 threads from 2013 to 2018. We use the OP title, which contains a proposition (e.g. *the minimum wage should be abolished*), to form the input prompt x. In our prior work, only the first paragraphs of high-quality counter-arguments are used for generation. Here we consider generating the full post, which is significantly longer. Keyphrases are identified as noun phrases and verb phrases that contain at least one topic signature word (Lin and Hovy, 2000), which is determined by a log-likelihood ratio test that indicates word salience. Following our prior work, we expand the set of topic signatures with their synonyms, hyponyms, hypernyms, and antonyms according to WordNet (Miller, 1994). The keyphrases longer than 10 tokens are further discarded.

	# Sample	|Prompt|	|Target|	# KP	KP Cov.
ArgGen	56,504	19.4	116.6	20.6	30.5%
Opinion	104,610	6.1	205.6	19.0	26.0%
News	239,959	7.0	282.7	30.3	32.6%

Table 1: Statistics of the three datasets. We report average lengths of the prompt and the target generation, number of unique keyphrases (# KP) used in the input, and the percentage of content words in target covered by the keyphrases (KP Cov.).

Task 2: Opinion Article Generation. We collect opinion articles from the New York Times (NYT) corpus (Sandhaus, 2008). An article is selected if its `taxonomies` label has a prefix of *Top/Opinion*. We eliminate articles with an empty headline or less than three sentences. Keyphrases are extracted in a similar manner as done in argument generation. Samples without any keyphrase are removed. The article headline is treated as the input, and our target is to construct the full article. Table 1 shows that opinion samples have shorter input than arguments, and the keyphrase set also covers fewer content words in the target outputs, requiring the model to generalize well to capture the unseen tokens.

Task 3: News Report Generation. Similarly, we collect and process news reports from NYT, filtering by taxonomy labels starting with "*Top/News*", removing articles that have no content word overlap with the headline, and ones with `material-types` labeled as one of "*statistics*", "*list*", "*correction*", "*biography*", or "*review*." News reports describe events and facts, and in this domain we aim to study and emphasize the impor-

	ARGGEN				OPINION				NEWS

Table 2: Key results on argument generation, opinion article writing, and news report generation. BLEU-4 (B-4), ROUGE-L (R-L), METEOR (MTR), and average output lengths are reported (for references, the lengths are 100, 166, and 250, respectively). PAIR$_{\text{light}}$, using keyphrase assignments only, consistently outperforms baselines; adding keyphrase positions, PAIR$_{\text{full}}$ further boosts scores. Improvements by our models over baselines are all significant ($p < 0.0001$, approximate randomization test). Iterative refinement helps on both setups.

tance of faithfully reflecting content plans during generation and refinement.

Data Split and Preprocessing. For argument generation, we split the data into 75%, 12.5%, and 12.5% for training, validation, and test sets. To avoid test set contamination, the split is conducted on thread level. For opinion and news generation, we reserve the most recent 5k articles for testing, another 5k for validation, and the rest (23k for news and 10k for opinion) are used for training. We apply the BPE tokenization (Sennrich et al., 2016) for the generation model as BART does, and use WordPiece (Wu et al., 2016) for BERT-based planner. To fit the data into our GPUs, we truncate the target size to 140 tokens for argument, sizes of 243 and 335 are applied for opinion and news, for both training and inference.

4.2 Implementation Details

Our code is written in PyTorch (Paszke et al., 2019). For fine-tuning, we adopt the standard linear warmup and inverse square root decaying scheme for learning rates, with a maximum value of 5×10^{-5}. Adam (Kingma and Ba, 2014) is used as the optimizer, with a batch size of 10 for refinement and 20 for content planning, and a maximum gradient clipped at 1.0. All hyperparameters are tuned on validation set, with early stopping used to avoid overfitting. More details are in Appendix A.

4.3 Baselines and Comparisons

We consider two baselines, both are fine-tuned from BART as in our models: (1) **SEQ2SEQ** directly generates the target from the prompt; (2) **KPSEQ2SEQ** encodes the concatenation of the prompt and the *unordered* keyphrase set. To study if using only sentence-level keyphrase assignments helps, we include a model variant (**PAIR$_{\text{light}}$**) by removing keyphrase position information ($\boldsymbol{s}$) from the input of our generator and using an initial template with all `[MASK]` symbols. Our model with full plans is denoted as **PAIR$_{\text{full}}$**. We first report generation results using *ground-truth content plans* constructed from human-written text, and also show the end-to-end results with *predicted content plans* by our planner.

5 Results

5.1 Automatic Evaluation

We report scores with BLEU (Papineni et al., 2002), which is based on n-gram precision (up to 4-grams); ROUGE-L (Lin, 2004), measuring recall of the longest common subsequences; and METEOR (Lavie and Agarwal, 2007), which accounts for paraphrase. For our models PAIR$_{\text{full}}$ and PAIR$_{\text{light}}$, we evaluate both the first draft and the final output after refinement. Table 2 lists the results when ground-truth content plans are applied.

First, *our content-controlled generation model with planning consistently outperforms comparisons and other model variants on all datasets*, with or without iterative refinement. Among our model variants, PAIR$_{\text{full}}$ that has access to full content plans obtains significantly better scores than PAIR$_{\text{light}}$ that only includes keyphrase assignments but not their positions. Lengths of PAIR$_{\text{full}}$'s outputs are also closer to those of human references. Both imply the benefit of keyphrase positioning.

Table 2 also shows that *the iterative refinement strategy can steadily boost performance* on both of our setups. By inspecting the performance of refinement in different iterations (Figure 4), we observe that both BLEU and ROUGE-L scores gradually increase while perplexity lowers as the

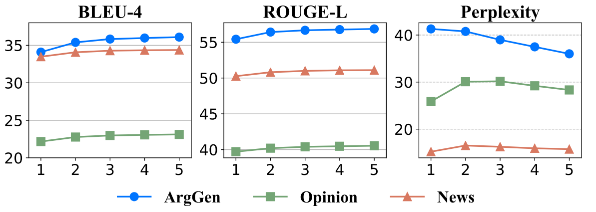

Figure 4: Results on iterative refinement with five iterations. Both BLEU and ROUGE-L scores steadily increase, with perplexity lowers in later iterations.

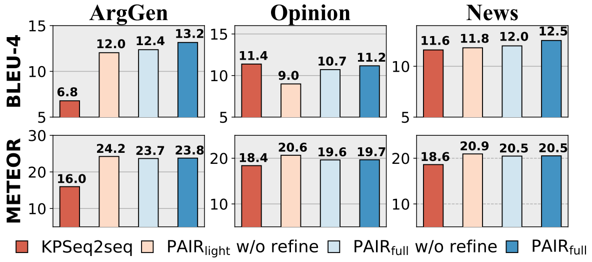

Figure 5: End-to-end generation results with automatically predicted content plans. Our models outperform KPSEQ2SEQ in both metrics, except for BLEU-4 on opinion articles where results are comparable.

refinement progresses. This indicates that iterative post-editing improves both content and fluency.

Results with Predicted Content Plans. We further report results by using content plans predicted by our BERT-based planner. Figure 5 compares PAIR$_{\text{full}}$ and PAIR$_{\text{light}}$ with KPSEQ2SEQ. Our models yield better METEOR scores on all three domains. That said, the improvement from predicted plans is not as pronounced as that from ground-truth plans. Upon inspection, we find that our planner often falls short of accurately positioning the given keyphrases, leading to degraded generation performance. This points to a potential direction for future work where better positioning model should be developed.

5.2 Human Evaluation

We hire four proficient English speakers[3] to rate three aspects of the generated arguments on a scale of 1 (worst) to 5 (best): **fluency**, **coherence**—if the information organization is natural and logical, and **relevance**—if the topic is related to the prompt and whether the stance is correct. 50 samples are randomly selected, with system outputs by KPSEQ2SEQ, PAIR$_{\text{full}}$ and PAIR$_{\text{light}}$ shown to human judges in random order. The evaluation guideline is in the supplementary material.

ARGGEN	**Fluency**	**Coherence**	**Relevance**
KPSEQ2SEQ	4.63	3.28	2.79
PAIR$_{\text{light}}$	**4.75**	**3.97***	**3.85***
PAIR$_{\text{full}}$	4.46	3.76*	3.79*

Table 3: Human evaluation for argument generation on fluency, coherence, and relevance, with 5 as the best. The Krippendorff's α are 0.28, 0.30, and 0.37, respectively. Our model outputs are significantly more coherent and relevant than KPSEQ2SEQ (*: $p < 0.0001$), with comparable fluency.

Prompt (News): *4 Arrested in Theft of Baby Jesus Figurines*

PAIR$_{\text{full}}$: **Four New Jersey teenagers arrested yesterday** were accused of stealing more than **25 plastic baby Jesus figurines** from a church before they **burn in a bonfire**, **the police** said. **The police** in **Sayreville**, N.J., **arrested Michael Payne, 18**, and T.J. Jones, 18, of Union City; **Nicholas M. Hess**, 18, of **Matawan**; and Jason L. O'Neill, 18, of Port New York, N.J., and charged them with burglary. Their vandals removed more than 100 figurines of Jesus from **a cemetery** outside **St. Stanislaus Kostka Church** in Sayreville, the police said. Detectives said the four had taken their **flashlights** to **the cemetery** and **jotted down the license plates** of several cars in **the vicinity** [. . .]

Prompt (Opinion): *Drowning in a Sea of College Debt*

PAIR$_{\text{full}}$: Once again, the appalling problem of **increasing debt** in **financing higher education** that has taken place is more **intolerable**, particularly because of the arrogance of our colleges and universities. The burden of **saddling college** students with debt in the middle of their **teenage years**, when they were in debt, is essential for **a good education**. Our educational system is designed to allow kids to develop the skills necessary, but it does not **create optimal conditions** for mature students who know they will not be able [. . .]

Table 4: Sample outputs in the news and opinion domain. Keyphrases assigned to different sentences are in boldface and color-coded.

Table 3 shows that both of our models are rated with better coherence and relevance than KPSEQ2SEQ which uses the same but unordered keyphrases as input. Interestingly, outputs by PAIR$_{\text{light}}$ are regarded as more fluent and coherent, though the difference is not significant. However, discourse analysis in § 6 reveals that clauses produced by PAIR$_{\text{light}}$ are more locally related, compared to PAIR$_{\text{full}}$, which can be perceived as easier to read. In addition to the sample argument in Figure 1, Table 4 shows PAIR$_{\text{full}}$'s output in the news and opinion domains. More samples by different systems are in the supplementary material.

Effect of Refinement and Keyphrase Enforce-

---

[3] They are all US-based college students. Each of them is paid $15 hourly for the task.

ment. We further ask *whether human judges prefer the refined text* and *whether enforcing keyphrases to be generated yields noticeable content improvement*. In a second study, we present the same 50 prompts from the previous evaluation on argument generation, and an additional 50 samples for opinion article writing to the same group of human judge. For each sample, PAIR$_{\text{full}}$'s outputs with and without refinement are shown in random order. Judges indicate their preference based on the overall quality. The same procedure is conducted to compare with a version where we do not enforce keyphrases to be copied at their predicted positions during decoding. Table 5 demonstrates that the refined text is preferred in more than half of the cases, for both domains. Enforcing keyphrase generation based on their positions is also more favorable than not enforcing such constraint.

	PAIR$_{\text{full}}$	*w/o refine*	PAIR$_{\text{full}}$	*w/o enforce*
ARGGEN	**52.7%**	33.3%	**45.3%**	40.0%
OPINION	**52.7%**	30.7%	**50.0%**	29.3%

Table 5: Percentages of samples preferred by human judges before and after refinement [Left]; with and without enforcing keyphrases to appear at the predicted positions [Right]. Ties are omitted.

What is updated during iterative refinement? Since refinement yields better text, we compare generations before and after the refinement. First, we find that masks are regularly put on "functional" words and phrases. For example, stopwords and punctuation along with their bigrams are often swapped out, with new words filled in to improve fluency. Moreover, about 85% of the refinement operations result in new content being generated. This includes changing prepositions and paraphrasing, e.g., replacing "*a research fellow*" with "*a graduate student*." On both news and opinion domains, numerical and temporal expressions are often incorrectly substituted, suggesting that better fact control needs to be designed to maintain factuality.

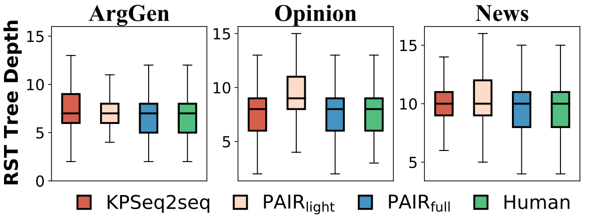

Figure 6: Distributions of RST tree depth. PAIR$_{\text{full}}$ better resembles the patterns in human-written texts.

6 Further Discussions on Discourse

Prior work's evaluation mainly focuses on fluency and content relevance, and largely ignores the discourse structure exposed by the generated text. However, unnatural discourse and lack of focus are indeed perceived as major problems of long-form neural generations, as identified by human experts.[4] Here, we aim to investigate whether content-controlled generation with ground-truth content plans resembles human-written text by studying discourse phenomena.

Are PAIR generations similar to human-written text in discourse structure? We utilize DPLP (Ji and Eisenstein, 2014), an off-the-shelf Rhetorical Structure Theory (RST) discourse parser. DPLP converts a given text into a binary tree, with elementary discourse units (EDUs, usually clauses) as nucleus and satellite nodes. For instance, a relation `NS-elaboration` indicates the second node as a satellite (`S`) elaborating on the first nucleus (`N`) node. DPLP achieves F1 scores of 81.6 for EDU detection and 71.0 for relation prediction on news articles from the annotated RST Discourse Treebank (Carlson et al., 2001). We run this trained model on our data for both human references and model generations.

First, we analyze the *depth of RST parse trees*, which exhibits whether the text is more locally or globally connected. For all trees, we truncate at a maximum number of EDUs based on the 90 percentile of EDU count for human references. Distributions of tree depth are displayed in Figure 6. As can be seen, generations by PAIR$_{\text{full}}$ show similar patterns to human-written arguments and articles. We also find that trees by PAIR$_{\text{light}}$ tend to have a more "linear" structure, highlighting the dominance of local relations between adjacent EDUs, compared with PAIR$_{\text{full}}$ which uses knowledge of keyphrases positions. This implies that content positioning helps with structure at a more global level. We further look into the *ratios of* `NS`*,* `NN`*,* `SN` *relations*, and observe that most model outputs have similar trends as human-written texts, except for KPSEQ2SEQ which has more `SN` relations, e.g., it produces twice as many `SN`s than others on arguments.

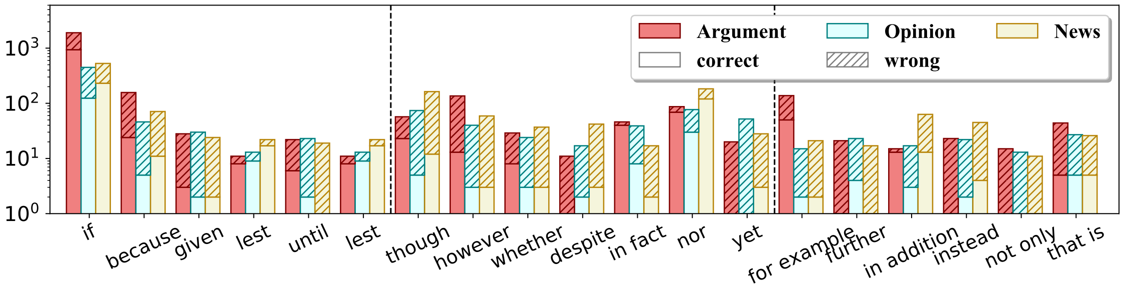

Figure 7: Discourse markers that are correctly and incorrectly (shaded) generated by $\text{PAIR}_{\text{full}}$, compared to aligned sentences in human references. Discourse markers are grouped (from left to right) into senses of CONTINGENCY (higher marker generation accuracy observed), COMPARISON, and EXPANSION. y-axis: # of generated sentences with the corresponding marker.

Can PAIR correctly generate discourse markers? Since discourse markers are crucial for coherence (Grote and Stede, 1998; Callaway, 2003) and have received dedicated research efforts in rule-based systems (Reed et al., 2018; Balakrishnan et al., 2019), we examine if $\text{PAIR}_{\text{full}}$ can properly generate them. For each sample, we construct sentence pairs based on content word overlaps between system generation and human reference. We manually select a set of unambiguous discourse markers from Appendix A of the Penn Discourse Treebank manual (Prasad et al., 2008). When a marker is present in the first three words in a reference sentence, we check if the corresponding system output does the same.

Figure 7 displays the numbers of generated sentences with markers produced as the same in human references (correct) or not (wrong). The markers are grouped into three senses: CONTINGENCY, COMPARISON, and EXPANSION. The charts indicates that $\text{PAIR}_{\text{full}}$ does better at reproducing markers for CONTINGENCY, followed by COMPARISON and EXPANSION. Manual inspections show that certain missed cases are in fact plausible replacements, such as using `at the same time` for `in addition`, or `also` for `further`, while in other cases the markers tend to be omitted. Overall, we believe that content control alone is still insufficient to capture discourse relations, motivating future work on discourse planning.

7 Ethics Statement

We recognize that the proposed system can generate fabricated and inaccurate information due to the systematic biases introduced during model pretraining based on web corpora. We urge the users to cautiously examine the ethical implications of the generated output in real world applications.

8 Conclusion

We present a novel content-controlled generation framework that adds content planning to large pretrained Transformers without modifying model architecture. A BERT-based planning model is first designed to assign and position keyphrases into different sentences. We then investigate an iterative refinement algorithm that works with the sequence-to-sequence models to improve generation quality with flexible editing. Both automatic evaluation and human judgments show that our model with planning and refinement enhances the relevance and coherence of the generated content.

A Reproducibility

Computing Infrastructure. Our model is built upon the PyTorch `transformers-2.6.0` library by Wolf et al. (2019), with `Pytorch-Lightning-0.7.3` (Falcon, 2019) for training routines. To improve training efficiency, we adopt mixed-precision floating point (FP16) computation using the `O2` option of NVIDIA `apex`[5]. For both training and decoding, we utilize the Titan RTX GPU card with 24 GB memory.

Model Sizes. Our generation model has the same architecture as BART (Lewis et al., 2020) with 406M parameters. The content planner is built on top of $\text{BERT}_{\text{base}}$, which has 110M parameters.

Running Time. Training the generation model takes 2.5 hours for argument, 5 hours for opinion, and 24 hours for news. The content planning model converges in 2.5-4 hours for three domains.

Decoding Settings. At inference time, we set $k = 50$, temperature=1.0, and $p = 0.9$ for nucleus sampling. The relatively large k value is determined based on a pilot study, where we find that the refinement lacks diversity if k is set to small values. Moreover, since the Transformer states need to be cached during autoregressive decoding and we perform three complete nucleus sampling runs in each refinement iteration, the GPU memory consumption is substantially increased. We therefore limit the maximum generation steps to 140 for argument, 243 and 335 for opinion and news.

Auto-Correction for Content Plan. When the content plan is predicted by the planner, the following post-processing steps are employed prior to the masked template construction: (1) For a predicted keyphrase, its token positions are adjusted to a consecutive segment, so that the phrase is kept intact in the template. (2) If the predicted positions are not monotonic to the assignment ordering, they will be rearranged. For instance, if the assignment contains $\texttt{KP}_1 \triangleright \texttt{KP}_2$, but position of $\texttt{KP}_2$ is not strictly larger than that of $\texttt{KP}_1$, we instead place $\texttt{KP}_2$ immediately after $\texttt{KP}_1$ in the template. (3) Finally, since the planner and generator have different subword vocabularies, it is necessary to detokenize the predicted keyphrase assignment, and re-tokenize with the BPE vocabulary of the generator.

	ARGGEN		OPINION		NEWS	
	sys	*ref*	*sys*	*ref*	*sys*	*ref*
# tokens	133.3	130.2	228.5	246.3	424.5	435.5

Table 6: Statistics on generated templates by our content planner. Tokens are measured in units of WordPiece (Sennrich et al., 2016). KP distance denotes the average number of tokens between two keyphrases that are in the same sentence. Both system output (*sys*) and human reference (*ref*) are reported.

B Template Construction Statistics

We characterize the content planning results in Table 6. Specifically, we show the statistics on the automatically created templates based on the planner's output. As we can see, our system predicted templates approach human reference in terms of length, per sentence keyphrase count, and the average keyphrase spacing. Sentence segmentation occurs more often in our templates than the reference text, likely due to the frequent generation of `[SEN]` tokens.

Abstract

Abductive and counterfactual reasoning, core abilities of everyday human cognition, require reasoning about what might have happened at time t, while conditioning on multiple contexts from the relative past and future. However, simultaneous incorporation of past and future contexts using generative language models (LMs) can be challenging, as they are trained either to condition only on the past context or to perform narrowly scoped text-infilling.

In this paper, we propose DELOREAN, a new unsupervised decoding algorithm that can flexibly incorporate both the past and future contexts using only off-the-shelf, left-to-right language models and no supervision. The key intuition of our algorithm is incorporating the future through *back-propagation*, during which, we only update the internal representation of the output while fixing the model parameters. By alternating between forward and backward propagation, DELOREAN can decode the output representation that reflects both the left and right contexts. We demonstrate that our approach is general and applicable to two nonmonotonic reasoning tasks: abductive text generation and counterfactual story revision, where DELOREAN outperforms a range of unsupervised and some supervised methods, based on automatic and human evaluation.[1]

1 Introduction

Everyday causal reasoning requires reasoning about the likely explanations to partially observable past and future (*abductive* reasoning (Peirce, 1960)) and reasoning about the alternative future based on counterfactual past (*counterfactual* reasoning). Such *nonmonotonic* reasoning requires inferring plausible but potentially defeasible conclusions from incomplete or hypothetical observations (Reiter, 1988). While humans are remarkably good at this type of causal reasoning, developing AI systems capable of nonmonotonic reasoning for

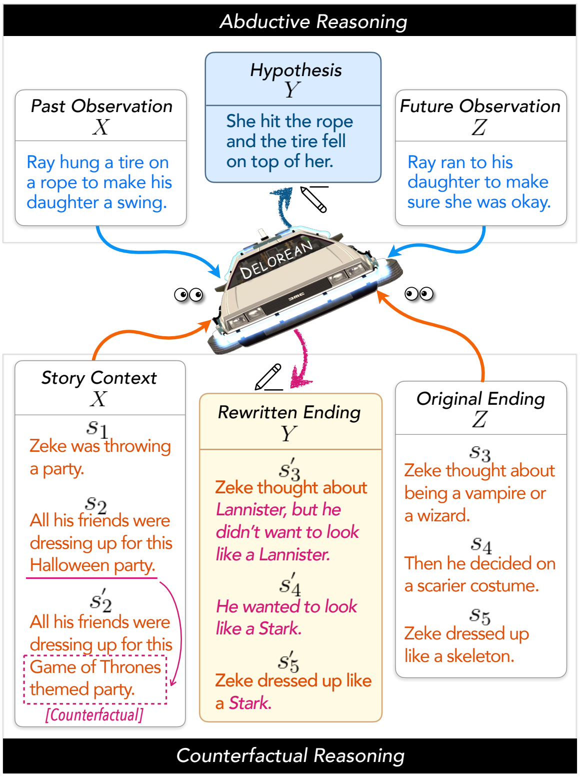

Figure 1: DELOREAN, our proposed method, with generated reasoning results. **Top**: the goal in abductive reasoning is to generate a hypothesis (Y) of what happened between the observed past (X) and future (Z) contexts. **Bottom**: In counterfactual reasoning, given a story context altered by a counterfactual condition, X, and the original ending Z, the goal is to generate a new ending Y which is coherent with X while remaining similar to Z. The story from TIMETRAVEL (Qin et al., 2019a) consists of five sentences. Our approach alternates forward (left-to-right) and backward (right-to-left) passes that iteratively refine the generated texts w.r.t context from each side.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 794–805,
November 16–20, 2020.

a wide range of situations describable in natural language has been a major open research question.

More concretely, with abductive reasoning, the goal is to find the most plausible explanation for incomplete observations (Peirce, 1960). In the top part of Figure 1, given the first observation that Ray is "making his daughter a swing" and the later observation that he "ran to [her] to make sure she was okay," we can hypothesize that she somehow got hurt by the swing.

In contrast, counterfactual reasoning concerns the causal changes to future events given a change in the past condition (i.e., "counterfactual condition"; Goodman, 1947). For example, the bottom part of Figure 1 shows the *original* five sentence story (S_1, ..., S_5) and an alternative *counterfactual condition* given in S'_2—that instead of being a generic "Halloween party", the new counterfactual condition is that it is going to be a "Game of Thrones themed party"! Given these, the problem we want to solve is to update the future events (S'_3, ..., S'_5), so that instead of "Zeke dressed up as skeleton", we have "Zeke dressed up like a Stark".[2]

Recently, two tasks and corresponding benchmarks have been introduced to tackle language-based nonmonotonic reasoning: the $\mathcal{ART}$ dataset for abductive NLG (Bhagavatula et al., 2019), and the TIMETRAVEL dataset for counterfactual story rewriting (Qin et al., 2019a). Both tasks are framed as conditional generation, with multiple contexts to condition on. The currently dominant paradigm for conditional text generation tasks is fine-tuning pre-trained language models (LMs), such as GPT2 (Radford et al., 2019a), on large-scale training data for supervision. However, despite the large number of training examples, supervised approaches still perform considerably worse than humans and are subject to developing superficial strategies such as repeating the observations as is or memorizing prevalent surface patters specific in the dataset (Qin et al., 2019a). Furthermore, having to require large-scale training data for each domain and task would be utterly inefficient for broad-coverage nonmonotonic reasoning in language.

In this paper, we investigate an alternative path toward language-based nonmonotonic reasoning using pre-trained language models as is. Intuitively, both the abductive and counterfactual reasoning requires learning coherent patterns in narrative, which should be already available in large-scale pretrained language models. However, the key challenge is that most generative language models are trained to condition only on the left context, or to perform narrowly scoped text-infilling.

This paper presents DELOREAN: DEcoding for nonmonotonic LOgical REAsoNing, an unsupervised decoding algorithm that only assumes off-the-shelf left-to-right language models with no supervision. The key intuition of our algorithm is incorporating the future through back-propagation, during which, we only update the internal representation of the output while fixing the model parameters. More specifically, DELOREAN alternates between the forward and backward passes, where the forward pass performs left-to-right inference given the left context (roughly maximizing $P(Y|X)$ in Figure 1), while the backward pass instills the right constraint through right-to-left backpropagation with a task-specific loss (roughly maximizing $P(Z|XY)$). The forward and backward outputs are mixed into a single vector, from which tokens are sampled to generate the desired output. To choose the best output across iterations, we employ an unsupervised ranking step based on BERT's next sentence prediction task to measure coherence (Devlin et al., 2018).

On both tasks, DELOREAN outperforms all other unsupervised methods in terms of both automatic metrics and human evaluation, demonstrating that nonmonotonic reasoning through conditional decoding is a promising research direction. Moreover, outputs produced by our model are judged as more coherent than those from the supervised models. In sum, our study shows that backpropagation-based decoding may enable additional future applications of unsupervised generation and reasoning.

2 Background

Most NLP benchmarks have focused on reasoning about information that is *entailed* from the premise. For instance, natural language inference (NLI; Bowman et al., 2015) focuses primarily on whether a hypothesis is entailed from a given premise, which means the information stated in the hypothesis is a subset of the information provided in the premise. However, it has been noted that human reasoning is often the other way, where hypotheses often contain new information that was not available in the premise, but plausibly true (but

---

[2] "Lannister" in S'_3 and "Stark" in S'_4 and S'_5 refer to character names in the TV show, "Game of the Thrones." All the output text shown in Figure 1 is the actual system output from DELOREAN.

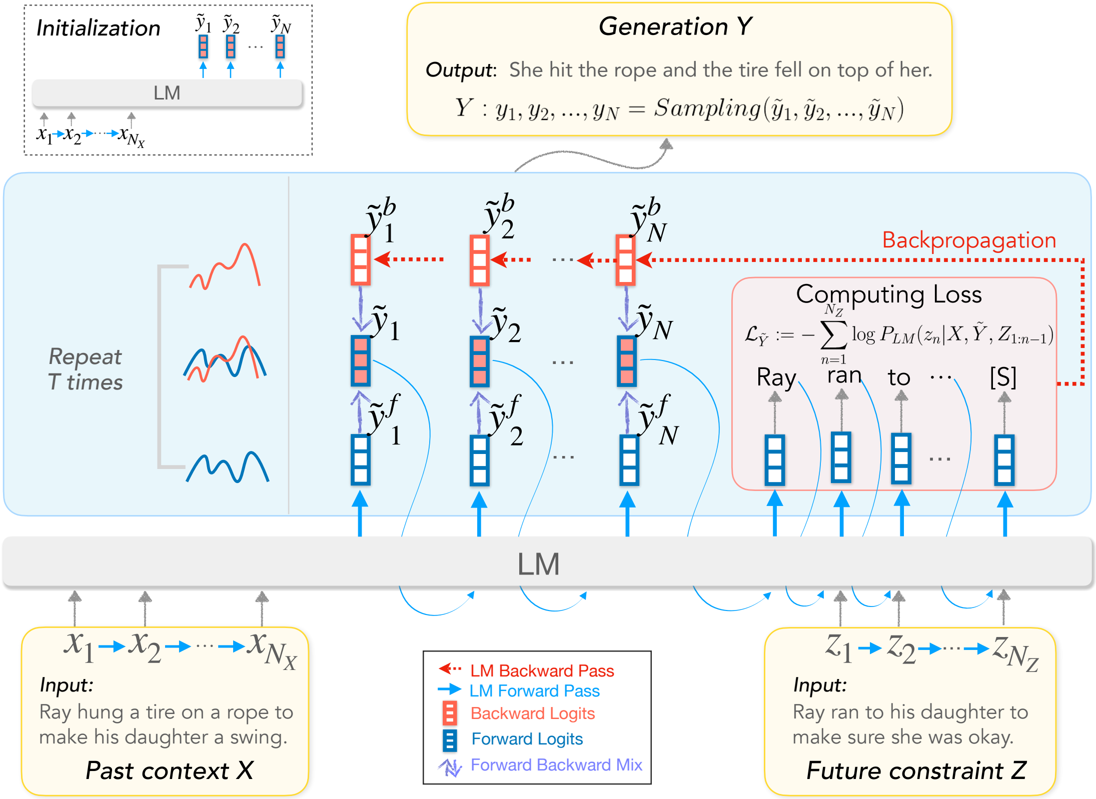

Figure 2: Illustration of the DELOREAN decoding procedure, using abductive reasoning as an example. At initialization (upper-left box), the language model (LM) initializes the logits ▤ $\tilde{Y} = \{\tilde{y}_1, \ldots, \tilde{y}_N\}$ of the hypothesis by reading the past context X and generating a continuation with regular decoding. At each forward-backward iteration, we compute the task-specific **loss** $\mathcal{L}_{\tilde{Y}}$ of the logits ▤ based on the future constraint Z (red box). The **backward pass** then performs back-propagation and produces the backward logits ▤ $\tilde{Y}^b = \{\tilde{y}^b_1, \ldots, \tilde{y}^b_N\}$. In the subsequent **forward pass**, for each step n, we compute the forward logits ▤ $\tilde{y}^f_n$ conditioning on the preceding logits ▤ $\tilde{y}_{n-1}$, and then mix it with the respective backward logits ▤ to produce the new logits ▤ $\tilde{y}_n$ at step n.

possibly defeasible with new additional context) (Johnson-Laird, 2006; Mercier and Sperber, 2017). This type of reasoning corresponds to nonmonotonic reasoning (Kraus et al., 1990), as it contradicts the monotonicity property according to which valid arguments cannot be made invalid by adding premises. We study two tasks of that nature: abductive reasoning (§2.1) and counterfactual reasoning (§2.2).

2.1 Abductive Reasoning

Abductive reasoning aims at finding the most likely explanation to partial observations (Peirce, 1960). It has a central role in the human ability to "read between the lines," and is crucial for language acquisition (Andersen, 1973), understanding sentences in discourse (Hobbs et al., 1993), and many more. Despite the importance, however, relatively little focus has been given to it in NLP research.

Recently, Bhagavatula et al. (2019) propose the abductive reasoning task. Given two observations, the goal is to determine the most likely explanation of what happened in-between. The dataset introduced for the task, $\mathcal{ART}$, consists of 20k observations derived from the first and last sentence of stories in the ROCStories dataset (Mostafazadeh et al., 2016a). We focus on the abductive NLG setup introduced in the paper, which is framed as a conditional generation task where a plausible explanation to the observations must be generated using language. The authors reported the performance of several pre-trained LM-based baselines and showed promises and limitations of such approaches.

2.2 Counterfactual Reasoning

Counterfactual reasoning aims at inferring alternative past events that could have happened given a certain change in conditions (Goodman, 1947; Starr, 2019). While counterfactual reasoning plays an important role in AI systems (Isard, 1974; Ginsberg, 1986), it requires causal reasoning abilities, which are arguably absent from current association-based AI (Pearl and Mackenzie, 2018). While there has been work on counterfactual reasoning in NLP, including recognizing counterfactuals in text (Son et al., 2017), and improving the performance of NLP tasks using *counterfactual learning* (Lawrence et al., 2017; Lawrence and Riezler, 2018), it remains a major research challenge.

Recently, Qin et al. (2019a) introduce the task of counterfactual story generation. Given a 5-sentence original story, and an alternative context in which the second sentence of the story was altered by a counterfactual, the task is to generate a new 3-sentence story ending that addresses the alternative beginning while minimally editing the original ending. The associated TIMETRAVEL dataset is based on fictional narratives from ROCStories, for which counterfactual contexts and alternative endings are crowdsourced, yielding 29,849 problem instances. Qin et al. (2019a) report several baseline performances, and find that models based on pre-trained LMs produce output that recognize the counterfactual, but generated endings which deviated considerably from the original storyline. In contrast, in the supervised setup, models optimize the easier of the two goals and generate endings that are overly similar to the original endings.

3 The DELOREAN Approach

Humans make inferences based on available information and refine them when new information arrives. Since currently available pre-trained LMs generate text by sequentially predicting the next token from left to right, they are incapable of conditioning on future constraints. Therefore, we propose DELOREAN: an unsupervised backprop-based decoding algorithm, which is summarized in Algorithm 1, illustrated in Figure 2, and detailed below. DELOREAN intermittently refines the predictions to cohere with either the context or the constraints (Section 3.1). The candidate generations are then ranked by coherence (Section 3.2).

3.1 Decoding Strategy

Given context text X, the goal is to generate continuation text $Y = (y_1, \ldots, y_N)$, such that Y satisfies certain constraints according to the reasoning tasks, usually defined based on another context Z (see Figure 1; we discuss the task-specific constraints in the respective task sections).

Algorithm 1: DELOREAN Decoding

```
Input: Pre-trained language model (LM)
       Context $X$
       Future constraint $Z$
Initialize logits $\tilde{Y}^{(0)}$
Initialize $Y_s$, list of candidate generations
for $t \leftarrow 1$ to $T$ do
    // Backward pass
    for $n \leftarrow N$ to $1$ do
        Compute backward logits $\tilde{\boldsymbol{y}}^{\mathrm{b}}_n$, Eq.(1)
    end for
    // Forward pass
    for $n \leftarrow 1$ to $N$ do
        Compute forward logits $\tilde{\boldsymbol{y}}^{\mathrm{f}}_n$, Eq.(2)
        Mix forward and backward logits, Eq.(3)
    end for
    Sample candidate $Y$ from logits $\tilde{Y}$ and add to $Y_s$
end for
Rank $Y_s$ by coherence
Output: The most coherent generated text $Y$ from $Y_s$
```

The proposed approach interleaves two procedures, namely, *forward* and *backward*, that produce and iteratively refine the generation, for a predefined number of iterations T. In particular, the *forward* pass ensures the generated text is a fluent continuation of the context X, while the *backward* pass informs the model about the constraint and steers the generation to satisfy it.

As detailed below, the backward pass uses gradient descent to update the generation Y. However, Y is a discrete text that is not differentiable. Instead, throughout the algorithm, we maintain a soft representation of the sequence $\tilde{Y} = (\tilde{\boldsymbol{y}}_1, \ldots, \tilde{\boldsymbol{y}}_N)$, where $\tilde{\boldsymbol{y}}_n \in \mathbb{R}^V$ represents the logits of the n-th token and V is the vocabulary size. After the logits are refined over multiple iterations of the forward and backward passes, we generate discrete text at each step by sampling from $y_n \sim \text{softmax}(\tilde{\boldsymbol{y}}_n / \tau)$, where $\tau > 0$ is the temperature.

We start by initializing the logits before the first iteration, $\tilde{Y}^{(0)} = (\tilde{y}^{(0)}_1 \ldots \tilde{y}^{(0)}_N)$, by feeding the context X into the LM and greedily decoding N continuation tokens.

Backward The backward pass uses gradient backpropagation to update the generation with respect to the constraint. Specifically, we express the task-specific constraint as a loss function $\mathcal{L}(X, \tilde{Y}^{(t-1)}, Z)$ that evaluates how well the generation Y (approximated with the soft representation $\tilde{Y}$) obeys the constraint (see the subsequent sections for concrete instantiations of the loss). The goal of this pass is thus to minimize the loss w.r.t the generation. Specifically, at iteration t, for each step n in the generation, we update its logits with:

$$\tilde{\boldsymbol{y}}_n^{(t),\mathrm{b}} = \tilde{\boldsymbol{y}}_n^{(t-1)} - \lambda \cdot \nabla_{\tilde{\boldsymbol{y}}_n} \mathcal{L}(X, \tilde{Y}^{(t-1)}, Z), \quad (1)$$

where $\nabla_{\tilde{\boldsymbol{y}}_n} \mathcal{L}(X, \tilde{Y}^{(t-1)}, Z)$ is the gradient of the constraint-informed loss $\mathcal{L}$ w.r.t the n-th logits, and $\lambda \in \mathbb{R}$ is the step size. In practice, we may repeat the gradient updates multiple times in a single pass.

Forward The forward pass ensures that Y is fluent and coherent with the preceding context X. At iteration t, for a particular step n, we compute the forward logits with the LM:

$$\tilde{\boldsymbol{y}}_n^{(t),\mathrm{f}} = \mathrm{LM}(X, \tilde{Y}_{1:n-1}^{(t)}). \quad (2)$$

We then *mix* the nth-step forward and backward logits to get the final logits of iteration t:

$$\tilde{\boldsymbol{y}}_n^{(t)} = \gamma \cdot \tilde{\boldsymbol{y}}_n^{(t),\mathrm{f}} + (1 - \gamma) \cdot \tilde{\boldsymbol{y}}_n^{(t),\mathrm{b}}, \quad (3)$$

where $0 < \gamma < 1$ is the mixing weight. The resulting logits $\tilde{\boldsymbol{y}}_n^{(t)}$ are then fed to the LM to compute the forward logits at the $(n+1)$th step (Eq.2). This way, information from the backward pass is integrated into the left-to-right generation process to produce text that is informed by the constraint.

We pre-define the number of tokens N required by the backward pass, but we allow the forward pass to generate more than N tokens if those are needed to obtain complete sentences. In that case, we set the logits of the extra tokens to the forward logits, without mixing: $\tilde{\boldsymbol{y}}_n^{(t)} = \tilde{\boldsymbol{y}}_n^{(t),\mathrm{f}}$ for $n > N$. We then prune any trailing tokens in the sampled text to get complete sentences.

3.2 Ranking

The output of the decoding step is a list of candidate generations for each iteration: $Y_s = \{Y^{(t)} | t = 1, ..., T\}$. We further use an unsupervised approach to rank and pick the best sample as the final output. Specifically, we take advantage of the BERT model, which was pre-trained with a next-sentence prediction (NSP) objective. Given two sentences A and B, we use NSP to compute the likelihood of B following A as a proxy for coherence:

$$c(A, B) = \mathrm{BERT\_NSP}(A, B), \quad (4)$$

where $c(\cdot, \cdot)$ denotes the coherence score. This score is used to evaluate the quality of a given candidate continuation Y by measuring (1) its compatibility with the subsequent text of the context X, (2) the internal consistency of Y if it consists of multiple sentences, and (3) the compatibility of Y with its right-side text when it is applicable.

Human	53.56	30.40	53.30

Table 1: Automatic evaluation results on the abductive task, using the test set of $\mathcal{ART}$.

4 Task 1: Abductive Reasoning

Each instance in the $\mathcal{ART}$ dataset consists of two observations O_1, O_2 and a hypothesis H that explains the two observations. These inputs naturally map to X, Z and Y in our framework. Formally, the abductive generation task aims to maximize $P(Y|X, Z)$ – i.e. models must consider both left and right contexts (X and Z) jointly.

4.1 Task Setup

Constraints We maximize Z given $X\tilde{Y}$ by defining the loss function as the cross-entropy loss of generating Z given $X\tilde{Y}$ with the LM:[3]

$$\mathcal{L}(X, \tilde{Y}, Z) := -\sum_{n=1}^{N_Z} \log P_{\mathrm{LM}}(z_n | X, \tilde{Y}, Z_{1:n-1}), \quad (5)$$

where $P_{\mathrm{LM}}(a_j | a_{1:j-1})$ is the likelihood of generating token a_j given the preceding text $a_{1:j-1}$.

Ranking We rank candidates by the overall coherence after inserting Y in between X and Z:

$$\mathrm{ranking\_score}(Y) = c(XY, Z) + c(X, YZ). \quad (6)$$

Hyperparameters We use GPT2-345M (Radford et al., 2019b) as the pre-trained LM for all models. We use the $\mathcal{ART}$ development set to select hyperparameters. We use greedy decoding for our method and top k decoding (Fan et al., 2018) ($k = 40, \tau = 0.7$) for our baselines. Other hyperparameters are outlined in Appendix A.1.

4.2 Experimental Setup

Baselines We compare our method against baselines from Bhagavatula et al. (2019). The unsupervised baselines use a pre-trained GPT-2 model

to generate Y given a prompt text—either the observation X alone (Zero-Shot$_X$) or $Z\langle e\rangle X$ (Zero-Shot$_{ZX}$), where $\langle e\rangle$ denotes a special end-of-text token. The supervised method (Sup) follows the same input format as Zero-Shot$_{ZX}$, but fine-tunes GPT-2 on the $\mathcal{ART}$ training set. Finally, our knowledge-informed baseline (+*COMET-Emb*) further augments the representation of Sup with knowledge from COMET (Bosselut et al., 2019).

To separately study the contribution of our decoding strategy and ranking component, we also report the performance of ranking the baseline outputs. Specifically, we let each baseline generate 20 candidates and rank them by coherence (Eq. 6).[4]

Table 3: Human pairwise comparison results on the test set of $\mathcal{ART}$, between DELOREAN and each of the baselines, by jointly considering all 3 criteria from Table 2. "Neutral" means "equally good/bad".

4.3 Results

Automatic Evaluation We report the same metrics as Bhagavatula et al. (2019): BLEU-4 (Papineni et al., 2002), ROUGE-L (Lin, 2004) and BERTSCORE (Zhang et al., 2019) (with the *bert-base-uncased* model). The results in Table 1 show that DELOREAN performs best among the unsupervised systems across all metrics. We also note that our ranking step improves both the performance of our model and that of the zero-shot baselines.

Human Evaluation We conduct two sets of human evaluations on 100 test examples using crowdworkers from Amazon Mechanical Turk. In the scoring setting, presented in Table 2, workers were presented a pair of observations (X and Z) and a generated hypothesis Y, and asked to rate the coherence of the hypothesis with respect to the observation X (X-Y), the observation Z (Y-Z), and both (X-Y-Z), on a 4-point Likert scale. In the pairwise comparison setting, presented in Table 3, workers were presented the outputs from a pair of systems (DELOREAN and baseline) and asked to choose the better output in terms of the same coherence criteria. Each example was labeled by 3 workers.[5]

In both evaluation setups, our method substantially outperform the unsupervised baselines, achieving a relative improvement of $36\% - 215\%$ with respect to Y-Z coherence. Our method also outperform the supervised methods with respect to X-Y coherence (Table 2), and achieve competitive performance in the pairwise comparison (Table 3).

---

[4] We tried ablating the ranking component from our method in preliminary experiments, and found that ranking is essential to obtaining good performance. By adding ranking to our baselines, we assess the contribution of our decoding strategy.

[5] The average inter-rater agreement measured by Fleiss' $\kappa = 0.44$ ("moderate agreement") (Fleiss, 1971).

Table 5: Human pairwise comparison results on the counterfactual task, between our best model and each baseline with respect to coherence and min-edits.

Again, the ranking component contributes to increasing performance for the zero-shot baselines. Finally, the large performance gap between the methods and human-written explanations stresses the difficulty of this reasoning task and warrants future research.

Qualitative Analysis Figure 3 presents two example outputs produced by Delorean. We can see our approach generates reasonable hypotheses by taking into account both the past and future contexts. For instance, in the first example, the future observation (O2) "car was totaled" indicates that Ray had a car accident, which is correctly captured in the generated hypothesis "car is hit by a car".

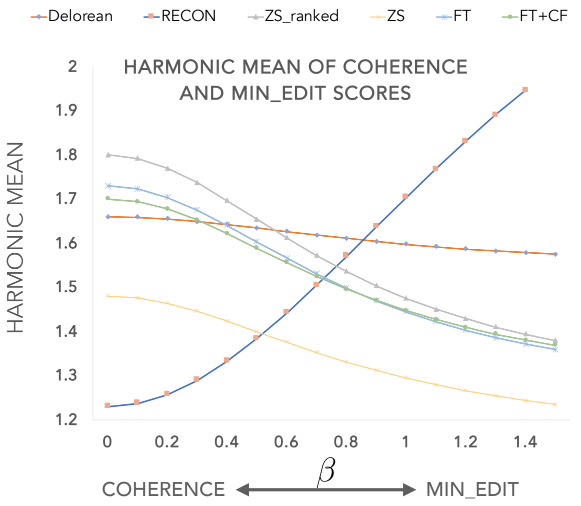

Figure 4: Human calibration results for counterfactual generation in terms of weighted harmonic mean of coherence and min-edit, $H_\beta = \frac{(1+\beta^2)\cdot\text{coherence}\cdot\text{min\_edit}}{\beta^2\cdot\text{coherence}+\text{min\_edit}}$, as a function of the scaling factor β. Low β values assign more weight to coherence, and high β values emphasize more on min-edit.

5 Task 2: Counterfactual Reasoning

Given an original story ending Z of story context X^{ori}, and a counterfactual condition X that changes X^{ori} to invalidate Z (see Fig. 1), the task is to generate a new story ending Y that minimally edits the original ending Z to regain coherence with the counterfactual condition X (Qin et al., 2019a).

5.1 Task Setup

Constraints The constraint we enforce is that Y is close to Z (i.e., minimal edits). We impose this constraint by minimizing their KL divergence:

$$\mathcal{L}(X,\tilde{Y},Z) := \mathrm{KL}\left(Z\|\mathrm{softmax}(\tilde{Y}/\tau)\right), \quad (7)$$

where, with a slight abuse of notation, Z is the one-hot distribution of the tokens in the original ending. That is, we encourage the generated logits to recover the original ending.

Ranking We rank the candidates based on both their coherence with the context, as well as the internal coherence between the multiple sentences of each candidate (rewritten ending, consists of 3 sentences). More concretely, given a candidate Y, we compute the aggregated coherence score:

$$\text{ranking\_score}(Y) = c(X,Y) + \textstyle\sum_{s=1}^{S-1} c(Y[s], Y[s+1]), \quad (8)$$

where each candidate has S sentences (here, $S = 3$) and $Y[s]$ denotes the sth sentence.

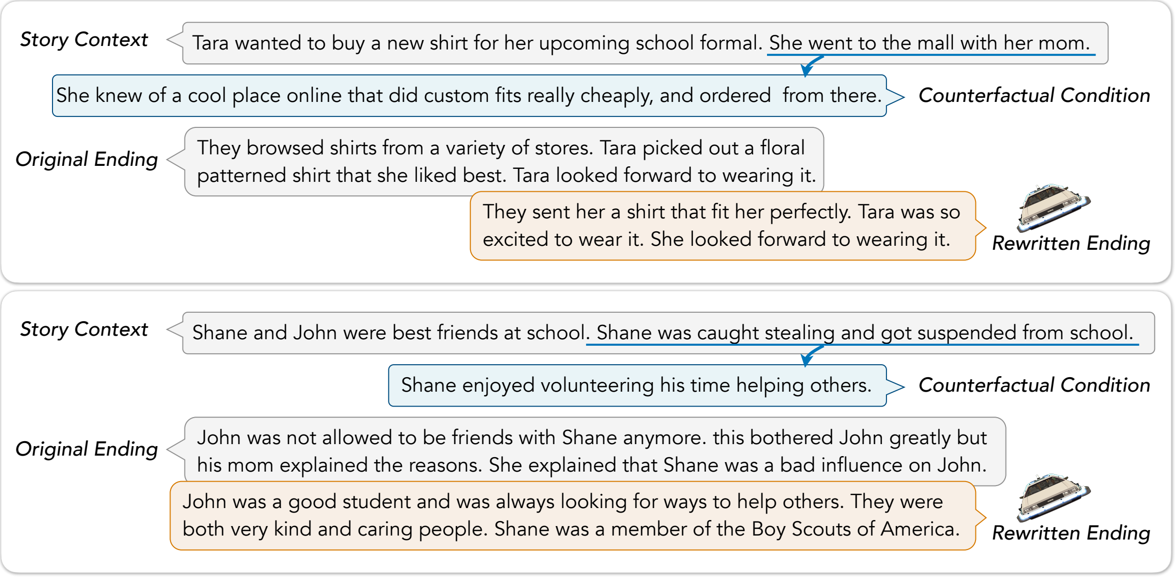

Figure 5: Examples of generated story endings on three counterfactual reasoning cases. Given a story context, a counterfactual condition, and a original ending, DELOREAN generates a rewritten ending which is coherent with the counterfactual condition and is similar to the original ending.

Hyperparameters We largely follow the same setting as in the abductive reasoning task, but tune hyperparameters on the TIMETRAVEL development set. Deviations from these settings are outlined in Appendix A.2.

5.2 Experimental Setup

Baselines We compare our method with baselines from Qin et al. (2019a). The zero-shot baseline uses the pre-trained GPT-2 model to generate Y as a continuation to the counterfactual condition X. It is the most apt comparison to our method which also doesn't require additional supervision. We also experiment with two baselines that fine-tune GPT-2 on the original story $X^{ori}Z$ to fit the model to the story domain, either with an LM objective (`FT`) or a tailored conditional objective that encourages minimal edits of Z (`Recon+CF`).[6] Finally, we report the performance of a supervised baseline (Sup), in which GPT-2 is fine-tuned to produce the gold Y from $X^{ori}Z$ and X.

5.3 Results

Automatic Evaluation Following Qin et al. (2019a), we report BERTSCORE (Zhang et al., 2019), which was shown to best correlate with human judges' notion of counterfactual coherence, and BLEU-4 and ROUGE-L, which better measure minimum-edits. We find that the discriminative baselines achieve the highest degree of plot fidelity. Meanwhile, DELOREAN achieves the highest BERTSCORE for counterfactual coherence.

Human Evaluation We repeat the human evaluation setup from Section 4.3. Presented with the original story, the counterfactual condition X, and the generated ending Y, workers were asked to judge (1) the *coherence* of Y with respect to the X; and (2) to what extent the generated ending *minimally-edits* the original ending.[7] In order to judge both criteria, we report the weighted harmonic mean H_β of these scores across a range of weights β (Figure 4).

Our results show that DELOREAN is the only model that maintains a consistent balance between *coherence* (1.66) and *minimal edits* (1.54). While the ranking-augmented zero-shot model produces the most coherent endings (*coherence* = 1.8), it deviates from the original ending. As β is increased (i.e., increasing importance of *minimal edits*), its weighted performance drops considerably, indicating it cannot generate new endings that follow the original plot of the story (*min-edit* = 1.25). Conversely, `Recon+CF` generates stories that are faithful to the original endings, but are far less coherent with the counterfactual condition (*coherence* = 1.23). Through human annotation, we found that `Recon+CF` copies the original ending word-for-word in a 84% of cases.

The pairwise comparison results in Table 5

---

[6] See Qin et al. (2019a) for more details.

[7] Fair inter-rater agreement with Fleiss' $\kappa = 0.34$

parallel these observations. DELOREAN significantly outperforms the discriminative approaches (`Recon+CF` and `Sup+Disc`) in coherence, while falling short of the Zero-shot re-ranked baselines. In minimal edits, this pattern is flipped with our approach outperforming Zero-shot baselines considerably and losing to the discriminative baselines.

Qualitative Analysis Figure 5 provides two example results for counterfactual story rewriting by DELOREAN. The approach successfully captures the causal relations between events and properly rewrites the endings with minimal edits. For instance, in the first example, given the counterfactual condition that "Tara ordered a shirt online" (as opposed to the original "went to mall"), the rewritten ending is about "sent shirt" to Tara (as opposed to the original "browsed from stores"). The last sentence of the original ending "She looked forward to wearing it" is correctly preserved as it is coherent with the counterfactual condition.

6 Related Work

Unsupervised text generation. Unsupervised approaches are often applied to problems that copy information from a source text into decoded text. Unsupervised paraphrasing requires repeating this information (Miao et al., 2019; Bao et al., 2019), as does translation, but with a bilingual transformation (Artetxe et al., 2017; Lample et al., 2018). In summarization there is an additional task to select a subset of the original text (Baziotis et al., 2019; Schumann et al., 2020; West et al., 2019). In cases where information is mostly copied from the original, auto-encoding objectives can ensure the correct information is captured (Bao et al., 2019; Baziotis et al., 2019; Artetxe et al., 2017). This work tackles problems where generation is more open-ended. Rather than reproducing information from the prompt, generations should agree with and expand on it, making autoencoding less applicable.

Controllable language generation. Earlier approaches for controllable generation involved preserving the content of text while changing it along discrete dimensions, such as theme, sentiment, or style (Koncel-Kedziorski et al., 2016; Hu et al., 2017; Ficler and Goldberg, 2017; Shen et al., 2017; Lample et al., 2019). Recent works such as Grover (Zellers et al., 2019) and CTRL model (Keskar et al., 2019) used these ideas to augment transformer language models that can condition on structured metadata such as source, domain, etc. The Plug & Play model (PPLM; Dathathri et al., 2019) controls topic and sentiment in an approach similar to ours that involves forward and backward passes to update token distributions. However, PPLM relies on trained attribute discriminators for supervision, while our method is unsupervised. While these models are restricted to specific dimensions, often with pre-defined values, our model can adjust to any open-ended textual constraint. Perhaps the most similar work in that aspect is the "text infilling" models, which, however, are in a more narrow setting by filling only a relatively short text span (Devlin et al., 2018; Zhu et al., 2019; Donahue et al., 2020), and more restrictive due to the reliance on an extra right-to-left language model (Sun et al., 2017) or a pre-specified generation length (Zeldes et al., 2020, which is not publicly available).

Reasoning about narratives. A prominent resource from recent years is the RocStories corpus (Mostafazadeh et al., 2016b), consisting of 98K crowdsourced 5-sentence everyday life stories. It was used for the story cloze task whose goal was to predict the story ending from its first 4 sentences, but gained popularity and became the base of additional benchmarks (Rashkin et al., 2018). Additional related work includes "script knowledge", i.e. learning about prototypical series of events (Schank and Abelson, 1977; Chambers and Jurafsky, 2008; Pichotta and Mooney, 2014), temporal commonsense (Granroth-Wilding and Clark, 2016; Li et al., 2018), and modeling pre- and post- conditions of events (Roemmele et al., 2011; Sap et al., 2019; Bosselut et al., 2019). Qin et al. (2019b) studied conversation modeling that reads and connects the dots of events in related documents. Finally, a recent line of work explores counterfactual questions in reading comprehension (Huang et al., 2019; Tandon et al., 2019), but instantiates the problem of counterfactual reasoning as a multiple choice task.

7 Conclusion

We presented DELOREAN, an unsupervised LM-based approach to generate text conditioned on past context as well as future constraints, through forward and backward passes considering each condition. We demonstrated its effectiveness for abductive and counterfactual reasoning, on which it performed substantially better than unsupervised baselines. Our method is general and can be easily adapted for other generative reasoning tasks.

Abstract

We present WHERE ARE YOU? (WAY), a dataset of ~6k dialogs in which two humans – an Observer and a Locator – complete a cooperative localization task. The Observer is spawned at random in a 3D environment and can navigate from first-person views while answering questions from the Locator. The Locator must localize the Observer in a detailed top-down map by asking questions and giving instructions. Based on this dataset, we define three challenging tasks: Localization from Embodied Dialog or LED (localizing the Observer from dialog history), Embodied Visual Dialog (modeling the Observer), and Cooperative Localization (modeling both agents). In this paper, we focus on the LED task – providing a strong baseline model with detailed ablations characterizing both dataset biases and the importance of various modeling choices. Our best model achieves 32.7% success at identifying the Observer's location within 3m in unseen buildings, vs. 70.4% for human Locators.

1 Introduction

Imagine getting lost in a new building while trying to visit a friend who lives or works there. Unsure of exactly where you are, you call your friend and start describing your surroundings (*'I'm standing near a big blue couch in what looks like a lounge. There are a set of wooden double doors opposite the entrance.'*) and navigating in response to their questions (*'If you go through those doors, are you in a hallway with a workout room to the right?'*). After a few rounds of dialog, your friend who is familiar with the building will hopefully know your location. Success at this cooperative task requires goal-driven questioning based on your friend's understanding of the environment, unambiguous answers communicating observations via language, and active perception and navigation to investigate the environment and seek out discriminative observations.

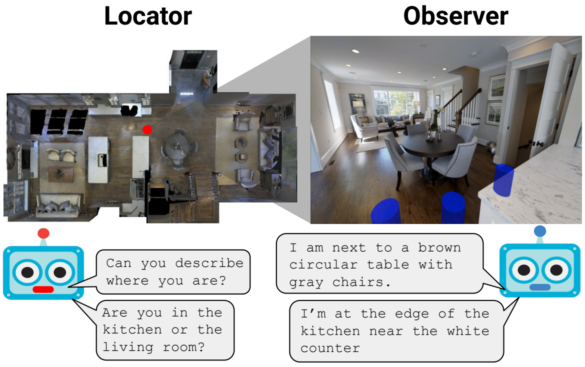

Figure 1: LED Task: The Locator has a top-down map of the building and is trying to localize the Observer by asking questions and giving instructions. The Observer has a first person view and may navigate while responding to the Locator. The turn-taking dialog ends when the Locator predicts the Observer's position.

In this work we present WHERE ARE YOU? (WAY), a new dataset based on this scenario. As shown in Fig. 1, during data collection we pair two annotators: an Observer who is spawned at random in a novel environment, and a Locator who must precisely localize the Observer in a provided top-down map. The map can be seen as a proxy for familiarity with the environment – it is highly detailed, often including multiple floors, but does not show the Observer's current or initial location. In contrast to the "remote" Locator, the Observer navigates within the environment from a first-person view but without access to the map. To resolve this information asymmetry and complete the task, the Observer and the Locator communicate in a live two-person chat. The task concludes when the Locator makes a prediction about the current location of the Observer. For the environments we use the Matterport3D dataset (Chang et al., 2017) of

November 16–20, 2020.

90 reconstructed indoor environments. In total, we collect ∼6K English dialogs of humans completing this task from over 2K unique starting locations.

The combination of localization, navigation, and dialog in WAY provides for a variety of modeling possibilities. We identify three compelling tasks encapsulating significant research challenges:

– **Localization from Embodied Dialog.** LED, which is the main focus of this paper, is the state estimation problem of localizing the Observer given a map and a partial or complete dialog between the Locator and the Observer. Although localization from dialog has not been widely studied, we note that indoor localization plays a critical role during calls to emergency services (Falcon and Schulzrinne, 2018). As 3D models and detailed maps of indoor spaces become increasingly available through indoor scanners (Chang et al., 2017), LED models could have the potential to help emergency responders localize emergency callers more quickly by identifying locations in a building that match the caller's description.

– **Embodied Visual Dialog.** EVD is the navigation and language generation task of fulfilling the Observer role. This involves using actions and language to respond to questions such as *'If you walk out of the bedroom is there a kitchen on your left?'* In future work we hope to encourage the transfer of existing image-based conversational agents (Das et al., 2017a) to more complex 3D environments additionally requiring navigation and active vision, in a step closer to physical robotics. The WAY dataset provides a testbed for this.

– **Cooperative Localization.** In the CL task, both the Observer and the Locator are modeled agents. Recent position papers (Baldridge et al., 2018; McClelland et al., 2019; Bisk et al., 2020) have called for a closer connection between language models and the physical world. However, most reinforcement learning for dialog systems is still text-based (Li et al., 2016) or restricted to static images (Das et al., 2017b; De Vries et al., 2017). Here, we provide a dataset to warm-start and evaluate goal-driven dialog in a realistic embodied setting.

Our main modeling contribution is a strong baseline model for the LED task based on LingUnet (Misra et al., 2018). In previously unseen test environments, our model successfully predicts the Locator's location within 3 meters 32.7% of the time, vs. 70.4% for the human Locators using the same map input, with random chance accuracy at 6.6%. We include detailed studies highlighting the importance of data augmentation and residual connections. Additionally, we characterize the biases of the dataset via unimodal (dialog-only, map-only) baselines and experiments with shuffled and ablated dialog inputs, finding limited potential for models to exploit unimodal priors.

Contributions: To summarize:

1. We present WAY, a dataset of ∼6k dialogs in which two humans with asymmetric information complete a cooperative localization task in reconstructed 3D buildings.
2. We define three challenging tasks: Localization from Embodied Dialog (LED), Embodied Visual Dialog, and Cooperative Localization.
3. Focusing on LED, we present a strong baseline model with detailed ablations characterizing both modeling choices and dataset biases.

2 Related Work

Image-based Dialog Several datasets grounding goal-oriented dialog in natural images have been proposed. The most similar settings to ours are Cooperative Visual Dialog (Das et al., 2017a,b), in which a question agent (Q-bot) attempts to guess which image from a provided set the answer agent (A-bot) is looking at, and GuessWhat?! (De Vries et al., 2017), in which the state estimation problem is to locate an unknown object in the image. Our dataset extends these settings to a situated 3D environment allowing for active perception and navigation on behalf of the A-bot (Observer), and offering a whole-building state space for the Q-bot (Locator) to reason about.

Embodied Language Tasks. A number of 'Embodied AI' tasks combining language, visual perception, and navigation in realistic 3D environments have recently gained prominence, including Interactive and Embodied Question Answering (Das et al., 2018; Gordon et al., 2018), Vision-and-Language Navigation or VLN (Anderson et al., 2018; Chen et al., 2019; Mehta et al., 2020; Qi et al., 2020), and challenges based on household tasks (Puig et al., 2018; Shridhar et al., 2020). While these tasks utilize only a single question or instruction input, several papers have extended the VLN task – in which an agent must follow natural language instructions to traverse a path in the environment – to dialog settings. Nguyen and Daumé III (2019) consider a scenario in which the agent can query an oracle for help while completing the navigation task. However, the closest work to ours is Cooperative Vision-and-Dialog Navigation (CVDN) (Thomason et al., 2019). CVDN is a dataset of dialogs in which a human assistant with access to visual observations from an oracle planner helps another human complete a navigation task. CVDN dialogs are set in the same Matterport3D buildings (Chang et al., 2017) and like ours they are goal-oriented and easily evaluated. The main difference is that we focus on localization rather than navigation. Qualitatively, this encourages more descriptive utterances from the first-person agent (rather than eliciting short questions). Our work is also related to Talk the Walk (de Vries et al., 2018) which presented a dataset for a similar task in an outdoor setting using a restricted, highly-abstracted map which encouraged language that is grounded in the semantics of building types rather than visual descriptions of the environment.

Table 1 compares the language in WAY against existing embodied perception datasets. Specifically, size, length and the density of different parts of speech (POS) are shown. Vocab size was determined by the total number of unique words. We used the (Loper and Bird, 2002) POS tagger to calculate the POS densities over the text in each dataset. We find that WAY has a higher density of adjectives, nouns, and prepositions than related datasets suggesting the dialog is more descriptive than the text in existing datasets.

Localization from Language. While localization from dialog has not been intensively studied, localization from language has been studied as a sub-component of instruction-following navigation agents (Blukis et al., 2018; Anderson et al., 2019; Blukis et al., 2019). The LingUnet model – a generic language-conditioned image-to-image network we use as the basis of our LED model in Section 4 – was first proposed in the context of predicting visual goals in images (Misra et al., 2018). This also illustrates the somewhat close connection between grounding language to a map and grounding referring expressions to an image (Kazemzadeh et al., 2014; Mao et al., 2016).

It is important to note that localization is often a precursor to navigation – one which has not been addressed in existing work in language-based navigation. In both VLN and CVDN, the instructions are conditioned on specific start locations – assuming the speaker knows the navigator's location prior to giving directions. The localization tasks of the WAY dataset fill this gap by introducing a dialog-based means to localize the navigator. This requires capabilities such as describing a scene, answering questions, and reasoning about how discriminative potential statements will be to the other agent.

3 WHERE ARE YOU? Dataset

We present the WHERE ARE YOU? (WAY) dataset consisting of 6,154 human embodied localization dialogs across 87 unique indoor environments.

Environments. We build WAY on Matterport3D (Chang et al., 2017), which contains 90 buildings captured in 10,800 panoramic images. Each building is also provided as a reconstructed 3D textured mesh. This dataset provides high-fidelity visual environments in diverse settings including offices, homes, and museums – offering numerous objects to reference in localization dialogs. We use the Matterport3D simulator (Anderson et al., 2018) to enable first-person navigation between panoramas.

Task. A WAY episode is defined by a starting location (i.e. a panorama p) in an environment e. The Observer is spawned at p_0 in e and the Locator is provided a top-down map of e (see Fig. 1). Starting with the Locator, the two engage in a turn-based dialog $(L_0, O_0, \dots L_{T-1}, O_{T-1})$ where each can pass one message per turn. The Observer may move around in the environment during their turn, resulting in a trajectory $(p_0, p_1, \dots, p_T)$ over the dialog. The Locator is not embodied and does not move but can look at the different floors of the house at multiple angles. The dialog continues until the Locator uses their turn to make a prediction $(\hat{p}_T)$ of the Observer's current location (p_T). The episode is successful if the prediction is within k meters of the true *final* position – i.e. $||p_T - \hat{p}_T||_2 < k$ m. This does not depend on the initial position, encouraging movement to easily-discriminable locations.

Map Representation. The Locator is shown top-down views of Matterport textured meshes as environment maps. In order to increase the visibility of walls in the map (which may be mentioned by the Observer), we render views using perspective rather than orthographic projections (see left in Fig. 1). We set the camera near and far clipping planes to render single floors such that multi-story buildings contain an image for each floor.

3.1 Collecting Human Localization Dialogs

To provide a human-performance baseline and gather training data for agents, we collect human

Table 1: Comparison of the language between the WAY dataset and related embodied perception datasets.

Method	Dataset Size	Vocab Size	Avg Text Length	Noun Density	Adj Density	Preposition Density	Dialog
CVDN	2050	2165	52	0.20	0.06	0.09	Yes
TtW	10K	7846	110	0.20	0.07	0.11	Yes
VLN	21K	3459	29	0.27	0.03	0.17	No
WAY	6154	5193	61	0.30	0.12	0.18	Yes

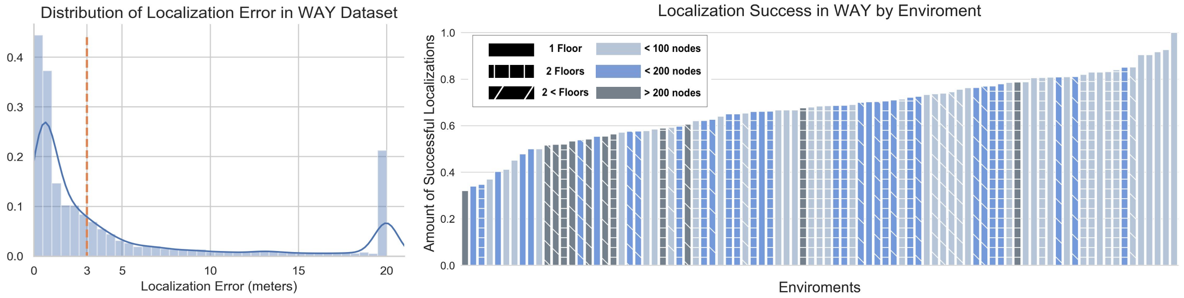

Figure 2: Left: Distribution of human localization error in WAY (20+ includes wrong floor predictions). Right: Human success rates (error <3m) by environment. Bar color indicates environment size (number of nodes) and pattern the number of floors.

localization dialogs in these environments.

Episodes. We generate 2020 episodes across 87 environments by rejection sampling to avoid spatial redundancy. For each environment, we iteratively sample start locations, rejecting ones that are within 5m of already-sampled positions. Three environments were excluded due to their size (too large or small) or poor reconstruction quality.

Data Collection. We collect dialogs on Amazon Mechanical Turk (AMT) – randomly pairing workers into Observer or Locator roles for each episode. The Observer interface includes a first-person view of the environment and workers can pan/tilt the camera in the current position or click to navigate to adjacent panoramas. The Locator interface shows the top-down map of the building, which can be zoomed and tilted to better display the walls. Views for each floor can be selected for multi-story environments. Both interfaces include a chat window where workers can send their message and end their dialog turn. The Locator interface also includes the option to make their prediction by clicking a spot on the top-down map – terminating the dialog. Note this option is only available after two rounds of dialog. Refer to the appendix for further details on the AMT interfaces.

Before starting, workers were given written instructions and a walk-through video on how to perform their role. We restricted access to US workers with at least a 98% success rate over 5,000 previous tasks. Further, we restrict workers from repeating tasks on the same building floor. In order to filter bad-actors, we monitored worker performance based on a running-average of localization error in meters and the number of times they disconnected from dialogs – removing workers who exceeded a 10m threshold and discarding their data.

Dataset Splits. We follow the standard splits for the Matterport3D dataset (Chang et al., 2017) – dividing along environments. We construct four splits: train, val-seen, val-unseen, and test comprising 3,967/299/561/1,165 dialogs from 58/55/11/18 environments respectively. Val-seen contains new start locations for environments seen in train. Both val-unseen and test contain new environments. This allows us to assess generalization to new dialogs and to new environments separately in validation. Following best practices, the final locations of the observer for the test set will not be released but we will provide an evaluation server where predicted localizations can be uploaded for scoring.

WAY includes dialogs in which the human Locator failed to accurately localize the Observer. In reviewing failed dialogs, we found human failures are often due to visual aliasing (e.g., across multiple floors), or are relatively close to the 3m threshold. We therefore expect that these dialogs still contain valid descriptions, especially when paired with the Observer's true location during training. In experiments when removing failed dialogs from the train set, accuracy did not significantly change.

3.2 Dataset Analysis

Data Collection and Human Performance. In total, 174 unique workers participated in our tasks. On average each episode took 4 minutes and the average localization error is 3.17 meters. Overall, 72.5% of episodes where considered successful localizations at an error threshold of 3 meters. Each starting location has 3 annotations by separate randomly-paired Observer-Locator teams. In 40.9% of start locations, all 3 teams succeeded, in 36.3% 2, 18.5% 1, and 4.3% 0 teams succeeded. Fig. 2 left shows a histogram of localization errors.

Why is it Difficult? Localization through dialog is a challenging task, even for humans. The teams success depends on the uniqueness of starting position, if and where the Observer chooses to navigate, and how discriminative the Locator's questions are. Additionally, people vary greatly in their ability to interpret maps, particularly when performing mental rotations and shifting perspective (Kozhevnikov et al., 2006), which are both skills required to solve this task. We also observe that individual environments play a significant role in human error – as illustrated in Fig. 2 right, larger buildings and buildings with multiple floors tend to have larger localization errors, as do buildings with multiple similar looking rooms (e.g., multiple bedrooms with similar decorations or office spaces with multiple conference rooms). The buildings with the highest and lowest error are shown in Fig. 3.

Characterizing WAY Dialogs. Fig. 4 shows two example dialogs from WAY. These demonstrate a common trend – the Observer provides descriptions of their surroundings and then the Locator asks clarifying questions to refine the position. More difficult episodes require multiple rounds to narrow down the correct location and the Locator may ask the Observer to move or look for landmarks. On average, dialogs contain 5 messages and 61 words.

The Observer writes longer messages on average (19 words) compared to the Locator (9 words). This asymmetry follows from their respective roles. The Observer has first-person access to high-fidelity visual inputs and must describe their surroundings, *'In a kitchen with a long semicircular black countertop along one wall. There is a black kind of rectangular table and greenish tiled floor.'*. Meanwhile, the Locator sees a top-down view and uses messages to probe for discriminative details, *'Is it a round or rectangle table between the chairs?'*, or to prompt movement towards easier to discriminate spaces, *'Can you go to another main space?'*.

As the Locator has no information at the start of the episode, their first message is often a short prompt for the Observer to describe their surroundings, further lowering the average word count. Conversely, the Observer's reply is longer on average at 24 words. Both agent's have similar word counts for further messages as they refine the location. See the appendix for details on common utterances for both roles in the first two rounds of dialog.

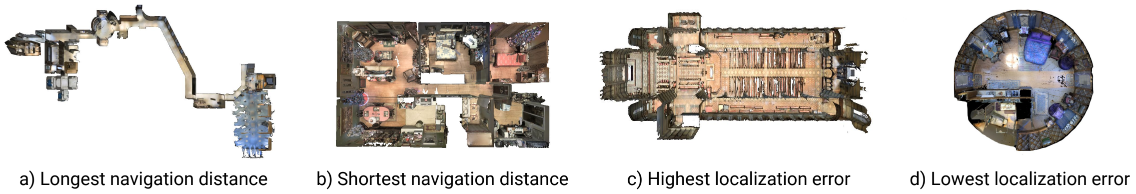
Role of Navigation. Often the localization task can be made easier by having the Observer move to reduce uncertainty (see bottom example of Fig. 4). This includes moving away from nondescript areas like hallways and moving to unambiguous locations. We observe at least one navigation step in 62.6% of episodes and an average of 2.12 steps. Episodes containing navigation have a significantly lower average localization error (2.70m) compared to those that did not (3.98m). We also observe the intuitive trend that larger environments elicit more navigation. The distributions for start and end locations for the most and least navigated environments in the appendix.

3.3 WHERE ARE YOU? Tasks

We now formalize the LED, EVD and CL tasks to provide a clear orientation for future work.

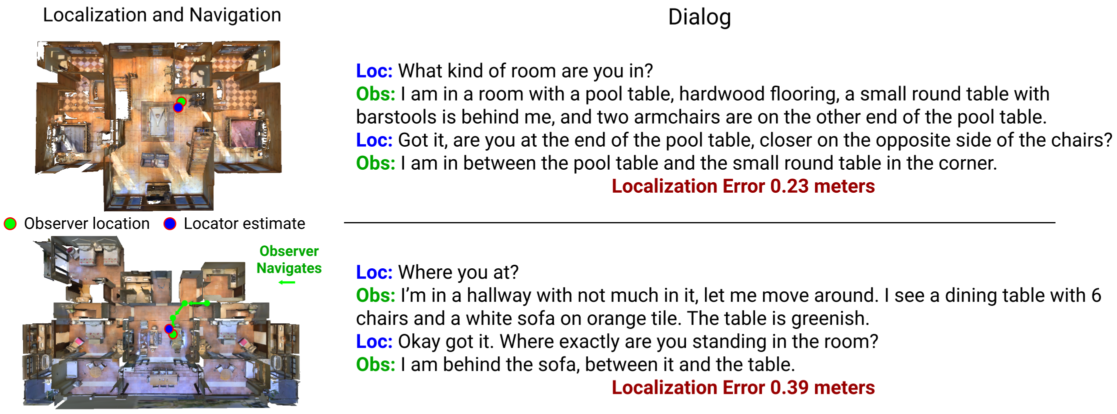
Localization from Embodied Dialog. The LED task is the following – given an episode comprised of a environment and human dialog – $(e, L_0, O_0, \dots L_{T-1}, O_{T-1})$ – predict the Observer's final location p_T. This is a grounded natural language understanding task with pragmatic evaluations – localization error and accuracy at a variable threshold which in this paper is set to 3 meters. This task does not require navigation or text generation; instead, it mirrors AI-augmented localization applications. An example would be a system that listens to emergency services calls and provides a real time estimate of the caller's indoor location to aid the operator.

Embodied Visual Dialog. This task is to replace the Observer by an AI agent. Given a embodied first-person view of a 3D environment (see Observer view in Fig. 1), and a partial history of dialog consisting of k Locator and $k-1$ Observer message pairs (L_0: *'describe your location.'*, O_0: *'I'm in a kitchen with black counters.'*, $L_1 \dots$): pre-



a) Longest navigation distance b) Shortest navigation distance c) Highest localization error d) Lowest localization error

Figure 3: Environments with the largest/smallest mean navigation distance (a, b) and mean localization error (c, d). Observers tend to navigate more in featureless areas, such as the long corridor in (a). Localization error is highest in buildings with many repeated indistinguishable features, such as the cathedral with rows of pews in (c).



Loc: What kind of room are you in?
Obs: I am in a room with a pool table, hardwood flooring, a small round table with barstools is behind me, and two armchairs are on the other end of the pool table.
Loc: Got it, are you at the end of the pool table, closer on the opposite side of the chairs?
Obs: I am in between the pool table and the small round table in the corner.
Localization Error 0.23 meters

Loc: Where you at?
Obs: I'm in a hallway with not much in it, let me move around. I see a dining table with 6 chairs and a white sofa on orange tile. The table is greenish.
Loc: Okay got it. Where exactly are you standing in the room?
Obs: I am behind the sofa, between it and the table.
Localization Error 0.39 meters

Figure 4: Examples from the dataset illustrating the Observer's location on the top-down map vs. the Locator's estimate (left) and the associated dialog (right). In the bottom example the Locator navigates to find a more discriminative location, which is a common feature of the dataset. The Observer navigates in 63% of episodes and the average navigation distance for these episodes is 3.4 steps (7.45 meters).

dict the Observer agent's next navigational action and natural language message to the Locator. To evaluate the agent's navigation path, the error in the final location can be used along with path metrics such as nDTW (Ilharco et al., 2019). Generated text can be evaluated against human responses using existing text similarity metrics.

Cooperative Localization. In this task, both the Observer and the Locator are modeled agents. Modeling the Locator agent requires goal-oriented dialog generation and confidence estimation to determine when to end the task by predicting the location of the Observer. Observer and Locator agents can be trained and evaluated independently using strategies similar to the EVD task, or evaluated as a team using localization accuracy as in LED.

4 Modeling Localization From Embodied Dialog

While the WAY dataset supports multiple tasks, we focus on Localization from Embodied Dialog as a first step. In LED, the goal is to predict the location of the Observer given a dialog exchange.

4.1 LED Model from Top-down Views

We model localization as a language-conditioned pixel-to-pixel prediction task – producing a probability distribution over positions in a top-down view of the environment. This choice mirrors the environment observations human Locators had during data collection, allowing straightforward comparison. However, future work need not be restricted to this choice and may leverage the panoramas or 3D reconstructions that Matterport3D provides.

Dialog Representation. Locator and Observer messages are tokenized using a standard toolkit (Loper and Bird, 2002). The dialog is represented as a single sequence with identical 'start' and 'stop' tokens surrounding each message, and then encoded using a single-layer bidirectional LSTM with a 300 dimension hidden state. Word embeddings are initialized using GloVe (Pennington et al., 2014) and finetuned end-to-end.

Environment Representation. The visual input to our model is the environment map which we scale to 780×455 pixels. We encode this map using a ResNet18 CNN (He et al., 2016) pretrained on ImageNet (Russakovsky et al., 2015), discarding

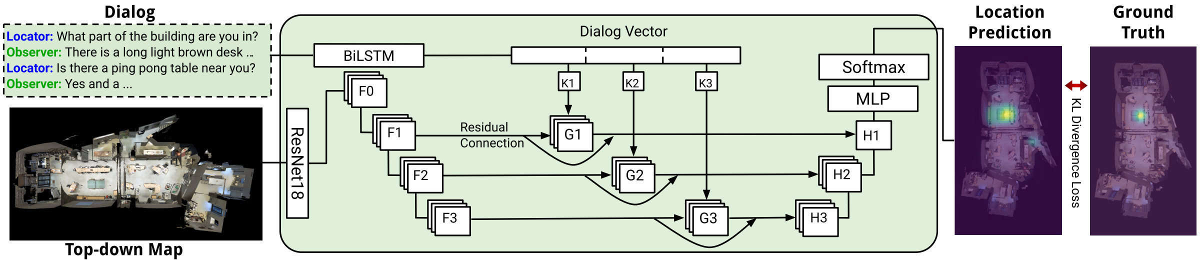


Figure 5: The 3-layer LingUNet-Skip architecture used to model the Localization from Embodied Dialog task.

the 3 final conv layers and final fully-connected layer in order to output a 98×57 spatial map with feature dimension 128. Although the environment map is a top-down view which does not closely resemble ImageNet images, in initial experiments we found that using a pretrained and fixed CNN improved over training from scratch.

Language-Conditioned Pixel-to-Pixel Model. We adapt a language-conditioned pixel-to-pixel LingUNet (Misra et al., 2018) to fuse the dialog and environment representations. We refer to the adapted architecture as LingUNet-Skip. As illustrated in Fig. 5, LingUNet is a convolutional encoder-decoder architecture. Additionally we introduce language-modulated skip-connections between corresponding convolution and deconvolution layers. Formally, the convolutional encoder produces feature maps $F_l = \text{Conv}(F_{l-1})$ beginning with the initial input F_0. Each feature map F_l is transformed by a 1×1 convolution with weights K_l predicted from the dialog encoding, i.e. $G_l = \text{Conv}_{K_l}(F_l)$. The language kernels K_l are linear transforms from components of the dialog representation split along the feature dimension. Finally, the deconvolution layers combine these transformed skip-connections and the output of the previous layer, such that $H_l = \text{Deconv}([H_{l+1}; (G_l + F_l)])$. There are three layers and the output of the final deconvolutional is processed by a MLP and a softmax to output a distribution over pixels.

Loss Function. We train the model to minimize the KL-divergence between the predicted location distribution and the ground-truth location, which we smooth by applying a Gaussian with standard deviation of 3m (matching the success criteria). During inference, the pixel with highest probability is selected as the final predicted location. For multi-story environments, we process each floor independently and the location with the highest predicted probability over all floors is selected.

4.2 Experimental Setup

Metrics. We evaluate performance using localization error (LE) defined as the Euclidean distance in meters between the predicted Observer location $\hat{p}_T$ and the Observer's actual terminal location p_T: $\text{LE} = ||p_T - \hat{p}_T||_2$. We also report a binary success metric that places a threshold k on the localization error – $\mathbb{1}(\text{LE} \leq k)$ – for 3m and 5m. The 3m threshold allows for about one viewpoint of error since viewpoints are on average 2.25m apart. We use euclidean distance for LE because localization predictions are not constrained to the navigation graph. Matterport building meshes contain holes and other errors around windows, mirrors and glass walls, which can be problematic when computing geodesic distances for points off the navigation graph.

Training and Implementation Details. Our LingUNet-Skip model is implemented in PyTorch (Paszke et al., 2019). Training the model involves optimizing around 16M parameters for 15–30 epochs, requiring ∼8 hours on a single GPU. We use the Adam optimizer (Kingma and Ba, 2014) with a batch size of 10 and an initial learning rate of 0.001 and apply Dropout (Srivastava et al., 2014) in non-convolutional layers with $p = 0.5$. We tune hyperparameters based on val-unseen performance and report the checkpoint with the highest val-unseen Acc@3m. To reduce overfitting we apply color jitter, 180° rotation, and random cropping by 5% to the map during training.

Baselines. We consider a number of baselines and human performance to contextualize our results and analyze WAY:

- **Human Locator.** The average performance of AMT Locator workers as described in Sec. 3.
- **Random.** Uniform random pixel selection.
- **Center.** Always selects the center coordinate.
- **Random Node.** Uniformly samples from Matterport3D node locations. This uses oracle knowledge about the test environments. While not a fair comparison, we include this to show the structural prior of the navigation graph which reduces the space of candidate locations.
- **Heuristic Driven.** For each dialog D_t in the validation splits we find the most similar dialog D_g in the training dataset based on BLEU score (Papineni et al., 2002). From the top-down map associated with D_g, a 3m x 3m patch is taken around the ground truth Observer location. We predict the location for D_t by convolving this patch with the top-down maps associated with D_t and selecting the most similar patch (according to Structural Similarity). The results (below) are only slightly better than random.

4.3 Results

Tab. 2 shows the performance of our LingUNet-Skip model and relevant baselines on the val-seen, val-unseen, and test splits of the WAY dataset.

Human and No-learning Baselines. Humans succeed 70.4% of the time in test environments. Notably, val-unseen environments are easier for humans (79.7%), see appendix for details. The Random Node baseline outperforms the pixel-wise Random setting (Acc@3m and Acc@5m for all splits) and this gap quantifies the bias in nav-graph positions. We find the Center baseline to be rather strong in terms of localization error, but not accuracy – wherein it lags behind our learned model significantly (Acc@3m and Acc@5m for all splits).

Table 3: Modality, modeling, and dialog ablations for our LingUNet-Skip model on the validation splits of WAY.

	val-seen		val-unseen	
	LE ↓	Acc@3m ↑	LE ↓	Acc@3m ↑
Full LingUNet-Skip Model	**4.73**±**0.32**	**53.5**±**2.9**	5.01±0.19	45.6±2.1
w/o Data Aug.	5.98±0.35	41.1±2.0	5.44±0.18	35.7±2.1
w/o Residual	5.26±0.33	47.5±2.9	4.74±0.17	43.1±2.1
No Dialog	7.17±0.42	26.1±2.5	5.72±0.20	32.1±2.0
First-half Dialog	5.06±0.33	50.5±2.8	**4.71**±**0.18**	**46.2**±**2.1**
Second-half Dialog	5.29±0.28	41.8±2.8	5.06±0.17	38.7±2.1
Observer-only	5.73±0.36	45.2±2.9	4.77±0.17	44.9±2.1
Locator-only	6.39±0.37	30.4±2.7	5.63±0.19	33.3±2.0
Shuffled Rounds	5.32±0.32	42.8±2.8	4.67±0.18	44.9±2.1

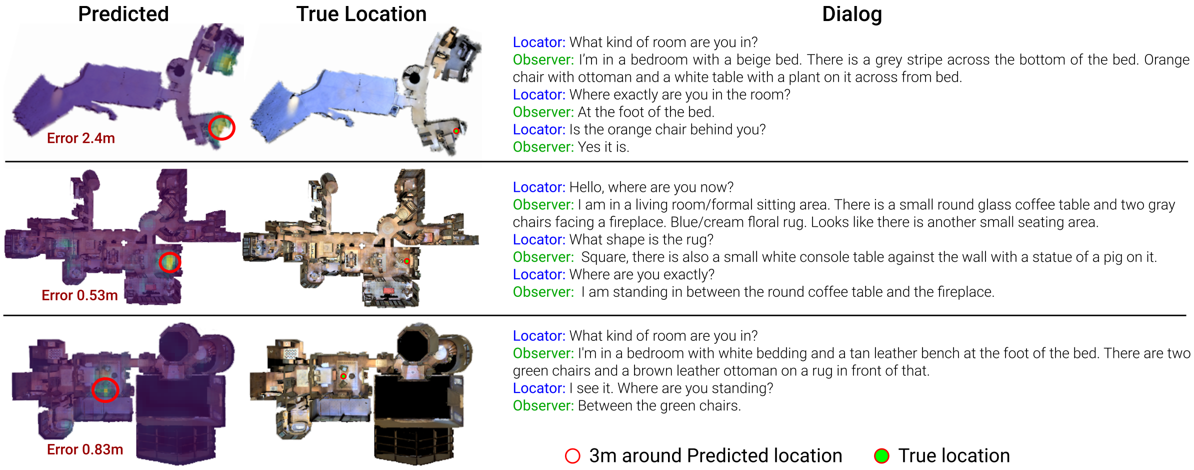
LingUNet-Skip outperforms baselines. Our LingUNet-Skip significantly outperforms the handcrafted baselines in terms of accuracy at 3m – improving the best baseline, Center, by an absolute 10% (test) to 30% (val-seen and val-unseen) across splits (a 45-130% relative improvement). Despite this, it achieves higher localization error than the Center model for val-unseen and test. This is a consequence of our model occasionally being quite wrong despite its overall stronger localization performance. There remains a significant gap between our model and human performance – especially on novel environments (70.4% vs 32.7% on test).

4.4 Ablations and Analysis

Tab. 3 reports detailed ablations of our LingUNet-Skip model. Following standard practice, we report performance on val-seen and val-unseen.

Navigation Nodes Prior We do not observe significant differences between val-seen (train environments) and val-unseen (new environments), which suggests the model is not memorizing the node locations. Even if the model did, learning this distribution would likely amount to free-space prediction which is a useful prior in localization.

Input Modality Ablations. No Vision explores the extent that linguistic priors can be exploited by LingUNet-Skip, while No Dialog does the same for visual priors. No Dialog beats the Center baseline (32.1% vs. 29.8% val-unseen Acc@3m) indicating that it has learned a visual centrality prior that is stronger than the center coordinate. This makes sense because some visual regions like nondescript hallways are less likely to contain terminal Ob-



Locator: What kind of room are you in?
Observer: I'm in a bedroom with a beige bed. There is a grey stripe across the bottom of the bed. Orange chair with ottoman and a white table with a plant on it across from bed.
Locator: Where exactly are you in the room?
Observer: At the foot of the bed.
Locator: Is the orange chair behind you?
Observer: Yes it is.

Locator: Hello, where are you now?
Observer: I am in a living room/formal sitting area. There is a small round glass coffee table and two gray chairs facing a fireplace. Blue/cream floral rug. Looks like there is another small seating area.
Locator: What shape is the rug?
Observer: Square, there is also a small white console table against the wall with a statue of a pig on it.
Locator: Where are you exactly?
Observer: I am standing in between the round coffee table and the fireplace.

Locator: What kind of room are you in?
Observer: I'm in a bedroom with white bedding and a tan leather bench at the foot of the bed. There are two green chairs and a brown leather ottoman on a rug in front of that.
Locator: I see it. Where are you standing?
Observer: Between the green chairs.

Figure 6: Examples of the predicted distribution versus the true location over top down maps of environment floors for dialogs in val-unseen. The red circle on the left represents the three meter threshold around the predicted localization. The green dot on the middle image represents the true location. The localization error in meters of the predicted location is shown in red.

server locations. Both No Vision and No Dialog perform much worse than our full model (7.8% and 32.1% val-unseen Acc@3m vs. 45.6%), suggesting that the task is strongly multimodal.

Dialog Halves. First-half Dialog uses only the first half of dialog pairs, while Second-half Dialog uses just the second half. Together, these examine whether the start or the end of a dialog is more salient to our model. We find that First-half Dialog performs marginally better than using the full dialog (46.2% vs 45.6% val-unseen Acc@3m) which we suspect is due to our model's failure to generalize second half dialog to unseen environments and problems handling long sequences. Further intuition for these results is that the first-half of the dialog contains coarser grained descriptions and discriminative statements ("I am in a kitchen"). The second-half of the dialog contains more fine grained descriptions (relative to individual referents in a room). Without the initial coarse localization, the second-half dialog is ungrounded and references to initial statements are not understood, therefore leading to poor performance.

Observer dialog is more influential. Observer-only ablates Locator dialog and Locator-only ablates Observer dialog. We find that Observer-only significantly outperforms Locator-only (44.9% vs. 33.3% val-unseen Acc@3m). This is an intuitive result as Locators in the WAY dataset commonly query the Observer for new information. We note that Observers were guided by the Locators in the collection process (e.g. *'What room are you in?'*), and that ablating the Locator dialog does not remove this causal influence.

Shuffling Dialog Rounds. Shuffle Rounds considers the importance of the order of Locator-Observer dialog pairs by shuffling the rounds. Shuffling the rounds causes our LingUNet-Skip to drop just an absolute 0.7% val-unseen Acc@3m (2% relative).

Model Ablations. Finally, we ablate two model-related choices. Without data augmentation (w/o Data Aug.), our model drops 9.9% val-unseen Acc@3m (22% relative). Without the additional residual connection (w/o Residual), our model drops 2.5% val-unseen Acc@3m (5% relative).

5 Conclusion and Future Work

In summary, we propose a new set of embodied localization tasks: Localization from Embodied Dialog - LED (localizing the Observer from dialog history), Embodied Visual Dialog - EVD (modeling the Observer), and Cooperative Localization - CL (modeling both agents). To support these tasks we introduce WHERE ARE YOU? a dataset containing ∼6k human dialogs from a cooperative localization scenario in a 3D environment. WAY is the first dataset to present extensive human dialog for an embodied localization task. On the LED task we show that a LingUNet-Skip model improves over simple baselines and model ablations but without taking full advantage of the second half of the dialog. Since WAY encapsulates multiple embodied localization tasks, there remains much to be explored.

6 Appendix

Val-Unseen has higher accuracy than other splits. Human's localization Acc@3m is 79.4% for val-unseen which is higher than all other splits such as test which as a Acc@3m of 70.4%. Following standard practice, the splits followed (Chang et al., 2017). The val-unseen split is notably smaller than the rest of the splits and through qualitative analysis, we found that the environments in the val-unseen split (Chang et al., 2017) are generally smaller and have discriminative features which we attribute to the split having a high localization performance. Our LingUNet-Skip model has lower performance on test than on val-unseen which we reason is be to the nature of the environments in the splits. Additionally the LingUNet-Skip model has lower performance on test than on val-seen which is expected because test environments are unseen environments and val-seen environments are contained in the training set.

Navigation differs between enviroments. As previously discussed, different environments in the WAY dataset have varying levels of navigation. This is likely attributed to a few factors such as size of the building and discriminative features of the building such as decorations. Additionally we see features like long hallways frequently lead to long navigational paths. The variances in navigation between environments is further illustrated in Fig. 7. While the distribution between the starting and final positions barely changes for the environment on the left, we see significant change in the environment on the right. Most noticeably we see that there are no final positions in the long corridor of the right environment despite it containing several start locations.

Data Collection Interface. Fig. 8 shows the data collection interface for the Observer and Locator human annotators. The annotator team was able to chat with each other via a message box that also displayed the chat history. The Locator had a top down map of the environment and had buttons to switch between floors. The Observer was given a first person view of the environment and could navigate the environment by clicking on the blue cylinders shown in Fig. 8

Closer Look at Dialog. Fig. 9 further breaks this down by looking at the average length of specific messages of the two agents. The Locator's first message is short in comparison to the average number of words per message of the agent. This is expected as this message is always some variation of getting the Observer to describe their location and it follows that the message has a low number of unique words. The Observer's first message is by far their longest, at 23.9 words, which is logical since in this message the Observer is trying to give the most unique description possible with no constraint on length. The distributions become more uniform in the 2nd messages from both the Locator and Observer. While the first message of the observer has a large number of unique words the distribution is not uniform over the words leading to the conclusion that the message has an common structure to it but that the underlying content is still discriminative for modeling the location. The word distribution of messages further down in the dialogue sequence are largely conditioned on the previous message from the other agent, which means that accurately encoding the dialogue history is important for accurate location estimation.

Distribution of Localization Error. In order to better understand the distribution of the LingUNet-Skip model's predictions we visualize the distributions in Fig. 10.

Success and Failure Examples. To qualitatively evaluate our model we visualize the predicted distributions, the true location over the top down map and the dialog in Fig. 11. We also show two failure cases in which the model predicts the wrong location.

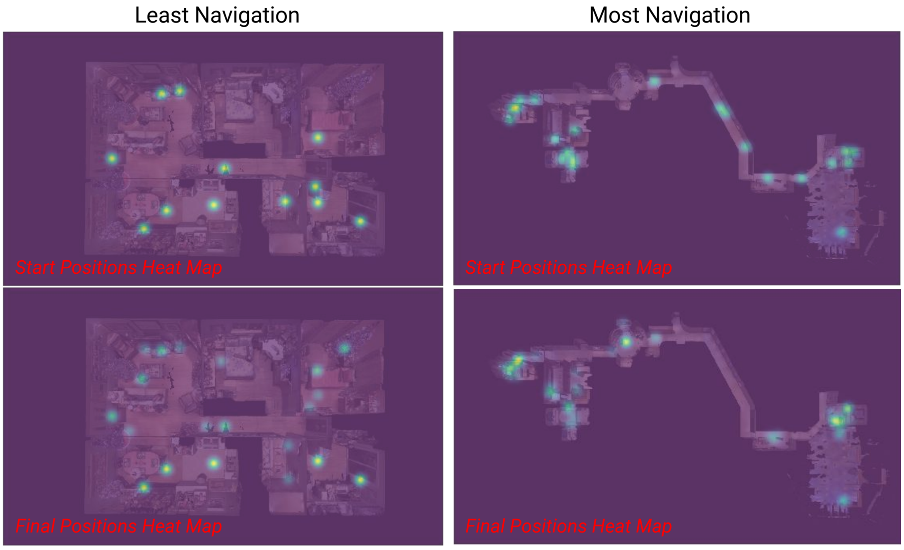

Figure 7: Shows the distribution of the starting and ending locations of the Observer for two environments in the WAY dataset. On the left is the environment that had annotations which the least amount of navigation. On the right is the environment that had annotations with the most amount of navigation.

Locator: What kind of room are you in?
Observer: I am in a bathroom, there is a white tub in the middle of the room, red carpet, a blue and white chair.
Locator: Got it, where in the bathroom are you standing?
Observer: Between the tub and the sink.
Error 0.93m

Locator: What kind of room?
Observer: I am standing in the doorway to a bathroom. There is light tile flooring. There is a stand up shower to my right. Looking into the room there is a dark cabinet with sink, it looks like a big jacuzzi tub in there too.
Locator: Is there anything else?
Observer: In the hallway behind the bathroom is a wood floor with a light colored rug.
Error 1.61m

Locator: Hey, what can you see?
Observer: I am on the top floor. There is a small square table in front of me, surrounded by different chairs size and shape chairs.
Locator: Is the floor wood planks?
Observer: Yes, but there's a carpet under this area.
Locator: Got it, where are you exactly?
Observer: I'm in between two of the chairs, closest to the corner of the room. There's a tv behind me.
Error 9.23m

Locator: Where are you? What do you see?
Observer: I have a fireplace to my left and a couch that is brown to my right.
Locator: Anything else?
Observer: In front of me a bit far away is a hutch.
Locator: I don't see a fireplace. Any more furniture?
Observer: There are two chairs across from the ends of the couch, one on each side side.
Error 8.8m

Figure 11: Examples of the predicted distribution versus the true location over top down map of a floor of an environment for a given dialog in val-unseen. On the left the red circle represents the three meter threshold around the predicted localization. On the middle image the green dot represents the true location. The localization error in meters of the predicted location shown in red in the dialog box.

Locator: Hi! What kind of room are you in?
Lost Friend: I am at the very top of the white marble spiral staircase. There is wood floor at the top and a balcony with black railing.
Locator: Are you between the two sets of stairs on the landing?
Lost Friend: I am at the top of the stairs.

Locator: Where are you located at?
Lost Friend: I'm in a kitchen that has a long curved wall. I'm near the entrance which is near some stairs.
Locator: Are the stairs going up or down?
Lost Friend: Down, it looks like I'm on the top floor.
Locator: What else do you see?
Lost Friend: There is a black table in the kitchen. One side is curved to match the curved of the kitchen wall.

Locator: What kind of room are you in?
Lost Friend: I am in a bedroom with one blue wall.
Locator: With the striped bed sheets and two tan nightstands??
Lost Friend: Yes! I am at the foot of the bed.

Locator: Hi, what kind of a room are you in?
Lost Friend: I'm in the kitchen standing in front of the stove.
Locator: How close to the stove are you?
Lost Friend: I could fry eggs if I wanted to without moving.

Locator: Hello, what type of room are you in?
Lost Friend: I am outside on the second step from the top of a windy staircase, overlooking the swimming pool.
Locator: Are you indoors or outdoors?
Lost Friend: am outside.
Locator: What material are you standing on?
Lost Friend: I am on the second step from the top of the staircase.
Locator: The only staircase I see is inside. Unless the rocks near the pool are the stairs you are talking about.
Lost Friend: I am outside, the staircase is spiral and it is black. There is a larger pool and smaller and I am on the side of the smaller one.

Locator: Hey. Where are you?
Lost Friend: I am in a study with a foosball table! There is a cream rug on the floor surrounded by white tile. A brown desk is in the corner between two brown bookcases on either side.
Locator: This is a very, very big house. Any colors that stand out will help. I would say there has got to be 30 rooms in this house. I am looking now.
Lost Friend: I am on the same floor as the swimming pool. There is a double door across from the study that looks out onto a patio and the pool is in the distance.
Locator: Found it. Where are you standing?
Lost Friend: Standing between the foosball table and the corner desk.

Abstract

Learning to fuse vision and language information and representing them is an important research problem with many applications. Recent progresses have leveraged the ideas of pre-training (from language modeling) and attention layers in Transformers to learn representation from datasets containing images aligned with linguistic expressions that describe the images. In this paper, we propose learning representations from a set of implied, visually grounded expressions between image and text, automatically mined from those datasets. In particular, we use denotation graphs to represent how specific concepts (such as sentences describing images) can be linked to abstract and generic concepts (such as short phrases) that are also visually grounded. This type of generic-to-specific relations can be discovered using linguistic analysis tools. We propose methods to incorporate such relations into learning representation. We show that state-of-the-art multimodal learning models can be further improved by leveraging automatically harvested structural relations. The representations lead to stronger empirical results on downstream tasks of cross-modal image retrieval, referring expression, and compositional attribute-object recognition. Both our codes and the extracted denotation graphs on the Flickr30K and the COCO datasets are publically available on `https://sha-lab.github.io/DG`.

1 Introduction

There has been an abundant amount of aligned visual and language data such as text passages describing images, narrated videos, subtitles in movies, etc. Thus, learning how to represent visual and language information when they are semantically related has been a very actively studied topic. There are many *vision + language* applications: image retrieval with descriptive sentences or captions (Barnard and Forsyth, 2001; Barnard et al., 2003; Hodosh et al., 2013; Young et al., 2014), image captioning (Chen et al., 2015; Xu et al., 2015), visual question answering (Antol et al., 2015), visual navigation with language instructions (Anderson et al., 2018b), visual objects localization via short text phrases (Plummer et al., 2015), and others. A recurring theme is to learn the representation of these two streams of information so that they correspond to each other, highlighting the notion that many language expressions are visually grounded.

A standard approach is to embed the visual and the language information as points in a (joint) visual-semantic embedding space (Frome et al., 2013; Kiros et al., 2014; Faghri et al., 2018). One can then infer whether the visual information is aligned with the text information by checking how these points are distributed.

How do we embed visual and text information? Earlier approaches focus on embedding each stream of information independently, using models that are tailored to each modality. For example, for image, the embedding could be the features at the last fully-connected layer from a deep neural network trained for classifying the dominant objects in the image. For text, the embedding could be the last hidden outputs from a recurrent neural network.

Recent approaches, however, have introduced several innovations (Lu et al., 2019; Li et al., 2019a; Chen et al., 2019). The first is to contextualize

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 823–839,
November 16–20, 2020.

the embeddings of one modality using information from the other one. This is achieved by using co-attention or cross-attention (in addition to self-attention) in Transformer layers. The second is to leverage the power of pre-training (Radford et al., 2019; Devlin et al., 2019): given a large number of parallel corpora of images and their descriptions, it is beneficial to identify pre-trained embeddings on these data such that they are useful for downstream *vision* $+$ *language* tasks.

Despite such progress, there is a missed opportunity of learning stronger representations from those parallel corpora. As a motivating example, suppose we have two paired examples: one is an image $\boldsymbol{x}_1$ corresponding to the text $\boldsymbol{y}_1$ of TWO DOGS SAT IN FRONT OF PORCH and the other is an image $\boldsymbol{x}_2$ corresponding to the text $\boldsymbol{y}_2$ of TWO DOGS RUNNING ON THE GRASS. Existing approaches treat the two pairs independently and compute the embeddings for each pair without acknowledging that both texts share the common phrase $\boldsymbol{y}_1 \cap \boldsymbol{y}_2 =$ TWO DOGS and the images have the same visual categories of two dogs.

We hypothesize that learning the correspondence between the common phrase $\boldsymbol{y}_1 \cap \boldsymbol{y}_2$ and the set of images $\{\boldsymbol{x}_1, \boldsymbol{x}_2\}$, though not explicitly annotated in the training data, is beneficial. Enforcing the alignment due to this *additionally constructed* pair introduces a form of structural constraint: the embeddings of $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ have to convey similar visual information that is congruent to the similar text information in the embeddings of $\boldsymbol{y}_1$ and $\boldsymbol{y}_2$.

In this paper, we validate this hypothesis and show that extracting additional and implied correspondences between the texts and the visual information, then using them for learning leads to better representation, which results in a stronger performance in downstream tasks. The additional alignment information forms a graph where the edges indicate how visually grounded concepts can be instantiated at both abstract levels (such as TWO DOGS) and specific levels (such as TWO DOGS SAT IN FRONT OF THE PORCH). These edges and the nodes that represent the concepts at different abstraction levels form a graph, known as denotation graph, previously studied in the NLP community (Young et al., 2014; Lai and Hockenmaier, 2017; Plummer et al., 2015) for grounding language expressions visually.

Our contributions are to propose creating visually-grounded denotation graphs to facilitate representation learning. Concretely, we apply the technique originally developed for the FLICKR30K dataset (Young et al., 2014) also to COCO dataset (Lin et al., 2014) to obtain denotation graphs that are grounded in each domain respectively (§ 3). We then show how the denotation graphs can be used to augment training samples for aligning text and image (§ 4). Finally, we show empirically that the representation learned with denotation graphs leads to stronger performance in downstream tasks (§ 5).

2 Related Work

Learning representation for image and text Single-stream methods learn each modality separately and align them together with a simple fusion model, often an inner product between the two representations. Frome *et al.* (Frome et al., 2013) learns the joint embedding space for images and labels and use the learned embeddings for zero-shot learning. Kiros *et al.* (Kiros et al., 2014) uses bi-directional LSTMs to encode sentences and then maps images and sentences into a joint embedding space for cross-modal retrieval and multi-modal language models. Li *et al.* (Li et al., 2019b) designs a high-level visual reasoning module to contextualize image entity features and obtain a more powerful image representation. Vendrov *et al.* (Vendrov et al., 2016) improves image retrieval performance by exploiting the hypernym relations among words. There is a large body of work that has been focusing on improving the visual or text embedding functions (Socher et al., 2014; Eisenschtat and Wolf, 2017; Nam et al., 2017; Huang et al., 2018; Gu et al., 2018).

Another line of work, referred to as cross-stream methods infer fine-grained alignments between local patterns of visual (*i.e.*, local regions) and linguistic inputs (*i.e.*, words) between a pair of image and text, then use them to derive the similarity between the image and the text. SCAN (Lee et al., 2018) uses cross-modal attention mechanism (Xu et al., 2015) to discover such latent alignments. Inspired by the success of BERT (Devlin et al., 2019), recent efforts have conducted visual-linguistic pre-training on large-scale datasets (Sharma et al., 2018), using a powerful sequence model such as

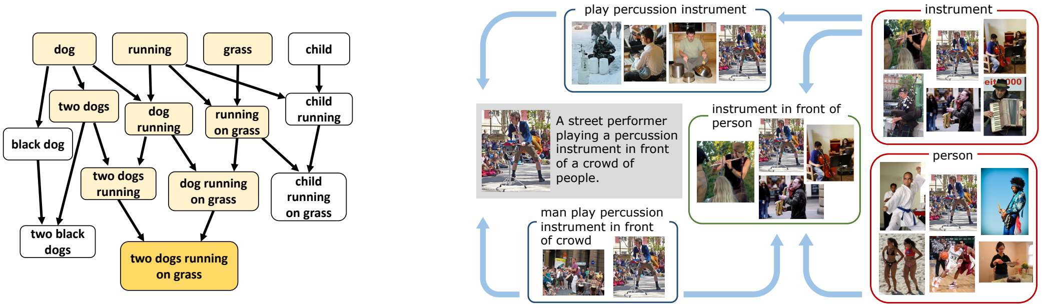

Figure 1: (Left) A schematic example of denotation graph showing the hierarchical organization of linguistic expression (adapted from `https://shannon.cs.illinois.edu/DenotationGraph/`) (Right) A random-subgraph from the denotation graph extracted from the FLICKR30K dataset, with images attached to concepts at different levels of hierarchy.

deep Transformers (Lu et al., 2019; Li et al., 2019a; Chen et al., 2019; Su et al., 2020; Li et al., 2019c). The pre-training strategies of these methods typically involve many self-supervised learning tasks, including the image-text matching (Lu et al., 2019), masked language modeling (Devlin et al., 2019; Lu et al., 2019) and masked region modeling (Chen et al., 2019).

In contrast to those work, we focus on exploiting additional correspondences between image and text that are not explicitly given in the many image and text datasets. By analyzing the linguistic structures of the texts in those datasets, we are able to discover more correspondences that can be used for learning representation. We show the learned representation is more powerful in downstream tasks.

***Vision* + *Language* Tasks** There has been a large collection of tasks combining vision and language, including *image captioning* (Chen and Lawrence Zitnick, 2015; Fang et al., 2015; Hodosh et al., 2013; Karpathy and Fei-Fei, 2015; Kulkarni et al., 2013), *visual QA* (Antol et al., 2015), *text-based image verification* (Suhr et al., 2017, 2018; Hu et al., 2019), *visual commonsense reasonin* (Zellers et al., 2019), and so on. In the context of this paper, we focus on studying *cross-modality retrieval* (Barnard et al., 2003; Barnard and Forsyth, 2001; Gong et al., 2014; Hodosh et al., 2013; Young et al., 2014; Zhang et al., 2018), as well as transfer learning on downstream tasks, including *compositional attribute-object recognition* (Isola et al., 2015; Misra et al., 2017) and *referring expressions* (Dale and Reiter, 1995; Kazemzadeh et al., 2014; Kong et al., 2014; Mitchell et al., 2012). Please refer to § 5 for explanation of these tasks.

3 Denotation Graph (DG)

Visually grounded text expressions denote the images (or videos) they describe. When examined together, these expressions reveal structural relations that do not exhibit when each expression is studied in isolation. In particular, through linguistic analysis, these expressions can be grouped and partially ordered and thus form a relation graph, representing how (visually grounded) concepts are shared among different expressions and how different concepts are related. This insight was explored by Young et al. (2014) and the resulting graph is referred to as a denotation graph, schematically shown in the top part of Fig. 1. In this work, we focus on constructing denotation graphs from the FLICKR30K and the COCO datasets, where the text expressions are sentences describing images.

Formally, a denotation graph $\mathcal{G}$ is a polytree where a node v_i in the graph corresponds to a pair of a linguistic expression $\boldsymbol{y}_i$ and a set of images $\boldsymbol{X}_i = \{\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_{n_i}\}$. A directed edge e_{ij} from a node v_i to its child v_j represents a subsumption relation between $\boldsymbol{y}_i$ and $\boldsymbol{y}_j$. Semantically, $\boldsymbol{y}_i$ is more abstract (generic) than $\boldsymbol{y}_j$, and the tokens in $\boldsymbol{y}_i$ can be a subset of $\boldsymbol{y}_j$'s. For example, TWO DOGS describes all the images which TWO DOGS ARE RUNNING describes, though less specifically. Note that the subsumption relation is defined on the semantics of these expressions. Thus, the tokens do not have to be exactly matched on their surface forms. For instance, IN FRONT OF PERSON or IN FRONT OF CROWD are also generic concepts that

Table 1: Key statistics of the two DGs: averaged over the all nodes in the graph, internal nodes and leaf nodes (formated as all/internal/leaf)

Dataset	DG-FLICKR30K	DG-COCO
# of edges	$1.94M$	$4.57M$
# of nodes	$597K/452K/145K$	$1.41M/841K/566K$
# of tokens/node	6.78/4.45/14.04	5.88/4.07/8.58
# of images/node	4.46/5.57/1.00	5.06/7.79/1.00

subsume IN FRONT OF A CROWD OF PEOPLE, see the right-hand side of Fig. 1 for another example.

More formally, the set of images that correspond to $\boldsymbol{v}_i$ is the union of all the images corresponding to $\boldsymbol{v}_i$'s children $\text{ch}(v_i)$: $\boldsymbol{X}_i = \bigcup_{v_j \in \text{ch}(v_i)} \boldsymbol{X}_j$. We also use $\text{pa}(v_j)$ to denote the set of v_j's parents.

Denotation graphs (DG) can be seen as a hierarchical organization of semantic knowledge among concepts and their visual groundings. In this sense, they generalize the tree-structured object hierarchies that have been often used in computer vision. The nodes in the DG are composite phrases that are semantically richer than object names and the relationship among them is also richer.

Constructing DG We used the publicly available tool[1], following Young *et al*. (Young et al., 2014). For details, please refer to the Appendix and the reference therein. Once the graph is constructed, we attach the images to the proper nodes by set-union images of each node's children, starting from the sentence-level node.

DG-FLICKR30K and DG-COCO[2] We regenerate a DG on the FLICKR30K dataset[3] (Young et al., 2014) and construct a new DG on the COCO (Lin et al., 2014) dataset. The two datasets come from different visual and text domains where the former contains more iconic social media photos and the latter focuses on photos with complex scenes and has more objects. Figure 1 shows a random subgraph of DG-FLICKR30K.

Table 1 lists the key statistics of the two DGs. We note that in both graphs, a large number of internal nodes (more abstract concepts or phrases) are introduced. For such concepts, the linguistic expressions are much shorter and the number of images they correspond to is also larger.

4 Learning with Denotation Graphs

The denotation graphs, as described in the previous section, provide rich structures for learning representations of text and image. In what follows, we describe three learning objectives, starting from the most obvious one that matches images and their descriptions (§ 4.1), followed by learning to discriminate between general and specialized concepts (§ 4.2) and learning to predict concept relatedness (§ 4.3). We perform ablation studies of those objectives in § 5.4.

4.1 Matching Texts with Images

We suppose the image $\boldsymbol{x}$ and the text $\boldsymbol{y}$ are represented by (a set of) vectors $\boldsymbol{\phi}(\boldsymbol{x})$ and $\boldsymbol{\psi}(\boldsymbol{y})$ respectively. A common choice for $\boldsymbol{\phi}(\cdot)$ is the last layer of a convolutional neural network (He et al., 2015; Xie et al., 2017) and for $\boldsymbol{\psi}(\cdot)$ the contextualized word embeddings from a Transformer network (Vaswani et al., 2017). The embedding of the *multimodal* pair is a vector-valued function over $\boldsymbol{\phi}(\boldsymbol{x})$ and $\boldsymbol{\psi}(\boldsymbol{y})$:

$$\boldsymbol{v}(\boldsymbol{x}, \boldsymbol{y}) = f(\boldsymbol{\phi}(\boldsymbol{x}), \boldsymbol{\psi}(\boldsymbol{y})) \quad (1)$$

There are many choices of $f(\cdot, \cdot)$. The simplest one is to concatenate the two arguments. We can also use the element-wise product between the two if they have the same embedding dimension (Kiros et al., 2014), or complex mappings parameterized by layers of attention networks and convolutions (Lu et al., 2019; Chen et al., 2019) – we experimented some of them in our empirical studies.

4.1.1 Matching Model

We use the following probabilistic model to characterize the joint distribution

$$p(\boldsymbol{x}, \boldsymbol{y}) \propto \exp(\boldsymbol{\theta}^{\mathrm{T}} \boldsymbol{v}(\boldsymbol{x}, \boldsymbol{y})) \quad (2)$$

where the exponent $s(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{\theta}^{\mathrm{T}} \boldsymbol{v}$ is referred as the matching score. To estimate $\boldsymbol{\theta}$, we use the

---

[1] Available online at `https://github.com/aylai/DenotationGraph`

[2] Both DGs are made publically available at `https://sha-lab.github.io/DG/`

[3] The original DG, while publicly available at `https://shannon.cs.illinois.edu/DenotationGraph/` contains 1.75 million nodes which are significantly less than ours, due to the difference in the version of the NLP toolkit.

maximum likelihood estimation

$$\boldsymbol{\theta}^* = \arg\max \sum\nolimits_{v_i} \sum\nolimits_k \log p(\boldsymbol{x}_{ik}, \boldsymbol{y}_i) \quad (3)$$

where $\boldsymbol{x}_{ik}$ is the kth element in the set $\boldsymbol{X}_i$. However, this probability is intractable to compute as it requires us to get all possible pairs of $(\boldsymbol{x}, \boldsymbol{y})$. To approximate, we use negative sampling.

4.1.2 Negative Sampling

For each (randomly selected) positive sample $(\boldsymbol{x}_{ij}, \boldsymbol{y}_i)$, we explore 4 types of negative examples and assemble them as a negative sample set $\mathcal{D}^-_{ik}$:

Visually mismatched pair We randomly sample an image $\boldsymbol{x}^- \notin \boldsymbol{X}_i$ to pair with $\boldsymbol{y}_i$, *i.e.*, $(\boldsymbol{x}^-, \boldsymbol{y}_i)$. Note that we automatically exclude the images from v_i's children.

Semantically mismatched pair We randomly sample a text $\boldsymbol{y}_j \neq \boldsymbol{y}_i$ to form the pair $(\boldsymbol{x}_{ik}, \boldsymbol{y}_j)$. Note that we constrain $\boldsymbol{y}_j$ not to include concepts that could be more abstract than $\boldsymbol{y}_i$ as the more abstract can certainly be used to describe the specific images $\boldsymbol{x}_{ik}$.

Semantically hard pair We randomly sample a text $\boldsymbol{y}_j$ that corresponds to an image $\boldsymbol{x}_j$ that is visually similar to $\boldsymbol{x}_{ik}$ to form $(\boldsymbol{x}_{ik}, \boldsymbol{y}_j)$. See (Lu et al., 2019) for details.

DG Hard Negatives We randomly sample a *sibling* (but not cousin) node v_j to v_i such that $\boldsymbol{x}_{ik} \notin \boldsymbol{X}_j$ to form $(\boldsymbol{x}_{ik}, \boldsymbol{y}_j)$

Note that the last 3 pairs have increasing degrees of semantic confusability. In particular, the 4*th* type of negative sampling is only possible with the help of a denotation graph. In that type of negative samples, $\boldsymbol{y}_j$ is semantically very close to $\boldsymbol{y}_i$ (from the construction) yet they denote different images. The "semantically hard pair", on the other end, is not as hard as the last type as $\boldsymbol{y}_i$ and $\boldsymbol{y}_j$ could be very different despite high visual similarity.

With the negative samples, we estimate $\boldsymbol{\theta}$ as the minimizer of the following negative log-likelihood

$$\ell_{\text{MATCH}} = -\sum_{v_i}\sum_{k} \log \frac{e^{s(\boldsymbol{x}_{ik}, \boldsymbol{y}_i)}}{\sum_{(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}) \sim \mathcal{D}_i} e^{s(\hat{\boldsymbol{x}}, \hat{\boldsymbol{y}})}} \quad (4)$$

where $\mathcal{D}_i = \mathcal{D}^-_{ik} \cup \{(\boldsymbol{x}_{ik}, \boldsymbol{y}_i)\}$ contains both the positive and negative examples.

4.2 Learning to Be More Specific

The hierarchy in the denotation graph introduces an opportunity for learning image and text representations that are sensitive to fine-grained distinctions. Concretely, consider a parent node $\boldsymbol{v}_i$ with an edge to the child node $\boldsymbol{v}_j$. While the description $\boldsymbol{y}_j$ matches any images in its children nodes, the parent node's description $\boldsymbol{y}_i$ on a higher level is more abstract. For example, the concepts INSTRUMENT and PLAY PERCUSSION INSTRUMENT in Fig 1 is a pair of examples showing the latter more accurately describes the image(s) at the lower-level.

To incorporate this modeling notion, we introduce

$$\ell_{\text{SPEC}} = \sum_{e_{ij}}\sum_{k}[s(\boldsymbol{x}_{jk}, \boldsymbol{y}_i) - s(\boldsymbol{x}_{jk}, \boldsymbol{y}_j)]_+ \quad (5)$$

as a specificity loss, where $[h]_+ = \max(0, h)$ denotes the hinge loss. The loss is to be minimized such that the matching score for the less specific description $\boldsymbol{y}_i$ is smaller than that for the more specific description $\boldsymbol{y}_j$.

4.3 Learning to Predict Structures

Given the graph structure of the denotation graph, we can also improve the accuracy of image and text representation by modeling high-order relationships. Specifically, for a pair of nodes v_i and v_j, we want to predict whether there is an edge from v_i to v_j, based on each node's corresponding embedding of a pair of image and text. Concretely, this is achieved by minimizing the following negated likelihood

$$\ell_{\text{EDGE}} = -\sum\nolimits_{e_{ij}} \sum\nolimits_{k,k'} \log p(e_{ij} = 1 | \boldsymbol{v}(\boldsymbol{x}_{ik}, \boldsymbol{y}_i), \boldsymbol{v}(\boldsymbol{x}_{jk'}, \boldsymbol{y}_j)) \quad (6)$$

We use a multi-layer perceptron with a binary output to parameterize the log-probability.

4.4 The Final Learning Objective

We combine the above loss functions as the final learning objective for learning on the DG

$$\ell_{\text{DG}} = \ell_{\text{MATCH}} + \lambda_1 \cdot \ell_{\text{SPEC}} + \lambda_2 \cdot \ell_{\text{EDGE}} \quad (7)$$

where λ_1, λ_2 are the hyper-parameters that trade-off different losses. Setting them to 1.0 seems to work well. The performance under different λ_1 and λ_2 are reported in Table 12 and Table 13. We study how each component could affect the learning of representation in § 5.4.

5 Experiments

We examine the effectiveness of using denotation graphs to learn image and text representations. We first describe the experimental setup and key implementation details (§ 5.1). We then describe key image-text matching results in § 5.2, followed by studies about the transfer capability of our learned representation (§ 5.3). Next, we present ablation studies over different components of our model (§ 5.4). Finally, we validate how well abstract concepts can be used to retrieve images, using our model (§ 5.5).

5.1 Experimental Setup

We list major details in the following to provide context, with the full details documented in the Appendix for reproducibility.

Embeddings and Matching Models Our aim is to show denotation graphs improve state-of-the-art methods. To this end, we experiment with two recently proposed state-of-the-art approaches and their variants for learning from multi-modal data: ViLBERT (Lu et al., 2019) and UNITER (Chen et al., 2019). The architecture diagrams and the implementation details are in the Appendix, with key elements summarized in the following.

Both the approaches start with an image encoder, which obtains a set of embeddings of image patches, and a text encoder which obtains a sequence of word (or word-piece) embeddings. For ViLBERT, text tokens are processed with Transformer layers and fused with the image information with 6 layers of co-attention Transformers. The output of each stream is then element-wise multiplied to give the fused embedding of both streams. For UNITER, both streams are fed into 12 Transformer layers with cross-modal attention. A special token CLS is used, and its embedding is regarded as the fused embedding of both streams.

For ablation studies, we use a smaller ViLBERT for rapid experimentation: ViLBERT (Reduced) where there are 3 Transformer layers and 2 co-attention Transformers for the text stream, and 1 Transformer layer for the image stream.

Constructing Denotation Graphs As described in §3, we construct denotation graphs DG-FLICKR30K and DG-COCO from the **FLICKR30K** (Young et al., 2014) and the **COCO** (Lin et al., 2014) datasets. FLICKR30K was originally developed for the tasks of image-based and text-based retrieval. It contains 29,000 images for training, 1,000 images for validation, and 1,000 images for testing. COCO is a significantly larger dataset, developed for the image captioning task. It contains 565,515 sentences with 113,103 images. We evaluate on both the 1,000 images testing split and the 5,000 images testing split (in the Appendix), following the setup in (Karpathy and Fei-Fei, 2015). Key characteristics for the two DGs are reported in Table 1.

Evaluation Tasks We evaluate the learned representations on three common *vision + language* tasks. In text-based image retrieval, we evaluate two settings: the text is either a sentence or a phrase from the test corpus. In the former setting, the sentence is a leaf node on the denotation graph, and in the latter case, the phrase is an inner node on the denotation graph, representing more general concepts. We evaluate the FLICKR30K and the COCO datasets, respectively. The main evaluation metrics we use are precisions at recall R@M where $\text{M} = 1, 5$ or 10 and RSUM which is the sum of the 3 precisions (Wu et al., 2019). Conversely, we also evaluate using the task of image-based text retrieval to retrieve the right descriptive text for an image.

In addition to the above cross-modal retrieval, we also consider two downstream evaluation tasks, *i.e.*, **Referring Expression** and **Compositional Attribute-Object Recognition**. (1) Referring Expression is a task where the goal is to localize the corresponding object in the image given an expression (Kazemzadeh et al., 2014). We evaluate on the dataset **REFCOCO+**, which contains 141,564 expressions with 19,992 images. We follow the previously established protocol to evaluate on the validation split, the TestA split, and the TestB split. We are primarily interested in zero-shot/few-shot learning performance. (2) Compositional Attribute-Object Recognition is a task that requires a model

Table 2: Text-based Image Retrieval (Higher is better)

Method	R@1	R@5	R@10	RSUM
FLICKR30K

UNITER + DG	51.4	78.7	87.0	217.1

to learn from images of SEEN (attribute, object) label pairs, such that it can generalize to recognize images of UNSEEN (attribute, object) label pairs. We evaluate this task on the **MIT-STATE** dataset (Isola et al., 2015), following the protocol by Misra et al. (2017). The training split contains 34,562 images from 1,262 SEEN labels, and the test split contains 19,191 images from 700 UNSEEN labels. We report the Top-1, 2, 3 accuracies on the UNSEEN test set as evaluation metrics.

Training Details Both ViLBERT and UNITER models are pre-trained on the Conceptual Caption dataset (Sharma et al., 2018) and the pre-trained models are released publicly[4]. On the DG-FLICKR30K, ViLBERT and UNITER are trained with a minibatch size of 64 and ViLBERT is trained for 17 epochs and UNITER for 15 epochs, with a learning rate of 0.00004. On the DG-COCO, ViLBERT is trained for 17 epochs and UNITER for 15 epochs with a minibatch size of 64 and a learning rate of 0.00004. The hyperparameters in Eq. (7) are set to 1.0, unless specified (see the Appendix).

5.2 Main Results

Table 2 and Table 3 report the performances on cross-modal retrieval. On both datasets, models trained with denotation graphs considerably outperform the corresponding ones which are not.

Table 4: Image Retrieval via Text (Transfer Learning)

SOURCE →TARGET	FLICKR→COCO R@1	FLICKR→COCO RSUM	COCO →FLICKR R@1	COCO →FLICKR RSUM
ViLBERT	43.5	199.5	49.0	209.0
+ SOURCE DG	44.9	200.5	52.8	218.2

For the image-based text retrieval task, ViLBERT and UNITER on FLICKR30K suffers a small drop in R@10 when DG is used. On the same task, UNITER on COCO 5K Test Split decreases more when DG is used. However, note that on both splits of COCO, ViLBERT is a noticeably stronger model, and using DG improves its performance.

5.3 Zero/Few-Shot and Transfer Learning

Transfer across Datasets Table 4 illustrates that the learned representations assisted by the DG have better transferability when applied to another dataset (TARGET DOMAIN) that is different from the SOURCE DOMAIN dataset which the DG is based on. Note that the representations are *not* fine-tuned on the TARGET DOMAIN. The improvement on the direction COCO →FLICKR30K is stronger than the reverse one, presumably because the COCO dataset is bigger than FLICKR30K. (R@5 and R@10 are reported in the Appendix.)

Zero/Few-shot Learning for Referring Expression We evaluate our model on the task of referring expression, a supervised learning task, in the setting of zero/few-shot transfer learning. In zero-shot learning, we didn't fine-tune the model on the referring expression dataset (*i.e.* REFCOCO+). Instead,

---

[4] The UNITER(Chen et al., 2019) model performs an additional online hard-negative mining (which we did not) during the training of image-text matching to improve their results. This is computationally very costly.

Table 5: Zero/Few-shot Learning for Referring Expression (Reported in R@1 on validation, TestA and TestB data)

Setting →	0% (Zero-shot)			25%			50%			100%		
Method	Val	TestA	TestB	Val	TestA	TestB	Val	TestA	TestB	Val	TestA	TestB

DG-COCO	19.4	30.4	37.6

Table 7: Ablation Studies of Learning from DG

ViLBERT variants →	Reduced	Full
w/o DG	215.4	236.7
w/ DG		
$+\ell_{\text{MATCH}}$ − DG HARD NEGATIVES	221.5	236.5
$+\ell_{\text{MATCH}}$	228.4	241.7
$+\ell_{\text{MATCH}}+\ell_{\text{SPEC}}$	228.8	242.6
$+\ell_{\text{MATCH}}+\ell_{\text{SPEC}}+\ell_{\text{EDGE}}$	231.2	243.3

we performed a "counterfactual" inference, where we measure the drop in the compatibility score (between a text describing the referring object and the image of all candidate regions) as we removed individual candidates results. The region that causes the biggest drop of compatibility score is selected. As a result, the selected region is most likely to correspond to the description. In the setting of few-shot learning, we fine-tune our COCO-pre-trained model on the task of referring expression in an end-to-end fashion on the referring expression dataset (*i.e.* REFCOCO+).

The results in Table 5 suggest that when the amount of labeled data is limited, training with DG performs better than training without. When the amount of data is sufficient for end-to-end training, the advantage of training with DG diminishes.

Compositional Attribute-Object Recognition We evaluate our model for supervised compositional attribute-object recognition (Misra et al., 2017), and report results on recognizing UNSEEN attribute-object labels on the MIT-STATE test data (Isola et al., 2015). Specifically, we treat the text of image labels (*i.e.*, attribute-object pairs as compound phrases) as the sentences to fine-tune the ViLBERT models, using the ℓ_{MATCH} objective. Table 6 reports the results (in top-K accuracies) of both prior methods and variants of ViLBERT, which are trained from scratch (N/A), pre-trained on COCO and DG-COCO, respectively. ViLBERT models pre-trained with parallel pairs of images and texts (*i.e.*, COCO and DG-COCO) improve significantly over the baseline that is trained on the MIT-STATE from scratch. The model pre-trained with DG-COCO achives the best results among ViLBERT variants. It performs on par with the previous state-of-the-art method in top-1 accuracy and outperforms them in top-2 and top-3 accuracies.

5.4 Ablation Studies

The rich structures encoded in the DGs give rise to several components that can be incorporated into learning representations. We study whether they are beneficial to the performances on the downstream task of text-based image retrieval. In the notions of §4, those components are: (1) remove "DG HARD NEGATIVES" from the ℓ_{MATCH} loss and only use the other 3 types of negative samples (§ 4.1); (2) align images with more specific text descriptions (§ 4.2); (3) predict the existences of edges between pairs of nodes (§ 4.3).

Table 7 shows the results from the ablation studies. We report results on two versions of ViLBERT: In ViLBERT (reduced), the number of parameters in the model is significantly reduced by making the model less deep, and thus faster for development. Instead of being pre-trained, they are trained on the FLICKR30K dataset directly for 15 epochs with a minibatch size of 96 and a learning rate of $4e^{-5}$. In ViLBERT (Full), we use the aforementioned settings. We report RSUM on the FLICKR30K dataset for the task of text-based image retrieval.

All models with DG perform better than the mod-

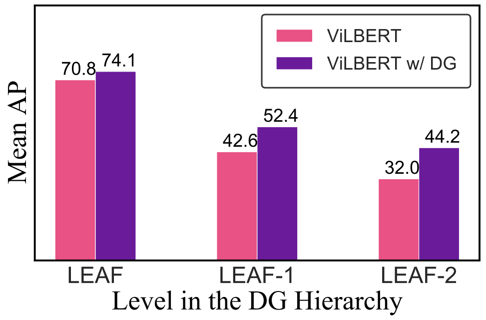

Figure 2: Image Retrieval using Mid-level Linguistic Expression on FLICKR30K Denotation Graph. The results are reported in Mean Average Precision (Mean AP).

els without DG. Secondly, the components of DG HARD NEGATIVES, ℓ_{SPEC}, and ℓ_{EDGE} contribute positively and their gains are cumulative.

5.5 Image Retrieval from Abstract Concepts

The leaf nodes in a DG correspond to complete sentences describing images. The inner nodes are shorter phrases that describe more abstract concepts and correspond to a broader set of images, refer to Table 2 for some key statistics in this aspect.

Fig. 2 contrasts how well abstract concepts can be used to retrieve images. The concepts are the language expressions corresponding to the leaf nodes, the nodes that are one level above (LEAF-1), or two levels above (LEAF-2) the leaf nodes from the DG-FLICKR30K. Since abstract concepts tend to correspond to multiple images, we use mean averaged precision (mAP) to measure the retrieval results. ViLBERT+DG outperforms ViLBERT significantly. The improvement is also stronger when the concepts are more abstract.

It is interesting to note that while the ℓ_{MATCH} used in ViLBERT w/ DG incorporates learning representations to align images at both specific and abstract levels, such learning benefits all levels. The improvement of retrieving at abstract levels does not sacrifice the retrieval at specific levels.

6 Conclusion

Image and text aligned data is rich in semantic correspondence. Besides treating text annotations as "categorical" labels, in this paper, we show that we can make full use of those labels. Concretely, denotation graphs (DGs) encode structural relations that can be automatically extracted from those texts with linguistic analysis tools. We proposed several ways to incorporate DGs into learning representation and validated the proposed approach on several tasks. We plan to investigate other automatic tools in curating more accurate denotation graphs with a complex composition of fine-grained concepts for future directions.

Appendix

In the Appendix, we provide details omitted from the main text due to the limited space, including:

- § A describes complete implementation details (cf. § 3 and § 5.1 of the main text).
- § B provides complete experimental results (cf. § 5.2 of the main text).
- § C visualizes the model's predictions on denotation graphs.

A Implementation Details

A.1 Constructing Denotation Graphs

We summarize the procedures used to extract DG from *vision* + *language* datasets. For details, please refer to (Young et al., 2014). We used the publicly available tool[5]. The analysis consists of several steps: (1) spell-checking; (2) tokenize the sentences into words; (3) tag the words with Part-of-Speech labels and chunk works into phrases; (4) abstract semantics by using the WordNet (Miller, 1995) to construct a hypernym lexicon table to replace the nouns with more generic terms; (5) apply 6 types of templated rules to create fine-to-coarse (*i.e.*, specific to generic) semantic concepts and connect the concepts with edges.

We set 3 as the maximum levels (counting from the sentence level) to extract abstract semantic concepts. This is due to the computation budget we can afford, as the final graphs can be huge in both the number of nodes and the edges. Specifically, without the maximum level constraint, we have 2.83M concept nodes in total for Flickr dataset. If the training is run on all these nodes, we will consume 19 times more iterations than training on the original dataset, which has 145K sentences (Young et al., 2014). As a result, much more time would be required for every experiment. With the 3 layers of DG from the leaf concepts, we have in 597K nodes. In this case, the training time would be cut down to 4.1 times of the original dataset.

Table 8: Text-based Image Retrieval Performance of ViLBERT trained with different number of DG levels

# of DG levels	R@1	R@5	R@10	RSUM
3 levels	65.9	91.4	95.5	252.7
5 levels	62.5	86.4	92.3	241.2
7 levels	62.8	86.3	91.6	240.7

Nonetheless, we experimented with more than 3 levels to train ViLBERT + DG-FLICKR30K with 5 and 7 maximum levels, respectively. The training hyper-parameters remain the same as ViLBERT + DG-FLICKR30K with 3 maximum layers. The aim is to check how much gain we could get from the additional annotations. We report the results in Table 8. It shows that actually, the model trained with 3 levels of DG achieves the best performance. This might be because those high-level layers of DG (counting from the sentences) contain very abstract text concepts, such as "entity" and "physical object", which is non-informative in learning the visual grounding.

Once the graph is constructed, we attach the images to the proper nodes by set-union images of each node's children, starting from the sentence-level node.

A.2 Model architectures of ViLBERT and UNITER

A comparison of these models is schematically illustrate in Fig. 3.

- ViLBERT. It has 6 basic Transformer layers for text and 8 layers for image. For all the Transformer layers on the text side, we use 12 attention heads and 256 feature dimensions, then linearly project down to 1024 feature dimensions. For all the Transformers on the image side, we use 8 attention heads and 128 feature dimensions, then combine into 1024 feature dimensions too.
- UNITER. All the Transformer layers have 12 heads and 256 feature dimensions.

The major difference between UNITER and ViLBERT is how attentions are used. In ViLBERT, one modality is used as a query, and the other is used as value and key. In UNITER, however, both are used as query, key, and value. Additionally, UNITER

---

[5] `https://github.com/aylai/DenotationGraph`

is similar to another model Unicoder-VL (Li et al., 2019a). However, the latter has not provided publicly available code for experimenting.

For ViLBERT model, each text and image co-attention Transformer layer contains 8 attention heads with 1024 dimensions in total. The text Transformer layer contains 12 attention heads with 3072 hidden dimensions in total. In contrast, the image Transformer layer has 8 attention heads with 1024 hidden dimensions in total. For UNITER model, each cross-attention Transformer layer contains 12 heads with 3072 hidden dimensions in total.

ViLBERT model contains 121 million parameters, while UNITER contains 111 million parameters.

A.3 Training Details

All models are optimized with the Adam optimizer (Kingma and Ba, 2015). The learning rate is initialized as $4e^{-5}$. Following ViLBERT (Lu et al., 2019), a warm-up training session is employed, during which we linearly increase the learning rate from 0 to $4e^{-5}$ in the first 1.5% part of the training epochs. The learning rate is dropped to $4e^{-6}$ and $4e^{-7}$ at the 10th and the 15th epochs, respectively. For ViLBERT (Reduced), we randomly initialized the model parameters in the image stream. The text stream is initialized from the first 3 layers of the pre-trained BERT model, and its co-attention Transformer layers are randomly initialized. For ViLBERT (Full) and UNITER (Chen et al., 2019), we load the model's weights pre-trained on the Conceptual Caption dataset to initialize them.

Training ViLBERT (Full) + DG with a minibatch size of 64 takes 2 to 3 days on an 8 TitanXp GPU server, or 1 day on TPU v2 cloud. The GPU server is equipped with Intel Xeon Gold 6154 CPU and 256G RAM.

A.4 Text Pre-processing

We follow BERT (Devlin et al., 2019) that uses WordPiece (Wu et al., 2016) tokenizer to tokenize the texts. For ViLBERT (Reduced) and ViLBERT (Full), we use the uncased tokenizer with a vocabulary size of 30,522. For UNITER, we use the cased tokenizer with a vocabulary size of 28,996. After tokenization, the tokens are transformed to 768 dimension features by a word embedding initialized from BERT pre-trained model. The 768-dimensional position features are included in the input to represent the position of each token.

A.5 Visual Pre-processing

For both ViLBERT and UNITER, we use the image patch features generated by the bottom-up attention features, as suggested by the original papers (Anderson et al., 2018a). The image patch features contain up to 100 image patches with their dimensions to be 2048. Besides this, a positional feature is used to represent the spatial location of bounding boxes for both ViLBERT and UNITER. Specifically, ViLBERT uses 5-dimensional position feature that encodes the normalized coordinates of the upper-left and lower-right corner for the bounding boxes, as well as one additional dimension encoding the normalized patch size. UNITER uses two additional spatial features that encode the normalized width and height of the object bounding box.

B Full Experimental Results

In this section, we include additional experimental results referred to by the main text. Specifically, we include results from a variety of models (*e.g.*, ViLBERT, ViLBERT + DG, UNITER, and UNITER + DG) on COCO dataset 5K test split (Karpathy and Fei-Fei, 2015) in § B.1. Then we provide a comprehensive ablation study on the impact of λ_1 and λ_2 of Eq. 7 in the main text in § B.3.

B.1 Complete Results on COCO Dataset

We report the full results on COCO dataset (1K test split and 5K test split) in Table 9 and Table 10. Additionally, we contrast to other existing approaches on these tasks. It could be seen that ViLBERT + DG and UNITER + DG improves the performance over the counterparts without DG by a significant margin on both COCO 1K and 5K test split – the only exception is that on the task of image-based text retrieval, UNITER performs better than UNITER+DG.

These results support our claim that training with DG helps the model to learn better visual and lin-

guistic features. Although ViLBERT and UNITER have different architectures, training with DG could improve the performance consistently.

B.2 Complete Results on FLICKR30K Dataset

We contrast to other existing approaches in Table 11 on the task of text-based image retrieval on the FLICKR30K dataset.

B.3 Ablation Study on λ_1 and λ_2

We conduct an ablation study on the impact of the two hyper-parameters λ_1 and λ_2 in Eq. 7 of the main text. We conduct the study with two ViLBERT variants: ViLBERT Reduced and ViLBERT. The results are reported in Table 12 and Table 13. As we have two hyper-parameters λ_1 and λ_2, we analyze their impacts on the final results by fixing one λ to be 1. Fixing the $\lambda_2 = 1$ and changing λ_1, we observe that ViLBERT prefers larger λ_1, while ViLBERT Reduced achieves slightly worse performance when λ_1 is smaller or larger. Fixing the $\lambda_1 = 1$ and changing λ_2, we observe that performance of both architectures slightly reduced when $\lambda_2 = 0.5$ and $\lambda_2 = 2$.

B.4 Full Results on Zero/Few-Shot and Transfer Learning

Implementation Details for Zero-shot Referring Expression Specifically, the learned ViLBERT and ViLBERT w/DG models are used first to produce a base matching score s_{BASE} between the expression to be referred and the whole image. We then compute the matching score s_{MASKED} between the expression and the image with each region feature being replaced by a random feature in turn. As the masked image region might be a noisy region, s_{MASKED} might be larger than s_{BASE}. Therefore, the model's prediction of which region the expression refers to is the masked region which causes the largest score in s_{REGION}, where

$$s_{\text{REGION}} = (s_{\text{BASE}} - s_{\text{MASKED}}) \cdot \mathbb{I}[s_{\text{MASKED}} > s_{\text{BASE}}].$$

Here $\mathbb{I}[\cdot]$ is an indicator function. Table 5 shows that ViLBERT + DG-COCO outperforms ViLBERT on this task.

Transfer Learning Results Table 14 reports the full set of evaluation metrics on transferring across datasets. Training with DG improves training without DG noticeably.

C Visualization of Model's Predictions on Denotation Graphs

We show several qualitative examples of both success and failure cases of ViLBERT + DG, when retrieving the text matched images, in Fig. 4 and Fig. 5. The image and text correspondence is generated by the Denotation Graph, which are derived from the caption and image alignment. We observe that in the Fig.4, the ViLBERT + DG successfully

Video2Commonsense: Generating Commonsense Descriptions to Enrich Video Captioning

Zhiyuan Fang[*] **Tejas Gokhale**[*] **Pratyay Banerjee** **Chitta Baral** **Yezhou Yang**

Abstract

Captioning is a crucial and challenging task for video understanding. In videos that involve active agents such as humans, the agent's actions can bring about myriad changes in the scene. Observable changes such as movements, manipulations, and transformations of the objects in the scene, are reflected in conventional video captioning. Unlike images, actions in videos are also inherently linked to social aspects such as intentions (why the action is taking place), effects (what changes due to the action), and attributes that describe the agent. Thus for video understanding, such as when captioning videos or when answering questions about videos, one must have an understanding of these commonsense aspects. We present the first work on generating *commonsense* captions directly from videos, to describe latent aspects such as intentions, effects, and attributes. We present a new dataset "Video-to-Commonsense (V2C)" that contains $\sim 9k$ videos of human agents performing various actions, annotated with 3 types of commonsense descriptions. Additionally we explore the use of open-ended video-based commonsense question answering (V2C-QA) as a way to enrich our captions. Both the generation task and the QA task can be used to enrich video captions.

1 Introduction

When humans watch videos they can typically understand and reason about various aspects of the scene beyond the visible objects and actions. This involves understanding that some objects are *active agents* that not only perform actions and manipulate objects, but are motivated by intentions, have pre-conditions, and that their actions have an effect on the world and their own mental states. For instance, in analyzing the video clip in Figure 1, humans employ various capabilities such as perception, reasoning, inference, and speculation, to come up with a description for the observable sequence of events, but also reason about latent aspects such as the intention of the group of runners *"to win the medal"*, the effect of being *"congratulated at the finish line"*, and the attribute *"athletic"*.

The above example also illustrates that recognition of objects, actions, and events is often not enough; understanding causal relationships, social interactions, and commonsense aspects behind them provides context and a more semantic interpretation of the video (Gupta et al., 2009). A model that can provide such detailed interpretations facilitates answering inferential questions, such as *"Will the player get angry later?"*. However, existing visual understanding systems are unable to perform such tasks that require speculative reasoning. A critical missing element in complex video understanding is the capability of performing commonsense inference, especially a generative model. Existing efforts seek to find textual explanations or intentions of human activities as a classification task (Vondrick et al., 2016) or a vision-to-text alignment problem (Zhu et al., 2015).

In this paper we propose the **V**ideo to **C**ommonsense (V2C) framework to generate visually grounded commonsense descriptions about the underlying event in the video, enriching the factual description provided by a caption. Under this framework a system is expected to generate captions as well as three types of commonsense descriptions (intention, effect, attribute) directly from an input video. The V2C model can also be used as a building block for downstream tasks such as video question answering for questions requiring commonsense. Inspired by (Bosselut et al., 2019), our model – the "V2C-Transformer" utilizes: (1) a video encoder to extract global representations of the video, (2) a transformer decoder that generates

captions and commonsense descriptions, and (3) a cross-modal self-attention module that exploits joint visual-textual embeddings.

We curate the V2C dataset for training and benchmarking models on this task. We adopt the MSR-VTT video description dataset (Xu et al., 2016) as a source of videos and captions. We first utilize the ATOMIC machine commonsense dataset (Sap et al., 2018) to get a list of candidate commonsense texts (intentions, effects, and attributes), and rank these using a BERT-based (Devlin et al., 2019) model. Since these candidates are retrieved without using the video and may not be accurate, we instruct humans to watch the videos and select, remove, or rewrite the texts retrieved from ATOMIC. The text retrieved by ATOMIC helps our human annotators to understand the format of desired annotations, and also gives them a list of suggestions. The human component in our annotation procedure makes our data visually grounded and relevant, linguistically diverse, and natural.

We additionally explore the use of our V2C-Transformer architecture for a open-ended video question answering task, where the questions are about commonsense aspects from the video. For this, we create a QA addendum of the V2C dataset called V2C-QA. By asking questions about the latent aspects in the video, our models are able to enrich caption generation with three specific types of commonsense knowledge.

Our contributions are summarized below:

1. We formulate the "V2C" task for enriching video captioning by generating descriptions of commonsense aspects.
2. We curate a video dataset annotated with captions and commonsense descriptions.
3. We present our V2C-Transformer architecture that generates relevant commonsense descriptions, and serves as a strong baseline.
4. We pose V2C as a video question answering task and show that it can assist commonsense caption generation.

2 Video to Commonsense (V2C)

Problem Formulation: Consider a video V consisting of N_v frames described by sentence S. Our Video-to-Commonsense (V2C) framework can be used for generating commonsense descriptions C under two settings. In the first setting (**V2C-Completion**), we use ground-truth captions to guide commonsense-enriched caption generation. This task can be viewed as providing supplementary explanations to the caption. In the second setting (**V2C-Generation**), we first learn to generate captions from videos, $\mathbf{g}(V)$, and then use them to generate commonsense descriptions.

$$\begin{array}{rl}\textbf{V2C-Completion} & C = \mathbf{f}(V, S). \\ \textbf{V2C-Generation} & C = \mathbf{f}(V, \mathbf{g}(V)).\end{array} \qquad (1)$$

2.1 V2C-Transformer

The proposed Video2Commonsense Transformer is a cross-modal model that generates captions and commonsense-enriched descriptions from videos. Our approach (Figure 2) adopts the "encoder-decoder" design: a video encoder that extracts global representations of the input video, and a transformer decoder that produces relevant commonsense knowledge along with captions.

Video Encoder: We obtain per-frame ResNet-152 (He et al., 2016) features for video V and process them using an LSTM model (Sundermeyer

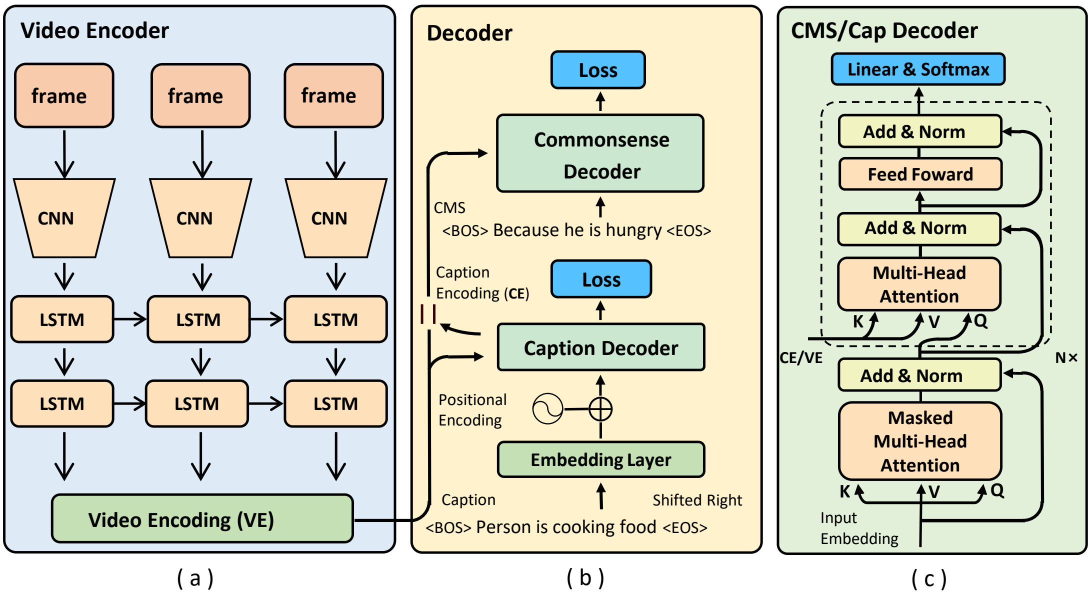

Figure 2: The V2C-Transformer model architecture contains: **(a)** Video Encoder designed to take video frames as input and encode them into frame-wise representations, **(b)** Decoder module consisting of a Caption Decoder and a Commonsense Decoder, and **(c)** Transformer Decoder module containing a stack of N consecutive transformer blocks (shown inside the dashed area).

et al., 2012), a standard architecture for modeling long temporal sequences, and use the last hidden states of the LSTM as the video representations. We concatenate all previous hidden states from each LSTM module as a final global video encoding $\mathbf{v}$, to provide the model with explicit context using the temporal attention mechanism.

Decoder: The video encoding is used as input to two decoder networks that use a transformer language model (Radford et al., 2018) to generate a caption and commonsense description, using an inference mechanism similar to Bosselut et al. (2019). Our model is a two-stage process that first predicts the current events directly from videos, and then produces the corresponding commonsense captions. During training, the caption decoder $\mathbf{D}_{\text{CAP}}$ takes the video encoding ($\mathbf{v}$) and ground truth caption ($\mathbf{s}$) as input to generate caption encoding ($\hat{\mathbf{s}}$), while the commonsense decoder $\mathbf{D}_{\text{CMS}}$ uses the concatenation of video and caption encoding to obtain the commonsense description ($\mathbf{c}$), as shown in Figure 1 (b). This arrangement enables the attention module in commonsense decoder to attend to both the video and caption context.

$$\hat{\mathbf{s}} = \mathbf{D}_{\text{CAP}}(\mathbf{v}, \mathbf{s}), \quad \mathbf{c} = \mathbf{D}_{\text{CMS}}(\mathbf{v}, \hat{\mathbf{s}}). \tag{2}$$

Transformer Decoder is composed of a stack of transformer blocks (dashed area in (c) Figure 2), whose main component is a self-attention architecture. It takes as input the summation of word embedding and the positional encoding offset by 1 position through masked multi-head attention, which prevents the future words been seen. In our model, we deploy two stacked decoder architectures for both caption decoding and commonsense knowledge decoding. The Transformer Block consists of consecutive linear transformation: a multi-head attention module (denoted as $\mathcal{H}_{\text{M-ATT}}$), a two-layer feed forward network ($\mathcal{H}_{\text{FFN}}$), a layer normalization operation, and a residual connection.

Multi-head Attention module To enable our transformer decoder to generate commonsense descriptions by using both the visual and textual content, we modify the multi-head attention module (which acts as the basic unit in recent transformer based language generation models (Radford et al., 2018, 2019)) as a cross-modal module. $\mathcal{H}_{\text{M-ATT}}$ takes the input of the embedding of key (K), value (V) and query (Q). The key and value in transformer block are the video encoding (caption decoder) or concatenation of video/caption encoding (commonsense decoder), while the query is the output from the previous transformer block. In the masked multi-head attention module, K, V and Q are the identical vectors of input embedding. For a self-attention block with h heads,

$$\mathcal{H}_{\text{M-ATT}}(\mathrm{K}, \mathrm{V}, \mathrm{Q}) = \mathcal{H}_{\text{FFN}}([x_1, \ldots, x_h]), \tag{3}$$

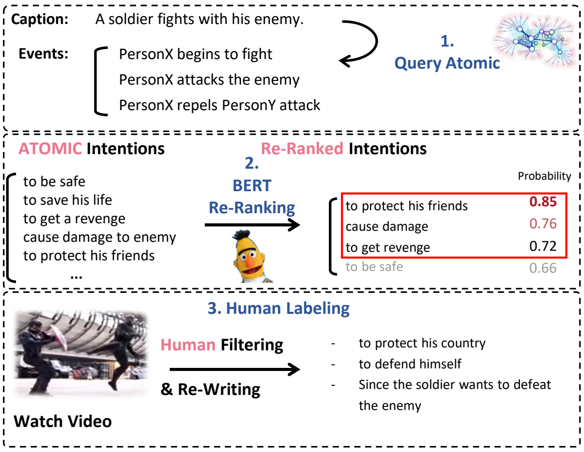

Figure 3: The overall three-step pipeline (retrieval from ATOMIC, BERT re-ranking, and human labeling) to construct our V2C dataset.

where x_i is computed by scaled dot-product attention operation, for head-index i, key-dimension d_kn, and transformation parameters W_i.

$$\textbf{for } \mathbf{D}_{\mathrm{CAP}}, \quad x_i = \mathrm{SOFTMAX}(\frac{\mathrm{W}_i^{\mathrm{Q}}\mathrm{Q} \cdot \mathrm{W}_i^{\mathrm{K}}\mathrm{K}'}{\sqrt{d_k}})\mathrm{W}_i^{\mathrm{V}}\mathrm{V},$$

$$\textbf{for } \mathbf{D}_{\mathrm{CMS}}, \quad x_i = \mathrm{SOFTMAX}(\frac{\mathrm{W}_i^{\mathrm{Q}}[\mathbf{v},\mathbf{s}] \cdot \mathrm{W}_i^{\mathrm{K}}[\mathbf{v},\mathbf{s}]'}{\sqrt{d_k}})\mathrm{W}_i^{\mathrm{V}}\mathrm{V}.$$

3 The V2C Dataset

For the V2C task we need video clips annotated with commonsense descriptions about the agents in the video, as shown in Figure 1. While there are video captioning datasets such as MSR-VTT (Xu et al., 2016), the captions in these datasets describe only the observable objects in the image, but do not describe latent and commonsense aspects. We are the first to curate such a dataset with annotations describing the intention of agent to perform an action, the effect of the action and the attribute of the agent given the action.

MSR-VTT contains around 10k videos each 10 to 30 seconds long, belonging to 20 categories covering a variety of topics such as sports, music, news, and home videos. Each video is accompanied by 20 human-annotated textual descriptions on average. For training and benchmarking the novel V2C task, we further complement MSR-VTT with event-level commonsense annotations, i.e. event descriptions with intentions, effects and attributes. We remove captions and videos that do not have clear human activities. This is because having such videos leads to an imbalance in the number of captions for each video, thus making it inappropriate to just evaluate caption generation using BLEU scores.

Type	Video Caption	Commonsense
Intention	Two guys are wrestling A man and woman are singing	to beat the opponent to express themselves musically
Attribute	A guy is singing in a crowd Group of riders race on motorcycles.	outgoing adventurous
Effect	A person is making a paper airplane A man and a woman are talking to each other	gets excited to fly it share ideas and opinions

Table 1: Examples of commonsense annotations (intentions, attributes and effects) retrieved from ATOMIC for captions in MSR-VTT.

ATOMIC (Sap et al., 2018) is an atlas of everyday commonsense knowledge and contains 880k triplets about causes and effects of human activities, organized as *if-then* relations, annotated by crowd-sourced workers. This data can be categorized based on causal relations, thereby giving us the categories "cause", "effect" and "attribute", e.g., "*if* X wants to relax, *then* he will play video game."

3.1 Querying from ATOMIC and Re-ranking

Since inferential knowledge in ATOMIC only covers human activities, we first retain only those captions in Msr-vtt that describe human activities. We then select three queries from ATOMIC most similar to the caption, and extract the commonsense descriptions corresponding to these queries. In order to select a more reasonable subset of commonsense descriptions, we first train a ranking model. We use the BERT (Devlin et al., 2019) architecture for the ranking model, trained on the ATOMIC dataset for a binary classification task, to predict the relevance of a candidate commonsense description with respect to the event. We select the top three relevant intentions, effects, and attributes for each caption. This allows us to obtain a preliminary set of 9 commonsense annotations per video directly from the ATOMIC dataset, relevant to the caption, albeit with noise and annotations that are not relevant to the video.

3.2 Detailed Human Annotation

Since we do not use the video to retrieve commonsense descriptions from ATOMIC, we employ human workers to annotate our dataset. We recruit

Relation	Model	CIDER	PPL ↓	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L

Table 2: Evaluation of V2C completion task using CIDER, BLEU, Perplexity, Rouge, and Meteor metrics. We use only BLEU-1 to evaluate the attribute generation since the average length of the ground truth is just less than 2.

two sets of human workers to watch the video, read the caption and select/annotate the relevant commonsense descriptions for each video. The first set is Amazon Mechanical Turkers (AMT) who select relevant descriptions. The second set is skilled human annotators, screened from a set of university students proficient in English, who are asked to provide annotations in their own words, and remove or edit irrelevant annotations that were provided by ATOMIC and AMT workers. This makes our annotations not only grounded in the video, but also more descriptive, linguistically diverse, and of higher quality (see Figure 3). The descriptions from ATOMIC, although not relevant to the video in some cases, give our workers an idea about the format of annotations desired. The skilled humans reported that 95% of the captions were relevant, and 65% of the ATOMIC descriptions were useful in understanding the annotation task. Through this procedure, we obtain 6819 videos for training and 2906 videos for testing, a total of 121,651 captions ($\sim$12 captions/video), each caption accompanied with 5 commonsense knowledge annotations (V2C-Raw set). In experiment, we use video captioning technique to conduct the V2C completion task on V2C-Raw set. In addition, we instruct human annotators to select and rewrite one raw phrase into complete sentences that complement the captions. In total we have 3 complete sentences per video for intention/effect/attribute respectively, and this yields a subset that allows our model to generate complete story-like sentences (V2C-Clean Set). Table 1 shows examples from the newly compiled dataset. We conduct rigorous human evaluation to evaluate the quality of our V2C dataset ("Gold Annotations" in Table 3). Details about the dataset creation process and quality control mechanisms can be found in the Appendix.

4 Experiments

In this section we describe the loss function used for training our model, additional details about video pre-processing, hyper-parameters, and baseline models, and the metrics used for evaluation.

Loss Function: The decoder parameters $\mathbf{\Theta}$ are trained to maximize the log-likelihood over the training set given by $\mathcal{L} = \mathcal{L}_{cap} + \mathcal{L}_{cms}$, where

$$\begin{aligned} \mathcal{L}_{cap} &= \sum_{t=1}^{N_S} \log \Pr(\mathbf{y}_t | \mathbf{y}_{t-1}, \mathbf{v}; \mathbf{\Theta}), and \\ \mathcal{L}_{cms} &= \sum_{t=1}^{N_C} \log \Pr(\mathbf{y}_t | \mathbf{y}_{t-1}, [\mathbf{v}, \tilde{\mathbf{s}}]; \mathbf{\Theta}). \end{aligned} \tag{4}$$

$\mathbf{y}_t$ denotes the one-hot vector probability of each word at time t, and N_S, N_C denote the length of the caption and commonsense respectively.

Setting: In order to obtain video representations, we uniformly sample 40 frames from each video and extract features using feed ResNet (He et al., 2016) pre-trained on Imagenet ILSVRC12 dataset (Deng et al., 2009) and get a 2048-d output from the last layer. We use one-hot input (1-of-N encoding) of the text input and pass it through an embedding layer to produce a 1028-d hidden vector. We use independent vocabularies for captioning and commonsense generation with sizes 27,603 and 24,010 respectively. Note that, as the generated

Hyperparameters: Our decoder is a lightweight transformer decoder consisting of 6 transformer blocks with 8 attention heads each. We use Adam optimizer with 5000 warm-up steps, and learning rate initialized at $1e$-4, and a dropout probability of 0.1 after the residual layer. Our model is trained on a machine with single NVIDIA 1080-Ti GPU.

Task	Model	Effect	Attribute	Intention	Average	Caption

Table 3: Human evaluation scores for V2C. Captions are an input for the **V2C-Completion** task, and generated for the **V2C-Generation** task. The best model is given in bold, while the overall best is underlined.

Baseline Model: We compare our method with strong video captioning baseline models like, S2VT (Venugopalan et al., 2015), "Attention-Enc-Dec" (Gao et al., 2017) – LSTM based models which reach competitive performing on MSR-VTT dataset. and "Dense Captioning" (Zhou et al., 2018), which is a transformer based video captioning model. As "Dense Captioning" is proposed to generate multiple continuous captions for a long untrimmed videos, we modify this by removing the temporal bounding boxes prediction module, and produce two continuous captions (caption + commonsense sentence) together without corresponded starting and ending time. All baselines are trained to predict commonsense descriptions from video on the V2C dataset. We do not compare with VideoBERT (Sun et al., 2019) which is trained on a limited set of cooking videos and hence non-transferable, and requires individual captions for multiple segments of the video.

Metrics: We report both the performances evaluated by automatic scores and human evaluations following the protocols from (Bosselut et al., 2019; Sap et al., 2018). We evaluate our method using BLEU (n=1-4) (Papineni et al., 2002), Meteor (Banerjee and Lavie, 2005), Rouge (Lin, 2004), and perplexity score of the generation on its corpus. We further conduct human evaluations using AMT workers, who are asked to identity whether the generated commonsense justifiably completes the events (V2C-completion). We follow the setup in (Sap et al., 2018) and randomly sample 100 videos from test set and collect 10 generations for each. To guarantee the objectiveness of the human evaluations, we hire 5 workers for each sample, yielding **30k** ratings in total for each model.

4.1 Results

Natural Language Generation Metrics: We show evaluation of the commonsense completion task in Table 2. Compared to the baseline model, our method exhibits a consistent and overall improvement on almost all metrics. Our V2C-Transformer significantly outperforms the LSTM based model in (Gao et al., 2017) by 7.7% at BLEU-4 for the intention prediction. Because the V2C-Transformer and the LSTM model share a similar video encoder, our performance improvement could be attributed to the use of self-attention mechanisms in the transformer block in decoding phase. This observation is consistent with the conclusion from (Bosselut et al., 2019), and yields further support to the transformer architecture being suited for commonsense inference tasks. Moreover, when compared with DenseCap which has a similar transformer architecture and parameters, our model exhibits better evaluation scores, verifying it as a strong baseline model for the V2C task.

Human Evaluation In Table 3, E2C (Event to Commonsense) is the task of commonsense completion given only textual events (Sap et al., 2018; Bosselut et al., 2019) as opposed to V2C which uses both text and video. 9Enc9Dec (Sap et al., 2018) is composed of nine GRU based encoder-decoders as a baseline model for commonsense completion on text, and Comet (Bosselut et al., 2019) is a large-scale generative pre-trained transformer (GPT) model (Radford et al., 2018). We would like to highlight that our transformer model is light-weight with only half of the parameters in GPT without any pre-training.

We evaluate our model on the tasks of caption generation with human evaluations, and also compare it with the gold annotations. Our gold annotation for ground-truth captions (sourced from the MSR-VTT dataset) points to the fact that a small percentage of captions from MSR-VTT are not relevant to the video, and this is amended by our human workers.

For the V2C-Completion task, our V2C-

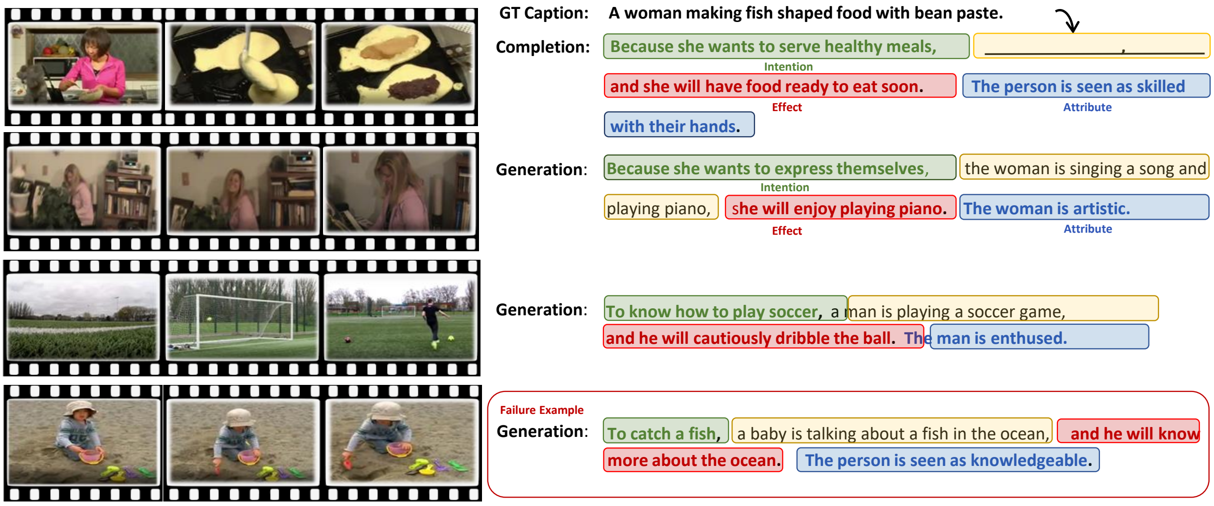

Figure 4: Examples of outputs of our model for the V2C Completion and Generation tasks along with the ground-truth (GT) caption. A failure example shown in the bottom red box.

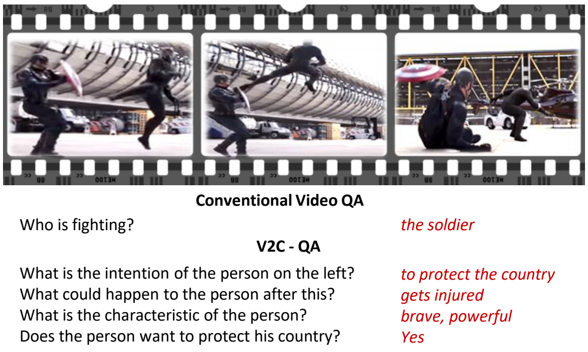
Transformer model is substantially better (by 7.73%) than the LSTM-based model from (Gao et al., 2017), and shows consistent lead on each dimension. Thus, when the ground-truth caption is given, our model is able to generate much more relevant commonsense descriptions, thereby consolidating it's ability of commonsense generation.

For the task of V2C-Generation, the difference between human scores for LSTM vs V2C-Transformer is reduced, but our VTC outperforms on average by 2.98%. This may be attributed to the fact that the LSTM-based model is slightly better at generating captions.

Generating Textual Stories with Commonsense

In order to generate story-like textual descriptions that complement the factual captions, we additionally train our model to exploit our diverse complete-sentence annotations. Specifically, instead of producing the commonsense knowledge given the videos and captions, we finetune our pre-trained V2C-Transformer model on predicting the human rewritten texts, and generate complete story-like captions. Since we do not have enough annotations per sample to compute a fair BLEU score for comparisons, we showcase some sample generated descriptions for qualitative analysis (see Figure 4). With that, we observe V2C-Transformer is able to produce complete stories that contain simple, while logically consistent storylines that complement both the visual content and the factual descriptions. We believe that collecting a set of story-like sentences will further enrich our models, and allow us to generate much more contextual, creative, and natural commonsense descriptions from a video.



Conventional Video QA

Who is fighting?	*the soldier*

V2C - QA

What is the intention of the person on the left?	*to protect the country*
What could happen to the person after this?	*gets injured*
What is the characteristic of the person?	*brave, powerful*
Does the person want to protect his country?	*Yes*

Figure 5: Example questions from V2C-QA compared with conventional video question answering.

5 V2C-QA

Another way of generating commonsense descriptions about the video is by asking pointed questions. Consider the example in 1 where we ask the question *"What happens next to the runners"*, about the *effect* of the action "prepare" performed by the agents *"group of runners"* observed in the video. We propose a V2C-QA – an open-ended commonsense video question-answering task, where we ask questions about the intents, effects and attributes of the agents in the video.

Dataset: We use the caption and commonsense annotations in the V2C dataset to create question-answer pairs for each video. We first extract the action and subject from the caption using SpaCy linguistic features (Honnibal and Johnson, 2015). For each intention, attribute and effect for a video, we use template-based generation to get 7 types

	Model	**top-1**		**top-3**		**top-5**	
		p	r	p	r	p	r
Intention	MSR-VTT QA	9.68	2.13	7.15	4.68	6.07	6.60
	V2C-T	10.34	2.31	7.69	5.03	6.37	6.87

	Pretrained V2C-T	10.77	**2.69**	8.01	5.58	**6.71**	7.88
	Pretrained V2C-T + Cap.	**11.04**	2.68	7.96	**5.70**	6.63	**7.79**
Effect	MSR-VTT QA	19.89	5.02	8.04	5.91	5.30	6.49
	V2C-T	20.95	5.43	8.65	6.57	5.65	7.06
	V2C-T + Captions	20.95	5.32	8.50	6.48	5.76	7.26
	Pretrained V2C-T	20.95	5.32	8.63	6.55	5.82	7.49
	Pretrained V2C-T + Cap.	**21.12**	**5.60**	**8.70**	**6.89**	**5.83**	**7.68**
Attribute	MSR-VTT QA	46.10	37.22	16.02	49.45	7.49	41.03
	V2C-T	59.52	48.30	22.39	51.40	13.97	52.57
	V2C-T + Captions	59.74	48.22	23.12	52.44	14.64	54.35
	Pretrained V2C-T	**60.72**	**49.00**	**23.18**	**52.73**	**14.98**	**55.40**
	Pretrained V2C-T +Cap.	59.57	48.24	23.10	52.54	14.94	54.91
	Text-Only Baseline	12.36	11.70	13.84	12.35	14.77	14.10

Table 4: Precision (p) and Recall (r) for V2C-QA for each type of question.

of questions – yielding 21 questions per sample, including negative questions as in Gokhale et al. (2020). In total, we have 1,250 training videos and 250 test videos, and a total of 37k questions. We have a set of 5,555 unique answers for our questions. Each question can have multiple possible true answers as shown in the example in Figure 5. The V2C-QA task asks questions that require commonsense reasoning about internal mental states, motivations, and latent aspects of agents in the video as opposed to the conventional video-QA questions about visible objects and actions.

Models: We utilize our V2C-Encoder followed by an open-ended answering module. We jointly predict the type of the question and combine it with the V2C encoding using a feed-forward network. For textual features, we use embeddings from BERT-base (Devlin et al., 2019). Our models are trained on the open-ended QA task and setup as a multi-label classification task similar to VQA (Antol et al., 2015), with an answering module design inspired by LXMERT (Tan and Bansal, 2019). Our loss function includes the classification loss for answering, the attention loss for question-type, and a label-ranking loss.

Results: MSR-VTT QA (Xu et al., 2017) is as a good baseline since it is trained on a conventional videoQA task on the MSR-VTT videos, and only takes video and query as input, unlike recent video understanding models (Lei et al., 2018) that take additional supervision, such as subtitles. However this model is trained for a multiple-choice QA scheme, so we modify it with our open-ended answering module. We compare our models when we use our encoder pretrained on the V2C caption generation task, and then finetune it on the V2C-QA task. We also train models with ground-truth factual captions as input. Our results are shown in Table 4, where we evaluate on prediction of top-k (1,3,5) answers, and report precision and recall. Our encoder pre-trained on the V2C task outperforms all other models. Attribute-related questions are easier to answer, while the models struggle the most for questions about intention. Captions help in questions about effects. The overall text-only baseline shows an insignificant bias between the question and answer-options.

6 Related Work

Video Captioning: Captioning is crucial for understanding visuals; however it is typically limited to describing observable objects and events (Yang et al., 2011; Thomason et al., 2014; Gan et al., 2017)), or for generating paragraphs or multi-sentence captions about the image or video (Krause et al., 2017; Krishna et al., 2017). However, for detailed video understanding, one needs to obtain descriptions that go beyond observable visual entities and use background knowledge and commonsense to reason about objects and actions. Work for inferring motivations of human actions in static images by incorporating commonsense knowledge are reflected in Pirsiavash et al. (2014); Vondrick et al. (2016). Commonsense caption generation has been approached on abstract scenes and clipart images in Vedantam et al. (2015). We present the first generative model for commonsense video captioning.

Video Question Answering: Since caption generation can only describe observable events, recent work seeks to move closer to comprehension, by learning to answer complex questions about videos. However, the datasets used for Video QA (Yang et al., 2003; Xu et al., 2016; Zhu et al., 2017) focus only on directly evident visual concepts and construct the questions mostly about "where" and "what" aspects. Question answering on movie videos has been explored by Tapaswi et al. (2016) who collect questions about "why" and "how" aspects. Recently Lei et al. (2018); Zadeh et al. (2019) have propose video-based QA tasks with open-ended high-order questions that need multi-modal understanding, social intelligence modeling, and spatio-temporal reasoning. We introduce a novel open-ended video question answering task in this paper, where the questions are about three aspects of commonsense human behavior.

Visual Reasoning: Aspects of visual reasoning have been explored by Yatskar et al. (2016) as a situation recognition task on single images, and in Visual Madlibs (Yu et al., 2015) as a "fill-in-the-blanks" task for single-image captioning that contains some categories which require reasoning about internal mental states and future events. Kim et al. (2018) provide textual explanations for actions in a self-driving scene. Zellers et al. (2019) propose a visual question answering task that requires commonsense reasoning to answer a question and to provide a rationale behind the answer. Spatial and compositional reasoning is required to answer questions about synthetic images in CLEVR (Johnson et al., 2017). Critical aspects of visual reasoning also include the model's ability to conduct object grounding by natural language descriptions (Rohrbach et al., 2016; Fang et al., 2018, 2019). Another aspect of visual reasoning is the ability predict a sequence of actions (procedure planning), or to reason about intermediate video frames (walkthrough planning) between two frames, explored in Gokhale et al. (2019); Chang et al. (2020).

Textual Commonsense: Commonsense-based question answering is an area of active research with several datasets and challenges requiring reasoning about conceptual commonsense (Talmor et al., 2019), physical commonsense (Bisk et al., 2020), social commonsense (Sap et al., 2019), and abductive commonsense (Bhagavatula et al., 2020). On the other hand, challenges such as ProPara (Mishra et al., 2018) and bAbI (Weston et al., 2015) require tracking elements, actions, and effects of actions. Commonsense-based text generation has recently been explored via the ATOMIC dataset (Sap et al., 2018), a corpus of 877k textual descriptions of inferential knowledge organized as *if-then* relations. Bosselut et al. (2019) adopt the ATOMIC dataset to learn a generative model of commonsense knowledge. To the best of our knowledge, ours is the first work on *generating* commonsense descriptions from visual inputs.

7 Outlook

A video typically contains one or many objects (sometimes performing actions) in different backgrounds, scenes, or situations. Some objects may be "passive" such as trees or buildings, while some objects may be "active" such as people performing actions like walking, singing, and driving. This paper is focused on describing such active agents in terms of their intentions, effects of their actions, and attributes that characterize these agents.

We distinguish V2C from the traditional video captioning task. Video captions describe observable objects, background, and actions, while commonsense descriptions in our task seek to describe the unobservable intentions of the agent (pre-conditions or mental conditions), effects of the action (that happen in the future), and attributes which characterize the agent. Thus commonsense generation goes *beyond the visible*. Ours is the first attempt at developing a generative video-based commonsense model. We anticipate that our framework can be utilized for many applications in video understanding, comprehension, human-robot interaction, and learning commonsense in a multi-modal setting.

8 Conclusion

In this paper, we explore a novel and challenging task to generate video descriptions with rich commonsense descriptions that complement the factual captions. We expand an existing video captioning dataset for the V2C task through automated retrieval from a textual commonsense corpus followed by human labeling, and present a novel V2C-Transformer model to serve as a strong baseline method for the V2C task. Our evaluation verifies the effectiveness of our method, while also indicating a scope for further study, enhancement, and extensions in the future. Our experiments on using the V2C-Transformer as a component for the V2C-QA task show that the model has transfer learning capabilities that can be applied to other vision-and-language tasks such as question-answering, that require commonsense reasoning.

Appendix

In this appendix, we provide the the following supplementary information:

- Additional details about our dataset creation process, including statistics and analysis for V2C and V2C-QA datasets,
- Examples of commonsense descriptions generated by our V2C-Transformer model,
- Details about our human evaluation interface, protocol, and metrics.

A V2C Dataset Construction

Our dataset creation methodology is a three-step procedure as shown in Figure 9. In the first step, we use the caption to query ATOMIC (Sap et al., 2018) and retrieve the top-3 intentions, effects, and attributes. These are re-ranked by a BERT based model in the second step. The final step involves humans in the annotation process. We ask human annotators to select the most relevant descriptions, and to provide additional descriptions in their own words. The annotators also convert a subset of our dataset into complete sentence descriptions.

A.1 Querying from ATOMIC

For every video-caption pair in the MSR-VTT dataset, we select 3 most similar events from ATOMIC. These are then used to retrieve textual descriptions of three types – *intentions, effects, attributes* from ATOMIC.

A.2 BERT Ranking Model

We implement a Bidirectional Encoder Representations from Transformers (BERT) model (Devlin et al., 2019) as a ranking model to rank and retrieve *top-3* most plausible commonsense aspects to complement the ground truth caption. This is done by treating the ranking task as a binarized next sentence prediction (NSP) task, trained on the ATOMIC (Sap et al., 2018) dataset. When choosing the sentences A and B for each training pair, for 50% of the training pairs we choose the actual next sentence that follows A, and a random sentence from the ATOMIC as a negative sentence. This setting is consistent with the NSP task in (Devlin et al., 2019). We train our model in ATOMIC, and use it to expand video captions from MSR-VTT (Xu et al., 2016). Our BERT model consists of 12 transformer blocks, 12 attention heads, and 768 hidden dimensions (110M parameters in total). In total, we have 115,312 pairs for training/testing. We evaluate our model using accuracy of the prediction in the test set of ATOMIC which is 30% of the entire set. BERT can achieve 86.21% accuracy in NSP task on average as shown in Table 5. In addition, we also conduct human evaluations to measure the overall quality of the expanded V2C dataset (see “gold annotations” in Table. 3, main paper).

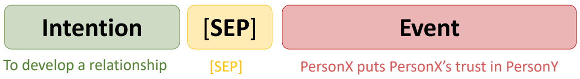

Figure 6: Next sentence prediction task in Bert model. A and B sentences are separated by token [SEP].

Commonsense Type	Accuracy (%)
Intention	84.87
Effect	86.53
Attribute	87.23
Average	86.21

Table 5: Accuracy of our BERT model for next sentence prediction on the ATOMIC test dataset split

A.3 Human Labeling

With querying from ATOMIC and BERT re-ranking, we obtain commonsense descriptions that are relevant to the caption. However, we want to make sure that these descriptions are also relevant to the video. Thus we utilize human workers from Amazon Mechanical Turk (AMT) for selecting the most relevant commonsense descriptions. Our annotation interface is shown in Figure 10. We ask the annotators to select descriptions that are most relevant to the video and to the caption, and also encourage them to add their own commonsense descriptions. This makes our dataset more natural and human-like. This also allows us to remove noisy annotations that may be produced due to text-only ATOMIC querying. We show additional samples from our V2C dataset in Figure. 11, word cloud in Figure. 7 and word frequency in 8.

A.4 Benefits of the Three-Step Pipeline

Since our videos are annotated with captions, we use the captions to retrieve commonsense descriptions from ATOMIC. The ATOMIC dataset has comprehensive annotations for human activities, actions, and events and as such **covers most of the events in MSR-VTT**. Thus using these two datasets together is a natural step for creating our V2C dataset.

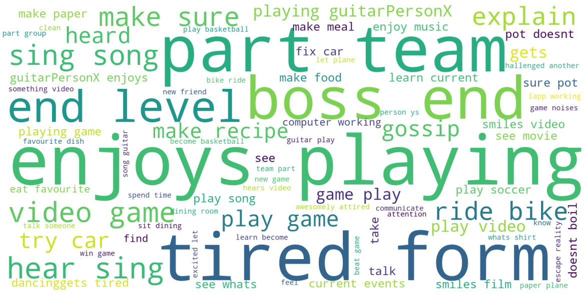

Figure 7: Word cloud figure of the intention commonsense annotations from our V2C dataset.

This purely caption-based retrieval unfortunately does not incorporate the latent aspects of the video, but only those from the caption. Moreover, since the video is not used for retrieving these, the commonsense annotations may be out-of-context. Thus, we bring in human annotators to watch the video, read the caption, and then use the set of descriptions from ATOMIC to select the relevant once and to discard the irrelevant or out of context descriptions. The human annotators then provide annotations about intention, effect, and attribute in their own words. The ATOMIC retrieved descriptions help the human annotators to get an idea about the task and also get a glimpse of the format of the desired annotations. This significantly reduces the noise in human annotations.

To guarantee and measure the overall quality of our V2C dataset, we have conducted human evaluations on the V2C annotations. Our results shows that 86.29% of the ⟨video-caption-commonsense⟩ triples are labeled as reasonable samples (see "Gold Annotations" in main paper, Table. 3), **verifying the quality** of our dataset

B V2C-QA Dataset

For the V2C Question Answering task, we repurpose our V2C dataset and convert it to a question-answering dataset. We choose a subset of 1500 videos: 1250 for training and 250 for testing, following the same train-test split as MSR-VTT. We use SpaCy linguistic features (Honnibal and Montani, 2017) along with the LemmInflect library (https://github.com/bjascob/LemmInflect) and template-based generation to convert the captions, intentions, effects, and attributes from V2C to create questions and ground-truth answers. Our templates are lingustically diverse, natural, and grammatically sound. We have 21 types of templates with each template having numerous possibilities for combinations of the slots in the template. Thus we get 21 types of questions (7 each for intention, effect, and attribute) as shown in Table 6. Since our task is open-ended question-answering, our questions are annotated with *all possible* correct answers for that question. To get answers for the "negative" questions as shown in Table 6, we use the adversarial matching strategy similar to (Zellers et al., 2019), by using RoBERTa (Liu et al., 2019) similarity. We will release our V2C-QA question and

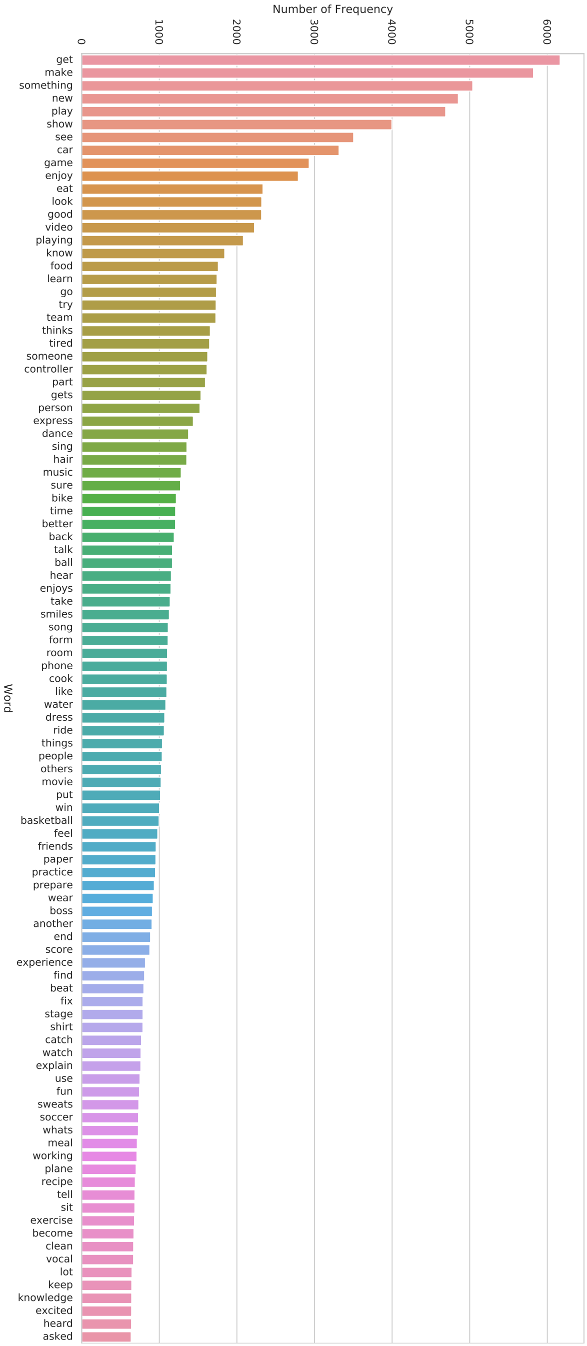

Figure 8: Top-100 most frequent words in our V2C dataset (stop words are ignored).

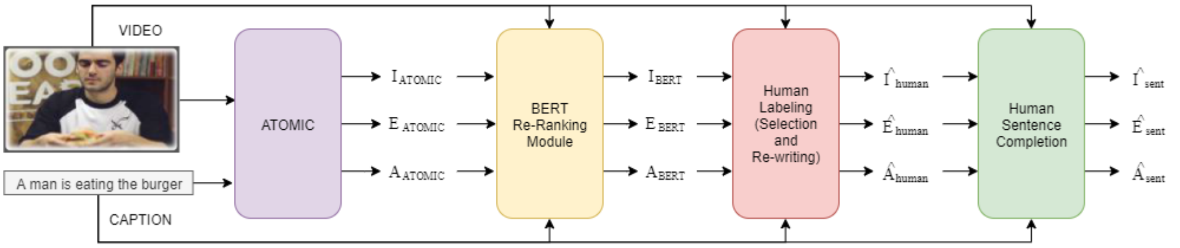

Figure 9: The data creation flow for V2C. We use the retrieved videos and captions from MSR-VTT and use the BERT re-ranking module to obtain a list of top-3 intentions (I), effects (E), and attributes (A). These are then further improved by human labeling. A subset of annotations is also converted to full sentences by human annotators.

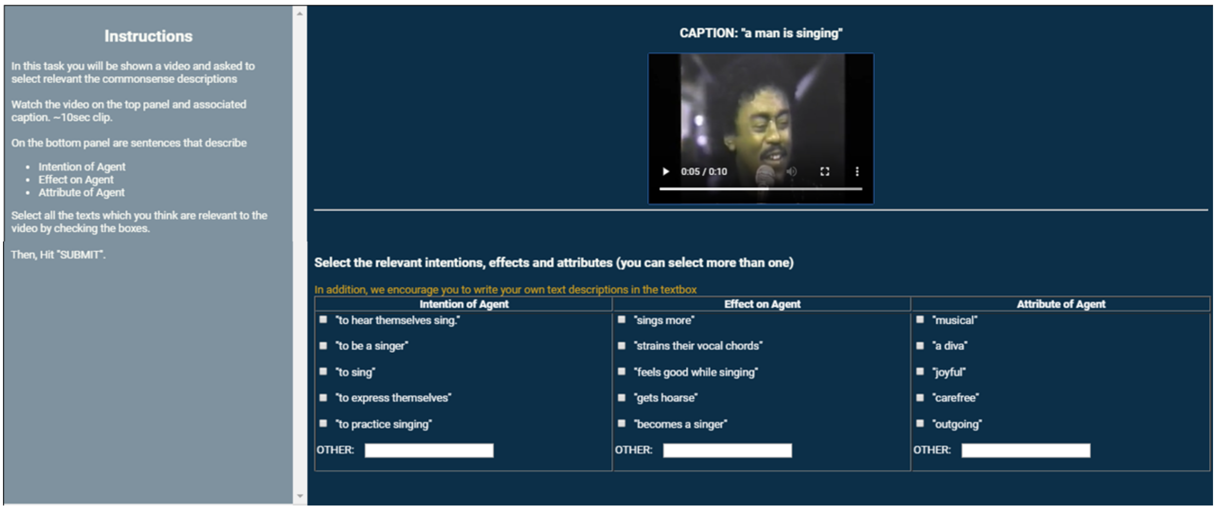

Instructions

In this task you will be shown a video and asked to select relevant the commonsense descriptions

Watch the video on the top panel and associated caption. ~10sec clip.

On the bottom panel are sentences that describe

- Intention of Agent
- Effect on Agent
- Attribute of Agent

Select all the texts which you think are relevant to the video by checking the boxes.

Then, Hit "SUBMIT".

CAPTION: "a man is singing"

Select the relevant intentions, effects and attributes (you can select more than one)

In addition, we encourage you to write your own text descriptions in the textbox

Intention of Agent	Effect on Agent	Attribute of Agent
☐ "to hear themselves sing."	☐ "sings more"	☐ "musical"
☐ "to be a singer"	☐ "strains their vocal chords"	☐ "a diva"
☐ "to sing"	☐ "feels good while singing"	☐ "joyful"
☐ "to express themselves"	☐ "gets hoarse"	☐ "carefree"
☐ "to practice singing"	☐ "becomes a singer"	☐ "outgoing"
OTHER:	OTHER:	OTHER:

Figure 10: Our human labeling interface. We ask human workers to select relevant commonsense descriptions as well provide additional texts in their own words

answer generation code publicly.

C Qualitative Generation Results

We show additional **V2C-Completion** samples by our V2C-Transformer model in Table. 7.

D Human Evaluation

Human evaluation is one of the important part to verify the performances of our model and the quality of the V2C dataset. In this section we describe our setup for human evaluation of the captions and commonsense descriptions in our dataset as well as those generated by our models.

D.1 Amazon Mechanical Turk Interface

We conduct our human evaluations by crowdsourcing ratings from workers on Amazon Mechanical Turk (AMT). We do these human evaluations on the same test set used for our automated metrics. We show an example of our interface in Figure 12 and 13 which shows the screenshot of the rating task as seen by the workers. The workers are given explicit instructions about this rating task, and depending on the task are asked to rate the commonsense descriptions and the caption.

For the V2C-Completion task, the workers are provided with the video and the ground-truth caption and asked to rate the only the generated commonsense (intention, effect or attribute) on a scale of 1 to 5. The workers are asked to provide this rating on the basis of whether the generated text is relevant to the video, i.e whether the caption/commonsense can plausibly complete the given event.

For the V2C-Generation task, the workers are asked to rate the caption as well as the commonsense texts with respect to the video. The workers are also asked to conduct identical tasks for the gold (ground-truth annotations) in our new V2C dataset.

Question Type	Question	Answer
Intention	What might be the goal of the person?	to record a music video
Intention (Negative)	What could the person not want to achieve?	to bake a cake
Intention (Action)	What prompts the person to do the action?	to express themselves
Intention (Action, Negative)	What did not lead the person to act like that?	to feed the dog
Intention (Why)	Why might the person be doing the action?	to entertain viewers
Intention (Yes-No)	Does the person wish to express himself?	Yes
Intention (Yes-No, Negative)	Does the person want to not get recognition?	No
Effect	What will the person do after this?	puts the video on YouTube
Effect (Negative)	What does not happen as a result?	the person gets sad
Effect (Action)	What does the dancing end up in?	becomes tired
Effect (Action, Negative)	What will not happen due to the action?	feels tense
Effect (How)	How does the person feel after performing?	feels accomplised
Effect (Yes-No)	Could the person put it on YouTube as a result?	Yes
Effect (Yes-No, Negative)	Will the person not learn a new dance?	No
Attribute	What trait does the man possess?	musical
Attribute (Negative)	What attribute does not match with the person?	angry
Attribute (How)	How can the person be described?	entertaining
Attribute (Action, How)	How can the dancing person be characterized?	rhythmic
Attribute (Yes-No, Action)	Is the person who is singing smiling?	Yes
Attribute (Yes-No)	Is the person entertaining?	Yes
Attribute (Yes-No, Negative)	Is the person not tense?	Yes

Table 6: Examples of open-ended V2C-QA samples

D.2 Scheme for Validity

Our ratings are measured on a scale of 1 to 5. Annotations which receive a score greater than 3 are considered "valid", so as to be consistent with the binary ratings used by (Bosselut et al., 2019) for their experiments. We then compute average validity scores for each commonsense aspect: intention, attribute and effect.

D.3 Statistics of Human Evaluations

In order to further analyze the human evaluations on our generated outputs, we use three metrics - standard deviation of the ratings, inter-rater agreement score (IRAS) and a smooth version of IRAS. Standard Deviation was calculated per sample based on the evaluations provided by multiple workers on each sample. We do so to evaluate how consistent our AMT workers are and how much they deviate or agree with each other. We use three different metrics so as to analyze our data and generations through multiple lenses, to be certain that the outputs and annotations are high-quality.

D.3.1 Inter-Rater Agreement Score

Inter-Rater Agreement Score is computed as the average of the percentage of raters for each sample that agree with the majority opinion. Let m be the size of the test-set, and n be the number of rating. Let $\mathcal{R}^j = \{r_1, \ldots, r_n\}$ be the set of ratings for test sample j. Then the mode r_{mode} is defined as the most frequently occurring (majority) rating in the set of ratings $\mathcal{R}^j$, i.e. $r_{mode} = \text{MODE}(\mathcal{R}^j)$.

Inter-Rater Agreement Score $\mathbf{IRAS}_{agree}$ is the average percentage of raters that agree with the majority opinion r_{mode}:

$$\mathbf{IRAS} = 100 \times \sum_{j=1}^{m} \frac{\sum_{i=1}^{n} \mathbb{I}(r_i = r_{mode})}{n \times m}, \quad (5)$$

where $\mathbb{I}$ is the indicator function.

D.3.2 Smooth Inter-Rater Agreement Score

While IRAS acts as a good metric to find out how our dataset fares in terms of rater agreement, it suffers from a flaw. Irrespective of the value of ratings, the indicator function $\mathbb{I}$ returns 0 for the tuple of ratings $(1, 5)$ as well as $(4, 5)$, although the

Intention	**Caption**	**Effect**	**Attribute**
to entertain people	a band is performing for a crowd	gets applause	acting
to try out PersonY's new car	a man checks out detail on a car	gets a speeding ticket	helpful
to learn about current events	a complex news host gives an update on rappers.	gets informed about current political events	talkative
to be in a good mood	a group of people trying to perform an exorcism on a girl	gets applause	fun
to show his knowledgeable	there is an old man is answering to somebody questions	gets another question	sporty
to score a point	a man is shooting a basketball ground	gets exercise	helpful
to share their message	a man giving a speech to important people	gets applause	orator
to be safe from anything that lurks in the dark	a group of people are being chased by crocodiles	gets tired from taking pictures	scared
to be informed about the world	a girl is describing about hot news	learns about whats happening worldwide	gossipy
to watch something interesting	a children s television show clip	smiles at the screen	entertained
to enjoy the evening with the concert band	a band composed of older gentlemen are playing blue grass music on a small stage and people are dancing along to the music swing-style	gets tired form dancing	fun
to be part of the team	there is a woman playing badminton in a court	gets tired after exercise	athletic
to try out person ys new car	a boy explaining the features of a car	they check car websites online to look at deals	helpful
to escape reality	a man explaining a video game	takes the video game home	gamer
to cook something	there is a man in black cutting the green leaves on the desk	gets clean dishes	hungry

Table 7: Illustrative samples generated by our V2C-Transformer model on **V2C-completion** task.

	Type	**Std. Dev (%) ↓**		**IRAS(%) ↑**		**smooth-IRAS (%) ↑**	
		ATTENCDEC	V2C-Transformer	ATTENCDEC	V2C-Transformer	ATTENCDEC	V2C-Transformer
V2C-Completion	**Intention**	17.99	15.02	56.02	59.80	69.43	73.36
	Effect	19.63	18.39	58.03	56.76	69.28	69.47
	Attribute	10.54	9.74	69.06	71.28	80.24	81.83
	Average	16.05	14.38	61.04	62.61	72.98	74.89
V2C-Generation	**Intention**	17.60	16.27	57.84	58.47	70.66	72.10
	Effect	18.54	17.56	56.69	57.40	69.54	70.21
	Attribute	15.42	13.16	59.80	62.25	73.51	76.12
	Average	17.19	15.66	58.11	59.37	71.24	72.81

Table 8: A comparison of the statistics of human evaluation scores for both tasks using the baseline (ATTENCDEC model vs. our model (V2C-Transformer)

ratings of 4 and 5 are close to each other but 1 and 5 are opposite. So to avoid this, we replace the indicator function with a smooth exponential term. The smooth inter-rater agreement score is given by:

$$\mathbf{IRAS}_{smooth} = 100 \times \sum_{j=1}^{m} \frac{\sum_{i=1}^{n} \left(\frac{1}{2}\right)^{|r_i - r_{mode}|}}{n \times m}. \tag{6}$$

D.3.3 Results

Table 8 shows our analysis in terms of the three metrics described above. Our V2C-Transformer architecture consistently outperforms the baseline model ATTENCDEC (Gao et al., 2017) in all three metrics for each type of commonsense. This means that raters are more consistent with their ratings (in terms of deviation or agreement) for commonsense descriptions generated by our model.

The person wants:

Does my multimodal model learn cross-modal interactions? It's harder to tell than you might think!

Abstract

Modeling expressive cross-modal interactions seems crucial in multimodal tasks, such as visual question answering. However, sometimes high-performing black-box algorithms turn out to be mostly exploiting unimodal signals in the data. We propose a new diagnostic tool, *empirical multimodally-additive function projection* (EMAP), for isolating whether or not cross-modal interactions improve performance for a given model on a given task. This function projection modifies model predictions so that cross-modal interactions are eliminated, isolating the additive, unimodal structure. For seven image+text classification tasks (on each of which we set new state-of-the-art benchmarks), we find that, in many cases, removing cross-modal interactions results in little to no performance degradation. Surprisingly, this holds even when expressive models, with capacity to consider interactions, otherwise outperform less expressive models; thus, performance improvements, even when present, often cannot be attributed to consideration of cross-modal feature interactions. We hence recommend that researchers in multimodal machine learning report the performance not only of unimodal baselines, but also the EMAP of their best-performing model.

1 Introduction

Given the presumed importance of reasoning across modalities in multimodal machine learning tasks, we should evaluate a model's ability to leverage cross-modal interactions. But such evaluation is not straightforward; for example, an early Visual Question-Answering (VQA) challenge was later "broken" by a high-performing method that ignored the image entirely (Jabri et al., 2016).

One response is to create multimodal-reasoning datasets that are specifically and cleverly balanced to resist language-only or visual-only models; examples are VQA 2.0 (Goyal et al., 2017), NLVR2 (Suhr et al., 2019), and GQA (Hudson and Manning, 2019). However, a balancing approach not always desirable. For example, if image+text data is collected from an online social network (such as for popularity prediction or sentiment analysis), post-hoc rebalancing may obscure trends in the original data-generating processs. So, what alternative diagnostic tools are available for better understanding what models learn?

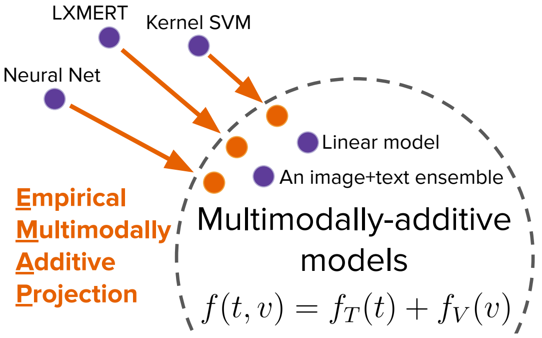

Figure 1: We introduce EMAP, a diagnostic for classifiers that take in $\underline{t}$extual and $\underline{v}$isual inputs. Given a (black-box) trained model, EMAP computes the predictions of an image/text ensemble that best approximates the full model predictions via empirical function projection. Although the projected predictions lose visual-textual interaction signals exploited by the original model, they often perform suprisingly well.

The main tool utilized by prior work is *model comparison.* In addition to comparing against text-only and image-only baselines, often, two multimodal models with differing representational capacity (e.g., a cross-modal attentional neural network vs. a linear model) are trained and their performance compared. The argument commonly made is that if model A, with greater expressive capacity, outperforms model B, then the performance differences can be at least partially attributed to that increased expressivity.

But is that a reliable argument? Model perfor-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 861–877,
November 16–20, 2020. ©2020 Association for Computational Linguistics

mance comparisons are an opaque tool for analysis, especially for deep neural networks: performance differences versus baselines, frequently small in magnitude, can often be attributed to hyperparameter search schemes, random seeds, the number of models compared, etc. (Yogatama and Smith, 2015; Dodge et al., 2019). Thus, while model comparisons are an acceptable starting point for demonstrating whether or not a model is learning an interesting set of (or any!) cross-modal factors, they provide rather indirect evidence.

We propose *Empirical Multimodally-Additive*[1] *function Projection* (EMAP) as an additional diagnostic for analyzing multimodal classification models. Instead of comparing two different models, a single multimodal classifier's predictions are *projected* onto a less-expressive space: the result is equivalent to a set of predictions made by the closest possible ensemble of text-only and visual-only classifiers. The projection process is computationally efficient, has no hyperparameters to tune, can be implemented in a few lines of code, is provably unique and optimal, and works on any multimodal classifier: we apply it to models ranging from polynomial kernel SVMs to deep, pretrained, Transformer-based self-attention models.

We first verify that EMAPs do degrade performance for synthetic cases and for visual question answering cases where datasets have been specifically designed to require cross-modal reasoning. But we then examine a test suite of several recently-proposed multimodal prediction tasks that have *not* been specifically balanced in this way. We first achieve state-of-the-art performance for all of the datasets using a linear model. Next, we examine more expressive interactive models, e.g., pretrained Transformers, capable of cross-modal attention. While these models sometimes outperform the linear baseline, EMAP reveals that performance gains are (usually) not due to multimodal interactions being leveraged.

Takeaways: For future work on multimodal classification tasks, we recommend authors report the performance of: 1) unimodal baselines; 2) any multimodal models they consider; and, *critically,* 3) the *empirical multimodally-additive projection* (EMAP) of their best performing multimodal model (see §6 for our full recommendations).

2 Related Work

Constructed multimodal classification tasks. In addition to image question answering/reasoning datasets already mentioned in §1, other multimodal tasks have been constructed, e.g., video QA (Lei et al., 2018; Zellers et al., 2019), visual entailment (Xie et al., 2018), hateful multimodal meme detection (Kiela et al., 2020), and tasks related to visual dialog (de Vries et al., 2017). In these cases, unimodal baselines are shown to achieve lower performance relative to their expressive multimodal counterparts.

Collected multimodal corpora. Recent computational work has examined diverse multimodal corpora collected from in-vivo social processes, e.g., visual/textual advertisements (Hussain et al., 2017; Ye and Kovashka, 2018; Zhang et al., 2018), images with non-literal captions in news articles (Weiland et al., 2018), and image/text instructions in cooking how-to documents (Alikhani et al., 2019). In these cases, multimodal classification tasks are often proposed over these corpora as a means of testing different theories from semiotics (Barthes, 1988; O'Toole, 1994; Lemke, 1998; O'Halloran, 2004, inter alia); unlike many VQA-style datasets, they are generally not specifically balanced to force models to learn cross-modal interactions.

Without rebalancing, should we expect cross-modal interactions to be useful for these multimodal communication corpora? Some semioticians posit: *yes! Meaning multiplication* (Barthes, 1988) between images and text suggests, as summarized by Bateman (2014):

> under the right conditions, the value of a combination of different modes of meaning can be worth more than the information (whatever that might be) that we get from the modes when used alone. In other words, text 'multiplied by' images is more than text simply occurring with or alongside images.

Jones et al. (1979) provide experimental evidence of conditional, compositional interactions between image and text in a humor setting, concluding that "it is the dynamic interplay between picture and caption that describes the multiplicative relationship" between modalities. Taxonomies of the specific types of compositional relationships image-text pairs can exhibit have been proposed (Marsh and Domas White, 2003; Martinec and Salway, 2005).

---

[1] In §3, we more formally introduce *additivity*.

Model Interpretability. In contrast to methods that design more interpretable algorithms for prediction (Lakkaraju et al., 2016; Ustun and Rudin, 2016), several researchers aim to explain the behavior of complex, black-box predictors on individual instances (Štrumbelj and Kononenko, 2010; Ribeiro et al., 2016). The most related of these methods to the present work is Ribeiro et al. (2018), who search for small sets of "anchor" features that, when fixed, largely determine a model's output prediction on the input points. While similar in spirit to ours and other methods that "control for" a fixed subset of features (e.g., Breiman (2001)), their work 1) focuses only on high-precision, local explanations on single instances; 2) doesn't consider multimodal models (wherein feature interactions are combinatorially more challenging in comparison to unimodal models); and 3) wouldn't guarantee consideration of multimodal "anchors."

3 EMAP

Background. We consider models f that assign scores to textual-visual pairs (t, v), where t is a piece of text (e.g., a sentence), and v is an image.[2] In multi-class classification settings, values $f(t, v) \in \mathbb{R}^d$ typically serve as per-class scores. In ranking settings $f(t_1, v_1)$ may be compared to $f(t_2, v_2)$ via a ranking objective.

We are particularly interested in the types of compositionality that f uses over its visual and textual inputs to produce scores. Specifically, we distinguish between *additive* models (Hastie and Tibshirani, 1987) and *interactive* models (Friedman, 2001; Friedman and Popescu, 2008).[3] A function f of a representation z of n input features is *additive* in I if it decomposes as

$$f(z) = f_I(z_I) + f_{\setminus I}(z_{\setminus I}),$$

where (setting $\mathcal{I} = \{1, \ldots, n\}$ for convenience) $I \subset \mathcal{I}$ indexes a subset of the features, $\setminus I = \mathcal{I} \setminus I$, and for any $S \subset \mathcal{I}$, z_S is the restriction of z to only those features whose indices appear in S.

In our case, because features are the union of Textual and Visual predictors, we say that a model is *multimodally additive* if it decomposes as

$$f(t, v) = f_T(t) + f_V(v) \qquad (1)$$

Additive multimodal models are simply ensembles of unimodal classifiers and as such, may be considered underwhelming to multiple communities. A recent ACL paper, for example, refers to such ensembles as "naive." On the semiotics side, the conditionality implied by meaning multiplication (Barthes, 1988) — that the joint semantics of an image/caption depends non-linearly on its accompaniment — cannot be modeled additively: multimodally additive models posit that each image, independent of its text pairing, contributes a fixed score to per-class logits (and vice versa).

In contrast, *multimodally interactive* models are the set of functions that *cannot* be decomposed as in Equation 1 — that is, f's output conditionally depends on its inputs in a non-additive fashion.

Machine learning models. One canonical multimodally additive model is a linear model trained over a concatenation of textual and visual features $[t; v]$, i.e.,

$$f(t, v) = w^T[t; v] + b = \underbrace{w_t^T t}_{f_T(t)} + \underbrace{w_v^T v + b}_{f_V(v)}. \qquad (2)$$

We later detail several multimodally interactive models, including multi-layer neural networks, polynomial kernel SVMs, pretrained Transformer attention-based models, etc. However, even though interactive models are *theoretically capable* of modeling a more expressive set of relationships, it's not clear that they will learn to exploit this additional expressivity, particularly when simpler patterns suffice.

Empirical multimodally-additive projections: EMAP. Given a fixed, trained model f (usually one theoretically capable of modeling visual-textual interactions) and a set of N labelled datapoints $\{(v_i, t_i, y_i)\}_{i=1}^N$, we aim to answer: *does f utilize cross-modal feature interactions to produce more accurate predictions for these datapoints?*

Hooker (2004) gives a general method for computing the projection of a function f onto a set of functions with a specified ANOVA structure (see also Sobol (2001); Liu and Owen (2006)): our algorithmic contributions are to extend the method to multimodal models with $d > 1$ dimensional outputs, and to prove that the multimodal empirical approximation is optimal. Specifically: we are

---

[2] The methods introduced here can be easily extended beyond just text/image pairs (e.g., to videos, audio, etc.), and to more than two modalites.

[3] The multimedia commonly makes a related distinction between *early fusion* (joint multimodal processing) and *late fusion* (ensembles) (Snoek et al., 2005).

Algorithm 1 Empirical Multimodally-Additive Projection (EMAP); worked example in Appendix G.

```
Input: a trained model $f$ that outputs logits; a set of text/visual pairs $\mathcal{D} = \{(t_i, v_i)\}_{i=1}^{N}$
Output: the predictions of $\hat{f}$, the empirical projection of $f$ onto the set of multimodally-additive functions, on $\mathcal{D}$.

$f_{cache} = 0_{N \times N \times d}$; $\text{preds}_{\hat{f}} = 0_{N \times d}$
for $i, j \in \{1, 2, \ldots, N\} \times \{1, 2, \ldots, N\}$ do
    $f_{cache}(i, j) = f(t_i, v_j)$
end for
$\hat{\mu} \in \mathbb{R}^d = \frac{1}{N^2} \sum_{i,j} f_{cache}(i, j)$
for $i \in \{1, 2, \ldots, N\}$ do
    $\text{proj}_t = \frac{1}{N} \sum_{j=1}^{N} f_{cache}(i, j)$
    $\text{proj}_v = \frac{1}{N} \sum_{j=1}^{N} f_{cache}(j, i)$
    $\text{preds}_{\hat{f}}[i] = \text{proj}_t + \text{proj}_v - \hat{\mu}$
end for
return $\text{preds}_{\hat{f}}$
```

interested in $\tilde{f}$, the following projection of f onto the set of multimodally-additive functions:

$$\tilde{f}(t, v) = \underbrace{\mathbb{E}_{v}[f(t, v)]}_{f_T(t)} + \underbrace{\mathbb{E}_{t}[f(t, v)]}_{f_V(v)} - \underbrace{\mathbb{E}_{t,v}[f(t, v)]}_{\mu}$$

where $\mathbb{E}_v[f(t, v)]$, a function of t, is the *partial dependence* of f on t, i.e., $f_T(t) = \mathbb{E}_v[f(t, v)] = \int f(t, v)p(v)dv$,[4] and similarly for the other expectations. An empirical approximation of the partial dependence function for a given t_i can be computed by looping over all observations:

$$\hat{f}_T(t_i) = \frac{1}{N} \sum_{j=1}^{N} f(t_i, v_j)\,.$$

We similarly arrive at $\hat{f}_V(v_i)$ and $\hat{\mu}$, yielding

$$\hat{f}(t_i, v_i) = \hat{f}_T(t_i) + \hat{f}_V(v_i) + \hat{\mu} \qquad (3)$$

which is what EMAP, Algorithm 1, computes for each (t_i, v_i). Note that Algorithm 1 involves evaluating the original model f on all N^2 $\langle v_i, t_j \rangle$ pairs — even mismatched image/text pairs that do not occur in the observed data. In practice, we recommend only computing this projection over the evaluation set.[5] Once the predictions of f and $\hat{f}$ are computed over the evaluation points, then their performance can be compared according to standard evaluation metrics, e.g., accuracy or AUC.

In Appendix A, we prove that the (mean-centered) sum of empirical partial dependence functions is optimal with respect to squared error, that is:

Claim. *Subject to the constraint that $\hat{f}$ is multimodally additive, Algorithm 1 produces a unique and optimal solution to*

$$\underset{\hat{f}\text{ values}}{\arg\min} \sum_{i,j} \|f(t_i, v_j) - \hat{f}(t_i, v_j)\|_2^2. \qquad (4)$$

4 Sanity Check: EMAP Hurts in Tasks that Require Interaction

In §5.1, we will see that EMAP provides a very strong baseline for "unbalanced" multimodal classification tasks. But first, we first seek to verify that EMAP degrades model performance in cases that are designed to require cross-modal interactions.

Synthetic data

We generate a set of "visual"/"textual"/label data (v, t, y) according to the following process:[6]

1. Sample random projection $V \in \mathbb{R}^{d_1 \times d}$ and $T \in \mathbb{R}^{d_2 \times d}$ from $U(-.5, .5)$.
2. Sample $v, t \in \mathbb{R}^d \sim N(0, 1)$; normalize to unit length.
3. If $|v \cdot t| > \delta$ proceed, else, return to the previous step.
4. If $v \cdot t > 0$, then $y = 1$, else $y = 0$.
5. Return the data point (Vv, Tt, y).

This function challenges models to learn whether or not the dot product of two randomly sampled vectors in d dimensions is positive or negative — a task that, by construction, requires modeling the multiplicative interaction of the features in these vectors. To complicate the task, the vectors are randomly projected to two "modalities" of different dimensions, d_1 and d_2 respectively.

We trained a linear model, a polynomial kernel SVM, and a feed-forward neural network on this data: the results are in Table 1. The linear model is additive and thus incapable of learning any meaningful pattern on this data. In contrast, the kernel SVM and feed-forward NN, interactive models, are able to fit the test data almost perfectly. However, when we apply EMAP to the interactive models, as expected, their performance drops to random.

---

[4] Both Friedman (2001) and Hooker (2004) argue that this expectation should be taken over the marginal $p(v)$ rather than the conditional $p(v|t)$.

[5] When even restricting to the evaluation set would be too expensive, as in the case of the R-POP data we experiment with later, one can repeatedly run EMAP on randomly-drawn 500-instance (say) samples from the test set.

[6] We sample 5K points in an 80/10/10 train/val/test split with $\langle d, d_1, d_2, \delta \rangle = \langle 100, 2000, 1000, .25 \rangle$, though similar results were obtained with different parameter settings.

	Linear (A)	Poly (I)	NN (I)
Test Acc	52.8%	99.6%	99.0%
↳ + EMAP	52.8%	49.4%	53.8%

Table 1: Prediction accuracy on synthetic dataset using additive (A) models, interactive (I) models, and their EMAP projections. Random guessing achieves 50% accuracy. Under EMAP, the interactive models degrade to (close to) random, as desired. See §5 for training details.

Balanced VQA Tasks

Our next sanity check is to verify that EMAP hurts the performance of interactive models on two real multimodal classification tasks that are specifically balanced to require modeling cross-modal feature interactions: VQA 2.0 (Goyal et al., 2017) and GQA (Hudson and Manning, 2019).

First, we fine-tuned LXMERT (Tan and Bansal, 2019), a multimodally-interactive, pretrained, 14-layer Transformer model (See §5 for full description) that achieves SOTA on both datasets. The LXMERT authors frame question-answering as a multi-class image/text-pair classification problem — 3.1K candidate answers for VQA2, and 1.8K for GQA. In Table 2, we compare, in cross-validation, the means of: 1) accuracy of LXMERT, 2) accuracy of the EMAP of LXMERT, and 3) accuracy of simply predicting the most common answer for all questions. As expected, EMAP decreases accuracy on VQA2/GQA by 30/19 absolute accuracy points, respectively: this suggests LXMERT is utilizing feature interactions to produce more accurate predictions on these datasets. On the other hand, performance of LXMERT's EMAP remains substantially better than constant prediction, suggesting that LXMERT's logits do nonetheless leverage some unimodal signals in this data.[7]

5 "Unbalanced" Datasets + Tasks

We now return to our original setting: multimodal classification tasks that have not been specifically formulated to force cross-modal interactions. Our goal is to explore what additional insights EMAP can add on top of standard model comparisons.

We consider a suite of 7 tasks, summarized in Table 3. These tasks span a wide variety of goals, sizes, and structures: some aim to classify semiotic properties of image+text posts, e.g., examining the extent of literal image/text overlap (I-SEM, I-CTX, T-VIS); others are post-hoc annotated according to taxonomies of social interest (I-INT, T-ST1, T-ST2); and one aims to directly predict community response to content (R-POP).[8] In some cases, the original authors emphasize the potentially complex interplay between image and text: Hessel et al. (2017) wonder if "visual and the linguistic interact, sometimes reinforcing and sometimes counteracting each other's individual influence;" Kruk et al. (2019) discuss meaning multiplication, emphasizing that "the text+image integration requires inference that creates a new meaning;" and Vempala and Preoţiuc-Pietro (2019) attribute performance differences between their "naive" additive baseline and their interactive neural model to the notion that "both types of information and their interaction are important to this task."

	LXMERT	→EMAP	Const Pred
VQA2	70.3	40.5	23.4
GQA	60.3	41.0	18.1

Table 2: As expected, for VQA2 and GQA, the mean accuracy of LXMERT is substantially higher than its empirical multimodally additive projection (EMAP). Shown are averages over $k = 15$ random subsamples of 500 dev-set instances.

Our goal is not to downplay the importance of these *datasets and tasks;* it may well be the case that conditional, compositional interactions occur between images and text, but the models we consider do not yet take full advantage of them (we return to this point in item 6). Our goal, rather, is to provide diagnostic tools that can provide additional clarity on the *remaining* shortcomings of current models and reporting schemes.

Additive and Unimodal Models

The additive model we consider is the linear model from Equation 2 trained over the concatenation of image and text representations.[9] To represent im-

---

[7] EMAPed LXMERT's performance is comparable to LSTM-based, text-only models, which achieve 44.3/41.1 accuracy on the full VQA2/GQA test set, respectively.

[8] In Appendix B, we include descriptions of our reproduction efforts for each dataset/task, but please see the original papers for fuller descriptions of the data/tasks.

[9] For all linear models in this work, we select optimal hyperparameters according to grid search, optimizing validation model performance for each cross-validation split separately. We optimize: regularization type (L1, L2, vs. L1/L2),

Original paper	Task (structure)	Abbrv.	# image+text pairs we recovered
Kruk et al. (2019)	Instagram		
	↳ intent (7-way classification)	I-INT	1.3K
	↳ semiotic (3-way clf)	I-SEM	1.3K
	↳ contextual (3-way clf)	I-CTX	1.3K
Vempala and Preoţiuc-Pietro (2019)	Twitter visual-ness (4-way clf)	T-VIS	3.9K
Hessel et al. (2017)	Reddit popularity (pairwise ranking)	R-POP	87.2K
Borth et al. (2013)	Twitter sentiment (binary clf)	T-ST1	.6K
Niu et al. (2016)	Twitter sentiment (binary clf)	T-ST2	4.0K

Table 3: The tasks we consider are not specifically balanced to force the learning of cross-modal interactions.

ages, we extract a feature vector from a pretrained EfficientNet B4[10] (Tan and Le, 2019). To represent text, we extract RoBERTa (Liu et al., 2019) token features, and mean pool.[11] Our single-modal baselines are linear models fit over EfficientNet/RoBERTa features directly.

Interactive Models

Kernel SVM. We train an SVM with a polynomial kernel using RoBERTa text features and EfficientNet-B4 image features as input. A polynomial kernel endows the model with capacity to model multiplicative interactions between features.[12]

Neural Network. We train a feed-forward neural network using the RoBERTa/EfficientNet-B4 features as input. Following Chen et al. (2017), we first project text and image features via an affine transform layer to representations t and v, respectively, of the same dimension. Then, we extract new features, feeding the concatenated feature vector $[t; v; v - t; v \odot t]$ to a multi-layer, feed-forward network.[13]

Fine-tuning a Pretrained Transformer. We fine-tuned LXMERT (Tan and Bansal, 2019) for our tasks. LXMERT represents images using 36 predicted bounding boxes, each of which is assigned a feature vector by a Faster-RCNN model (Ren et al., 2015; Anderson et al., 2018). This model uses ResNet-101 (He et al., 2016) as a backbone and is pretrained on Visual Genome (Krishna et al., 2017). Bounding box features are fed through LXMERT's 5-layer Transformer (Vaswani et al., 2017) model. Text is processed by a 9-layer Transformer. Finally, a 5-layer, cross-modal transformer processes the outputs of these unimodal encoders jointly, allowing for feature interactions to be learned. LXMERT's parameters are pre-trained on several cross-modal reasoning tasks, e.g., masked image region/language token prediction, cross-modal matching, and visual question answering. LXMERT achieves high performance on balanced tasks like VQA 2.0: thus, we *know* this model can learn compositional, cross-modal interactions in some settings.[14]

LXMERT + logits: We also trained versions of LXMERT where fixed logits from a pretrained linear model (described above) are fed in to the final classifier layer. In this case, LXMERT is only tasked with learning the residual between the strong additive model and the labels. Our intuition was that this augmentation might enable the model to focus more closely on learning interactive, rather than additive, structure in the fine-tuning process.

5.1 Results

Our main prediction results are summarized in Table 4. For all tasks, the performance of our baseline additive linear model is strong, but we are usually able to find an interactive model that outperforms this linear baseline, e.g., in the case of T-ST2, a polynomial kernel SVM outperforms the linear model by 4 accuracy points. This observation alone *seems* to provide evidence that models

---

regularization strength (10**(-7,-6,-5,-4,-3,-2,-1,0,1.0)), and loss type (logistic vs. squared hinge). We train models using `lightning` (Blondel and Pedregosa, 2016).

[10] For reproducibility, we used ResNet-18 features for the Kruk et al. (2019) datasets; more detail in Appendix E.

[11] Feature extraction approaches are known to produce competitive results relative to full fine-tuning (Devlin et al., 2019, §5.3); in some cases, mean pooling has been found to be similarly competitive relative to LSTM pooling (Hessel and Lee, 2019).

[12] We again use grid search to optimize: polynomial kernel degree (2 vs. 3), regularization strength (10**(-5,-4,-3,-2,-1,0)), and gamma (1, 10, 100).

[13] Parameters are optimized with the Adam optimizer (Kingma and Ba, 2015). We decay the learning rate when validation loss plateaus. The hyperparameters optimized in grid search are: number of layers (2, 3, 4), initial learning rate (.01, .001, .0001), activation function (relu vs. gelu), hidden dimension (128, 256), and batch norm (use vs. don't).

[14] We follow the original authors' fine-tuning recommendations, but also optimize the learning rate according to validation set performance for each cross-validation split/task separately between 1e-6, 5e-6, 1e-5, 5e-5, and 1e-4.

Table 4: Prediction results for 7 multimodal classification tasks. First block: the evaluation metric, setup, constant prediction performance, and previous state-of-the-art results (we outperform these baselines mostly because we use RoBERTa). Second block: the performance of our image only/text only linear models. Third block: the predictive performance of our **(I)**nteractive models. Fourth block: comparison of the performance of the best **(I)**nteractive model to the **(A)**dditive linear baseline. Crucially, we also report the EMAP of the best interactive model, which reveals whether or not the performance gains of the **(I)**nteractive model are due to modeling cross-modal interactions, or not. Italics=computed using 15 fold cross-validation over each cross-validation split (see footnote 5). Bolded values are within half a point of the best model.

are taking advantage of some cross-modal interactions for performance gains. Previous analyses might conclude here, arguing that cross-modal interactions are being utilized by the model meaningfully. *But is this necessarily the case?*

We utilize EMAP as an additional model diagnostic by projecting the predictions of our best-performing interactive models. Surprisingly, for I-INT, I-SEM, I-CTX, T-ST1, T-ST2, and R-POP, EMAP results in *essentially no performance degradation.* Thus, even (current) expressive interactive models are usually unable to leverage cross-modal feature interactions to improve performance. This observation would be obfuscated without the use of additive projections, even though we compared to a strong linear baseline that achieves state-of-the-art performance for each dataset. *This emphasizes the importance of not only comparing to additive/linear baselines, but also to the EMAP of the best performing model.*

In total, for these experiments, we observe a single case, LXMERT + Linear Logits trained on T-VIS, wherein modeling cross-modal feature interactions appears to result in noticeable performance increases — here, the EMAPed model is 2.4 F1 points worse.

How much does EMAP change a model's predictions? For these datasets, a model and its EMAP usually make very similar predictions. For all datasets except T-VIS (where EMAP degrades performance) the best model and its EMAP agree on the most likely label in more than 95% of cases on average. For comparison, retraining the full models with different random seeds results in a 96% agreement on average. (Full results are in Appendix C.)

6 Implication FAQs

Q1: What is your recommended experimental workflow for future work examining multimodal classification tasks?

A: With respect to automated classifiers, we recommend reporting the performance of:

1. A constant and/or random predictor

   to provide perspective on the interplay between the label distribution and the evaluation metrics.

2. As-strong-as-possible single-modal models $f(t, v) = g(t)$ and $f(t, v) = h(v)$

   to understand how well the task can be addressed unimodally with present techniques.

3. An as-strong-as-possible multimodally additive model $f(t,v) = f_T(t) + f_V(v)$

   to understand multimodal model performance without access to sophisticated cross-modal reasoning capacity.

4. An as-strong-as-possible multimodally interactive model, e.g., LXMERT,

   to push predictive performance as far as possible.

5. The EMAP of the strongest multimodally interactive model.

   to determine whether or not the best interactive model is truly using cross-modal interactions to improve predictive performance.

We hope this workflow can be extended with additional, newly developed model diagnostics going forward.

Q2: Should papers proposing new tasks be rejected if image-text interactions aren't shown to be useful?

A: *Not necessarily.* The value of a newly proposed task should not depend solely on how well current models perform on it. Other valid ways to demonstrate dataset/task efficacy: human experiments, careful dataset design inspired by prior work, or real-world use-cases.

Q3: Can EMAP tell us anything fundamental about the type of reasoning required to address different tasks themselves?

A: *Unfortunately, no more than model comparisons can (at least for real datasets).* EMAP is a tool that, like model comparison, provides insights about how specific, fixed models perform on specific, fixed datasets. In FAQ 5, we attempt to bridge this gap in a toy setting where we are able to fully enumerate the sample space.

Q4: Can EMAP tell us anything about individual instances?

A: *Yes; but with caveats.* While a model's behavior on individual cases is difficult to draw conclusions from, EMAP can be used to identify single instances within evaluation datasets for which the model is performing enough non-additive computation to change its ultimate prediction, i.e., for a given (t,v), it's easy to compare $f(t,v)$ to $\mathsf{EMAP}(f(t,v))$: these correspond to the inputs and outputs respectively of Algorithm 1. An example instance-level qualitative evaluation of T-VIS is given in Appendix F.

Q5: Do the strong EMAP results imply that most functions of interest are actually multimodally additive?

Short A: *No.*

Long A: A skeptical reader might argue that, while multimodally-additive models cannot account for cross-modal feature interactions, such feature interactions may not be required for cross-modal reasoning. While we authors are not aware of an agreed-upon definition,[15] we will assume that "cross-modal reasoning tasks" are those that challenge models to compute (potentially arbitrary) logical functions of multimodal inputs. Under this assumption, we show that additive models cannot fit (nor well-approximate) most non-trivial logical functions.

Consider the case of multimodal boolean target functions $f(t,v) \in \{0,1\}$, and assume our image/text input feature vectors each consist of n binary features, i.e., $t, v = \langle t_1, \dots t_n \rangle, \langle v_1, \dots v_n \rangle$ where $t_i, v_i \in \{0,1\}$. Our goal will be to measure how well multimodally additive models can fit arbitrary logical functions f. To simplify our analysis in this idealized case: we assume 1) access to a training set consisting of all 2^{2n} input vector pairs, and only measure training accuracy (vs. the harder task of generalization) and 2) "perfect" unimodal representations in the sense that t, v contain all of the information required to compute $f(t,v)$ (this is not the case for, e.g., CNN/RoBERTa features for actual tasks).

For very small cross-modal reasoning tasks, additive models can suffice. At $n = 1$, there are 16 possible binary functions $f(t_1, v_1)$, and 14/16 can be perfectly fit by a function of the form $f_T(t_1) + f_V(v_1)$ (the exceptions being XOR and XNOR). For $n = 2$, non-trivial functions are still often multimodally additively representable; an arguably surprising example is this one: $(t2 \land \neg v2) \lor (t1 \land t2 \land v1) \lor (\neg t1 \land \neg v1 \land \neg v2)$. But for cross-modal reasoning tasks with more variables,[16] even in this toy setting, multimodally-

---

[15] Suhr et al. (2019), for example, do not define "visual reasoning with natural language," but do argue that some tasks offer a promising avenue to study "reasoning that requires composition" via visual-textual grounding.

[16] As a lower bound on the number of variables required in a more realistic case, consider a cross-modal reasoning task where questions are posed regarding the counts of, say, 1000 object types in images. It's likely that a separate image variable representing the count of each possible type of object would be required. While an oversimplification, for most cross-modal reasoning tasks, $2n = 6$ variables is still relatively small.

additive models ultimately fall short: for the $n = 3$ case, we sampled over 5 million random logical circuits and none were perfectly fit by the additive models. To better understand how well additive models can *approximate* various logical functions, we fit two types of them for the $n > 2$ case: 1) the EMAP of the input function f directly, and 2) AdaBoost (Freund and Schapire, 1995) with the weak learners restricted to unimodal models.[17] For a reference interactive model, we employ AdaBoost without the additivity restriction.

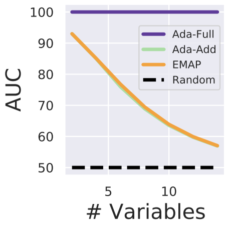

Figure 2: Perf. of additive models on fitting logical circuits.

Figure 2 plots the AUC of the 3 models on the training set; we sample 10K random logical circuits for each problem size. As the number of variables increases, the performance of the additive models quickly decreases (though full AdaBoost gets 100% accuracy in all cases). While these experiments are only for a toy case, they show that EMAPs, and additive models generally, have very limited capacity to compute or approximate logical functions of multimodal variables.

7 Conclusion and Future Work

The last question on our FAQ list in §6 leaves us with the following conundrum: 1) Additive models are incapable of most cross-modal reasoning; but 2) for most of the unbalanced tasks we consider, EMAP finds an additive approximation that makes nearly identical predictions to the full, interactive model. We postulate the following potential explanations, pointing towards future work:

- Hypothesis 1: These unbalanced tasks don't require complex cross-modal reasoning. This purported conclusion cannot account for gaps between human and machine performance: if an additive model underperforms relative to human judgment, the gap could plausibly be explained by cross-modal feature interactions. But even in cases where an additive model matches or exceeds human performance on a fixed dataset, additive models may still be insufficient. The mere fact that unimodal and additive models *can* often be disarmed by adding valid (but carefully selected) instances post hoc (as in, e.g., Kiela et al. (2020)) suggests that their inductive bias can simultaneously be sufficient for train/test generalization, but also fail to capture the spirit of the task. Future work would be well-suited to explore 1) methods for better understanding which datasets (and individual instances) can be rebalanced and which cannot; and 2) the non-trivial task of estimating additive *human* baselines to compare against.
- Hypothesis 2: Modeling feature interactions can be data-hungry. Jayakumar et al. (2020) show that feed-forward neural networks can require a very high number of training examples to learn feature interactions. So, we may need models with different inductive biases and/or much more training data. Notably, the feature interactions learned even in balanced cases are often not interpretable (Subramanian et al., 2019).
- Hypothesis 3: Paradoxically, unimodal models may be too weak. Without expressive enough single-modal processing methods, opportunities for learning cross-modal interaction patterns may not be present during training. So, improvements in unimodal modeling could feasibly improve feature interaction learning.

Concluding thoughts. Our hope is that future work on multimodal classification tasks report not only the predictive performance of their best model + baselines, but also the EMAP of that model. EMAP (and related algorithms) has practical implications beyond image+text classification: there are straightforward extensions to non-visual/non-textual modalities, to classifiers using more than 2 modalities as input, and to single-modal cases where one wants to check for feature interactions between two groups of features, e.g., premise/hypothesis in NLI.

Acknowledgments

In addition to the anonymous reviewers and meta-reviewer, the authors would like to thank Ajay Divakaran, Giles Hooker, Jon Kleinberg, Julia Kruk, Tianze Shi, Ana Smith, Alane Suhr, and Gregory Yauney for the helpful discussions and feedback. We thank the NVidia Corporation for providing some of the GPUs used in this study. JH performed this work while at Cornell University. Partial support for this work was kindly provided by a grant from The Zillow Corporation, and a Google

---

[17] AdaBoost is chosen because it has strong theoretical guarantees to fit to training data: see Appendix D.

A Theoretical Analysis of Algorithm 1

We assume we are given a (usually evaluation) dataset $D = \{\langle t_i, v_i \rangle\}_{i=1}^{n}$ and a trained model f that maps $\langle t_i, v_i \rangle$ pairs to a d-dimensional vector of scores. We seek a multimodally-additive function $\hat{f}$ that matches the values of f on any $\langle t_i, v_j \rangle$ for which there exist v', t' such that $\langle t_i, v' \rangle \in D$ and $\langle t', v_j \rangle \in D$; that is, $\langle t_i, v_j \rangle$ represents any text-image pair we could construct if we decoupled the existing pairs in D.[18]

For simplicity, first assume that $d = 1$ (we handle the $d > 1$ case later). Since $\hat{f}$ is multimodally-additive by assumption, $\exists\, \hat{f}_t, \hat{f}_v$ such that $\hat{f}(t_i, v_j) = \hat{f}_t(t_i) + \hat{f}_v(v_j)$. Our goal is to find the "best" $2n$ values $\hat{f}_t(t_i), \hat{f}_v(v_j)$, or — writing f_{ij} for $f(t_i, v_j)$, τ_i for $\hat{f}_t(t_i)$, and ϕ_j for $\hat{f}_v(v_j)$ for notational convenience — to find τ_i, ϕ_j minimizing

$$\mathcal{L} = \frac{1}{2} \sum_i \sum_j (f_{ij} - \tau_i - \phi_j)^2 \tag{5}$$

Claim 1. *$\mathcal{L}$ is convex.*

Proof. The first-order partial derivatives are:

$$\frac{\partial \mathcal{L}}{\partial \tau_i} = n \cdot \tau_i + \sum_j (\phi_j - f_{ij})$$

$$\frac{\partial \mathcal{L}}{\partial \phi_j} = n \cdot \phi_j + \sum_i (\tau_i - f_{ij})$$

and the Hessian $\mathcal{H}$ is

$$\mathcal{H} = \begin{bmatrix} nI & \mathbf{1} \\ \mathbf{1} & nI \end{bmatrix}, \quad I, \mathbf{1} \in \mathbb{R}^{n \times n}$$

It suffices to show that $\mathcal{H}$ is positive semi-definite, i.e., for any $z \in \mathbb{R}^{2n}$, $z^T \mathcal{H} z \geq 0$. Indeed,

$$\begin{aligned} z^T \mathcal{H} z &= z^T \begin{bmatrix} nz_1 + \sum_{j=n+1}^{2n} z_j \\ nz_2 + \sum_{j=n+1}^{2n} z_j \\ \vdots \\ nz_n + \sum_{j=n+1}^{2n} z_j \\ nz_{n+1} + \sum_{i=1}^{n} z_i \\ nz_{n+2} + \sum_{i=1}^{n} z_i \\ \vdots \\ nz_{2n} + \sum_{i=1}^{n} z_i \end{bmatrix} \\ &= \sum_{i=1}^{n} \left(nz_i^2 + \sum_{j=n+1}^{2n} z_i z_j \right) \\ &\quad + \sum_{j=n+1}^{2n} \left(nz_j^2 + \sum_{i=1}^{n} z_j z_i \right) \\ &= \sum_{i=1}^{n} \sum_{j=n+1}^{2n} \left(z_i^2 + 2 z_i z_j + z_j^2 \right) \\ &= \sum_{i=1}^{n} \sum_{j=n+1}^{2n} (z_i + z_j)^2 \geq 0 \end{aligned}$$

□

Now, for the optimal solutions to our minimization problem, we can set the first-order partial derivatives to 0 and solve for our $2n$ parameters τ_i, ϕ_j. These solutions will correspond to global minima due to the convexity result we established above. It turns out to be equivalent to find solutions to:

$$\mathcal{H} \begin{bmatrix} \tau_1 \\ \vdots \\ \tau_n \\ \phi_1 \\ \vdots \\ \phi_n \end{bmatrix} = \begin{bmatrix} \sum_{k=1}^{n} f_{1k} \\ \vdots \\ \sum_{k=1}^{n} f_{nk} \\ \sum_{k=1}^{n} f_{k1} \\ \vdots \\ \sum_{k=1}^{n} f_{kn} \end{bmatrix} \tag{6}$$

We can do this by finding one solution s to the above, and then analyzing the nullspace of $\mathcal{H}$,

---

[18] Note that multimodally-additive models do not rely on particular t_i, v_j couplings, as this family of functions decomposes as $f(t_i, v_j) = f_t(t_i) + f_v(v_j)$; thus, a multimodally-additive $\hat{f}$ *should* be able to fit any image-text pair we could construct from D, not just the image-text pairs we observe.

which will turn out to be the 1-dimensional subspace spanned by

$$r = \langle \underbrace{1, 1, \dots 1}_{n}, \underbrace{-1, -1, \dots - 1}_{n} \rangle$$

That $\mathcal{H}r = 0$ can be verified by direct calculation. Then, all solutions will have the form $s + cr$ for any $c \in \mathbb{R}$.[19]

Claim 2. *Algorithm 1 computes a solution to Equation 6 as a byproduct.*

Proof. Algorithm 1 computes $s = \langle \tau_i, \phi_j \rangle$ as:

$$\tau_i = \frac{1}{n} \sum_k f_{ik} - \frac{1}{n^2} \sum_i \sum_j f_{ij} \tag{7}$$

$$\phi_j = \frac{1}{n} \sum_k f_{kj} \tag{8}$$

s is a solution to Equation 6, as can be verified by direct substitution. ☐

Claim 3. *The rank of $\mathcal{H}$ is $2n - 1$, which implies that its nullspace is 1-dimensional.*

Proof. Solutions to $\mathcal{H}x = \lambda x$ occur when:

$$\lambda = n, \ 0 = \sum_{i=1}^{n} x_i \text{ and } 0 = \sum_{j=n+1}^{2n} x_j$$

$$\lambda = 2n, \ x = \mathbf{1}$$

$$\lambda = 0, \ x = r$$

So, zero is an eigenvalue of $\mathcal{H}$ with multiplicity 1, which shows that $\mathcal{H}$'s rank is $2n - 1$.[20] ☐

Because the nullspace of $\mathcal{H}$ is 1-dimensional, all solutions to Equation 6 are given by $s + cr$ for any $c \in \mathbb{R}$. Returning to the notation of the original problem, we see that all optimal solutions are given by:

$$\tau_i = \frac{1}{n} \sum_k f_{ik} - \frac{1}{n^2} \sum_i \sum_j f_{ij} + c \tag{9}$$

$$\phi_j = \frac{1}{n} \sum_k f_{kj} - c \tag{10}$$

Claim 4. *Algorithm 1 produces a unique solution for the values of $\hat{f}$.*

Proof. We have shown that Algorithm 1 produces *an* optimal solution, and have derived the parametric form of all optimal solutions in Equation 9 and Equation 10. Note that Algorithm 1 outputs $\tau_i + \phi_j$ (rather than τ_i, ϕ_j individually). This cancels out the free choice of c. Thus, any algorithm that outputs optimal $\tau_i + \phi_j$ will have the same output as Algorithm 1. ☐

Extension to multiple dimensions. So far, we have shown that Algorithm 1 produces an optimal and unique solution for Equation 4, but only in cases where $f_{ij}, \tau_i, \phi_j \in \mathbb{R}$. In general, we need to show the algorithm works for multi-dimensional outputs, too. The full loss function includes a summation over dimension as:

$$\mathcal{L} = \frac{1}{2} \sum_i \sum_j \sum_d (f_{ijd} - \tau_{id} - \phi_{jd})^2 \tag{11}$$

This objective decouples entirely over dimension d, i.e., the loss can be rewritten as:

$$\frac{1}{2} \Bigg(\underbrace{\sum_{ij} (f_{ij1} - \tau_{i1} - \phi_{j1})^2}_{\mathcal{L}_1} + \underbrace{\sum_{ij} (f_{ij2} - \tau_{i2} - \phi_{j2})^2}_{\mathcal{L}_2} + \dots \underbrace{\sum_{ij} (f_{ijd} - \tau_{id} - \phi_{jd})^2}_{\mathcal{L}_d} \Bigg)$$

Furthermore, notice that the parameters in $\mathcal{L}_i$ are disjoint from the parameters in $\mathcal{L}_j$ if $i \neq j$. Thus, to minimize the multidimensional objective in Equation 11, it suffices to minimize the objective for each $\mathcal{L}_i$ independently, and recombine the solutions. This is precisely what Algorithm 1 does.

B Dataset Details and Reproducibility Efforts

B.1 I-INT, I-SEM, I-CTX

This data is available from `https://github.com/karansikka1/documentIntent_emnlp19`. We use the same 5 random splits provided by the authors for evaluation. The

---

[19] Proof: Assume that s' is a solution of Equation 6. $s' - s$ will be in the nullspace of $\mathcal{H}$. Clearly, $s' = s + (s' - s)$, so s' can be written as $s + x$ for x in the nullspace of $\mathcal{H}$.

[20] We can make explicit the eigenbasis for the $\lambda = n$ solutions. Let $M \in \mathbb{R}^{n \times (n-1)}$ be I_{n-1} with an additional row of -1 concatenated as the n^{th} row. The eigenbasis is given by the columns of

$$\begin{bmatrix} M & \mathbf{0} \\ \mathbf{0} & M \end{bmatrix}.$$

authors provide ResNet18 features, which we use for our non-LXMERT experiments instead of EfficientNet-B4 features. After contacting the authors, they extracted bottom-up-top-down FasterRCNN features for us, so we were able to compare to LXMERT. State of the art performance numbers are derived from the above github repo; these differ slightly from the values reported in the original paper because the github versions are computed without image data augmentation.

B.2 T-VIS

This data is available from https://github.com/danielpreotiuc/text-image-relationship/. The raw images are not available, so we queried the Twitter API for them. The corpus has 4472 tweets in it initially, but we were only able to re-collect 3905 tweets (87%) when we re-queried the API. Tweets can be missing for a variety of reasons, e.g., the tweet being permanently deleted, or the account's owner making the their account private at the time of the API request. A handful of tweets were available, but were missing images when we tried to re-collect them. This can happen when the image is a link to an external page, and the image is deleted from the external page.

B.3 R-POP

This data is available from http://www.cs.cornell.edu/~jhessel/cats/cats.html. We just use the pics subreddit data. We attempted to rescrape the pics images from the imgur urls. We were able to re-collect 87215/88686 of the images (98%). Images can be missing if they have been, e.g., deleted from imgur. We removed any pairs with missing images from the ranking task; we trained on 42864/44343 (97%) of the original pairs. The data is distributed with training/test splits. From the training set for each split, we reserve 3K pairs for validation. The state of the art performance numbers are taken from the original releasing work.

B.4 T-ST1

This data is available from http://www.ee.columbia.edu/ln/dvmm/vso/download/twitter_dataset.html and consists of 603 tweets (470 positive, 133 negative). The authors distribute data with 5 folds pre-specified for cross-validation performance reporting. However, we note that the original paper's best model achieves 72% accuracy in this setting, but a constant prediction baseline achieves higher performance: 470/(470+133) = 78%. Note that the constant prediction baseline likely performs worse according to metrics other than accuracy, but only accuracy is reported. We attempted to contact the authors of this study but did not receive a reply. We also searched for additional baselines for this dataset, but were unable to find additional work that uses this dataset in the same fashion. Thus, given the small size of the dataset, lack of reliable measure of SOTA performance, and label imbalance, we decided to report ROC AUC prediction performance.

B.5 T-ST2

This data is available from https://www.mcrlab.net/research/mvsa-sentiment-analysis-on-multi-view-social-data/. We use the MVSA-Single dataset because human annotators examine both the text and image simultaneously; we chose not to use MVSA-Multiple because human annotators do not see the tweet's image and text at the same time. However, the dataset download link only comes with 4870 labels, instead of the 5129 described in the original paper. We contacted the authors of the original work about the missing data, but did not receive a reply.

We follow the preprocessing steps detailed in Xu and Mao (2017) to derive a training dataset. After preprocessing, we are left with 4041 data points, whereas prior work compares with 4511 points after preprocessing. The preprocessing consists of removing points that are (positive, negative), (negative, positive), or (neutral, neutral), which we believe matches the description of the preprocessing in that work. We contacted the authors for details, but did not receive a reply. The state-of-the-art performance number for this dataset is from Xu et al. (2018).

C Are EMAPs just regularizers?

One reason why EMAPs may often offer strong performance is by acting as a regularizer: projecting to a less expressive hypothesis space may reduce variance/overfitting. But in many cases, the original model and its EMAP achieve similar predictive accuracy. This suggests two explanations: *either* the EMAPed version makes

	I-INT	I-SEM	I-CTX	T-VIS	R-POP	T-ST1	T-ST2

% Inst. Orig. Better	51.2	52.0	51.5	55.2	*51.2*	5/12 cases ($\approx 6/12 = 50\%$)	53.0

Table 5: Consistency results. The first block provides details about the task and the model that performed best on it. The second block gives the performance (italicized results represent cross-validation EMAP computation results; see footnote 5). The third block gives the percent of time the original model's prediction is the same as for EMAP, and, for comparison, the percent of time the original model's predictions match the identical model trained with a different random seed: in all cases except for T-VIS, the original model and the EMAP make the same prediction in more than 95% of cases. The final row gives the percent of instances (among instances for which the original model and the EMAP disagree) that the original model is correct. Except for T-VIS, when the EMAP and the original model disagree, each is right around half the time.

significantly different predictions with respect the original model (e.g., because it is better regularized), but it happens that those differing predictions "cancel out" in terms of final prediction accuracy; *or*, the original, unprojected functions are quite close to additive, anyway, and the EMAP doesn't change the predictions all that much.

We differentiate between these two hypotheses by measuring the percent of instances for which the EMAP makes a different classification prediction than the full model. Table 5 gives the results: in all cases except T-VIS, the match between EMAP and the original model is above 95%. For reference, we retrained the best performing models with different random seeds, and measured the performance difference under this change.

When EMAP changes the predictions of the original model, does the projection generally change to a more accurate label, or a less accurate one? We isolate the instances where a label swap occurs, and quantify this using: (num orig better) / (num orig better + num proj better). In most cases, the effect of projecting improves and degrades performance roughly equally, at least according to this metric. For T-VIS, however, the original model is better in over 55% of cases: this is also reflected in the corresponding F-scores.

D Logic Experiment Details

In §6, we describe experiments using AdaBoost. We chose AdaBoost (Freund and Schapire, 1995) to fit to the training set because of its strong convergence guarantees. In short: if AdaBoost can find a weak learner at each iteration (that is: if it can find a candidate classifier with above-random performance) it will be able to fit the training set. A more formal statement of AdaBoost's properties can be found in the original work.

The AdaBoost classifiers we consider use decision trees with max depth of 15 as base estimators. We choose a relatively large depth because we are not concerned with overfitting: we are just measuring training fit. The additive version of AdaBoost we consider is identical to the full AdaBoost classifier, except, at each iteration, either the image features or the text features individually are considered.

E Additional Reproducibility Info

Computing Hardware. Linear models and feed-forward neural networks were trained using consumer-level CPU/RAM configurations. LXMERT was fine-tuned on single, consumer GPUs with 12GB of vRAM.

Runtime. The slowest algorithm we used was LXMERT (Tan and Bansal, 2019), and the biggest

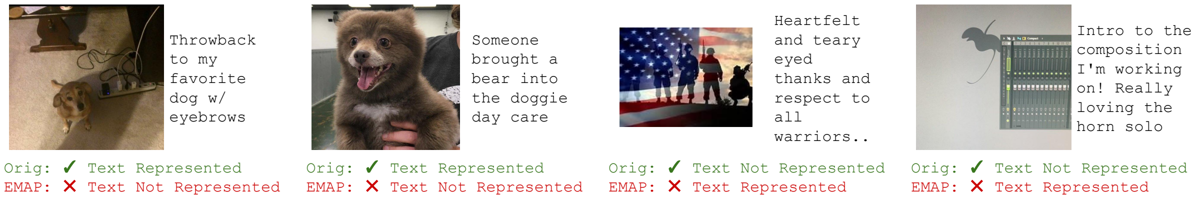

Figure 3: Examples of cases from for which EMAP degrades the performance of LXMERT + Logits. All cases are labelled as “image does not add meaning” in the original corpus. Text of tweets may be gently modified for privacy reasons.

dataset we fine-tuned on was R-POP. LXMERT was fine-tuned on the order of 1500 times. Depending on the dataset, the fine-tuning process took between 10 minutes and an hour. Overall, we estimate that we spent on the order of 50-100 GPU days doing this work.

Number of Parameters. The RoBERTa features we used were 2048-dimensional, and the EfficientNetB4 features were 1792 dimensional. The linear models and feed forward neural networks operated on those. We cross-validated the number of layers and the width, but the maximal model, for these cases, has on the order of millions of parameters. The biggest model we used was LXMERT, which has a comparable memory footprint to the original BERT Base model.

F Qualitative Analysis of T-VIS

To demonstrate the potential utility of EMAP in qualitative examinations, we identified the individual instances in T-VIS for which EMAP changes the test-time predictions of the LXMERT + Linear Logits model. Recall that in this dataset, EMAP hurts performance.

In introducing this task, Vempala and Preoţiuc-Pietro (2019) propose categorizing image+text tweets into four categories: “Some or all of the content words in the text are represented in the image” (or not) × “Image has additional content that represents the meaning of the text and the image” (or not).

As highlighted in Table 5, when EMAP changes the prediction of the full model (14.5% of cases), the prediction made is incorrect more often not: among label swapping cases, when the EMAP or the original model is correct, the original prediction is correct in 55% of the cases.

The most common label swaps of this form are between the classes: “image does not add” × {“text is represented”, “text is not represented”}; as shorthand for these two classes, we will write IDTR (“image doesn’t add, text represented”) and IDTN (“image doesn’t add, text not represented”). Across the 10 cross-validation splits, EMAP incorrectly maps the original model’s correct prediction of INTR → IDTN 255 times. For reference, there are 165 cases where EMAP maps the *incorrect* INTR prediction of the original model to the correct IDTN label. So, when EMAP makes the change INTR → IDTN, in 60% of cases the full model is correct. Similarly, EMAP incorrectly maps the original model’s correct prediction of INTN → IDTR 77 times (versus 48 correct mappings, original model correct in 62% of cases).

Figure 3 gives some instances from T-VIS where images do not add meaning and the EMAP projection causes a swap from a correct to an incorrect prediction. While it’s difficult to draw conclusions from single instances, some preliminary patterns emerge. There are a cluster of animal images coupled with captions that may be somewhat difficult to map. In the case of the dog with eyebrows, the image isn’t centered on the animal, and it might be difficult to identify the eyebrows without the prompt of the caption (hence, interactions might be needed). Similarly, the bear-looking-dog case is difficult: the caption doesn’t explicitly mention a dog, and the image itself depicts an animal that isn’t canonically canine-esque; thus, modeling interactions between the image and the caption might be required to fully disambiguate the meaning.

Figure 3 also depicts two cases where the original model predicts that the text is not represented (but EMAP does). They are drawn from a cluster of similar cases where the captions seem indirectly connected to the image. Consider the 4th, music composition example: just looking at the text, one could envision a more literal manifestation: i.e., a person playing a horn. Similarly, looking just at the screenshot of the music production software, one could envision a more literal caption, e.g., "producing a new song with this software." But, the real connection is less direct, and might require additional cross-modal inferences. Other common cases of INTR → IDTN are "happy birthday" messages coupled with images of their intended recipients and selfies taken at events (e.g., sports games), with descriptions (but not direct visual depictions).

G Worked Example of EMAP

We adopt the notation of Appendix A and give an concrete worked example of EMAP. Consider the following f output values, which are computed on three image+text pairs for a binary classification task. We assume that f outputs an un-normalized logit that can be passed to a scaling function like the logistic function σ for a probability estimate over the binary outcome, e.g., $f_{11} = -1.3$ and $\sigma(f_{11}) = P(y = 1) \approx .21$.

$$f_{11} = -1.3 \quad f_{12} = .3 \quad f_{13} = -.2$$
$$f_{21} = .8 \quad f_{22} = 3 \quad f_{23} = 1.1$$
$$f_{31} = 1.1 \quad f_{32} = -.1 \quad f_{33} = .7$$

We can write this equivalently in matrix form:

$$\begin{bmatrix} f_{11} & f_{12} & f_{13} \\ f_{21} & f_{22} & f_{23} \\ f_{31} & f_{32} & f_{33} \end{bmatrix} = \begin{bmatrix} -1.3 & 0.3 & -0.2 \\ 0.8 & 3.0 & 1.1 \\ 1.1 & -.1 & 0.7 \end{bmatrix}$$

Note that the mean logit predicted by f over these 3 examples is .6. We use Equation 8 to compute the ϕ_js; this is equivalent to taking a column-wise mean of this matrix, which yields (approximately) $[.2, 1.07, .53]$. Similarly, we can use Equation 7, equivalent to taking a row-wise mean of this matrix, which yields (approximately) $[-.4, 1.63, .57]$, and then subtract the overall mean .6 to achieve $[-1, 1.03, -.03]$. Finally, we can sum these two results to compute $[\hat{f}_{11}, \hat{f}_{22}, \hat{f}_{33}] = [-.8, 2.1, .5]$. These predictions are the closest approximations to the full evaluations $[f_{11}, f_{22}, f_{33}] = [-1.3, 3, .7]$ for which the generation function obeys the additivity constraint over the three input pairs.

Abstract

While progress has been made on the visual question answering leaderboards, models often utilize spurious correlations and priors in datasets under the i.i.d. setting. As such, evaluation on out-of-distribution (OOD) test samples has emerged as a proxy for generalization. In this paper, we present *MUTANT*, a training paradigm that exposes the model to perceptually similar, yet semantically distinct *mutations* of the input, to improve OOD generalization, such as the VQA-CP challenge. Under this paradigm, models utilize a consistency-constrained training objective to understand the effect of semantic changes in input (question-image pair) on the output (answer). Unlike existing methods on VQA-CP, *MUTANT* does not rely on the knowledge about the nature of train and test answer distributions. *MUTANT* establishes a new state-of-the-art accuracy on VQA-CP with a 10.57% improvement. Our work opens up avenues for the use of semantic input mutations for OOD generalization in question answering.

1 Introduction

Availability of large-scale datasets has enabled the use of statistical machine learning in vision and language understanding, and has lead to significant advances. However, the commonly used evaluation criterion is the performance of models on test-samples drawn from the same distribution as the training dataset, which cannot be a measure of generalization. Training under this "independent and identically distributed" (i.i.d.) setting can drive decision making to be highly influenced by dataset biases and spurious correlations as shown in both natural language inference (Kaushik and Lipton, 2018; Poliak et al., 2018; McCoy et al., 2019) and visual question answering (Goyal et al., 2017; Agrawal et al., 2018a; Selvaraju et al., 2020). As such, evaluation on out-of-distribution (OOD) samples has emerged as a metric for generalization.

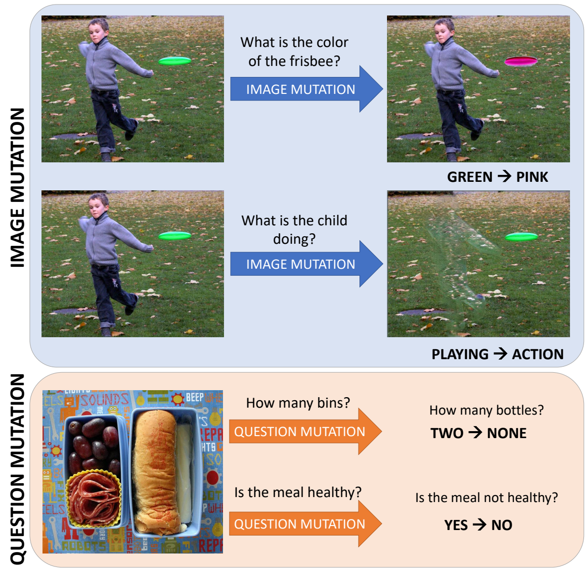

Figure 1: Illustration of the mutant samples. The input mutation, either by manipulating the image or the question, results in a change in the answer.

Visual question answering (VQA) (Antol et al., 2015) is a task at the crucial intersection of vision and language. The aim of VQA models is to provide an answer, given an input image and a question about it. Large datasets (Antol et al., 2015) have been extensively used for developing VQA models. However over-reliance on datasets can cause models to learn spurious correlations such as linguistic priors (Agrawal et al., 2018a) that are specific to certain datasets and do not generalize to "Out-of-Distribution" (OOD) samples, as shown in Figure 1. While learning patterns in the data is important, learning dataset-specific spurious correlations is not a feature of robust VQA models. Developing robust models has thus become a key pursuit for recent work in visual question answer-

ing through data augmentation (Goyal et al., 2017), reorganization (Agrawal et al., 2018a).

Every dataset contains biases; indeed inductive bias is *necessary* for machine learning algorithms to work. Mitchell (1980) states that an unbiased learner's ability to classify is no better than a look-up from memory. However this bias has a component which is useful for generalization (positive bias), and a component due to spurious correlations (negative bias). We use the term "positive bias" to denote the correlations that are necessary to perform a task — for instance, the answer to a "What sport is ..." question is correlated to a name of a sport. The term "negative bias" is used for spurious correlations tat may be learned from the data — for instance, always predicting "tennis" as the answer to "What sport..." questions. The goal of OOD generalization is to mitigate negative bias while learning to perform the task. However existing methods such as LMH (Clark et al., 2019) try to remove all biases between question-answer pairs, by penalizing examples that can be answered without looking at the image; we believe this to be counter-productive. The analogy of antibiotics which are designed to remove pathogen bacteria, but also end up removing useful gut microbiome (Willing et al., 2011) is useful to understand this phenomenon.

We present a method that focuses on increasing positive bias and mitigating negative bias, to address the problem of OOD generalization in visual question answering. Our approach is to enable the **mutation** of inputs (questions and images) in order to expose the VQA model to perceptually similar yet semantically dissimilar samples. The intuition is to implicitly allow the model to understand the critical changes in the input which lead to a change in the answer. This concept of mutations is illustrated in Figure 1. If the color of the frisbee is changed, or the child removed, i.e. *when an image-mutation is performed*, the answer to the question changes. Similarly, if a word is substituted by an adversarial word (bins→bottles), an antonym, or negation (healthy→not healthy), i.e. *when a question-mutation is performed*, the answer also changes. Notice that both mutations do not significantly change the input, most of the pixels in the image and words in the question are unchanged, and the type of reasoning required to answer the question is unchanged. However the mutation significantly changes the answer.

In this work, we use this concept of mutations to enable models to focus on parts of the input that are critical to the answering process, by training our models to produce answers that are consistent with such mutations. We present a question-type exposure framework which teaches the model that although such linguistic priors may exist in training data (such as the dominant answer "tennis" to "What sport is ..." questions), other sports can also be answers to such questions, thus mitigating negative bias. This is in contrast to Chen et al. (2020a) who focus on using data augmentation as a means for mitigating language bias.

Our method uses a pair-wise training protocol to ensure consistency between answer predictions for the original sample and the mutant sample. Our model includes a projection layer, which projects cross-modal features and true answers to a learned manifold and uses Noise-Contrastive Estimation Loss (Gutmann and Hyvärinen, 2010) for minimizing the distance between these two vectors. Our results establish a new state-of-the-art accuracy of 69.52% on the VQA-CP-v2 benchmark outperforming the current best models by 10.57%. At the same time, our models achieves the best accuracy (70.24%) on VQA-VQA-v2 among models designed for the VQA-CP task.

This work takes a step away from explicit debiasing as a method for OOD generalization and instead proposes amplification of positive bias and implicit attenuation of spurious correlations as the objective. Our contributions are as follow.

- We introduce the Mutant paradigm for training VQA models and the sample-generation mechanism which takes advantage of semantic transformations of the input image or question, for the goal of OOD generalization.
- In addition to the conventional classification task, we formulate a novel training objective using Noise Contrastive Estimation over the projections of cross-modal features and answer embeddings on a shared projection manifold, to predict the correct answer.
- Our pairwise consistency loss acts as a regularization that seeks to bring the distance between ground-truth answer vectors closer to the distance between predicted answer vectors for a pair of original and mutant inputs.
- Extensive experiments and analyses demonstrate advantages of our method on the VQA-CP dataset, and establish a new state-of-the-art of $\mathbf{69.52}\%$, an improvement of $\mathbf{10.57}\%$.

2 MUTANT

We consider the open-ended VQA problem as a multi-class classification problem. The VQA dataset $\mathcal{D} = \{Q_i, I_i, a_i\}_{i=1}^{N}$ consists of questions $Q_i \in \mathcal{Q}$ and images $I_i \in I$, and answers $a_i \in \mathcal{A}$. Many contemporary VQA models such as Up-Dn (Anderson et al., 2018) and LXMERT (Tan and Bansal, 2019) first extract cross-modal features from the image and question using attention layers, and then use these features as inputs to a neural network answering module which predicts the answer classes. In this section we define our Mutant paradigm under this formulation of the VQA task.

2.1 Concept of Mutations

Let $X = (Q, I)$ denote an input to the VQA system with true answer a. A *mutant* input X^* is created by a small transformation in the image (Q, I^*) or in the question (Q^*, I) such that this transformation leads to a new answer a^*, as shown in Figure 1. There are three categories of transformation T that create the mutant input $X^* = T(X)$, addition, removal, or substitution. For image mutations, these correspond to addition or removal of objects, and morphing the attributes of the objects, such as color, texture, and lighting conditions. For instance addition or removal of a person from the image in Figure 3 changes the answer to the question "How many persons are pictured". Question mutations can be performed by addition of a negative word ("no", "not", etc.) to the question, masking critical words in the question, and substituting an object-word with an antonym or adversarial word. Thus for each sample in the VQA dataset, we can obtain a mutant sample and use it for training.

2.2 Training with Mutants

Our method of training with mutant samples relies on three key concepts that supplement the conventional VQA classification task.

Answer Projection: The traditional learning strategy of VQA models optimizes for a standard classification task using softmax cross-entropy:

$$\mathcal{L}_{\scriptscriptstyle VQA} = \frac{-1}{N} \sum_{i=1}^{N} log(softmax(f_{\scriptscriptstyle VQA}(X_i), a_i)). \quad (1)$$

QA as a classification task is popular since the answer vocabulary follows a long-tailed distribution over the dataset. However this formulation is problematic since it does not consider the meaning of the answer while making a decision, but instead learns a correlation between the one-hot vector of the answer-class and input features. Thus to answer the question "What is the color of the banana", models learn a strong correlation between the question features and the answer-class for "yellow", but do not encode the notion of *yellowness* or *greenness* of bananas. This key drawback negatively impacts the generalizability of these models to raw green or over-ripe black bananas at test-time.

To mitigate this, in addition to the classification task, we propose a training objective that operates in the space of answer embeddings. The key idea is to map inputs (image-question pairs) and outputs (answers) to a shared manifold in order to establish a metric of similarity on that manifold. We train a projection layer that learns to project features and answers to the manifold as shown in Figure 2. We then use Noise Contrastive Estimation (Gutmann and Hyvärinen, 2010) as a loss function to minimize the distance between the projection of cross modal features z and projection of glove vector v for ground-truth answer a, given by:

$$\mathcal{L}_{NCE} = -log\left(\frac{e^{cos(z_{feat},\ z_a)}}{\sum_{a_i \in \mathcal{A}} e^{cos(z_{feat},\ z_a^i)}}\right), \quad (2)$$

where $z_{feat} = f_{proj}(z)$ and $z_a = f_{proj}(glove(a))$, and $\mathcal{A}$ is the set of all possible answers in our training dataset. It is important to note that this similarity metric is not between the true answer and the predicted answer, but between the projection of input features and the projection of answers, to incorporate context in the answering task.

Type Exposure: Linguistic priors in datasets have led models to learn spurious correlations between question and answers. For instance, in VQA, the most common answer for "What sport ..." questions is "tennis", and for "How many ..." questions is "two". Our aim is to remove this negative bias from the models. Instead of removing *all bias* from these models, we teach models to identify the question type, and learn which answers can be valid for a particular question type, irrespective of their frequency of occurrence in the dataset. For instance, the answer to "How many ..." can be all numbers, answers to "What color ..." can be all colors, and answers to questions such as "Is the / Are there ..." questions is either yes or no. We call this *Type Exposure* since it instructs the model that although a strong correlation may exist between a question-answer pair, there are other answers which are also

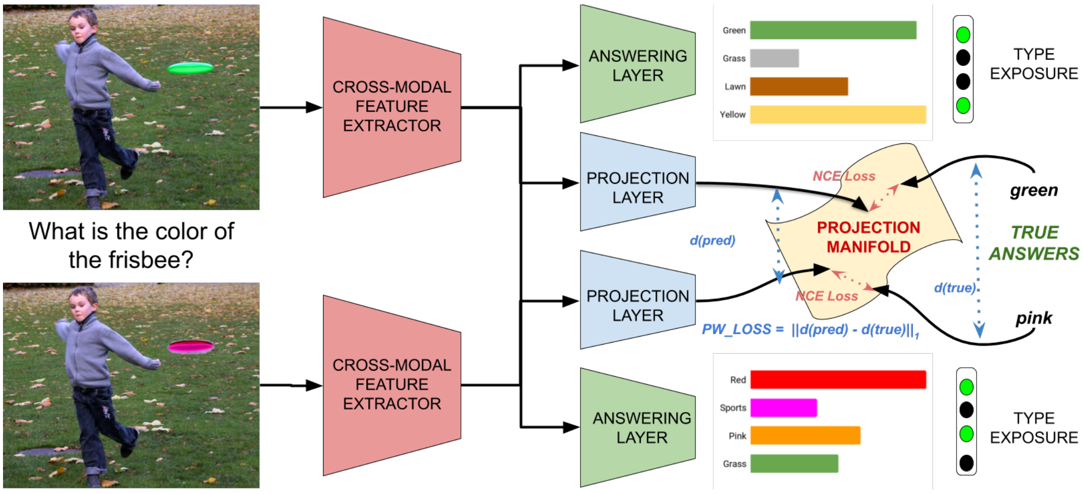

Figure 2: Overall architecture of the Mutant Method includes a cross-modal feature extractor, answer projection layer, answering layer and type exposure model

valid for the specific type of question. Our Type Exposure model uses a feedforward network to predict question type and to create a binary mask over answer candidates that correspond to this type.

Pairwise-Consistency: The final component of Mutant is pairwise consistency. We jointly train our models with the original and mutant sample pair, with a loss function that ensures that the distance between two predicted answer vectors is close to the distance between two ground-truth answer vectors. The pairwise consistency loss is given below, where z_a is the vector for answer a, m, GT denote mutant sample and ground-truth respectively.

$$\mathcal{L}_{PW} = ||cos(z_{a_{GT}}, z^m_{a_{GT}}) - cos(z_{a_{pred}}, z^m_{a_{pred}})||_1.$$

This pairwise consistency is designed as a regularization that incorporates the notion of semantic shift in answer space as a consequence of a mutation. For instance, consider the image mutation in Figure 3 which changes the ground-truth answer from ”two” to ”one”. This shift in answer-space should be reflected by the predictor.

3 Generating Input Mutations for VQA

In order to train VQA models under the mutant paradigm, we need a mechanism to create mutant samples. Mutations are transformations that act on semantic entities in either the image or the question, in ways that can reliably lead to a new answer. For the question, semantic entities are words, while for images, semantic entities are objects. It is important to note that our mutation process is automated and does not use the knowledge about the test set distribution in order to create new samples. In this section, we delineate our automated generation process for both image and question-mutation.

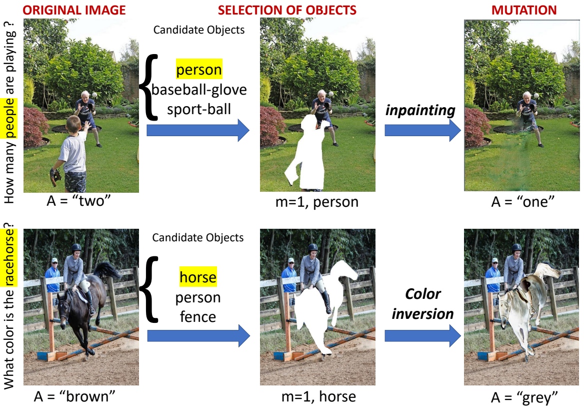

Figure 3: Figure illustrating our dataset creation pipeline for image mutations. m object instances of “critical” object are identified from the question and image, and mutation performed either by removal or color inversion. A represents the answer to the question.

3.1 Image Mutations

For image mutation, we first identify critical objects from the image that results in a change in the answer, and either remove instances of these objects (removal) or morph their color (substitution).

Removing Object Instances: Removing an instance of an object class can be either critical to the question (i.e. the answer to the question changes) or non-critical (i.e. answer is unchanged). If an object (or it’s synonym or hypernym) is mentioned in the question, we deem it to be critical to the question, otherwise it is deemed non-critical. For

Mutation Type	Question	Answer
Original	Is the lady holding the baby?	Yes
Substitution (Negation)	Is the lady not holding the baby?	No
Substitution (Adversarial)	Is the cat holding the baby?	No
Original	How many people are there?	Three
Deletion (Masking)	How many [MASK] are there?	“Number”
Original	What is the color of the man’s shirt?	Blue
Substitution (Negation)	What is not the color of the man’s shirt?	Magenta
Deletion (Masking)	Is the [MASK] holding the baby?	Can’t say
Original	What color is the umbrella ?	Pink
Deletion (Masking)	What color is the [MASK]?	“color”

Table 1: Examples of our question mutation. The image is shown on the left, and the original question is in the first row of the table. Examples of the two types of mutation are shown in the table.

each object with M instances in the image, we randomly remove m instances from the image s.t. $m \in \{0, \ldots, M\}$ using polygon annotations from the COCO (Lin et al., 2014) dataset. Thus for each image, we get multiple masked images, with pixels inside the instance bounding-box removed, as shown in Figure 3. These masked images are fed to a GAN-based inpainting network (Yu et al., 2018) that makes the mutant image photo-realistic, and also prevents the model from getting cues from the shape of the mask. In the case of numeric questions, if m critical objects are removed, the answer to for the mutant image changes from n to $n - m$. For yes-no questions, removal of all critical objects ($m = n$) will flip the answer from “yes” to “no”, while removing $m < n$ critical objects will not. Note that $m = 0$ corresponds to the original image and does not result in a change in the answer.

Color Inversion: For mutations that involve a change in color, we use samples with questions about the color of objects in the image, and change the color of critical objects by pixel-level color inversion in RGB-space. The true answer is replaced with the new color of the critical objects. To get objects with new colors, we do not use the knowledge about colors of objects in the world. In some cases, the new colors of the object may not correspond to real-world scenes, thus forcing the model to actually identifying colors, and not answer from language priors, such as “bananas are yellow”.

3.2 Question Mutations

We use three types of question mutations as shown in the example in Table 1. We first identify the critical object and then apply template-based question operators similar to (Gokhale et al., 2020). The first operator is negation for yes-no questions, which is achieved by a template based procedure that negates the question by adding a “no” or “not” before a verb, preposition or noun phrase. The second is the use of antonyms or adversarial object-words to substitute critical words. The third mutation masks words in the question and thus introduces ambiguity in the question. Questions for which the new answer cannot be deterministically identified are annotated with a broad category label such as *color, location, fruit* instead of the exact answers such as *red, library, apple* which the model cannot be expected to answer since some words have been masked or replaced with adversarial words. Yet, we want the model to be able to identify this broad category of answers even under partially occluded inputs. The answer remains unchanged for mutations with non-critical objects or words.

Mutation Category	Number of Samples
Object Removal	159,899
Color Change	30,759
Negation	237,611
Adversarial Substitution	146,814
Word Masking	104,666

Table 2: Distribution of generated mutant samples by category of mutation

3.3 Mutant Statistics:

We use the training set of VQA-CP-v2 (Agrawal et al., 2018a) to generate mutant samples. For each original sample, we generate 1.5 mutant samples on average, thus obtaining a total of 679k samples. Table 2 shows the distribution of our generated mutations with respect to the type of mutation. Addition of mutant samples does not change the distribution of samples per question-type.[1]

---

[1] More details about mutant samples are in Supp. material.

Model	VQA-CP v2 test (%) ↑				VQA-v2 val (%) ↑				Gap (%)
	All	Yes/No	Num	Other	All	Yes/No	Num	Other

4 Experiments

4.1 Setting

Datasets: We train and evaluate our models on VQA-CP-v2. This is a natural choice for evaluating OOD generalization since VQA-CP is a non-i.i.d. reorganization of the VQA dataset, and was created in order to evaluate VQA models in a setting where language priors cannot be relied upon for a correct prediction. This is because for every question type (65 types according to the question prefix), the prior distribution of answers is different in train and test splits of VQA-CP. We also train and evaluate our models on the VQA-v2 (Goyal et al., 2017) validation set, and compare the gap between the imbalanced and non-i.i.d. setting of VQA-CP against the balanced i.i.d. setting of VQA.

Hyperparameters: All of our models are trained on two NVIDIA Tesla V100 16GB GPUs for 10 epochs with batch size of 32 and learning rate $1e$–5. Each epoch takes approximately three hours for UpDn and four hours for LXMERT.

4.2 Baseline Models

We compare our method with GVQA (Agrawal et al., 2018b), RUBI (Cadene et al., 2019), SCR (Wu and Mooney, 2019), LMH (Clark et al., 2019), CSS (Chen et al., 2020a) as our baselines. Since most of these methods are built with UpDn (Anderson et al., 2018) as the backbone, we investigate the efficacy of UpDn under the mutant paradigm. On the other hand, LXMERT (Tan and Bansal, 2019) has emerged as a powerful transformer-based cross-modal feature extractor, and is pre-trained on tasks such as masked language modeling and cross-modality matching, inspired by BERT (Devlin et al., 2019). LXMERT is a top performing single-model on multiple vision-and-language tasks such as VQA, GQA (Hudson and Manning, 2019), ViZWiz (Bigham et al., 2010), and NLVR2 (Suhr et al., 2019). We therefore use is as a strong baseline for our experiments. LXMERT is representative of the recent trend towards using BERT-like pre-trained models (Lu et al., 2019; Su et al., 2019; Li et al., 2020; Chen et al., 2019) and fine-tuning them on multiple downstream vision and language tasks. Note that we do not use ensemble models for our experiments and focus only on single-model baselines.

4.3 Results on VQA-CP-v2 and VQA-v2

Performance on two benchmarks VQA-CP-v2 and VQA-v2 is shown in Table 3. We compare existing models against UpDn and LXMERT incorporated into our Mutant method. For the VQA-CP benchmark, our method improves the performance of LXMERT by 23.29%, thus establishing a new state of the art on VQA-CP, beating the previous best by 10.57%. Our method shows improvements across all categories, with 8.78% on the Yes-No category, 17.75% on Number-based questions, and 9.57% on other questions. We use negation as one of the question mutation operators on yes-no questions, but such questions are not present in the test set. However our model takes advantage of this mutation and improves substantially on yes-no questions. The Mutant method also consistently improves the performance of the UpDn model by 21.98% overall. Note that baseline models AReg, RUBI, SCR, LMH, and CSS all modify UpDn by

Model	Data	VQA-CP v2 test ↑ (%)			
		All	Yes/No	Num	Other

LXM + TE + PW	64.17	94.71	35.19	48.80
LXM + AP + TE + PW	**69.52**	**93.15**	**67.17**	**57.78**

Table 5: Ablation study to investigate the effect of each component of our method: Answer Projection (AP), Type Exposure (TE), Pairwise Consistency (PW), and independent effect of image and question mutations.

adding de-biasing techniques. We show our de-biasing method improves on two SOTA models and outperforms all of the above baselines, unlike previous work which only modifies UpDn. This empirically shows Mutant to be model-agnostic.

When trained and evaluated on the balanced i.i.d. VQA-v2 dataset, our method achieves the best performance amongst methods designed specifically for OOD generalization, with an accuracy of 70.24%. This is closest among baselines to the SOTA established by LXMERT, which is trained explicitly for the balanced, i.i.d. setting. To make this point clear, we report the *gap* between the overall scores for VQA-CP and VQA-v2, following the protocol from Chen et al. (2020a) in Table 3.

Results on VQA-v2 without re-training: Additionally, we use our best model trained on VQA-CP and evaluate it on the VQA test standard set without re-training on VQA-v2 data. The objective here is to evaluate whether models trained on biased data (VQA-CP) and mutant data is able to generalize to VQA-v2 which uses an i.i.d. train-test split. This gives us an overall accuracy of 67.63% comprising with 88.56% on yes-no questions, 50.76% on number-based questions, and 54.56% on other questions. This is better than all existing VQA-CP models that are explicitly trained on VQA-v2 (reported in Table 3), and thus demonstrates the generalizability of our approach.

4.4 Analysis

Effect of Training with Mutant Samples: In this analysis we measure the effect of augmenting the training data with mutant samples on UpDn and LXMERT without any architectural changes. The results are reported in Table 4. Both models improve when exposed to the mutant samples, UpDn by 10.42% and LXMERT by 13.46%. There is a markedly significant jump in performance for both models for the yes-no and number categories. UpDn especially benefits from Mutant samples in terms of the accuracy on numeric questions (a boost of 23.94%).

We also compare our final model when trained only with image mutations and only with question mutations in Table 4. While this is worse than training with both types of mutations, it can be seen that question mutations are better than image mutations in the case of yes-no and other questions, while image mutations are better on numeric questions.

Ablation Study: We conduct ablation studies to evaluate the efficacy of each component of our method, namely Answer Projection, Type Exposure and Pairwise Consistency, on both baselines, as shown in Table 5. Introduction of Answer Projection significantly improves yes-no performance, while Type Exposure improves performance on other questions. We also observe that the pairwise consistency loss significantly boosts performance on numeric questions and yes-no questions. Note that there is a minor difference between the original and the mutant sample, and the model needs to understand this difference, which in turn can enable the model to reason about the question and predict the new answer. For instance the pairwise consistency loss allows the

Model	Method	VQA-CP v2 test ↑ (%)			
		All	Yes/No	Num	Other
UpDn + Ours	Base	61.72	88.90	49.68	50.78
UpDn + Ours	LMH	55.38	90.99	39.74	40.99
Drop in Accuracy		*6.34*	*-2.09*	*9.95*	*9.80*
LXMERT + Ours	Base	69.52	93.16	67.17	57.78
LXMERT + Ours	LMH	63.85	88.34	48.23	55.28
Drop in Accuracy		*5.67*	*4.82*	*18.86*	*2.50*

Table 6: Effect of combining LMH de-biasing with the Mutant paradigm, measured as drop in accuracy (%)

model to learn the correlation between one missing object and a change in answer from “two” to “one” in Figure 3, resulting in an improvement in the counting ability of our VQA model. Similarly, the pairwise consistency allows the model to improve on yes-no questions for which the answer changes when a critical object is removed.

Effect of LMH Debiasing on Mutant:
We compare the results of our model when trained with or without the explicit de-biasing method LMH (Clark et al., 2019). LMH is an ensemble-based method trained for *avoiding* dataset biases, and is the most effective among all de-biasing strategies developed for the VQA-CP challenge. LMH implements a learned mixing strategy, by using the main model in combination with a bias-only model trained only with the question, without the image. The learned mixing strategy uses the bias-only model to remove biases from the main model. It can be seen from Table 6 that LMH leads to a drop in performance when used in combination with Mutant. This is potentially because in the process of debiasing, LMH ends up attenuating positive bias introduced by Mutant that is useful for generalization. Kervadec et al. (2020) have concurrently shown that de-biasing methods such as LMH indeed result in a decrease in performance on out-of-distribution (OOD) test samples in the GQA (Hudson and Manning, 2019) dataset, mirroring our analysis on VQA-CP shown in Table 6.

5 Related Work

De-biasing of VQA datasets: The VQA-v1 dataset (Antol et al., 2015) contained imbalances and language priors between question- answer pairs. This was mitigated by VQA-v2 (Goyal et al., 2017) which balanced the data by collecting complementary images such that each question was associated with two images leading to two different answers. Identifying that the distribution of answers in the VQA dataset led models to learn superficial correlations, Agrawal et al. (2018a) proposed the VQA-CP dataset by re-organizing the train and test splits such that the the distribution of answers per question-type was significantly different for each split.

Robustness in VQA: Ongoing efforts seek to build robust VQA models for VQA for various aspects of robustness. Shah et al. (2019) propose a model that uses cycle-consistency to not only answer the question, but also generate a complimentary question with the same answer, in order to increase the linguistic diversity of questions. In contrast, our work generates questions with a different answer. Selvaraju et al. (2020) provide a dataset which contains perception-related sub-questions for each VQA question. Antonym-consistency has been tackled in Ray et al. (2019). Inspired by invariant risk minimization (Arjovsky et al., 2019) which links out-of-distribution generalization to invariance and causality, Teney et al. (2020b) provide a method to identify invariant correlations in the training set and train models to ignore spurious correlations. Asai and Hajishirzi (2020); Gokhale et al. (2020) explore robustness to logical transformation of questions using first-order logic connectives *and* ($\wedge$), *or* ($\vee$), *not* ($\neg$). Removal of bias has been a focus of Ramakrishnan et al. (2018); Clark et al. (2019) for the VQA-CP task. We distinguish our work from these by amplifying positive bias and attenuating negative bias.

Data Augmentation: It is important to note that the above work on data de-biasing and robust models focuses on the language priors in VQA, but not much attention has been given to visual priors. Within the last year, there has been interest in augmenting VQA training data with counterfactual images (Agarwal et al., 2020; Chen et al., 2020a). Independently, Teney et al. (2020a) have also demonstrated that counterfactual images obtained via minimal editing such as masking or inpainting can lead to improved OOD generalization of VQA models, when trained with a pairwise gradient-based regularization. Self-supervised data augmentation has been explored in recent work (Lewis et al., 2019; Fabbri et al., 2020; Banerjee and Baral, 2020) in the domain of text-based question answering. The mutant paradigm presented in this work is one of the first enable the generation of VQA samples that result in different answers, coupled with a novel architecture and a consistency loss between original and mutant samples as a training objective.

Answer Embeddings: In one of the early works on VQA, Teney and Hengel (2016) use a combination of image and question representations and answer embeddings to predict the final answer. Hu et al. (2018) learn two embedding functions that transform image-question pair and answers to a shared latent space. Our method is different from this since we use a combination of classification and NCE Loss on the projection of answer vectors, as opposed to a single training objective. This means that although the predicted answer is obtained as the most probable answer from a set of candidate answers, the NCE Loss in the answer-space embeds the notion of semantic similarity between the answer. Our Type Exposure model is in principal similar to Kafle and Kanan (2016) who use the predicted answer-type probabilities in a Bayesian framework, while we use it as an additional constraint, i.e. as a regularization for a maximum likelihood objective.

6 Discussion and Conclusion

In this paper, we present a method that uses input mutations to train VQA models with the goal of Out-of-Distribution generalization. Our novel answer projection module trained for minimizing distance between answer and input projections complements the canonical VQA classification task. Our Type Exposure model allows our network to consider all valid answers per question type as equally probable answer candidates, thus moving away from the negative question-answer linguistic priors. Coupled with pairwise consistency, these modules achieve a new state-of-the-art accuracy on the VQA-CP-v2 dataset and reduce the gap between model performance on VQA-v2 data.

We differentiate our work from methods using random adversarial perturbations for robust learning (Madry et al., 2018). Instead we view input mutations as *structured perturbations* which lead to a semantic change in the input space and a deterministic change in the output space. We envision that the concept of input mutations can be extended to other vision and language tasks for robustness. Concurrent work in the domain of image classification shows that carefully designed perturbations or manipulations of the input can benefit generalization and lead to performance improvements (Chen et al., 2020b; Hendrycks et al., 2019). While perception is a cornerstone of understanding, the ability to imagine changes in the scene or language query, and predict outputs for that *imagined* input allows models to supplement "what" decision making (based on observed inputs) with "what if" decision making (based on imagined inputs). The Mutant paradigm is an effort towards "what if" decision making. Code is available here.

Appendix

A Datasets

A.1 VQA-CP

VQA-CP (Visual Question Answering under Changing Priors) (Agrawal et al., 2018a) is a re-organization of the VQA dataset (Antol et al., 2015; Goyal et al., 2017). The aim of VQA-CP is to have a different distribution of answers per question type is different in test and train splits. There are 65 question types based on the prefix of the questions such as *"how many"*, *"what color"*, *"what sport"*, *"is there"*, *"what is the"*, *"which"*. In VQA-v2, samples are drawn at randomly and independently and assigned either to train or test, thus resulting in the same distribution for both splits.

$$P^{VQA}_{train}(A|Q,I) = P^{VQA}_{test}(A|Q,I).$$

In VQA-CP however, samples are assigned using a greedy re-splitting algorithm, either to train or test, in a way that makes sure that questions with the same type an same answer are not shared by train and test. It is important to note that there is no leakage between train and test splits compared to the original VQA splits.

$$P^{VQA-CP}_{train}(A|Q,I) \neq P^{VQA-CP}_{test}(A|Q,I).$$

The train set for VQA-CP-v2 contains 121k images, 245k questions and 2.5M answers, while the test set contains 98k images, 220k questions and 2.2M answers.

A.2 COCO

The source of images in both VQA and VQA-CP is the MS-COCO dataset (Lin et al., 2014). COCO contains natural images representing complex, real-world scenes containing common objects of 91 categories such as *"person"*, *"chair"*, *"fork"*, *"horse"*, *"sports-ball"*, etc. For each image, COCO provides 5 captions along with bounding boxes and polygon annotations for each object instance in the image.

B Image Mutant Generation Process

In this section we provide additional details about our process for generating mutant samples from original question-image-answer triplets (Q-I-A) in the VQA-CP dataset. For all linguistic operations we use a combination of SpaCy (Honnibal and Montani, 2017) and the LemmInflect library (Jascob, v0.2.1 (February 22, 2020) for lemmatization and inflection.

Figure 4: Illustration of COCO bounding box and polygon annotations for m instances of an object, and the inpainting results after removal

B.1 Selection of Objects

For each VQA sample, a list of words W is created, which contains words from the ground-truth answers and the question. All nouns in W are converted to their singular form. For yes-no questions, numeric questions, and questions about colors of objects, a list of objects O is obtained from COCO. Background and crowd objects are filtered out from O. From O critical objects O_C and and non-critical objects O_{NC} are obtained. Critical objects are those objects in the image that when manipulated or removed, may change the answer to the question being asked. For this we follow a simple heuristic that states that if an object-word or it's synonym or hyponym is present in W, then it is a critical object. Then a critical object $o \in O$ is chosen at random, and m instances of this object are chosen at random. The polygon annotations (a polygon border) for this object are obtained from the COCO dataset as shown in Figure 4. Using these annotations, either a removal or color-inversion operation is applied to create the mutant image.

B.2 Object Removal and In-painting

After the object instance is selected, it is removed from the image by replacing all pixel values by 1 (white). This masked image is then input to a GAN-based image inpainting network (Yu et al., 2018) that fills up this pixels in the mask. This makes the

Figure 5: Illustration of color inversion procedure

image photorealistic. This network is one of the best available off-the-shelf blind image inpainting models, and is trained on the ImageNet (Deng et al., 2009). The masked image could also be used as the mutant image however we prefer to use photorealistic images for two main reasons. First, masked images do not lie in the same distribution as natural images, and secondly, the mask boundary may give clues to the network about the the shape or outline of the missing object.

B.3 Color Inversion Process

For mutation that involves a change in the color of the object, we perform a simple pixel-wise color inversion operation on each pixel in the mask to get the mutant image as shown in Figure 5. This is to ensure that we do not use any prior knowledge about valid colors of a specific object. For instance, bananas can typically be yellow, green, or black. However, if we only change the color or a banana to one of these three colors, we would be using domain knowledge and inadvertently introducing answers from the test set, defeating the purpose of OOD generalization. Although the simple inversion process can introduce unnatural colors like blue bananas, it forces the model to understand colors in the image to answer the question instead of simply answering from linguistic priors (such as the memorized knowledge that bananas can be green, yellow, or black).

B.4 Answer Generation

The new answers are generated based on the type of question. For **yes-no questions**, if all instances of the object are removed then the answer changes from yes to no. If only some instances are removed or if the object is non-critical, the answer remains the same. For **number questions**, if m instances of a critical object are removed, the answer changes from n to $n - m$, else the answer remains the same. For **color-based questions** we convert the answer color to their HEX value using Webcolors [2], invert the value, and find the color in CSS-21 colors closest to this value to generate the new answer.

C Question Mutant Generation Process

For generating question mutants, we use three operators: negation, substitution by antonyms or adversarial words, and masking critical words.

C.1 Negation

For yes-no questions and color-based questions, we use a template-based negation technique that puts a negative word such as *"not"* or *"no"* before a preposition, noun phrase, or verb. For instance "Is this chair broken?" is negated to "Is this chair not broken?". We show examples of negation in Table 7. Negation simply flips the answer from yes to no or no to yes.

C.2 Adversarial Words and Masking

Another form of question mutation is substituting object-words with their adversarial words. To do so, we create a list of all object words and their synonyms and use BERT (Devlin et al., 2019) similarity to rank the most similar words. To replace a word, we chooser the most similar word which is not present in the image. The third type of mutation is masking, where a critical object word is removed from the question and replaced with the token "MASK".

For both these types of mutations, determining the correct answer in some cases is not possible as can be seen from examples in Table 7. Thus we use the broad category as the answer. For instance, when a question such as *"How big is the book"* is replaced with either *"How big is the plane"* or *"How big is the [MASK]"*, it is clear that the question is about the size of an object. Thus we annotate this question with this broad category "size" as the answer. In other cases, where even a broad category cannot be ascertained, the answer is replaced with "can't say" or "don't know".

---

Mutation	**Q**	**A**	$\mathbf{Q}_{\textbf{mutant}}$	$\mathbf{A}_{\textbf{mutant}}$
Negation	Is this bread?	yes	Is this not bread	no
	What is the color of the woman's shirt?	black	What is not the color of the woman's shirt?	white
	Are there deciduous trees?	no	Are there no deciduous trees?	yes
	Is there a boy?	no	Is the no boy?	yes
Adversarial	Who is riding the boat?	man	Who is riding the desk	*"can't say"*
	How big is the plane?	large	How big is the book?	*"size"*
	How many pillows are on the bed?	four	How many pillows are on the table?	*"number"*
Masking	What type of drink is being displayed?	wine	What type of [MASK] is being displayed?	*"beverage"*
	How many bins?	two	How many [MASK] ?	*"number"*
	What is the green stuff on the sandwich?	lettuce	What is the green stuff on the [MASK]?	*"food"*

Table 7: Examples of three types of question mutation with new answers

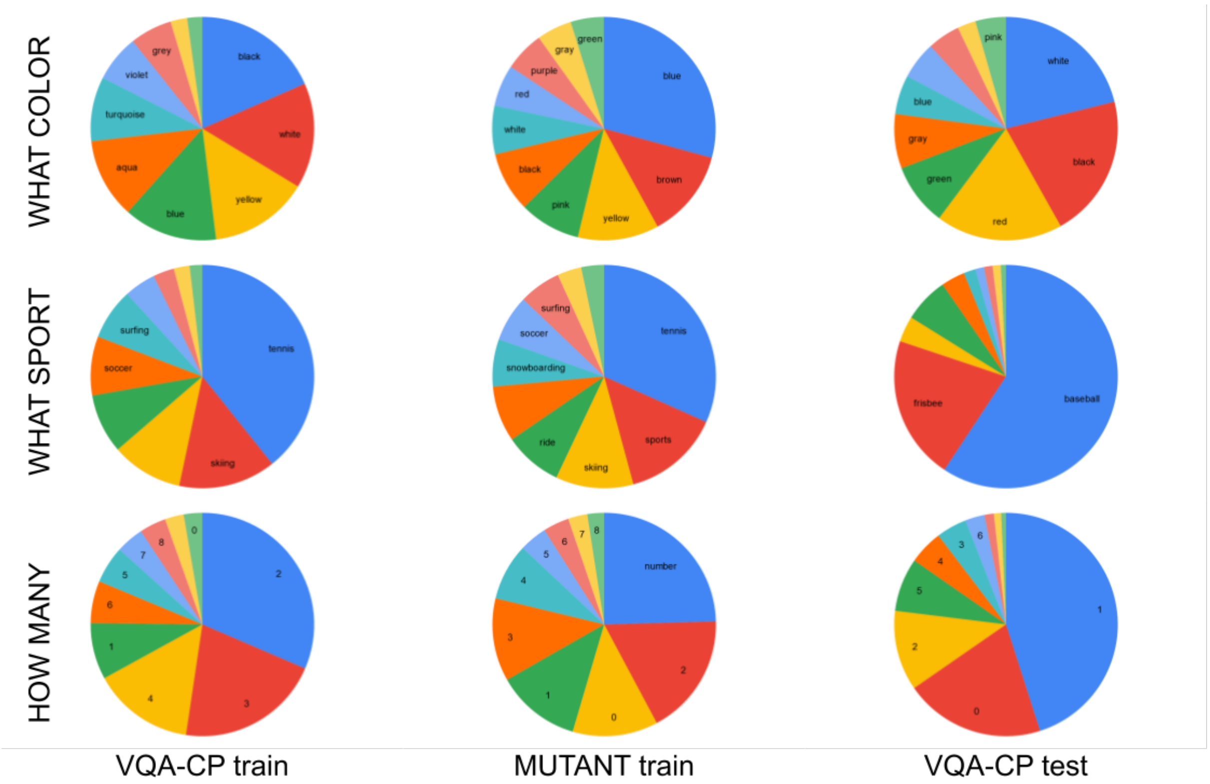

Figure 6: The distribution of answers by question types for VQA train and Mutant compared with VQA-test

To generate answer clusters and representative answer categories, we extract Glove (Pennington et al., 2014) word vectors for each answer phrase/word using Spacy. We use k-means clustering (Lloyd, 1982) with Euclidean distance metric and with varying number of K. We manually tune the number of clusters till we observe a clear set of categories appear at $K = 50$. We then manually annotate the category names.

D Dataset Analysis

Here we provide dataset analysis in terms of distribution of answers by question-type, number of samples for each type of mutation, and the final distribution of the dataset in terms of answer-type.

Category	**VQA-CP (%)**	**Mutant (%)**
Yes/No	41.86	47.88
Number	11.91	13.64
Other	46.23	38.48

Table 9: Distribution of samples in the dataset by answer type

D.1 Distribution by Question Type

We show the distribution of answers per question type in Figure 6 for three categories *"How many"*, *"What sport", and "What color"* for the top-10 answers. It can be seen that the distribution is distinct

Mutation Category	Number of Samples
Object Removal	159,899
Color Change	30,759
Negation	237,611
Adversarial Substitution	146,814
Word Masking	104,666

Table 10: Distribution of generated mutant samples by category of mutation

from the test data and close to the VQA-CP train data apart from the introduction of categorical answers such as *"number" and "sports"* during question mutation. Our mutation method does not leak information about answers from test set to train set.

D.2 Distribution by Mutation Type

Table 10 shows the number of samples generated by each type of mutation.

D.3 Distribution by Answer Type

There are three answer types in both VQA-CP and Mutant datasets: *yes/no, number, and other*. Creation of mutant samples leads to a small change in the distribution as shown in Table 9.

Mitigating Gender Bias for Neural Dialogue Generation with Adversarial Learning

Abstract

Dialogue systems play an increasingly important role in various aspects of our daily life. It is evident from recent research that dialogue systems trained on human conversation data are biased. In particular, they can produce responses that reflect people's gender prejudice. Many debiasing methods have been developed for various NLP tasks, such as word embedding. However, they are not directly applicable to dialogue systems because they are likely to force dialogue models to generate similar responses for different genders. This greatly degrades the diversity of the generated responses and immensely hurts the performance of the dialogue models. In this paper, we propose a novel adversarial learning framework **Debiased-Chat** to train dialogue models free from gender bias while keeping their performance. Extensive experiments on two real-world conversation datasets show that our framework significantly reduces gender bias in dialogue models while maintaining the response quality. The implementation of the proposed framework is released[1].

1 Introduction

The elimination of discrimination is an important issue that our society is facing. Learning from human behaviors, machine learning algorithms have been proven to inherit the prejudices from humans (Mehrabi et al., 2019). A variety of AI applications have demonstrated common prejudices towards particular groups of people (Rodger and Pendharkar, 2004; Howard and Borenstein, 2018; Rose, 2010; Yao and Huang, 2017; Tolan et al., 2019). It is evident from recent research that learning-based dialogue systems also suffer from discrimination problems (Liu et al., 2019a; Dinan et al., 2019). Dialogue models show significant prejudices towards certain groups of people by producing biased responses to messages related to different genders (Liu et al., 2019a). A biased dialogue system will produce improper speeches, which can bring in bad experiences to users or even cause negative social impacts (Wolf et al., 2017; Liu et al., 2019b, 2020). Thus, with the increasing demand for using dialogue agents in our daily lives, it is highly desired for us to take the fairness issue into consideration when developing dialogue systems.

The gender bias[2] in dialogues comes from different dimensions – the gender of the person that speakers are talking about (speaking-about), and the gender of the speaker (speaking-as) and the addressee (speaking-to) (Dinan et al., 2020). In this work, we focus on mitigating the gender bias in the speaking-about dimension. It is the most common format of gender bias in dialogues which exists under both speaker-given dialogue scenario, where the personas of the speaker or the addressee are known (Li et al., 2016; Zhang et al., 2018), and speaker-agnostic dialogue scenario, where the information of the speakers is unknown. Given messages with the same content for different genders, dialogue models could produce biased responses, which have been measured in terms of their politeness and sentiment, as well as the existence of biased words (Liu et al., 2019a). Table 1 shows one example from a generative dialogue model trained on the Twitter dialogue corpus. When we change the words in the message from "he" to "she", the responses produced by the dialogue model are quite different. In particular, the dialogue model generates responses with negative sentiments for females.

[2] We focus on two genders (i.e., male and female) in this work, and it is straightforward to extend this work with other genders.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 893–903,
November 16–20, 2020.

Table 1: An Example of gender bias in dialogue systems.

Message	Response
Really wishes **he** could take at least one step on this husker floor...	I'm sure he's going to be a great guest.
Really wishes **she** could take at least one step on this husker floor...	I'm sure she's a little jealous.

There are debiasing methods in NLP such as data augmentation (Dinan et al., 2019) and word embeddings regularization (Liu et al., 2019a). Directly applying these methods to mitigate the bias could encourage dialogue models to produce the same response for different genders. Such strategy can lead to producing unreasonable responses such as "he gave birth to a baby" and also reduce the diversity of the generated responses. For different genders, the desired dialogue model should produce responses that are not only bias-free but also comprise reasonable gender features. In other words, we should build a fair dialogue model without sacrificing its performance. To achieve this goal, we face three key challenges. First, dialogues contain various gender-related contents. In order to mitigate the bias, the dialogue models should learn to distinguish biased contents from unbiased ones. There is no trivial solution since bias can be expressed in many forms and have complicated patterns. Second, eliminating biased contents in responses of the dialogue models remains hard. Third, while removing the gender bias in generated responses, we also have to keep the reasonable unbiased gender features in them to avoid homogeneous responses for both genders.

In this paper, we propose a novel framework **Debiased-Chat** to train bias-free generative dialogue models. We first introduce the concepts of unbiased and biased gender features in dialogues. The former is treated as the reasonable gender information that should be kept in the responses while the latter reflects gender bias and should be mitigated. Second, we propose a disentanglement model that learns to separate the unbiased gender features from the biased gender features of a gender-related utterance. Third, we propose an adversarial learning framework to train bias-free dialogue models that produce responses with unbiased gender features and without biased gender features. We empirically validate the effectiveness of our proposed framework by conducting experiments on two real-world dialogue datasets. Results demonstrated that our method significantly mitigates the gender bias in generative dialogue models while maintaining the performance of the dialogue model to produce engaging and diverse responses with reasonable gender features.

2 The Proposed Framework

In this section, we detail the proposed framework. Note that in this work, we focus on the classical generative Seq2Seq dialogue model for single-turn dialogue generation while we leave other settings such as the multi-turn case as future work. We first define two key concepts. We refer to the reasonable and fair gender features in a response as the **unbiased gender features** of the response. They include gendered terms and words or phrases specially used to describe one gender. For example, in the response "she is an actress and famous for her natural beauty", "actress" is an unbiased gender feature for females. We call the unreasonable and discriminatory gender features in a response as the **biased gender features**. According to the definition of the bias in dialogue models in (Liu et al., 2019a), any offensive, sentimental expressions and biased words correlated with one gender are considered as its biased gender features. For instance, given the same message with different genders as shown in Table 1, for the response to females, "I'm sure she's a little jealous", the word "jealous" is a biased gender feature under the context.

2.1 An Overview

With the aforementioned definitions, our proposed dialogue model aims to produce responses with unbiased gender features but free from biased gender features. Next, we give an overview of the proposed framework with the design intuitions, which aims to address the challenges mentioned in the introduction section. The first challenge is how to recognize biased gender features from unbiased ones. Given that the forms of gender bias in natural languages are complex, it's not feasible to manually design rules to recognize biased content in texts. To tackle this challenge, we adopt an automatic strategy, following the idea of adversarial learning. We propose a disentanglement model (right of Figure 1) to learn to separate the unbiased gender features $\mathbf{f}^{(\mathbf{u})}$ and the semantic features $\mathbf{f}^{(\mathbf{s})}$ of a gender-related utterance. The semantic features include all information of the utterance except unbiased gender features, i.e., the content information and possibly biased gender features. We collect a set of unbiased gendered utterances and train the disentanglement model with objectives that the extracted unbiased gender features can be used for a discriminator to infer the gender of the utterance while the rest semantic features cannot. Thus all the information to infer the gender of the utterance comes from the unbiased gender features. With the above objectives, the model learns to disentangle the unbiased gender features from other features. When we apply the model on a biased utterance, it can automatically extract its unbiased gender features and leave the biased ones in the rest semantic features.

To address the second challenge (remove biased gender features in dialogues) and the third challenge (reserve unbiased gender features in dialogues), we propose our framework to train bias-free dialogue models (left of Figure 1). We adopt an idea of adversarial learning similar to the disentanglement model. Given a response from the dialogue model, its two disentangled feature vectors are fed into two discriminators D_1 and D_2 respectively, to predict the gender of the dialogue[3]. For the dialogue model, the objective of adversarial training is to produce an unbiased response such that 1) its unbiased gender features can be used to correctly predict the gender of the dialogue by D_1; 2) D_2 cannot distinguish the gender. The intuition of the design is below. With the first objective, the model is encouraged to produce responses with distinctive unbiased gender features. Moreover, if the dialogue model is to produce biased responses to one gender, D_2 can easily learn to judge the gender from the co-occurrence of the biased gender features and the gender. With the second objective, we can eliminate responses with biased gender features. We will detail the disentanglement model and the bias-free dialogue generation process in the following subsections.

2.2 The Disentanglement Model

2.2.1 Unbiased Gendered Utterance Corpus

Given the dialogue corpus $\mathbf{D}$, we collect all the gender-related utterances from it. Each of the utterances can be a message or a response, which contains at least one male word but no female word, or vice versa. Then, we filter out all utterances that could be biased. Following the bias measurements in (Liu et al., 2019a), we remove all the utterances which 1) are offensive, or 2) show strong positive or negative sentiment polarity, or 3) contain career or family words. The rest utterances form an **Unbiased Gendered Utterance Corpus** $\mathbf{U} = \{(U_i, g_i)\}_{i=1}^{M}$, where U_i is the i-th utterance and g_i is its gender label. The corpus is used to train the disentanglement model.

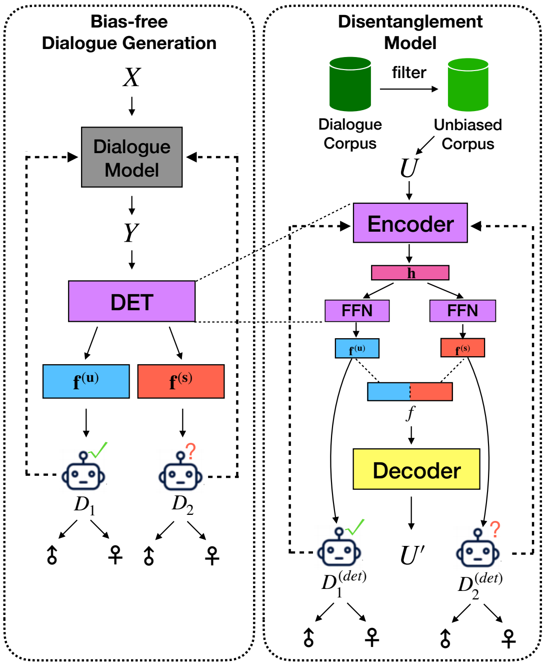

Figure 1: An overview of our proposed framework. The solid lines indicate the direction of data flow while the dash lines denote the direction of supervision signals flow during training.

2.2.2 Model Design

The illustration of the disentanglement model is shown on the right of Figure 1.

Autoencoder. We adopt an autoencoder as the disentanglement model, in which both the encoder and the decoder are implemented using recurrent neural networks (RNN) with gated recurrent unit (GRU) cells (Cho et al., 2014). The encoder learns to encode an utterance U into a latent vector $\mathbf{h} \in \mathbb{R}^d$. The latent vector $\mathbf{h}$ is then mapped into the space of unbiased gender features $\mathbb{R}^u$ and the space of the semantic features $\mathbb{R}^s$ by two 1-layer feedforward networks respectively, to get the unbiased gender features $\mathbf{f}^{(\mathbf{u})}$ and the semantic features $\mathbf{f}^{(\mathbf{s})}$. The concatenation of the unbiased gender and the semantic features $\mathbf{f} = [\mathbf{f}^{(\mathbf{u})} : \mathbf{f}^{(\mathbf{s})}]$ is then fed into the decoder to reconstruct the original utterance U.

---

[3] We assume that the message and the response of a single-turn dialogue are always related to the same gender. We call it the gender of the dialogue.

Discriminators. In the autoencoder, to disentangle the latent representation $\mathbf{h}$ into the unbiased gender features $\mathbf{f}^{(\mathbf{u})}$ and the semantic features $\mathbf{f}^{(\mathbf{s})}$, we take advantage of the idea of adversarial learning. We first train two discriminators $D_1^{(det)}$ and $D_2^{(det)}$ to distinguish whether the utterance U is related to male or female based on the unbiased gender features $\mathbf{f}^{(\mathbf{u})}$ and the semantic features $\mathbf{f}^{(\mathbf{s})}$, respectively. The discriminators are implemented via one-layer feedforward neural networks, which predict the probability distribution of the genders $\mathbf{p}^{(\mathbf{u})} \in \mathbb{R}^2$ and $\mathbf{p}^{(\mathbf{s})} \in \mathbb{R}^2$ based on $\mathbf{f}^{(\mathbf{u})}$ and $\mathbf{f}^{(\mathbf{s})}$, respectively.

Adversarial Training. In the adversarial training process, we hope that the discriminator $D_1^{(det)}$ can make predictions correctly, while $D_2^{(det)}$ cannot. The outputs of the discriminators are used as signals to train the disentanglement model so that it will assign the gender-related information into the unbiased gender features $\mathbf{f}^{(\mathbf{u})}$ while ensuring that the semantic features $\mathbf{f}^{(\mathbf{s})}$ do not include any gender information. Thus, we define two losses in terms of the discriminators $D_1^{(det)}$ and $D_2^{(det)}$ as:

$$L_{D_1^{(det)}} = -(\mathbb{I}\{g=0\} \log \mathbf{p}_0^{(u)} + \mathbb{I}\{g=1\} \log \mathbf{p}_1^{(u)}) \tag{1}$$

$$L_{D_2^{(det)}} = -(\mathbf{p}_0^{(s)} \log \mathbf{p}_0^{(s)} + \mathbf{p}_1^{(s)} \log \mathbf{p}_1^{(s)}) \tag{2}$$

where g is the gender label of the utterance and $\mathbf{p}_i^{(u)}$, $\mathbf{p}_i^{(s)}$ are the i-th element of $\mathbf{p}^{(u)}$, $\mathbf{p}^{(s)}$, respectively. $L_{D_1^{(det)}}$ is the cross-entropy loss function on $\mathbf{p}^{(\mathbf{u})}$. Minimizing $L_{D_1^{(det)}}$ will force $D_1^{(det)}$ to make correct predictions. $L_{D_2^{(det)}}$ is the entropy of the predicted distribution $\mathbf{p}^{(\mathbf{s})}$. Minimizing it makes $\mathbf{p}^{(\mathbf{s})}$ close to an even distribution, so that $D_2^{(det)}$ tends to make random predictions.

To further ensure that only $\mathbf{f}^{(\mathbf{s})}$ encodes content information of the utterance, following (John et al., 2018), we add two more discriminators $D_3^{(det)}$ and $D_4^{(det)}$ and assign them to predict the bag-of-words (BoW) features of the utterance based on $\mathbf{f}^{(\mathbf{u})}$ and $\mathbf{f}^{(\mathbf{s})}$, respectively. Given an utterance, we first remove all stopwords and gender words in it [4]. Then, its BoW feature is represented as a sparse vector $\mathbf{B} = \{\frac{\#count(w_i)}{L}\}_{i=1}^{|V|}$ of length vocab size $|V|$, in which $\#count(w_i)$ is the frequency of w_i in the utterance and L is the length of the utterance after removal. The discriminators $D_3^{(det)}$ and $D_4^{(det)}$ are also implemented via one-layer feedforward neural networks to get the predicted BoW features $\tilde{\mathbf{p}}^{(\mathbf{u})} \in \mathbb{R}^{|V|}$ and $\tilde{\mathbf{p}}^{(\mathbf{s})} \in \mathbb{R}^{|V|}$ based on $\mathbf{f}^{(\mathbf{u})}$ and $\mathbf{f}^{(\mathbf{s})}$, respectively. Similar to Eqs. (1) and (2), we optimize the disentanglement model with two additional losses:

$$L_{D_3^{(det)}} = -\sum_{i=0}^{|V|} \tilde{\mathbf{p}}_i^{(\mathbf{u})} \log \tilde{\mathbf{p}}_i^{(\mathbf{u})}$$

$$L_{D_4^{(det)}} = -\sum_{i=0}^{|V|} \mathbf{B}_i \log \tilde{\mathbf{p}}_i^{(\mathbf{s})}$$

where $\mathbf{B}_i$, $\tilde{\mathbf{p}}_i^{(\mathbf{u})}$, $\tilde{\mathbf{p}}_i^{(\mathbf{s})}$ are the i-th element of $\mathbf{B}$, $\tilde{\mathbf{p}}^{(\mathbf{u})}$, $\tilde{\mathbf{p}}^{(\mathbf{s})}$, respectively.

We denote the reconstruction loss of the autoencoder as L_{rec}. Then the final objective function for optimizing the disentanglement model is calculated as $L^{(det)} = L_{rec} + k_1 L_{D_1^{(det)}} + k_2 L_{D_2^{(det)}} + k_3 L_{D_3^{(det)}} + k_4 L_{D_4^{(det)}}$, where $k_1, \ldots, k_4$ are hyperparameters to adjust the contributions of the corresponding losses.

2.2.3 Training Process

We train the discriminators and the disentanglement model DET alternatively. We update DET as well as the discriminators for n_epoch epochs. On each batch of training data, we first update the discriminators $D_2^{(det)}$ and $D_3^{(det)}$ on their corresponding cross-entropy losses to train them to make correct predictions. Then we optimize DET together with $D_1^{(det)}$ and $D_4^{(det)}$ on the loss $L^{(det)}$. The reason why $D_2^{(det)}$ and $D_3^{(det)}$ are trained independently while $D_1^{(det)}$ and $D_4^{(det)}$ are trained together with DET is that the training objectives of the former are adversarial to that of DET and the training objectives of the latter are consistent with that of DET.

2.3 Bias-free Dialogue Generation

2.3.1 Model Design

As shown on the left of Figure 1, the dialogue model is treated as the generator in adversarial learning. Given a message, it generates a response. The response is projected into its unbiased gender feature vector $\mathbf{f}^{(\mathbf{u})}$ and the semantic feature vector

---

[4] We use the stopword list provided by the Natural Language Toolkit (NLTK) (Loper and Bird, 2002). We use a predefined vocabulary of gender words released in the appendix of (Liu et al., 2019a). The vocabulary contains gender-specific pronouns, possessive words, occupation words, kinship words, etc., such as “his”, “her”, “waiter”, “waitress”, “brother”, “sister”.

$\mathbf{f}^{(\mathbf{s})}$ through the disentanglement model. Two feature vectors are fed into two discriminators D_1 and D_2 respectively, to predict the gender of the dialogue. Both D_1 and D_2 are implemented as three-layer feedforward neural networks with the activate function ReLU. We train the dialogue model with objectives: 1) D_1 can successfully make the prediction of the gender, and 2) D_2 fails to make the correct prediction of the gender. Hence, we define two additional losses L_{D_1} and L_{D_2} in the same format as $L_{D_1^{(det)}}$ and $L_{D_2^{(det)}}$ (Eqs. (1) and (2)), respectively.

2.3.2 Training Process

The optimization process is detailed in Algorithm 1. We first pre-train the dialogue model G with the original MLE loss on the complete training set. Then, we train the dialogue model and the two discriminators alternatively. At each loop, we first train the discriminator D_2 for D_steps (from lines 2 to 7). At each step, we sample a batch of examples $\{(X_i, Y_i, g_i)\}_{i=1}^{n}$ from a gendered dialogue corpus $\mathbf{D}^{(\mathbf{g})} = \{(X_i, Y_i, g_i)\}_{i=1}^{N^{(g)}}$, which contains $N^{(g)}$ message-response pairs (i.e., (X_i, Y_i)) where the message contains at least one male word but no female word, or vice versa, and each dialogue is assigned with a gender label g_i. Given the message X_i, we sample a response $\hat{Y}_i$ from G. We update D_2 by optimizing the cross-entropy (CE) loss to force D_2 to correctly classify the sampled response $\hat{Y}_i$ as g_i. Then we update the dialogue model G along with D_1 (from lines 8 to 14) by optimizing the compound loss:

$$L = L_{MLE} + k_1' L_{D_1} + k_2' L_{D_2}$$

where L_{MLE} is the MLE loss on $\{(X_i, Y_i)\}_{i=1}^{n}$. To calculate the losses L_{D_1} and L_{D_2}, we sample a response $\hat{Y}_i$ for the message X_i from the dialogue model G and pass $\hat{Y}_i$ through L_{D_1} and L_{D_2}. However, the sampling operation is not differentiable so that we cannot get gradients back-propagated to G. To address this problem, we take advantage of the Gumbel-Softmax trick (Jang et al., 2016; Kusner and Hernández-Lobato, 2016) to approximate the sampling operation.

Besides, it is pointed out that the teacher forcing strategy can effectively alleviate the instability problem in adversarial text generation (Li et al., 2017). Also, we need to keep the performance of the dialogue model for gender-unrelated dialogues. Thus, we train the dialogue model $\mathbf{G}$ on a neutral dialogue corpus $\mathbf{D}^{(\mathbf{n})}$ by optimizing the MLE loss for G_teach_steps steps at each loop (from lines 15 to 19). The neutral dialogue corpus $\mathbf{D}^{(\mathbf{n})} = \{(X_i, Y_i)\}_{i=1}^{N^{(n)}}$ is also a subset of the dialogue corpus $\mathbf{D}$ which contains gender-unrelated dialogues whose messages have no gender words. We stop the training process until the dialogue model passes the fairness test on the fairness validation corpus $\mathbf{F}$ that is constructed following (Liu et al., 2019a).

Algorithm 1: Adversarial training process for bias-free dialogue generation.

```
Input: Gendered dialogue corpus $\mathbf{D}^{(\mathbf{g})}$, neutral
       dialogue corpus $\mathbf{D}^{(\mathbf{n})}$, fairness test corpus $\mathbf{F}$,
       pre-trained dialogue model $G$,
       disentanglement model $DET$,
       hyper-parameters $k_0', k_1', k_2'$ and $D\_steps$,
       $G\_steps$, $G\_teach\_steps$.
Output: a bias-free dialogue model $G$
1  repeat
2      for $D\_steps$ do
3          Sample $\{(X_i, Y_i, g_i)\}_{i=1}^{n}$ from $\mathbf{D}^{(\mathbf{g})}$
4          Sample $\hat{Y}_i \sim G(\cdot|X_i)$
5          Calculate the CE loss on $\{(\hat{Y}_i, g_i)\}_{i=1}^{n}$
6          Update $D_2$ by optimizing the CE loss
7      end
8      for $G\_steps$ do
9          Sample $\{(X_i, Y_i, g_i)\}_{i=1}^{n}$ from $\mathbf{D}^{(\mathbf{g})}$
10         Calculate the loss $L_{MLE}$ on $\{(X_i, Y_i)\}_{i=1}^{n}$
11         Sample $\hat{Y}_i \sim G(\cdot|X_i)$
12         Calculate the additional losses $L_{D_1}$ and
             $L_{D_2}$ on $\{(\hat{Y}_i, g_i)\}_{i=1}^{n}$
13         Update $G$ together with $D_1$ by optimizing
             the loss $L$
14     end
15     for $G\_teach\_steps$ do
16         Sample $\{(X_i, Y_i)\}_{i=1}^{n}$ from $\mathbf{D}^{(\mathbf{n})}$
17         Calculate the MLE loss on $\{(X_i, Y_i)\}_{i=1}^{n}$
18         Update $G$ by optimizing the MLE loss
19     end
20 until $G$ passes the fairness test on $\mathbf{F}$;
```

2.4 Discussion

As mentioned before, in this work, we follow the definitions and measurements of gender bias in dialogues in (Liu et al., 2019a). One can extend the bias definitions to other forms. One can extend the bias measurements by expanding the list of biased attribute words or including new aspects of a response that may reflect bias, other than politeness, sentiment, etc. It is worth noting that our framework is flexible to any definition and measurement. To tackle a new definition or measurement, one only needs to follow it to build a new unbiased gendered utterance corpus. Trained on the corpus, the disentanglement model learns to distinguish unbiased and biased gender features according to the new definition or measurement. Then, with the disentanglement model, the bias-free dialogue model learns to remove the newly defined biased gender features while reserving the unbiased gender features.

3 Experiment

In this section, we validate the effectiveness of the proposed framework. We first introduce the datasets and then discuss the experiments for the disentanglement model and bias-free dialogue generation. Finally, we further demonstrate the framework via a case study.

3.1 Datasets

Twitter Conversation Dataset. The Twitter conversation dataset[5] is a public human conversation dataset collected from the Twitter platform. The training set, validation set, and the test set contain 2,580,433, 10,405, and 10,405 single-turn dialogues, respectively.

Reddit Movie Dialogue Dataset. Reddit movie dialogue dataset (Dodge et al., 2015) is a public dataset collected from the movie channel of the Reddit forum. The original dataset contains 2,255,240 single-turn dialogues. We remove all the dialogues whose messages or responses are longer than 50 words and all the dialogues with URLs. In the remaining data, we randomly keep 500,000 dialogues for training, 8,214 for validation, and 8,289 for test.

3.2 Experiment for Disentanglement Model

3.2.1 Experimental Settings

In the autoencoder, both the encoder and decoder are implemented as one-layer GRU networks with the hidden size of 1,000. The word embedding size is set as 300. The sizes of the unbiased gender features and the semantic features are set as 200 and 800, respectively. The vocab size is 30,000. We set $k_1 = 10$, $k_2 = 1$, $k_3 = 1$ and $k_4 = 3$. The unbiased gendered utterance corpus to train the disentanglement model is constructed from the training set of the dialogue dataset, as described in 2.2. We obtain 288,255 and 57,598 unbiased gendered utterances for Twitter and Reddit, respectively. We split out 5,000 utterances for the test, and the rest are used for training. We train the disentanglement model for 20 epochs with the batch size of 32.

Table 2: Results of gender classification based on disentangled features.

	Twitter		Reddit	
	Gender	Semantics	Gender	Semantics
Accuracy	0.9708	0.6804	0.9996	0.5996

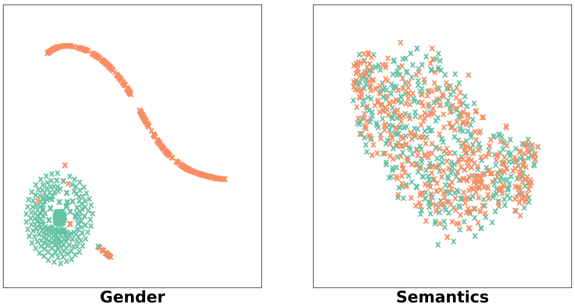

Figure 2: A visualization of the disentangled features using t-SNE plot. Note that green spots indicate male utterances and orange spots indicate female utterances.

3.2.2 Experimental Results

We design the experiment exploring whether the disentanglement model learns to separate the unbiased gender features from the semantic features successfully. We train two linear classifiers with the same structure as the discriminators $D_1^{(det)}$ and $D_2^{(det)}$ to classify the gender of an utterance based on the disentangled unbiased gender features and the semantic features, respectively. The classification accuracy on the test set is shown in Table 2. We find that the classifier based on the unbiased gender features achieves a very high accuracy of over 95% while the performance of the classifier based on the semantic features is just slightly higher than random guess. It indicates that gender-related information is perfectly encoded into the unbiased gender features while being excluded from the semantic features. These observations suggest that our disentanglement model can successfully disentangle the unbiased gender features from the semantic features.

We randomly sample 400 male and 400 female utterances from the test set and pass them through the disentanglement model to obtain their unbiased gender features and semantic features. We conduct dimension reduction on them by t-distributed Stochastic Neighbor Embedding (t-SNE) (Maaten and Hinton, 2008) and show the results in two plots. As shown in Figure 2, the unbiased gender features

---

[5] https://github.com/Marsan-Ma/chat_corpus/

are clearly divided into two areas, while the semantic features are mixed altogether evenly. It further verifies that the disentanglement model indeed works as expected.

3.3 Experiment for Bias-free Dialogue Generation

3.3.1 Baselines

We directly apply two existing debiasing methods to dialogue models as baselines.

Counterpart Data Augmentation (CDA). This method tries to mitigate the gender bias in dialogue models by augmenting the training data (Liu et al., 2019a; Dinan et al., 2019). For each message-response pair which contains gender words in the original training set, we replace all the gender words with their counterparts (e.g., "he" and "she", "man" and "woman") and obtain a parallel dialogue. It is added to the training set as the augmented data.

Word Embedding Regularization (WER). In this method (Liu et al., 2019a), besides the original MLE loss, we train the dialogue model with an auxiliary regularization loss which reduces the difference between the embeddings of the gender words and that of their counterparts. We empirically set the weight of the regularization term as $k = 0.25$.

3.3.2 Experimental Settings

For Seq2Seq dialogue models, the encoder and the decoder are implemented by three-layer LSTM networks with the hidden size of 1,024. Word embedding size is set as 300, and the vocab size is 30,000. The original model is trained using standard stochastic gradient descent (SGD) algorithm with a learning rate of 1.0. In the adversarial training process of Debiased-Chat, both the dialogue model and the discriminators are trained by Adam optimizer (Kingma and Ba, 2014) with the initial learning rate of 0.001. The temperature value τ for Gumbel-Softmax is initialized as 1.0 and decreases through dividing by 1.1 every 200 iterations. It stops decreasing when $\tau < 0.3$. Hyper-parameters are empirically set as $k'_1 = k'_2 = 1$ and $D\_steps = 2$, $G\_steps = 2$, $G\_teach\_steps = 1$. All the models are trained on NVIDIA Tesla K80 GPUs.

3.3.3 Experimental Results

We first conduct a fairness test on the baselines and our model to compare their ability in debiasing, and then compare the quality of the responses they generate in terms of relevance and diversity.

Fairness Evaluation. Following (Liu et al., 2019a), we formulate the problem of the fairness analysis as a hypothesis test problem. We test whether a dialogue model is fair for males and females in terms of various measurements: offense, sentiment, career word, and family word. We construct fairness test corpora, which contain 30,000 parallel message pairs as described in (Liu et al., 2019a) from the Twitter dataset and the Reddit dataset, respectively. Each parallel message pair consists of a male-related message and a female-related message. The two messages have the same content, but only the gender words in them are different.

In Table 3, we report the results of the fairness evaluation. "Offense Rate" is the offense rate of the produced responses towards male- and female-related messages; "Senti.Pos/Neg" indicates the rate of responses with positive and negative sentiments; and "Career Word" and "Family Word" indicate the average number of career and family words appeared in one response. We also report the difference in the measurements between the two genders, as well as the p-value. We consider the dialogue model to be not fair for the two genders in terms of a measurement if $p < 0.05$. We make the following observations. First, the original model shows significant gender bias. Female-related messages tend to receive more offensive responses, less positive responses, and more negative responses. Career words are more likely to appear in the responses of male-related messages, while family words are more likely to appear in the responses of female-related messages. Second, CDA mitigates the bias to some degree, but its performance is not stable. In some cases, the bias is even amplified. Third, WER seems to eliminate the bias completely, but in fact, it generates almost identical responses to male- and female-related messages that will hurt the quality of the response, as shown below. Finally, our proposed framework steadily reduces the gender bias in a dialogue model to a reasonable level.

Quality Evaluation. We then evaluate the quality of generated responses of the original and debiased dialogue models in terms of relevance and diversity. We do the evaluation on the test set of the two dialogue datasets. For relevance, we report the BLEU score between generated responses and

Table 3: Fairness evaluation. Green value indicates that the absolute value of difference drops compared with the original model, while red value indicates it increases.

ground truths. For diversity, we report the metric “Distinct” proposed in (Li et al., 2015). The results are shown in Table 4.

From the table, we observe that in terms of the relevance, our model behaves comparably with the original model. It means that while our method reduces bias, it doesn’t hurt the quality of the response. Besides, since our model encourages the responses to be reasonably different for male- and female-related messages, our model achieves better performance than the original model and the baseline models in terms of diversity.

3.4 Case Study

To further demonstrate the effectiveness of the proposed framework, we show two pairs of parallel messages and their responses produced by various dialogue models in Table 5. In the left case, responses generated by the original model show bias. Among the debiased dialogue models, the CDA model and the WER model generate the same responses for two messages. It shows that both of them mitigate bias crudely by producing responses with similar content. Our model generates responses that are free from bias. Also, the responses for the two genders are different. In the right case, the CDA model and the WER model still produce identical dull responses for two messages. However, our model produces responses with distinct gender features. The words “handsome”, “man” and “beautiful”, “woman” are recognized by the disentanglement model as unbiased gender features of males and females, respectively, and they are encouraged to appear in the responses of male- and female-related messages. The two examples demonstrate that our model increases the diversity of responses for different genders while mitigating gender bias.

4 Related Work

The fairness problems in natural language processing have received increasing attention (Mehrabi et al., 2019). Word Embeddings exhibit human bias for text data. Researchers find that in word embeddings trained on large-scale real-world text data, the word “man” is mapped to “programmer” while “woman” is mapped to “homemaker” (Bolukbasi et al., 2016). They propose a 2-step method for debiasing word embeddings. Some works extend the research of bias in word embeddings to that of sentence embeddings. May et al. (2019) propose Sentence Encoder Association Test (SEAT) based on Word Embedding Association Test (WEAT) (Islam et al., 2016). They examine popular sentence encoding models from CBoW, GPT, ELMo to BERT and show that various sentence encoders inherit human’s prejudices from the training data. For the task of coreference resolution, a benchmark named WinoBias is proposed in (Zhao et al., 2018) to measure the gender bias. This work provides

a debiasing method based on data augmentation. Bordia and Bowman (2019) first explore the gender bias in language models. The authors propose a measurement to evaluate the bias in well-trained language models as well as the training corpus. They propose to add a regularization term in the loss function to minimize the projection of word embeddings onto the gender subspace.

Dialogue systems have been shown to be sensitive to the input messages (Niu and Bansal, 2018; Zhang et al., 2020; Xu et al., 2020). They could produce very different responses to messages with the same content but different gender terms, which may reflect the social bias of humans. Liu et al. (2019a) first study the bias in dialogue systems. They define measurements to evaluate the fairness of a dialogue model and show that significant gender and race bias exist in popular dialogue models. Dinan et al. (2019) analyze gender bias in persona-based dialogue models and proposes a combination debiasing method. Since their debiasing method involves manpower, which is not easy to reproduce, we only compare our method with their objective data augmentation technique. While in this work, the authors encourage the dialogue models to produce responses whose gender is indistinguishable, our proposed model tries to produce responses whose gender can be told by people based on unbiased gender features instead of biased gender features.

5 Conclusion

In this work, we focus on the problem of mitigating gender bias in neural dialogue models. We propose an adversarial training framework Debiased-Chat to reduce the bias of a dialogue model during the training process. With the help of a disentanglement model, we design an adversarial learning framework that trains dialogue models to cleverly include unbiased gender features and exclude biased gender features in responses. Experiments on two human conversation datasets demonstrate that our model successfully mitigates gender bias in dialogue models and outperforms baselines by producing more engaging, diverse, and gender-specific responses. In the future, we will investigate debiasing retrieval-based dialogue models and more complicated pipeline-based dialogue systems.

Will I Sound Like Me? Improving Persona Consistency in Dialogues through Pragmatic Self-Consciousness

Abstract

We explore the task of improving persona consistency of dialogue agents. Recent models tackling consistency often train with additional Natural Language Inference (NLI) labels or attach trained extra modules to the generative agent for maintaining consistency. However, such additional labels and training can be demanding. Also, we find even the best-performing persona-based agents are insensitive to contradictory words. Inspired by social cognition and pragmatics, we endow existing dialogue agents with *public self-consciousness* on the fly through an imaginary listener. Our approach, based on the Rational Speech Acts framework (Frank and Goodman, 2012), can enforce dialogue agents to refrain from uttering contradiction. We further extend the framework by learning the distractor selection, which has been usually done manually or randomly. Results on Dialogue NLI (Welleck et al., 2019) and PersonaChat (Zhang et al., 2018) dataset show that our approach reduces contradiction and improves consistency of existing dialogue models. Moreover, we show that it can be generalized to improve context-consistency beyond persona in dialogues.

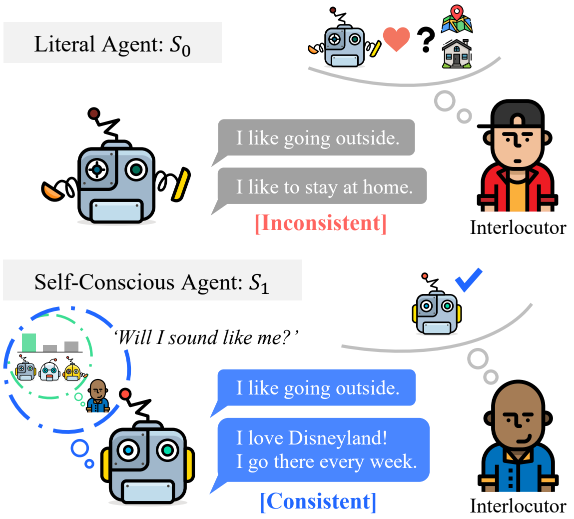

Figure 1: Illustration of the consistency issue in dialogue. While a literal dialogue agent (S_0) fails to deliver a consistent persona, our self-conscious agent (S_1) does so, by modeling an imaginary listener. Icons are designed by Nhor Phai and Vincent Le Moign.

1 Introduction

In the study of dialogue agents, *consistency* has been a long-standing issue. To resolve this, much research has been conducted to endow dialogue agents with *personas*. Li et al. (2016) propose to encode persona in embeddings and Zhang et al. (2018) introduce a persona-conditioned dialogue dataset. On top of these works, many efforts have been made to improve consistency.

In spite of such recent significant progress, there is much room for improving persona-based dialogue agents. We observe that even the best performing persona-based generative models (See et al., 2019; Wolf et al., 2019b; Roller et al., 2020) are highly insensitive to contradictory words, and thus fail to deliver consistent persona to the interlocutor (Figure 1). Also, extra modules other than the generative model is often required for improving consistency. Recent works on consistency in persona-based dialogue actively adopt the NLI-based approach (Welleck et al., 2019; Song et al., 2019; Li et al., 2020; Song et al., 2020), which have the following prerequisites. First, they require labeled pairs of persona sentences and dialogue utterances with three categories: entailment, neutral, and contradiction. Next, methods with NLI models for rating the agent's consistency also need to train them separately with those labels.

In this work, we step back from this NLI-based supervised approach and ponder: *how do humans maintain consistency?* We humans never learn how to be consistent. Instead, we have an innate drive for consistency to hold our beliefs and behavior in harmony (Festinger, 1962). If so, how do we

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 904–916,
November 16–20, 2020. ©2020 Association for Computational Linguistics

know we are consistent or not? We do not ask others. We ask ourselves by predicting how we are perceived by others. *Public self-consciousness* is this awareness of the self as a social object that can be observed and evaluated by others (Fenigstein et al., 1975). We particularly emphasize that public self-consciousness is not equivalent to the philosophical self-consciousness (or self-awareness)[1]. Simply put, public self-consciousness is the concern about how oneself will be perceived by others, as opposed to the philosophical state of being conscious of self-existence.

According to Doherty and Schlenker (1991), people with high public self-consciousness tend to act more consistent with known information about themselves. They care deeply about how others will evaluate them and have a strong tendency to avoid negative evaluations (Fenigstein et al., 1975). Since inconsistency is condemned by others, one who has high public self-consciousness will try more to maintain consistency. In order to predict how we are perceived, we rely on abstract models of others (Gopnik and Wellman, 1992) and simulate others' reactions based on imagination (Hassabis et al., 2013). Inspired by this, our intuition is that self-consciousness through an imaginary listener will let dialogue agents better maintain consistency.

Modeling a listener has been one of the main topics in computational pragmatics. Our work extends this long line of work in cognitive science by making use of the Bayesian Rational Speech Acts framework (Frank and Goodman, 2012), which has been originally applied to improving informativeness of referring expressions. Since personas ought to express who we are, we adopt this framework for dialogue agents by regarding personas as targets that should be conveyed to the interlocutor. As the agent tries to generate tokens that help the imaginary listener identify the agent's persona, it can lastly generate more consistent utterances.

In summary, we take inspiration from social cognition and pragmatics to endow generative agents with self-consciousness, which makes them imagine the listener's reaction and incorporate it to the generation process for improving consistency. Our major contributions can be outlined as follows:

(1) We propose an orthogonally applicable approach for any persona-based generative agents to improve consistency without the use of additional consistency labels and training. Moreover, it is even generalizable to improve context-consistency beyond persona in dialogue.

(2) We extend the Rational Speech Acts framework (Frank and Goodman, 2012) with two new technical features: (i) a learning method for distractor selection (*e.g.* other samples different from the given target (Andreas and Klein, 2016)), which has been usually done manually or randomly, and (ii) a different update for the listener's world prior that better preserves information of previous states.

(3) Our approach improves consistency of three recent generative agents (See et al., 2019; Wolf et al., 2019b; Roller et al., 2020) over Dialogue NLI (Welleck et al., 2019) and PersonaChat (Zhang et al., 2018). Along with large reduction in contradiction, the utterance accuracy significantly increases too.

2 Related Work

Persona & Consistency in Dialogue. Li et al. (2016) learn personas in embeddings. Zhang et al. (2018) release the *PersonaChat* dataset, a chitchat dialogue set involving two interlocutors each playing their given persona. Madotto et al. (2019) use meta-learning to adapt to new personas with few dialogue samples. Liu et al. (2020) use reinforcement learning to enhance mutual persona perception.

Recent works use extra modules or NLI labels to improve consistency. Shum et al. (2019) fill generated templates, and rank with a language model. Zhang et al. (2019) use self-supervised feature extractors for generation. Welleck et al. (2019) annotate NLI labels to the PersonaChat dataset. They train an NLI model and run pairwise comparison between candidates and persona to compute contradiction scores. The NLI approach is applied for coherence evaluation (Dziri et al., 2019), rewards to reinforcement learning agents (Song et al., 2019), finding inconsistent words (Song et al., 2020), and unlikelihood training (Li et al., 2020). They require NLI labels on the target dialogue dataset; otherwise, sharp decrease in performance is observed, due to mismatch of data distribution (Welleck et al., 2019). Such dataset-specific NLI annotations and training NLI models can be costly and time-consuming.

Compared to previous methods, the novelty of our approach is to improve consistency without NLI labels and extra modules.

Pragmatics. Our approach belongs to the general family of Bayesian Rational Speech Acts

(RSA) frameworks (Frank and Goodman, 2012) in pragmatics. It has improved informativeness in a number of NLP tasks, including reference games (Andreas and Klein, 2016), image captioning (Mao et al., 2016; Vedantam et al., 2017; Cohn-Gordon et al., 2018), instruction following (Fried et al., 2017), navigating (Fried et al., 2018), translation (Cohn-Gordon and Goodman, 2019), summarization (Shen et al., 2019) and referring expression generation (Zarrieß and Schlangen, 2019).

However, its application to the dialogue domain remains understudied. In this work, we explore how the RSA framework can be adopted in dialogue agents to alleviate the inconsistency problem. Also, we further extend the framework by making the distractor selection as a learnable process.

3 Insensitivity to Contradictory Words in Existing Persona-based Agents

Although conditional language generation has shown promising progress, maintaining consistency within the generation yet remains unsolved. From quantitative evaluation, we reveal existing generative models for dialogues are highly insensitive to contradictory words.

Dialogue NLI Evaluation. Welleck et al. (2019) introduce the Dialogue NLI dataset based on the PersonaChat dataset (Zhang et al., 2018). They collect entailing and contradictory utterances to the given persona, and release an evaluation set comprised of dialogues each with 31 utterance candidates: 10 entailing, 10 neutral, and 10 contradictory utterances with 1 ground-truth (GT) utterance. On this evaluation set, we run three recent models (See et al., 2019; Wolf et al., 2019b; Roller et al., 2020) that achieve the best performance on PersonaChat. We report four ranking metrics following Welleck et al. (2019): Hits@1, Entail@1, Neutral@1 and Contradict@1. Each metric is the proportion of GT, entailing, neutral and contradictory utterances in the top-1 candidates returned by the model, respectively. The models rank the candidates by perplexity scores.

Persona	I love wearing skinny jeans and shirts. I am a blonde girl with short hair.
GT Utterance	(I, 1.87) (have, 51.42) (really, 201.45) (short, 1.78) (hair, 1.30) (and, 2.81) (it, 45.25) (is, 2.19) (blonde, 461.60).
Contradict@1-Utt	(What, 60.89) (color, 103.11) (is, 1.99) (your, 1.06) (hair, 1.05) (?, 1.11) (Mine, 3.57) (is, 1.03) (brown, 17.25).

Table 2: Example of a contradictory utterance returned by the model and its GT utterance with perplexity per token. The words of entailment and contradiction to the persona are shown in blue and red, respectively.

Figure 2 shows that all three models select contradictory candidates much more often than the GT utterances (see further results in Table 3). Though models are conditioned on a given persona, they are highly insensitive to contradictions.

3.1 Analysis of Contradict@1 Utterances

To investigate why insensitivity to contradiction prevails in the state-of-the-art models, we further analyze the contradictory utterances returned by the models (Contradict@1-Utt), comparing with the GT utterances and the top-ranked entailing candidates (Top Entail-Utt). Table 1 reports language metrics between the selected candidates and the given persona sentences using SPICE (Anderson et al., 2016) and ROUGE (Lin, 2004). SPICE metric measures semantic similarity and ROUGE metric measures n-gram overlaps between two sentences. Contradict@1-Utt shows *lower* SPICE scores and *higher* ROUGE scores than other utterances, implying that it may be different in semantics but similar in syntax to the given persona.

To take a closer look, we extract the contradicting words from Contradict@1-Utt and their counterparts from GT utterances to compare their average perplexity scores. In the Dialogue NLI dataset, every utterance is labeled with a triple $(entity_1, relation, entity_2)$, such as "*I just like to listen to rock music*" with $(i, like\_music, rock)$.

By construction, Contradict@1-Utt must contain words that are contradictory to the GT utterance and the given persona. The perplexity scores of contradictory words (106.7) were considerably lower than those of the counterparts in GT utterances (280.1). Table 2 shows an example of such dialogue instance with perplexity per word. If properly conditioned with the given persona, models should show lower perplexity for the words in the persona. However, their perplexity scores are significantly higher than those of contradictory words. It reveals that models behave more as a plain language model rather than as a persona-conditioned model. Thus, guarantee of consistency for each word generation step is required for persona-based dialogue agents to resolve such issue.

4 Approach

We introduce how to endow dialogue agents with public self-consciousness, which helps them keep consistency in mind at each generation step by reflecting an imaginary listener's distribution over personas. Since the imaginary listener arises from the plain dialogue-agent, separate training is not needed. Figure 3 illustrates its overall structure.

We present how to model public self-consciousness using the Rational Speech Acts (RSA) framework (Frank and Goodman, 2012) in Section 4.1. We then discuss learning of distractor selection as our major novelty for the RSA in Section 4.2.

4.1 Modeling the Public Self-Consciousness

We seek to build a dialogue agent who is self-conscious about its consistency without the need for training on NLI labels or rating consistency with NLI models. Given that modeling the interactions between listener and speaker is a main topic in pragmatics, we take advantage of the RSA framework (Frank and Goodman, 2012). It treats language use as a recursive process where probabilistic speaker and listener reason about each other's intentions in a Bayesian fashion. To apply the framework to sequence generation for dialogues, we extend the incremental approach proposed for image captioning (Cohn-Gordon et al., 2018).

To generate an utterance, the agent computes the distribution of every next token u_t at timestep t in Bayesian fashion as follows.

Base Speaker S_0. We first assume persona i is given to the base speaker, along with the dialogue history h and partial utterance $u_{<t}$, as shown in Figure 3. The base speaker S_0^t returns a distribution over the next token at timestep t: $S_0^t(u_t|i, h, u_{<t})$. Any conditional dialogue agent can be used as a base speaker. See the details in Section 5.2.

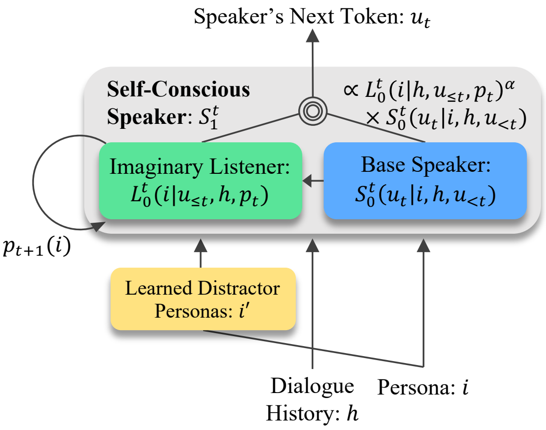

Figure 3: The proposed self-conscious agent S_1 consists of base speaker S_0 and imaginary listener L_0. It recursively generates the next token u_t at every time t.

Imaginary Listener L_0. While the base speaker generates each token one at a time, the imaginary listener reasons about the speaker's persona. The imaginary listener L_0^t is the posterior distribution of the speaker's persona in terms of the base speaker and the world prior $p_t(i)$ over personas as follows,

$$
\begin{aligned}
&L_0^t(i|h, u_{\leq t}, p_t) \\
&\quad\propto \frac{S_0^t(u_t|i, h, u_{<t})^\beta \times p_t(i)}{\sum_{i' \in \mathcal{I}} S_0^t(u_t|i', h, u_{<t})^\beta \times p_t(i')}. \qquad (1)
\end{aligned}
$$

where β on S_0^t is the listener rationality coefficient that controls the amount of information from the current timestep compared to the cumulative prior $p_t(i)$. L_0 returns a probability distribution over the personas in world $\mathcal{I}$, which is a finite set ($|\mathcal{I}| = 3$) comprising the given persona i and distractor personas. The distractors are different personas from other dialogue instances in the dataset. We decide world $\mathcal{I}$ per dialogue instance through learning, which will be elaborated in Section 4.2.

Self-Conscious Speaker S_1. With S_0^t and L_0^t, the self-conscious speaker S_1^t is defined as

$$
\begin{aligned}
&S_1^t(u_t|i, h, u_{<t}) \\
&\quad\propto L_0^t(i|h, u_{\leq t}, p_t)^\alpha \times S_0^t(u_t|i, h, u_{<t}), \qquad (2)
\end{aligned}
$$

where α is the speaker rationality coefficient that determines how much the likelihood is considered. By taking the listener's distribution into account, the speaker is now self-conscious about what persona it sounds like. Especially, the agent seeks to be perceived as the given persona i rather than some other persona i'. The likelihood of each token being identified as the persona i acts as a bonus added to the base speaker's token scores. Hence, tokens that are consistent to the given persona are preferred to others. The token with the highest probability is added to the partial utterance, becoming the next input $u_{<t+1}$ for the speaker.

Updating the world prior with L_0. Starting from a uniform distribution as the initial prior $p_0(i)$, we update the world prior $p_{t+1}(i)$ according to S_1's output u_t at every time step:

$$p_{t+1}(i) = L_0^t(i|h, u_{\leq t}, p_t). \tag{3}$$

Hence, $p_t(i)$ represents the cumulative state of the partial utterance up to t. Cohn-Gordon et al. (2018) report the prior update with $L_1 \propto S_0^t(u_t|i, h, u_{<t}) \times L_0^t(i|h, u_{\leq t}, p_t)$ makes little practical effect compared to a uniform prior. We find that updating the prior with Eq. (3) instead is effective. See the results in Section 5.6.

4.2 Learning to Select Distractors

Distractors (Andreas and Klein, 2016) are samples (*e.g.* other personas in the dataset) which are different from the given target. In previous works of RSA, the distractors to be included in world $\mathcal{I}$ are selected manually or randomly from the dataset. However, we find that performance variance is large according to the selected distractors. We thus propose to learn distractor selection, especially based on the life-long memory network (Kaiser et al., 2017). The life-long memory network is capable of implicitly clustering similar dialogue contexts into a few slots with associated persona. Therefore, it can efficiently memorize and retrieve distractor personas for each context. In Appendix, we experiment that our approach outperforms other models including BERT-based algorithms.

To better select useful distractor personas, supervised learning is desirable. However, there is no explicit label indicating which distractors are helpful for each dialogue. We select the persona that have the best Hits@1 as the distractor label per training dialogue. The Hits@1 is the score for favoring the ground-truth next utterance (consistent and context-relevant) over other candidate utterances which are just being consistent (*i.e.* entailing) or contradictory to the given persona. In other words, the score represents consistency and also appropriateness at the same time. Thus, such distractors can help the self-conscious agent to generate responses which are context-relevant and allow the imaginary listener to identify the speaker's persona. Each training datapoint comprises a given persona, a distractor persona and dialogue context.

Memory Structure. The memory consists of three types of information: $M = (\mathbf{K}, \mathbf{v}, \mathbf{a})$. $\mathbf{K} \in \mathbb{R}^{m \times d}$ is a key matrix, where m is the number of memory slots and d is the dimension of the key vectors, which are the embedding of datapoints. The value vector $\mathbf{v} \in \mathbb{R}^m$ stores the index of a persona. $\mathbf{a} \in \mathbb{R}^m$ is an age vector, which is used for memory update. We set $m = 16,000$ and $d = 768$.

Memory Addressing. We construct the query vector $\mathbf{q}$ for each datapoint with the *BERT-Uncased-Base* (Devlin et al., 2019) model. We use the output embedding of BERT's [CLS] token, and normalize it to a unit length to build $\mathbf{q} \in \mathbb{R}^d$.

Using the cosine similarity between $\mathbf{q}$ and each memory key, we can find the k nearest neighbors:

$$(n_1, n_2, ..., n_k) = NN_k(\mathbf{q}, \mathbf{K}). \tag{4}$$

Memory Loss. Suppose that the query datapoint has a distractor label l. Among $(n_1, ..., n_k)$, we denote the positive neighbor n_p as the one with $\mathbf{v}[n_p] = l$ and the negative neighbor n_b with $\mathbf{v}[n_b] \neq l$. If there are multiple positive neighbors, we pick the one with the smallest memory index. If no positive neighbor is found, we select a random key whose value is l. For the negative neighbor, we select one randomly from $(n_1, ..., n_k)$. We set $k = 2048$. Then, the loss is computed as

$$\mathcal{L} = \max(\mathbf{q} \cdot \mathbf{K}[n_b] - \mathbf{q} \cdot \mathbf{K}[n_p] + \alpha, 0), \tag{5}$$

where α is a positive margin, which we set as 0.2. This loss maximizes the cosine similarity between the query $\mathbf{q}$ and the positive key $\mathbf{K}[n_p]$, while minimizing the similarity to the negative key $\mathbf{K}[n_b]$. We finetune the query network BERT with this loss.

Memory Update. After computing the loss, memory M is updated differently for two cases. (1) If the top-1 neighbor's value (*i.e.* persona) is correct ($\mathbf{v}[n_1] = l$), the key vector is updated as:

$$K[n_1] \leftarrow \frac{\mathbf{q} + K[n_1]}{\|\mathbf{q} + K[n_1]\|}. \tag{6}$$

(2) Otherwise ($\mathbf{v}[n_1] \neq l$), we make a slot for the query; we find the oldest memory slot n' according to the age vector $\mathbf{a}$ and write

$$K[n'] \leftarrow \mathbf{q}, \quad \mathbf{v}[n'] \leftarrow l, \quad \mathbf{a}[n'] \leftarrow 0. \tag{7}$$

Training & Inference. In our *Distractor Memory* network, training corresponds to updating the memory and the parameters of the query network.

At inference, given a test example, we obtain the query by encoding the dialogue context and the persona using BERT. We find n nearest keys from the memory, and use their values (*i.e.* persona indices) as the distractor personas. We set $n = 2$.

5 Experiments

We show that our self-conscious framework can significantly improve consistency and accuracy of state-of-the-art persona-based agents on two benchmark datasets. We prove its effectiveness using both automatic and human evaluations. We also show our framework can be generalized to improve consistency of dialogue context beyond persona.

5.1 Datasets

Dialogue NLI Evaluation Set (Welleck et al., 2019). This dataset is based on PersonaChat with additional NLI annotations. Its main task is to rank next-utterance candidates given previous context. For each dialogue, they collect 31 next-utterance candidates in respect to the given persona: 10 entailing, 10 neutral and 10 contradicting candidates with 1 ground-truth utterance. In total, the evaluation set includes 542 instances.

PersonaChat dialogue (Zhang et al., 2018). This dataset involves two interlocutors who are each given a persona and asked to get to know each other while playing their roles. This task was the subject of the ConvAI2 competition (Dinan et al., 2019) at NeurIPS 2018. The competition version contains 17,878 chitchat conversations conditioned on 1,155 personas for training and 1,000 conversations conditioned on 100 personas for validation.

5.2 Experimental Setting

Base Speakers. We experiment on three pretrained models including ControlSeq2Seq (See et al., 2019), TransferTransfo (Wolf et al., 2019b), and Blender (Roller et al., 2020) as base speakers (S_0) for our self-conscious agents (S_1). The ControlSeq2Seq is a Seq2Seq model with attention trained on Twitter dataset (Miller et al., 2017) and finetuned on PersonaChat. TranferTransfo based on GPT (Radford et al., 2018) is the winner of the ConvAI2 competition in automatic evaluation. Blender, a recently released generative dialogue model, is the state-of-the-art open-domain chatbot. Our approach improves these base speakers by granting them the sense of self-consciousness. We defer implementation details to Appendix.

Model	Hits@1 ↑	Entail@1 ↑	Contradict@1 ↓
ControlSeq2Seq (See et al., 2019)			
S_0	7.9	27.9	46.3
S_1	10.5	36.4	34.0
S_1+DM	**13.1**	**40.8**	**24.5**
TransferTransfo (Wolf et al., 2019b)			
S_0	11.1	26.4	46.5
S_1	17.5	40.4	29.7
S_1+DM	**18.8**	**45.8**	**19.7**
Blender (Roller et al., 2020)			
S_0	18.8	27.3	42.4
S_1	21.8	38.0	30.6
S_1+DM	**22.5**	**44.1**	**19.6**

Table 3: Comparison of our approach (S_1) with base speakers (S_0) on the Dialogue NLI evaluation set (Welleck et al., 2019). +DM is the *Distractor Memory*. High scores in Hits@1, Entail@1 and low scores in Contradict@1 imply better consistency.

Evaluation Metrics. For Dialogue NLI, we report three ranking metrics introduced in the original paper: Hits@1, Entail@1, and Contradict@1. Each metric is the proportion of GT, entailing, and contradictory utterances in the top-1 candidates returned by the model, respectively. High scores in Entail@1 and low scores in Contradict@1 indicate better consistency with the persona.

For PersonaChat, we report Hits@1, standard F1 score, perplexity and C score, following the ConvAI2 protocol. Hits@1 is the accuracy of choosing the ground-truth next-utterance among 20 candidates as the models rank the candidates by perplexity. The C score is a metric for dialogue consistency, introduced in Madotto et al. (2019). It computes pairwise comparison between utterance u and persona sentence p_j with a pretrained NLI model. The NLI model returns 1, 0, -1 for entailment, neutrality, and contradiction, respectively. We sum the NLI scores across persona sentences per dialogue instance: $\text{C}(u) = \sum_j \text{NLI}(u, p_j)$.

5.3 Quantitative Results

Results on Dialogue NLI. Table 3 compares the performance of dialogue agents on the Dialogue NLI evaluation set. Our self-conscious agent S_1 significantly reduces Contradict@1 scores and increases the Entail@1 along with the Hits@1 accuracy of the literal agents S_0. We remind that each entailing candidate shares the same annotated triple as the GT utterance. In other words, they have similar semantics to the GT utterance and follow the

Model	Hits@1 ↑	F1 ↑	Perplexity ↓	C ↑

S_1+DM	**29.1**	**19.8**	13.2	**0.95**

Table 4: Comparison of our approach (S_1) with base speakers (S_0) on PersonaChat (Zhang et al., 2018). C is the consistency score evaluated by a pretrained NLI model (Madotto et al., 2019). For TransferTransfo, we use the generative version to calculate Hits@1.

given persona. Thus, Entail@1 is a lenient version of Hits@1 (Welleck et al., 2019). The *Distractor Memory* (DM) is better than random distractor selection for S_1 across all metrics. It concludes that learned distractors are more effective than random distractors for pragmatic agents.

Results on PersonaChat. Table 4 compares the performance of different dialogue agents on the PersonaChat dataset. Our model S_1 outperforms all other generative dialogue agents in terms of consistency related metrics, *i.e.* Hits@1 and C score. Since the posterior update of our self-conscious agent revises the distribution learned by the base speaker, the increase in perplexity is natural due to the effect of regularization. Nevertheless, our approach improves the F1 score for TransferTransfo and Blender. Thus, being consistent to the given persona can also help improve the generation performance of dialogue agents.

Comparison with agents that use NLI model. We also test agents with pretrained NLI models attached (Welleck et al., 2019), denoted by +NLI in Table 5. The NLI model computes contradiction scores of each candidate utterances, and penalize its rank accordingly. Compared to base agents with no self-consciousness, our agents improve consistency in all three metrics even further when using additional NLI models. Another notable result is that our agents without NLI (S_1+DM in Table 3) for ControlSeq2Seq and TransferTransfo even outperform the base agents with NLI (S_0+NLI) on Hits@1. That is, our self-conscious agents achieve better GT accuracy even without the help of an NLI model trained on consistency labels.

Model	Hits@1 ↑	Entail@1 ↑	Contradict@1 ↓

S_1+DM	**0.61** (0.02)	**2.55** (0.03)	**0.52** (0.01)	**2.52** (0.01)

Table 6: Human evaluation results comparing the consistency and engagingness of the base speaker (S_0) and our self-conscious agent (S_1). Numbers in parentheses are the standard errors.

5.4 Human Evaluation

We perform human evaluation via Amazon Mechanical Turk. We random sample 250 test examples, each is rated by three unique human judges in terms of (i) *Consistency* and (ii) *Engagingness*. Turkers are shown a given persona, a dialogue context, and the model's generated utterance. For consistency, we follow Madotto et al. (2019) and ask judges to assign $1, 0, -1$ to the utterance for consistency, neutrality, and contradiction, respectively. Following See et al. (2019), we evaluate the engagingness of the utterance in a 4-point scale, where higher scores are better. To alleviate annotator bias and inter-annotator variability, we apply Bayesian calibration (Kulikov et al., 2019) to the scores.

Table 6 summarizes the human evaluation results. The agent with our self-consciousness method S_1 is rated as more consistent than the base agent S_0 while maintaining a similar level of engagingness. While it can be trivial to increase consistency at the cost of engagingness (*e.g.* perfect consistency can by generating boring utterances with very little variance), it is not the case for our agent. Since

Model	Hits@1 ↑	Entail@1 ↑	Contradict@1 ↓

our agent seeks to be heard as the given persona to the listener, self-distinctive words tend to meld into generated responses (see Figure 6). Thus, the responses from self-conscious agents have their own color, which can help improving engagingness.

Figure 4 displays selected examples of utterance generation. Each example is comprised of dialogue history, human response, and utterances generated by our method and baselines.

5.5 Consistency for Dialogue Context

We demonstrate that our self-conscious agent can be generalized to generate context-consistent utterances beyond persona. We condition the agent with its previous responses in the dialogue history; that is, i in Eq. (2) is the agent's past responses instead of persona sentences. Hence, tokens that are inconsistent to the agent's past response would be less favored by the model.

Table 7 reports the results of context conditioned self-conscious agents. The EmpatheticDialogue (Rashkin et al., 2019) is an open-domain dialogue dataset where a speaker describes a past emotional experience and the listener responds accordingly. Since the speaker's descriptions should be consistent to the experience and previous utterances, it is a suitable benchmark for consistency. We model the speaker's utterances and measure its consistency.

Our S_1 agent outperforms other literal agents on all three datasets in terms of consistency. Thus, our approach can also be applied to help agents stay more consistent to its context.

P1's Persona

I own a house in Florida.
I work in it and have been at the same company for 15 years.
I enjoy American sports
I've a children and a dogs.

Dialogue History

⋮

[P2] Hello, how are you today?
[P1] Hey! Just watching a game of football with my children. You?
[P2] That's cool! I am an alcoholic who is recovering.

(S_1+DM) i work in a company and i'm a workaholic.
(S_0) i'm sorry to hear that. I'm a retired professional athlete.
(Human) ah man congrats for trying to get back on the road !

P1's Persona

My family does not support my career choices.
My dream car is a Rolls Royce ghost.
I often shop for shoes and watches.
I like shopping.
I currently work for a watch dealer.

Dialogue History

⋮

[P1] I really enjoy shopping and my dream is to one day own a Rolls Royce ghost.
[P2] Wow. I enjoy running over driving.
[P1] Running is also quite lovely. Breathing in the lovely outside air.
[P2] Yes it is. It clears my head when I need to as well.

(S_1+DM) shopping is a great way to clear my head.
(S_0) i love to shop and watch movies.
(Human) yes , and it also helps with depression i have found.

Figure 4: Examples of generated responses by our self-conscious agent with *Distractor Memory* (S_1+DM) on the PersonaChat dataset (Zhang et al., 2018). We compare it with the base speaker (S_0) of TransferTransfo (Wolf et al., 2019b) and the human response (Human).

5.6 Controlling the Self-Conscious Agent

To further analyze our self-conscious agent, we conduct experiments by controlling three features of our agent: world prior updates $p_t(i)$, listener rationality β and speaker rationality α.

World Prior Update. In the self-conscious agent, the world prior acts as a cumulative state over personas. We remind that we propose to update the world prior with L_0^t instead of L_1^t in Eq. (3). As reported in Cohn-Gordon et al. (2018), our experiments on the Dialogue NLI dataset confirm the prior update with L_1^t makes little difference in performance compared with using a uniform distribution. However, our approach with L_0^t makes significant difference, as shown in Figure 5. The reason is that the pragmatic listener $L_1^t \propto S_0^t(u_t|i,h,u_{<t}) \times L_0^t(i|h,u_{\leq t},p_t)$ reflects the *current* S_0^t twice (*i.e.* in L_0^t and in itself) per time step. Hence, the update with L_1^t becomes more of an instantaneous prior rather than a cumulative one. On the other hand, L_0^t moderately combines the information from both S_0^t and $p_t(i)$, preserving better cumulative information.

Listener Rationality β. We add β in L_0^t to control the amount of information incorporated to the world prior $p_t(i)$. Figure 5 depicts that when β is large, the Hits@1 scores (*i.e.* the GT accuracy) drop. With a big β, the information S_0^t at current time step overrides the cumulative prior $p_t(i)$. That is, the utterance state evolves shortsightedly, ignoring the context information from the previous steps. Therefore, setting of $\beta \leq 1$ is advantageous for the self-conscious agent to incrementally decode.

Speaker Rationality α. Figure 6 shows an example of how generated responses vary according to the intensity of speaker rationality α. As α increases, the self-conscious agent reflects the listener's distribution (*i.e.* the likelihood) more into the posterior. When α is too large, the posterior distribution is overwhelmed by the likelihood of the persona. Then, the language model degenerates to favor uttering fragments of the given persona while even ignoring the syntax. Hence, α can control the degree of copying the given condition text. An appropriate α value allows the given persona condition to blend smoothly in the utterance.

6 Conclusion

This work investigated how modeling public self-consciousness can help dialogue agents improve persona-consistency. We showed existing dialogue agents are highly insensitive to contradiction, and introduced an orthogonally applicable method using the RSA framework (Frank and Goodman, 2012) to alleviate the issue. We also designed a learning method for distractor selection, named *Distractor Memory* and proposed a better update for the listener's world prior. Furthermore, we demonstrated how our approach can be generalized to improve dialogue context-consistency. Our self-conscious agents improved the base agents on the Dialogue NLI (Welleck et al., 2019) and PersonaChat (Zhang et al., 2018) dataset, without consistency labels and NLI models. An important future direction will be generating the distractors and learning the rationality coefficients.

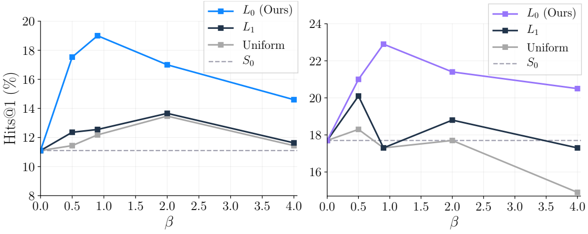

Figure 5: Performance variation of the self-conscious agent for TransferTransfo (left) and Blender (right) according to β. We compare different methods of updating the world prior $p_t(i)$ with L_0 (Ours), L_1 and a uniform prior. The dashed line is the base speaker S_0.

Persona	I've 5 cats. I am a construction worker. My cats are very special to me. I enjoy building houses.
($\alpha = 0$)	i'm a construction worker. i'm going to be a vet.
($\alpha = 2$)	i work construction. i'm a construction worker.
($\alpha = 8$)	construction work is great. i build houses for my cats.
($\alpha = 10$)	construction workers earn 5 cats so building houses affords us special pets. yours? kittens! d ou

A Results on Variants of Distractor Selection (Section 4.2)

Model	Hits@1 ↑	Entail@1 ↑	Contradict@1 ↓
ControlSeq2Seq (See et al., 2019)			
Random	8.5	32.8	37.6
Nearest	7.6	32.8	36.5
Farthest	9.4	33.6	35.4
BERT-Classifier	9.2	33.6	35.6
BERT-Ranker	9.6	33.3	35.1
DM	**11.1**	**36.0**	**28.2**

Table 8: Quantitative results of the proposed *Distractor Memory* (DM) and other distractor selection methods on the Dialogue NLI evaluation set (Welleck et al., 2019).

We compare our proposed *Distractor Memory* (DM) with three heuristic methods, and two variants of the pretrained BERT model (Devlin et al., 2019). As a straightforward baseline, we randomly select k personas from training set and directly use it as distractors. Second, we test the k-nearest search by speaker's persona, denoted by Nearest; for a given persona descriptions, we find its closest training persona embedding using cosine similarity on average pooled BERT features. The third baseline denoted by Farthest is to find the k-farthest persona among the training personas.

We also compare with two variants of the BERT model. The first variant is BERT-Classifier, which takes dialogue context as input and returns the index of persona from training set as output. The second variant is bi-encoder ranking model of Miller et al. (2017), denoted by BERT-Ranker. It encodes dialogue context and candidate persona with separate BERT encoders measuring its ranking with cosine similarity. For both methods, we use top-k ranked personas as distractors and set $k = 4$ for all the methods. We use Adam optimizer (Kingma and Ba, 2015) with learning rate 2e-5 and finetune *BERT-Uncased-Base* up to 3 epochs.

Table 8 compares the performance of different distractor selecting methods on the Dialogue NLI evaluation set (Welleck et al., 2019). We set $\alpha = 8$, $\beta = 0.5$, and $|\mathcal{I}| = 5$. The DM model outperforms all the baselines across all metrics. The Farthest shows better performance than the Nearest.It can be understood that dissimilar distractors are more effective in the Rational Speech Acts framework (Frank and Goodman, 2012). The BERT-Ranker performs the best among baselines, but not as good as ours, which validates that memorization capability is effective for selecting useful distractors.

B Implementation Details

Base Codes and Datasets. We use the ParlAI framework[2] (Miller et al., 2017) and HuggingFace's Transformers[3] (Wolf et al., 2019a) to implement our models and baselines. We use Dialogue NLI (Welleck et al., 2019) and PersonaChat (Zhang et al., 2018) datasets from the ParlAI framework as is. We use the default preprocessing in ParlAI.

Training. Our self-consciousness approach improves consistency for any pretrained dialogue-agents without additional consistency labels and pretrained NLI models. Since it post-processes the output probability of pretrained dialogue-agents in a Bayesian fashion, no additional model parameters are added to the dialogue agents. Thus, it does not require any training. In the case of using the Distractor Memory (DM), first we initialize *BERT-Uncased-Base* with pretrained weights and finetune it up to 3 epochs with Adam optimizer with learning rate 2e-5. Then we find the best distractor persona for each model and use those labels to train our DM. We train our DM on one NVIDIA TITAN Xp GPU up to 7 epochs.

Hyperparameters. For Dialogue NLI evaluation, we set the speaker rationality $\alpha = 8.0$, the listener rationality $\beta = 1.0$, and the cardinality of the world $\mathcal{I}$ to 3. In PersonaChat evaluation, we set $\alpha = 2.0$, $\beta = 0.3$ for ControlSeq2Seq (See et al., 2019), $\alpha = 2$, $\beta = 0.9$ for TransferTransfo (Wolf et al., 2019b), and $\alpha = 2.0$, $\beta = 0.5$ for Blender 90M (Roller et al., 2020). We also set $|\mathcal{I}| = 3$. We experiment $\alpha = \{1.0, 2.0, 4.0, 8.0, 16.0\}$, $\beta = \{0.3, 0.5, 0.9, 1.0, 2.0, 4.0\}$, and $|\mathcal{I}| = \{2, 3, 5\}$. We choose the hyper-parameter configuration showing the best performance in Hits@1 for Dialogue NLI and F1 score for PersonaChat. The posterior distribution of our self-conscious agents are computed deterministically. For our Distractor Memory, we set the memory key matrix as $\mathbf{K} \in \mathbb{R}^{m \times d}$, where $m = 16000$ and $d = 768$. We set the number of nearest neighbor $k = 2048$.

Inference. We use greedy decoding for all methods. The average runtime for our self-conscious approach is dependent on the base dialogue agents and the cardinality of world $\mathcal{I}$ which can be run in parallel like beam search.

Evaluation. We follow the evaluation of the ParlAI framework. Following Madotto et al. (2019), we use the finetuned BERT-based NLI model[4] to compute the C score.

C Dialogue Examples

Figure 7 shows selected examples of generated responses. In each set, we show given persona, dialogue context, human responses, and generated responses by our self-conscious agent and the base speaker. We use TransferTransfo (Wolf et al., 2019b) as a base speaker.

P1's Persona
I've 5 cats. I am a construction worker. My cats are very special to me. I enjoy building houses.
Dialogue History
⋮ [P2] It is going very great. I just have homework to do [P1] Oh what are you in school for? [P2] High school. On my sophomore year. [P1] Are you planning to go to college ? [P2] I am ! I want to be a professional soccer player.
(S_1+DM) i work construction. i'm a construction worker. **(S_0)** i'm a construction worker. i'm going to be a vet. **(Human)** exciting ! i played soccer in high school too , long ago

P1's Persona
I own a house in Florida. I work in it and have been at the same company for 15 years. I enjoy American sports I've a children and a dogs.
Dialogue History
[P2] Hello, how are you today? [P1] Hey! Just watching a game of football with my children. You? [P2] That's cool! I am an alcoholic who is recovering.
(S_1+DM) i work in a company and i'm a workaholic. **(S_0)** i'm sorry to hear that. I'm a retired professional athlete. **(Human)** ah man congrats for trying to get back on the road !

P1's Persona
I'm a huge star wars fan. I try various coffees as a hobby. I enjoy poetry. I played football for a division a college.
Dialogue History
⋮ [P1] I'm good, taking a break from my assignments before heading to Europe. [P2] I went to Spain then, learned I love cooking paella. What team are you for? [P1] I'm with Ohio state. Born and raised in Ohio. [P2] Awesome. What do you do for a living?
(S_1+DM) i play football for a local college. **(S_0)** i'm a student. i'm a student **(Human)** i'm a student , going to school for veterinary medicine .

P1's Persona
My family does not support my career choices. My dream car is a Rolls Royce ghost. I often shop for shoes and watches. I like shopping. I currently work for a watch dealer.
Dialogue History
⋮ [P1] I really enjoy shopping and my dream is to one day own a Rolls Royce ghost. [P2] Wow. I enjoy running over driving. [P1] Running is also quite lovely. Breathing in the lovely outside air. [P2] Yes it is. It clears my head when I need to as well.
(S_1+DM) shopping is a great way to clear my head. **(S_0)** i love to shop and watch movies. **(Human)** yes , and it also helps with depression i have found.

Figure 7: Examples of generated responses by our self-conscious agent with *Distractor Memory* (S_1+DM) on the PersonaChat dataset (Zhang et al., 2018). We compare it with the base speaker (S_0) of TransferTransfo (Wolf et al., 2019b) and the human response (Human).

TOD-BERT: Pre-trained Natural Language Understanding for Task-Oriented Dialogue

Chien-Sheng Wu, Steven Hoi, Richard Socher, and Caiming Xiong
Salesforce Research
`[wu.jason, shoi, rsocher, cxiong]@salesforce.com`

Abstract

The underlying difference of linguistic patterns between general text and task-oriented dialogue makes existing pre-trained language models less useful in practice. In this work, we unify nine human-human and multi-turn task-oriented dialogue datasets for language modeling. To better model dialogue behavior during pre-training, we incorporate user and system tokens into the masked language modeling. We propose a contrastive objective function to simulate the response selection task. Our pre-trained task-oriented dialogue BERT (TOD-BERT) outperforms strong baselines like BERT on four downstream task-oriented dialogue applications, including intention recognition, dialogue state tracking, dialogue act prediction, and response selection. We also show that TOD-BERT has a stronger few-shot ability that can mitigate the data scarcity problem for task-oriented dialogue.

1 Introduction

Pre-trained models with self-attention encoder architectures (Devlin et al., 2018; Liu et al., 2019) have been commonly used in many NLP applications. Such models are self-supervised based on a massive scale of general text corpora, such as English Wikipedia or books (Zhu et al., 2015). By further fine-tuning these representations, breakthroughs have been continuously reported for various downstream tasks, especially natural language understanding.

However, previous work (Rashkin et al., 2018; Wolf et al., 2019) shows that there are some deficiencies in the performance to apply fine-tuning on conversational corpora directly. One possible reason could be the intrinsic difference of linguistic patterns between human conversations and writing text, resulting in a large gap of data distributions (Bao et al., 2019). Therefore, pre-training dialogue language models using chit-chat corpora from social media, such as Twitter or Reddit, has been recently investigated, especially for dialogue response generation (Zhang et al., 2019) and retrieval (Henderson et al., 2019b). Although these open-domain dialogues are diverse and easy-to-get, they are usually short, noisy, and without specific chatting goals.

On the other hand, a task-oriented dialogue has explicit goals (e.g. restaurant reservation or ticket booking) and many conversational interactions. But each dataset is usually small and scattered because obtaining and labeling such data is time-consuming. Moreover, a task-oriented dialogue has explicit user and system behaviors where a user has his/her goal, and a system has its belief and database information, which makes the language understanding component and dialogue policy learning more important than those chit-chat scenarios.

This paper aims to prove this hypothesis: self-supervised language model pre-training using task-oriented corpora can learn better representations than existing pre-trained models for task-oriented downstream tasks. We emphasize that what we care about the most is not whether our pre-trained model can achieve state-of-the-art results on each downstream task since most of the current best models are built on top of pre-trained models, and ours can easily replace them. We avoid adding too many additional components on top of the pre-training architecture when fine-tuning in our experiments.

We collect and combine nine human-human and multi-turn task-oriented dialogue corpora to train a task-oriented dialogue BERT (TOD-BERT). In total, there are around 100k dialogues with 1.4M utterances across over 60 different domains. Like BERT (Devlin et al., 2018), TOD-BERT is formulated as a masked language model and uses a deep bidirectional Transformer (Vaswani et al., 2017)

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 917–929,
November 16–20, 2020.

encoder as its model architecture. Unlike BERT, TOD-BERT incorporates two special tokens for user and system to model the corresponding dialogue behavior. A contrastive objective function of response selection task is combined during pre-training stage to capture response similarity. We select BERT because it is the most widely used model in NLP research recently, and our unified datasets can be easily applied to pre-train any existing language models.

We test TOD-BERT on task-oriented dialogue systems on four core downstream tasks, including intention recognition, dialogue state tracking, dialogue act prediction, and response selection. What we observe is: TOD-BERT outperforms BERT and other strong baselines such as GPT-2 (Radford et al., 2019) and DialoGPT (Zhang et al., 2019) on all the selected downstream tasks, which further confirms its effectiveness for improving dialogue language understanding. We find that response contrastive learning is beneficial, but it is currently overlooked not well-investigated in dialogue pre-training research. More importantly, TOD-BERT has a stronger few-shot ability than BERT on each task, suggesting that it can reduce the need for expensive human-annotated labels. TOD-BERT can be easily leveraged and adapted to a new task-oriented dialogue dataset. Our source code and data processing are released to facilitate future research on pre-training and fine-tuning of task-oriented dialogue [1].

2 Related Work

General Pre-trained Language Models, which are trained on massive general text such as Wikipedia and BookCorpus, can be roughly divided into two categories: uni-directional or bi-directional attention mechanisms. GPT (Radford et al., 2018) and GPT-2 (Radford et al., 2019) are representatives of uni-directional language models using a Transformer decoder, where the objective is to maximize left-to-right generation likelihood. These models are commonly applied in natural language generation tasks. On the other hand, BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and their variances are pre-trained using a Transformer encoder with bi-directional token prediction. These models are usually evaluated on classification tasks such as GLUE benchmark (Wang et al., 2018) or span-based question answering tasks (Rajpurkar et al., 2016).

Some language models can support both uni-directional and bi-directional attention, such as UniLM (Dong et al., 2019). Conditional language model pre-training is also proposed. For example, CTRL (Keskar et al., 2019) is a conditional Transformer model, trained to condition on control codes that govern style, content, and task-specific behavior. Recently, multi-task language model pre-training with unified sequence-to-sequence generation is proposed. Text-to-text Transformer (T5) (Raffel et al., 2019) unifies multiple text modeling tasks and achieves the promising results in various NLP benchmarks.

Dialogue Pre-trained Language Models are mostly trained on open-domain conversational data from Reddit or Twitter for dialogue response generation. Transfertransfo (Wolf et al., 2019) achieves good performance on ConvAI-2 dialogue competition using GPT-2. DialoGPT (Zhang et al., 2019) is an extension of GPT-2 that is pre-trained on Reddit data for open-domain response generation. ConveRT (Henderson et al., 2019a) pre-trained a dual transformer encoder for response selection task on large-scale Reddit (input, response) pairs. PLATO (Bao et al., 2019) uses both Twitter and Reddit data to pre-trained a dialogue generation model with discrete latent variables. All of them are designed to cope with the response generation task for open-domain chatbots.

Pretraining for task-oriented dialogues, on the other hand, has few related works. Budzianowski and Vulić (2019) first apply the GPT-2 model to train on response generation task, which takes system belief, database result, and last dialogue turn as input to predict next system responses. It only uses one dataset to train its model because few public datasets have database information available. Henderson et al. (2019b) pre-trained a response selection model for task-oriented dialogues. They first pre-train on Reddit corpora and then fine-tune on target dialogue domains, but their training and fine-tuning code is not released. Peng et al. (2020) focus on the natural language generation (NLG) task, which assumes dialogue acts and slot-tagging results are given to generate a natural language response. Pre-training on a set of annotated NLG corpora can improve conditional generation quality using a GPT-2 model.

Table 1: Data statistics for task-oriented dialogue datasets.

3 Method

This section discusses each dataset used in our task-oriented pre-training and how we process the data. Then we introduce the selected pre-training base model and its objective functions.

3.1 Datasets

We collect nine different task-oriented datasets which are English, human-human and multi-turn. In total, there are 100,707 dialogues, which contain 1,388,152 utterances over 60 domains. Dataset statistics is shown in Table 1.

- **MetaLWOZ** (Lee et al., 2019): Meta-Learning Wizard-of-Oz is a dataset designed to help develop models capable of predicting user responses in unseen domains. This large dataset was created by crowdsourcing 37,884 goal-oriented dialogs, covering 227 tasks in 47 domains. The MetaLWOZ dataset is used as the fast adaptation task for DSTC8 (Kim et al., 2019) dialogue competition.

- **Schema** (Rastogi et al., 2019): Schema-guided dialogue has 22,825 dialogues and provides a challenging testbed for several tasks, in particular, dialogue state tracking. Each schema is a set of tracking slots, and each domain could have multiple possible schemas. This allows a single dialogue system to support many services and facilitates the simple integration of new services without requiring much training data. The Schema dataset is used as the dialogue state tracking task for DSTC8 (Kim et al., 2019) dialogue competition.

- **Taskmaster** (Byrne et al., 2019): This dataset includes 13,215 dialogues comprising six domains, including 5,507 spoken and 7,708 written dialogs created with two distinct procedures. One is a two-person Wizard of Oz approach that one person acts like a robot, and the other is a self-dialogue approach in which crowdsourced workers wrote the entire dialog themselves. It has 22.9 average conversational turns in a single dialogue, which is the longest among all task-oriented datasets listed.

- **MWOZ** (Budzianowski et al., 2018): Multi-Domain Wizard-of-Oz dataset contains 10,420 dialogues over seven domains, and it has multiple domains in a single dialogue. It has a detailed description of the data collection procedure, user goal, system act, and dialogue state labels. Different from most of the existing corpora, it also provides full database information.

- **MSR-E2E** (Li et al., 2018): Microsoft end-to-end dialogue challenge has 10,087 dialogues in three domains, movie-ticket booking, restaurant reservation, and taxi booking. It also includes an experiment platform with built-in simulators in each domain.

- **SMD** (Eric and Manning, 2017): Stanford multi-domain dialogue is an in-car personal assistant dataset, comprising 3,301 dialogues and three domains: calendar scheduling, weather information retrieval, and point-of-interest navigation. It is designed to smoothly interface with knowledge bases, where a knowledge snippet is attached with each dialogue as a piece of simplified database information.

- **Frames** (Asri et al., 2017): This dataset comprises 1,369 human-human dialogues with an average of 14.6 turns per dialogue, where users are given some constraints to book a trip and assistants who search a database to find appropriate trips. Unlike other datasets, it has labels to keep track of different semantic frames, which is the decision-making behavior of users throughout each dialogue.

- **WOZ** (Mrkšić et al., 2016) and **Cam-Rest676** (Wen et al., 2016): These two corpora use the same data collection procedure and same ontology from DSTC2 (Henderson et al., 2014). They are one of the first task-oriented dialogue datasets that use Wizard of Oz style with text input instead of speech input, which improves the model's capacity for the semantic understanding instead of its robustness to automatic speech recognition errors.

3.2 TOD-BERT

We train our TOD-BERT based on BERT architecture using two loss functions: masked language modeling (MLM) loss and response contrastive loss (RCL). Note that the datasets we used can be used to pre-train any existing language model architecture, and here we select BERT because it is the most widely used model in NLP research. We use the BERT-base uncased model, which is a transformer self-attention encoder (Vaswani et al., 2017) with 12 layers and 12 attention heads with its hidden size $d_B = 768$.

To capture speaker information and the underlying interaction behavior in dialogue, we add two special tokens, [USR] and [SYS], to the byte-pair embeddings (Mrkšić et al., 2016). We prefix the special token to each user utterance and system response, and concatenate all the utterances in the same dialogue into one flat sequence, as shown in Figure 1. For example, for a dialogue $D = \{S_1, U_1, \dots, S_n, U_n\}$, where n is the number of dialogue turns and each S_i or U_i contains a sequence of words, the input of the pre-training model is processed as "[SYS] S_1 [USR] $U_1 \dots$ " with standard positional embeddings and segmentation embeddings.

Masked language modeling is a common pre-training strategy for BERT-like architectures, in which a random sample of tokens in the input sequence is selected and replaced with the special token [MASK]. The MLM loss function is the cross-entropy loss on predicting the masked tokens. In the original implementation, random masking and replacement are performed once in the beginning and saved for the training duration. Here we conduct token masking dynamically during batch training. TOD-BERT is initialized from BERT, a good starting parameter set, then is further pre-trained on those task-oriented corpora. The MLM loss function is

$$L_{mlm} = -\sum_{m=1}^{M} \log P(x_m), \tag{1}$$

where M is the total number of masked tokens and $P(x_m)$ is the predicted probability of the token x_m over the vocabulary size.

Response contrastive loss can also be used for dialogue language modeling since it does not require any additional human annotation. Pre-training with RCL can bring us several advantages: 1) we can learn a better representation for the [CLS] token, as it is essential for all the downstream tasks, and 2) we encourage the model to capture underlying dialogue sequential order, structure information, and response similarity.

Unlike the original next sentence prediction (NSP) objective in BERT pre-training, which concatenates two segments A and B to predict whether they are consecutive text with binary classification, we apply a dual-encoder approach (Henderson et al., 2019a) and simulate multiple negative samples. We first draw a batch of dialogues $\{D_1, \dots, D_b\}$ and split each dialogue at a randomly selected turn t. For example, D_1 will be separated into two segments, one is the context $\{S_1^1, U_1^1, \dots, S_t^1, U_t^1\}$ and the other is the response $\{S_{t+1}^1\}$. We use TOD-BERT to encode all the contexts and their corresponding responses separately.

Afterwards, we have a context matrix $C \in \mathbb{R}^{b \times d_B}$ and a response matrix $R \in \mathbb{R}^{b \times d_B}$ by taking the output [CLS] representations from the b dialogues. We treat other responses in the same batch as randomly selected negative samples. The RCL objective function is

$$\begin{gathered} L_{rcl} = -\sum_{i=1}^{b} \log M_{i,i}, \\ M = \text{Softmax}(CR^T) \in \mathbb{R}^{b \times b}. \end{gathered} \tag{2}$$

Increasing batch size to a certain amount can obtain better performance on downstream tasks, especially for the response selection. The Softmax function normalizes the vector per row. In our setting, increasing batch size also means changing the positive and negative ratio in the contrastive learning. Batch size is a hyper-parameter that may be

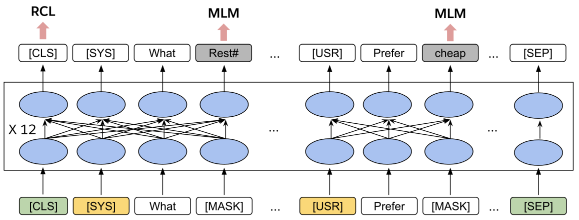

Figure 1: Dialogue pre-training based on Transformer encoder with user and system special tokens. Two objective functions are used: masked language modeling and response contrastive learning.

limited by hardware. We also try different negative sampling strategies during pre-training such as local sampling (Saeidi et al., 2017), but do not observe significant change compared to random sampling.

Overall pre-training loss function is the weighted-sum of L_{mlm} and L_{rcl}, and in our experiments, we simply sum them up. We gradually reduce the learning rate without a warm-up period. We train TOD-BERT with AdamW (Loshchilov and Hutter, 2017) optimizer with a dropout ratio of 0.1 on all layers and attention weights. GELU activation functions (Hendrycks and Gimpel, 2016) is used. Models are early-stopped using perplexity scores of a held-out development set, with mini-batches containing 32 sequences of maximum length 512 tokens. Experiments are conducted on two NVIDIA Tesla V100 GPUs.

4 Downstream Tasks

We care the most in this paper whether TOD-BERT, a pre-trained language model using aggregated task-oriented corpora, can show any advantage over BERT. Therefore, we avoid adding too many additional components on top of its architecture when fine-tuning on each downstream task. Also, we use the same architecture with a similar number of parameters for a fair comparison. All the model parameters are updated with a gradient clipping to 1.0 using the same hyper-parameters during fine-tuning. We select four crucial task-oriented downstream tasks to evaluate: intent recognition, dialogue state tracking, dialogue act prediction, and response selection. All of them are core components in modularized task-oriented systems (Wen et al., 2016).

Intent recognition task is a multi-class classification problem, where we input a sentence U and models predict one single intent class over I possible intents.

$$P_{int} = \text{Softmax}(W_1(F(U))) \in \mathbb{R}^I, \tag{3}$$

where F is a pre-trained language model and we use its [CLS] embeddings as the output representation. $W_1 \in \mathbb{R}^{I \times d_B}$ is a trainable linear mapping. The model is trained with cross-entropy loss between the predicted distributions P_{int} and the true intent labels.

Dialogue state tracking can be treated as a multi-class classification problem using a predefined ontology. Unlike intent, we use dialogue history X (a sequence of utterances) as input and a model predicts slot values for each (domain, slot) pair at each dialogue turn. Each corresponding value v_i^j, the i-th value for the j-th (domain, slot) pair, is passed into a pre-trained model and fixed its representation during training.

$$S_i^j = Sim(G_j(F(X)), F(v_i^j)) \in \mathbb{R}^1, \tag{4}$$

where Sim is the cosine similarity function, and $S^j \in \mathbb{R}^{|v^j|}$ is the probability distribution of the j-th (domain, slot) pair over its possible values. G_j is the slot projection layer of the j slot, and the number of layers $|G|$ is equal to the number of (domain, slot) pairs. The model is trained with cross-entropy loss summed over all the pairs.

Dialogue act prediction is a multi-label classification problem because a system response may contain multiple dialogue acts, e.g., request and inform at the same time. Model take dialogue history as input and predict a binary result for each possible dialogue act:

$$A = Sigmoid(W_2(F(X))) \in \mathbb{R}^N, \tag{5}$$

where $W_2 \in \mathbb{R}^{d_B \times N}$ is a trainable linear mapping, N is the number of possible dialogue acts, and each value in A is between $[0, 1]$ after a Sigmoid layer. The model is trained with binary cross-entropy loss and the i-th dialogue act is considered as a triggered dialogue act if $A_i > 0.5$.

Response selection is a ranking problem, aiming to retrieve the most relative system response from a candidate pool. We use a dual-encoder strategy (Henderson et al., 2019b) and compute similarity scores between source X and target Y,

$$r_i = Sim(F(X), F(Y_i)) \in \mathbb{R}^1, \tag{6}$$

where Y_i is the i-th response candidate and r_i is its cosine similarity score. Source X can be truncated, and we limit the context lengths to the most recent 256 tokens in our experiments. We randomly sample several system responses from the corpus as negative samples. Although it may not be a true negative sample, it is common to train a ranker and evaluate its results (Henderson et al., 2019a).

5 Evaluation Datasets

We pick up several datasets, OOS, DSTC2, GSIM, and MWOZ, for downstream evaluation. The first three corpora are not included in the pre-trained task-oriented datasets. For MWOZ, to be fair, we do not include its test set dialogues during the pre-training stage. Details of each evaluation dataset are discussed in the following:

- **OOS** (Larson et al., 2019): The out-of-scope intent dataset is one of the largest annotated intent datasets, including 15,100/3,100/5,500 samples for the train, validation, and test sets, respectively. It covers 151 intent classes over ten domains, including 150 in-scope intent and one out-of-scope intent. The out-of-scope intent means that a user utterance that does not fall into any of the predefined intents. Each of the intents has 100 training samples.

- **DSTC2** (Henderson et al., 2014): DSTC2 is a human-machine task-oriented dataset that may include a certain system response noise. It has 1,612/506/1117 dialogues for train, validation, and test sets, respectively. We follow Paul et al. (2019) to map the original dialogue act labels to universal dialogue acts, which results in 9 different system dialogue acts.

- **GSIM** (Shah et al., 2018a): GSIM is a human-rewrote machine-machine task-oriented corpus, including 1500/469/1039 dialogues for the train, validation, and test sets, respectively. We combine its two domains, movie and restaurant domains, into one single corpus. It is collected by Machines Talking To Machines (M2M) (Shah et al., 2018b) approach, a functionality-driven process combining a dialogue self-play step and a crowdsourcing step. We map its dialogue act labels to universal dialogue acts (Paul et al., 2019), resulting in 6 different system dialogue acts.

- **MWOZ** (Budzianowski et al., 2018): MWOZ is the most common benchmark for task-oriented dialogues, especially for dialogue state tracking. It has 8420/1000/1000 dialogues for train, validation, and test sets, respectively. Across seven different domains, in total, it has 30 (domain, slot) pairs that need to be tracked in the test set. We use its revised version MWOZ 2.1, which has the same dialogue transcripts but with cleaner state label annotation.

6 Results

For each downstream task, we first conduct the experiments using the whole dataset, and then we simulate the few-shot setting to show the strength of our TOD-BERT. We run at least three times with different random seeds for each few-shot experiment to reduce data sampling variance, and we report its mean and standard deviation for these limited data scenarios. We investigate two versions of TOD-BERT; one is TOD-BERT-mlm that only uses MLM loss during pre-training, and the other is TOD-BERT-jnt, which is jointly trained with the MLM and RCL objectives. We compare TOD-BERT with BERT and other baselines, including two other strong pre-training models GPT-2 (Radford et al., 2019) and DialoGPT (Zhang et al., 2019). For a GPT-based model, we use mean pooling of its hidden states as its output representation, which we found it is better than using only the last token.

6.1 Linear Probe

Before fine-tuning each pre-trained models, we first investigate their feature extraction ability by probing their output representations. Probing methods are proposed to determine what information is carried intrinsically by the learned embeddings (Tenney et al., 2019). We probe the output representation using one single-layer perceptron on top of a “fixed” pre-trained language model and only fine-tune that layer for a downstream task with the same hyper-parameters. Table 3 shows the probing results of domain classification on MWOZ, intent identification on OOS, and dialogue act prediction on MWOZ. TOD-BERT-jnt achieves the highest performance in this setting, suggesting its representation contains the most useful information.

6.2 Intent Recognition

TOD-BERT outperforms BERT and other strong baselines in one of the largest intent recognition

	Model	**Acc (all)**	**Acc (in)**	**Acc (out)**	**Recall (out)**

GPT2	63.5%	74.7%	85.7%
DialoGPT	63.0%	65.7%	84.2%
BERT	60.5%	71.1%	85.3%
TOD-BERT-mlm	63.9%	70.7%	83.5%
TOD-BERT-jnt	**68.7%**	**77.8%**	**86.2%**

Table 3: Probing results of different pre-trained language models using a single-layer perceptron.

datasets, as shown in Table 2. We evaluate accuracy on all the data, the in-domain intents only, and the out-of-scope intent only. Note that there are two ways to predict out-of-scope intent, one is to treat it as an additional class, and the other is to set a threshold for prediction confidence. Here we report the results of the first setting. TOD-BERT-jnt achieves the highest in-scope and out-of-scope accuracy. Besides, we conduct 1-shot and 10-shot experiments by randomly sampling one and ten utterances from each intent class in the training set. TOD-BERT-jnt has 13.2% all-intent accuracy improvement and 16.3% in-domain accuracy improvement compared to BERT in the 1-shot setting.

6.3 Dialogue State Tracking

Two evaluation metrics are commonly used in dialogue state tracking task: joint goal accuracy and slot accuracy. The joint goal accuracy compares the predicted dialogue states to the ground truth at each dialogue turn. The ground truth includes slot values for all the possible (domain, slot) pairs. The output is considered as a correct prediction if and only if all the predicted values exactly match its ground truth values. On the other hand, the slot accuracy individually compares each (domain, slot, value) triplet to its ground truth label.

In Table 5, we compare BERT to TOD-BERT-jnt on the MWOZ 2.1 dataset and find the latter has 2.4% joint goal accuracy improvement. Since the original ontology provided by Budzianowski et al. (2018) is not complete (some labeled values are not included in the ontology), we create a new ontology of all the possible annotated values. We also list several well-known dialogue state trackers as reference, including DSTReader (Gao et al., 2019), HyST (Goel et al., 2019), TRADE (Wu et al., 2019), and ZSDST (Rastogi et al., 2019). We also report the few-shot experiments using 1%, 5%, 10%, and 25% data. Note that 1% of data has around 84 dialogues. TOD-BERT outperforms BERT in all the setting, which further show the strength of task-oriented dialogue pre-training.

6.4 Dialogue Act Prediction

We conduct experiments on three different datasets and report micro-F1 and macro-F1 scores for the dialogue act prediction task, a multi-label classification problem. For the MWOZ dataset, we remove the domain information from the original system dialogue act labels. For example, the "taxi-inform" will be simplified to "inform". This process reduces the number of possible dialogue acts from 31 to 13. For DSTC2 and GSIM corpora, we follow Paul et al. (2019) to apply universal dialogue act mapping that maps the original dialogue act labels to a general dialogue act format, resulting in 9 and 6 unique system dialogue acts in DSTC2 and GSIM, respectively. We run two other baselines, MLP and RNN, to further show the strengths of BERT-based

		MWOZ (13)		**DSTC2** (9)		**GSIM** (6)

Table 5: Dialogue state tracking results on MWOZ 2.1. We report joint goal accuracy and slot accuracy for the full data setting and the simulated few-shot settings.

models. The MLP model simply takes bag-of-word embeddings to make dialogue act prediction, and the RNN model is a bi-directional GRU network.

In Table 4, one can observe that in full data scenario, TOD-BERT consistently works better than BERT and other baselines, no matter which datasets or which evaluation metrics. In the few-shot experiments, TOD-BERT-mlm outperforms BERT by 3.5% micro-F1 and 6.6% macro-F1 on MWOZ corpus in the 1% data scenario. We also found that 10% of training data can achieve good performance that is close to full data training.

6.5 Response Selection

To evaluate response selection in task-oriented dialogues, we follow the k-to-100 accuracy, which is becoming a research community standard (Yang et al., 2018; Henderson et al., 2019a). The k-of-100

		MWOZ		DSTC2		GSIM	
		1-to-100	3-to-100	1-to-100	3-to-100	1-to-100	3-to-100

	TOD-BERT-mlm	13.0% ± 1.1%	34.6% ± 0.4%	12.5% ± 6.7%	24.9% ± 10.7%	7.2% ± 4.0%	15.4% ± 8.0%
	TOD-BERT-jnt	-	-	**37.5%** ± 0.6%	**55.9%** ± 0.4%	**12.5%** ± 0.9%	**26.8%** ± 0.8%
10% Data	BERT	20.9% ± 2.6%	45.4% ± 3.8%	8.9% ± 2.3%	21.4% ± 3.1%	9.8% ± 0.1%	24.4% ± 1.2%
	TOD-BERT-mlm	22.3% ± 3.2%	48.7% ± 4.0%	19.0% ± 16.3%	33.8% ± 20.4%	11.2% ± 2.5%	26.0% ± 2.7%
	TOD-BERT-jnt	-	-	**49.7%** ± 0.3%	**66.6%** ± 0.1%	**23.0%** ± 1.0%	**42.6%** ± 1.0%
Full Data	GPT2	47.5%	75.4%	53.7%	69.2%	39.1%	60.5%
	DialoGPT	35.7%	64.1%	39.8%	57.1%	16.5%	39.5%
	BERT	47.5%	75.5%	46.6%	62.1%	13.4%	32.9%
	TOD-BERT-mlm	48.1%	74.3%	50.0%	65.1%	36.5%	60.1%
	TOD-BERT-jnt	**65.8%**	**87.0%**	**56.8%**	**70.6%**	**41.0%**	**65.4%**

Table 6: Response selection evaluation results on three corpora for 1%, 10% and full data setting. We report 1-to-100 and 3-to-100 accuracy, which is similar to recall1 and recall@3 given 100 candidates.

metric is computed using a random batch of 100 examples so that responses from other examples in the same batch can be used as random negative candidates. This allows us to be compute the metric across many examples in batches efficiently. While it is not guaranteed that the random negatives will indeed be "true" negatives, the 1-of-100 metric still provides a useful evaluation signal. During inference, we run five different random seeds to sample batches and report the average results.

In Table 6, we conduct response selection experiments on three datasets, MWOZ, DSTC2, and GSIM. TOD-BERT-jnt achieves 65.8% 1-to-100 accuracy and 87.0% 3-to-100 accuracy on MWOZ, which surpasses BERT by 18.3% and 11.5%, respectively. The similar results are also consistently observed in DSTC2 and GSIM datasets, and the advantage of the TOD-BERT-jnt is more evident in the few-shot scenario. We do not report TOD-BERT-jnt for MWOZ few-shot setting because it is not fair to compare them with others as the full MWOZ training set is used for response contrastive learning during pre-training stage. The response selection results are sensitive to the training batch size since the larger the batch size the harder the prediction. In our experiments, we set batch size equals to 25 for all the models.

7 Visualization

In Figure 2, we visualize the embeddings of BERT, TOD-BERT-mlm, and TOD-BERT-jnt given the same input from the MWOZ test set. Each sample point is a system response representation, which is passed through a pre-trained model and reduced its high-dimension features to a two-dimension point using the t-distributed stochastic neighbor embedding (tSNE) for dimension reduction. Since we know the true domain and dialogue act labels for each utterance, we use different colors to represent different domains and dialogue acts. As one can observe, TOD-BERT-jnt has more clear group boundaries than TOD-BERT-mlm, and two of them are better than BERT.

To analyze the results quantitatively, we run K-means, a common unsupervised clustering algorithms, on top of the output embeddings of BERT and TOD-BERT. We set K for K-means equal to 10 and 20. After the clustering, we can assign each utterance in the MWOZ test set to a predicted class. We then compute the normalized mutual information (NMI) between the clustering result and the actual domain label for each utterance. Here is what we observe: TOD-BERT consistently achieves higher NMI scores than BERT. For K=10, TOD-BERT has a 0.143 NMI score, and BERT only has 0.094. For K=20, TOD-BERT achieves a 0.213 NMI score, while BERT has 0.109.

8 Conclusion

We propose task-oriented dialogue BERT (TOD-BERT) trained on nine human-human and multi-turn task-oriented datasets across over 60 domains. TOD-BERT outperforms BERT on four dialogue downstream tasks, including intention classification, dialogue state tracking, dialogue act prediction, and response selection. It also has a clear advantage in the few-shot experiments when only limited labeled data is available. TOD-BERT is easy-to-deploy and will be open-sourced, allowing the NLP research community to apply or fine-tune any task-oriented conversational problem.

Abstract

In order to alleviate the shortage of multi-domain data and to capture discourse phenomena for task-oriented dialogue modeling, we propose **RiSAWOZ**, a large-scale multi-domain Chinese Wizard-of-Oz dataset with Rich Semantic Annotations. RiSAWOZ contains 11.2K human-to-human (H2H) multi-turn semantically annotated dialogues, with more than 150K utterances spanning over 12 domains, which is larger than all previous annotated H2H conversational datasets. Both single- and multi-domain dialogues are constructed, accounting for 65% and 35%, respectively. Each dialogue is labeled with comprehensive dialogue annotations, including dialogue goal in the form of natural language description, domain, dialogue states and acts at both the user and system side. In addition to traditional dialogue annotations, we especially provide linguistic annotations on discourse phenomena, e.g., ellipsis and coreference, in dialogues, which are useful for dialogue coreference and ellipsis resolution tasks. Apart from the fully annotated dataset, we also present a detailed description of the data collection procedure, statistics and analysis of the dataset. A series of benchmark models and results are reported, including natural language understanding (intent detection & slot filling), dialogue state tracking and dialogue context-to-text generation, as well as coreference and ellipsis resolution, which facilitate the baseline comparison for future research on this corpus.[1]

1 Introduction

In recent years, we have witnessed that a variety of datasets tailored for task-oriented dialogue have been constructed, such as MultiWOZ (Budzianowski et al., 2018), SGD (Rastogi et al., 2019a) and CrossWOZ (Zhu et al., 2020), along with the increasing interest in conversational AI in both academia and industry (Gao et al., 2018). These datasets have triggered extensive research in either end-to-end or traditional modular task-oriented dialogue modeling (Wen et al., 2019; Dai et al., 2020). Despite of substantial progress made based on these newly built corpora, more efforts in creating challenging datasets in terms of size, multiple domains, semantic annotations, multilinguality, etc., are still in demand (Wen et al., 2019).

Among the existing datasets, the majority of them are not large in size, e.g., ATIS (Hemphill et al., 1990), WOZ 2.0 (Wen et al., 2017), FRAMES (El Asri et al., 2017) and KVRET (Eric et al., 2017), which might not well support data-hungry neural dialogue models. Very large task-oriented dialogue datasets can be created in a machine-to-machine fashion, such as M2M (Shah et al., 2018) and SGD (Rastogi et al., 2019a). Datasets collected in this way need to simulate both user and system and contain unnatural conversations.

MultiWOZ (Budzianowski et al., 2018), probably the most promising and notable dialogue corpus collected in a Wizard-of-Oz (i.e., Human-to-Human) way recently, is one order of magnitude larger than the aforementioned corpora collected in the same way. However, it contains noisy system-side state annotations and lacks user-side dialogue acts[2] (Eric et al., 2019; Zhu et al., 2020). Yet another very recent dataset CrossWOZ (Zhu et al., 2020), the first large-scale Chinese H2H dataset for task-oriented dialogue, provides semantic annotations on both user and system side although it is relatively smaller than MultiWOZ. The number of domains in both MultiWOZ and CrossWOZ is

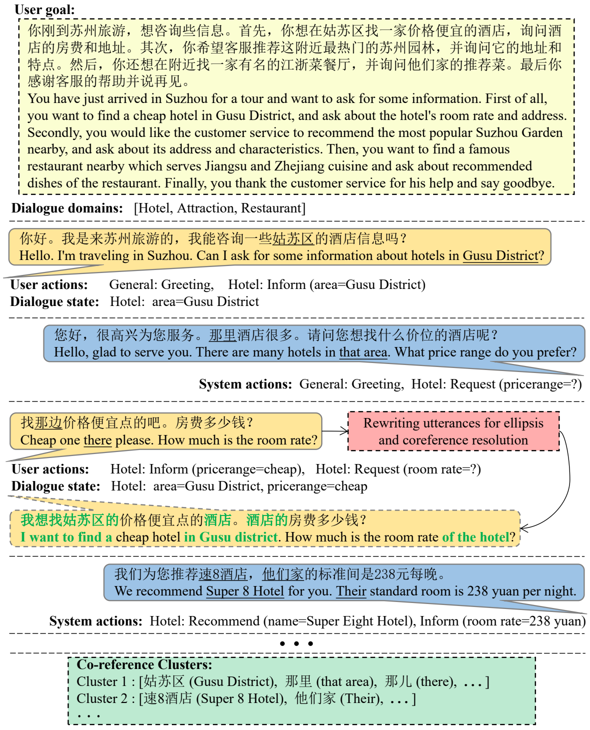
Table 1: Comparison of our dataset to other task-oriented dialogue datasets (training set). H2H, H2M, M2M represent human-to-human, human-to-machine, machine-to-machine respectively.

fewer than 10. MultiWOZ dialogues cover 7 domains. However, the distribution of dialogues over these domains is imbalanced. Dialogues from two domains (*hospital*, *police*) account for less than 6% in the training set and don't appear in either the development or test set. CrossWOZ involves 5 domains and dialogue goal descriptions for the domain *taxi* and *metro* are relatively simple than those from other domains. Neither MultiWOZ nor CrossWOZ provide linguistic annotations to capture discourse phenomena which are ubiquitous in multi-turn dialogues and are important in dialogue modeling (Quan et al., 2019; Su et al., 2019; Rastogi et al., 2019b; Zhang et al., 2019a)

In order to alleviate the aforementioned issues, we propose **RiSAWOZ**, a large-scale Chinese multi-domain Wizard-of-Oz task-oriented dialogue dataset with rich semantic annotations. Compared with existing datasets (particularly MultiWOZ and CrossWOZ), our contributions can be summarized as follows:



User goal:

你刚到苏州旅游，想咨询些信息。首先，你想在姑苏区找一家价格便宜的酒店，询问酒店的房费和地址。其次，你希望客服推荐这附近最热门的苏州园林，并询问它的地址和特点。然后，你还想在附近找一家有名的江浙菜餐厅，并询问他们家的推荐菜。最后你感谢客服的帮助并说再见。

You have just arrived in Suzhou for a tour and want to ask for some information. First of all, you want to find a cheap hotel in Gusu District, and ask about the hotel's room rate and address. Secondly, you would like the customer service to recommend the most popular Suzhou Garden nearby, and ask about its address and characteristics. Then, you want to find a famous restaurant nearby which serves Jiangsu and Zhejiang cuisine and ask about recommended dishes of the restaurant. Finally, you thank the customer service for his help and say goodbye.

Dialogue domains: [Hotel, Attraction, Restaurant]

你好。我是来苏州旅游的，我能咨询一些姑苏区的酒店信息吗？
Hello. I'm traveling in Suzhou. Can I ask for some information about hotels in Gusu District?

User actions: General: Greeting, Hotel: Inform (area=Gusu District)
Dialogue state: Hotel: area=Gusu District

您好，很高兴为您服务。那里酒店很多。请问您想找什么价位的酒店呢？
Hello, glad to serve you. There are many hotels in that area. What price range do you prefer?

System actions: General: Greeting, Hotel: Request (pricerange=?)

找那边价格便宜点的吧。房费多少钱？
Cheap one there please. How much is the room rate?

User actions: Hotel: Inform (pricerange=cheap), Hotel: Request (room rate=?)
Dialogue state: Hotel: area=Gusu District, pricerange=cheap

我想找姑苏区的价格便宜点的**酒店**。**酒店的**房费多少钱？
I want to find a cheap hotel **in Gusu district**. How much is the room rate **of the hotel**?

我们为您推荐速8酒店，他们家的标准间是238元每晚。
We recommend Super 8 Hotel for you. Their standard room is 238 yuan per night.

System actions: Hotel: Recommend (name=Super Eight Hotel), Inform (room rate=238 yuan)

We show dialogue annotations and necessary linguistic annotations (green words for ellipsis resolution and green box for coreference clusters) for each user utterance (in yellow callout) and system utterance (in blue callout). Better viewed in color.

- RiSAWOZ is to date the largest fully annotated human-to-human task-oriented dialogue dataset to our knowledge. It contains 11,200 multi-turn dialogues with more than 150K utterances ranging over 12 domains, namely *Attraction*, *Restaurant*, *Hotel*, *Flight*, *Train*, *Weather*, *Movie*, *TV*, *Computer*, *Car*, *Hospital* and *Education* (particularly after-school remedial courses), several of which are not covered in previous datasets. Compared with other Wizard-of-Oz datasets (e.g. MultiWOZ and CrossWOZ), RiSAWOZ offers a wider and more balanced coverage on both domains and slots, making it suitable for not only practical use in industrial scenarios of related domains but also research on domain adaptation, few/zero-shot learning in task-oriented dialogue. Detailed comparison of RiSAWOZ to existing task-oriented dialogue datasets is shown in Table 1.
- We provide richer manual semantic annotations on the crowd-sourced dialogues, including both dialogue annotations (i.e., various structured semantic labels for dialogue modeling) and linguistic annotations that are not available in previous Wizard-of-Oz datasets (e.g., MultiWOZ or CrossWOZ). Figure 1

shows a dialogue example that demonstrates semantic annotations in RiSAWOZ. User goal description, domain label, dialogue states and dialogue acts at both user and system side are annotated for each dialogue. In order to facilitate the study of ellipsis and coreference in dialogue, we also provide two kinds of linguistic annotations collected in two different ways. Annotations for unified ellipsis/coreference resolution via utterance rewriting are more comprehensive and at least one order of magnitude larger than existing datasets with such annotations (Quan et al., 2019; Su et al., 2019; Zhang et al., 2019a; Rastogi et al., 2019b). Coreference clusters in each dialogue are also manually annotated, providing a new large-scale coreference dataset on dialogue, which is complementary to previous coreference datasets on documents (Pradhan et al., 2012). In a nutshell, RiSAWOZ integrates human-to-human conversations, dialogue annotations and linguistic annotations on ellipsis/coreference into a single unified dataset.

- We use RiSAWOZ as a new benchmark testbed and report benchmark results on 5 tasks for future comparison study and tracking progress on this dataset. The 5 tasks are NLU, DST, Dialogue Context-to-Text Generation, Coreference Resolution and Unified Generative Ellipsis and Coreference Resolution. We discuss the usability of the dataset for other tasks, e.g., Dialogue Policy Learning, Natural Language Generation, User Simulator, Dialogue Summarization, etc. The dataset and the benchmark models will be publicly available soon.

2 Related Work

We follow Budzianowski et al. (2018) to roughly categorize existing task-oriented dialogue datasets into three groups: machine-to-machine, human-to-machine, and human-to-human. From the perspective of domain quantity and data scale, most existing datasets cover only one single or a few domains while large-scale multi-domain datasets are not widely available. As suggested by Wen et al. (2019), task-oriented dialogue datasets in languages other than English are few. To the best of our knowledge, there has been no large-scale dialogue datasets with linguistic annotations aiming at ubiquitous discourse phenomena (e.g., ellipsis and coreference) in dialogue. Although some recent works have proposed datasets with utterance completion annotation for ellipsis or coreference in dialogue (Quan et al., 2019; Su et al., 2019), these datasets are at small scale and with simple dialogue goals. No dialogue datasets provide annotations of coreference clusters.

Machine-to-Machine Collecting data of this type requires to create a user and system simulator to generate multi-turn dialogue outlines, which are further transformed into natural language utterances via paraphrasing with predefined rules or crowdsourced workers (Shah et al., 2018; Rastogi et al., 2019a). Despite of less human effort required in this approach, the diversity and complexity of created dialogues greatly depend on the quality of user and system simulators. It's also difficult to avoid mismatch between machine-created dialogues and real human conversations.

Human-to-Machine In this method, humans converse with an existing dialogue system to collect dialogue data. The Dialogue State Tracking Challenges (DSTC) has provided several datasets created in this way (Williams et al., 2013; Henderson et al., 2014a,b). Generally, the quality of human-to-machine data heavily relies on the performance of the given dialogue system.

Human-to-Human To collect data of this type, crowdsourced workers talk to each other according to given dialogue goals to create diverse and natural dialogues. ATIS (Hemphill et al., 1990), WOZ 2.0 (Wen et al., 2017), FRAMES (El Asri et al., 2017) and KVRET (Eric et al., 2017) are small-scale datasets built in this way. In contrast, MultiWOZ Budzianowski et al. (2018) and CrossWOZ (Zhu et al., 2020) are two large-scale H2H datasets proposed recently.

Coreference Resolution Coreference is ubiquitous in dialogue. However, there is no available dialogue dataset with labeled coreference clusters. Generally, coreference datasets are created on text paragraphs or documents. The OntoNotes 5.0 dataset (Pradhan et al., 2012) is one of the most widely-used document-level dataset on coreference resolution from the CoNLL-2012 shared task.

Generative Ellipsis and Coreference Resolution In recent years, ellipsis and coreference resolution in dialogue has been treated as an end-to-end generative task. Su et al. (2019) propose to rewrite dialogue utterances to recover all co-referred and omitted information with an annotated Chinese

Domain	Attraction	Restaurant	Hotel	Flight	Train	Weather	Movie	TV	Computer	Car	Hospital	Courses

Table 3: All informable and requestable slots in each domain.

chit-chat dialogue dataset. Quan et al. (2019) annotate an off-the-shelf task-oriented dialogue dataset CamRest676 (Wen et al., 2016a,b) with coreference and ellipsis information and propose an end-to-end generative resolution model for both ellipsis and coreference in a single unified framework. This task is also treated as an auxiliary module to improve dialogue understanding (Zhang et al., 2019a) and dialogue state tracking (Rastogi et al., 2019b). However, the scale of these built or used dialogue datasets is relatively small.

3 Dataset Creation

The whole process of data collection consists of database and ontology construction, goal generation, dialogue collection and two rounds of annotations.

3.1 Database and Ontology Construction

We crawl 3,325 unique entities with their attributes from several Chinese public websites. Statistics on entities and slots across 12 domains are shown in Table 2. An ontology is constructed over these entities and attributes, which defines all possible slots for each domain and all possible values for each slot. Slots in the dataset can be divided into two categories: informable and requestable, as shown in Table 3. Informable slots are attributes that allow the user to constrain the search into the database. Requestable slots represent specific attributes that the user wants to know about an entity.

3.2 Dialogue Goal

First of all, we design dialogue goal templates with placeholders representing slots and values. We have designed 80 dialogue goal templates for 12 domains, including 52 single-domain goals and 28 multi-domain goals. Then we randomly sample actual slots and values from the ontology to fill in the placeholders in the templates to generate dialogue goal instances. We finally generate 5,600 dialogue goal instances. An example of dialogue goal (i.e. user goal) is shown at the top of Figure 1. A dialogue goal is a natural language description that only the user can see. The user needs to talk with the system step by step according to the given goal description until the task is finished. We assign each dialogue goal to two different pairs of workers to accomplish. In this way, we can collect two different dialogues from one dialogue goal. The

User action type	Inform, request, greeting, bye, general
System action type	Inform, recommend, request, no-offer, greeting, bye, general

Table 4: Dialogue act types.

total of dialogues is therefore $2 * 5,600 = 11,200$. This setting can ensure the diversity of collected dialogues while the amount of cost for crowdsourced workers is under the budget.

3.3 Dialogue Collection and Annotation

In order to collect high-quality coherent dialogues and annotations, we develop a collecting platform based on the Client-Server architecture, including two versions of client platform for user and system side respectively. Crowdsourced workers can choose to play the role of either user or system. They work in pairs and enter the chat room to construct dialogues. To ensure the quality of dialogue collection, we hire workers via our in-house crowdsourcing platform and train the workers strictly in advance. Finally, we select 92 well-trained workers to participate in our dialogue collection and annotation. At this stage, we collect task-oriented dialogue data with dialogue annotations including domain labels, dialogue states and acts.

3.3.1 User Side

During dialogue collection, a user first reads through the natural language description of a given dialogue goal to understand the task that is required to finish. After that, the user communicates with the system step by step to accomplish the given goal. We encourage the users to follow their own personalized language style in communication and train different workers to play the role of user, which makes created dialogues more complex and diverse, and more similar to the spoken conversations in our daily life. According to the instructions described in the given dialogue goal, the user should provide specific constraints to the system step by step and request the corresponding information. The user can terminate the dialogue when he/she believes the task has been accomplished.

3.3.2 System Side

The worker who plays the role of system (i.e. wizard) provides consulting services in various domains to users. When receiving an utterance from the user side, the wizard needs to first determine which domain the user is talking about and convert the user utterance into structured user acts. A dialogue act for both user and system side consists of the act type (i.e. intent) and slot-value pairs such as *inform (area=Gusu District)*. All the dialogue act types are shown in Table 4. We define 5 different user act types. **Inform** represents that a user provides specific constraints to information search from the database. **Request** denotes that a user asks for the values of specific slots. **Greeting** and **bye** are to express greeting and farewell. **General** represents other behaviors that are not covered above.

By understanding the goal of a user utterance, the wizard needs to annotate the constraints the user wants to provide and the slots requested by the user. The constraints are called belief states which are a set of slot-value pairs. The belief state is persistent across turns and is used to query the database. The wizard then retrieves the database according to the constraints. Considering both the results of database retrieval and the dialogue context, the wizard should send a natural language response to the user. In addition, the wizard needs to convert the natural language system response into structured system acts.

Similar to the user acts, 7 different system act types are predefined. **Inform** represents that the system informs the user about the attribute values of specific entities. **Recommend** denotes that the system recommends required entities to the user. **Request** represents that the system asks the user whether there are special constraints for the slots in question. **No offer** means that the system tells the user there is no matched entity. The remaining three act types, **greeting**, **bye** and **general**, are the same as those user act types described above.

Although the tasks for the system side look complex at the first glance, we design a simple and easy-to-operate graphical user interface (GUI). The wizard only needs to follow the prompts to perform simple operations, such as checking the multi-check box, picking the drop-down box, filling in the input box, clicking specific buttons, etc., which can be easily done by well-trained workers.

In this way, the information of domains, belief states, dialogue acts for both user and system side can be annotated during the process of collecting dialogues. A dialogue example with these annotations are demonstrated in Figure 1.

Different from the data collecting way that multiple workers contribute to one dialogue adopted

	Train	Dev	Test	Single-domain	Multi-domain	All
Dialogues	10,000	600	600	7,261	3,939	11,200
Turns	134,580	8,116	9,286	88,618	63,364	151,982
Tokens	1,462,727	87,886	108,032	954,298	704,347	1,658,645
Vocab.	11,486	4,514	4,927	10,065	8,031	11,971
Avg. turns	13.46	13.53	15.48	12.20	16.09	13.57
Avg. tokens	10.87	10.83	11.63	10.77	11.12	10.91

by MultiWOZ (Budzianowski et al., 2018), in our dataset, the construction and annotation for each dialogue are completed by a pair of well-trained workers. This is to guarantee the coherence and consistency of each created dialogue and the accuracy of the annotation for them. Moreover, we train each worker to play different roles to diversify dialogue utterances.

3.4 Linguistic Annotation

3.4.1 Coreference Clusters Annotation

We develop a toolkit with easy-to-operate GUI for annotating coreference clusters. With this annotation toolkit, well-trained annotators read through a dialogue to locate all entity mentions. They then group each of these mentions into an appropriate cluster. As shown at the bottom of Figure 1, entity mentions in each cluster are co-referential to one another.

3.4.2 Ellipsis and Coreference Annotation via Utterance Rewriting

As shown in Figure 1, both referenced and absent information can be recovered by rewriting an incomplete utterance into a complete version. In this way, we can reformulate ellipsis and coreference resolution as sentence rewriting in a unified framework. The merit of such rewriting is to help the dialogue model better understand the goal of a user utterance in context.

In order to facilitate such task reformulation, we provide the second type of linguistic annotation on RiSAWOZ: utterance rewriting for ellipsis and coreference resolution. We train crowdsourced workers to accomplish this annotation task and develop an annotation toolkit for them. Each annotator needs to read an entire dialogue sentence by sentence, detecting ellipsis or coreference phenomena in user utterances. For an utterance with ellipsis or coreference, the annotator rewrites the utterance into its complete version with recovered referenced/absent information according to dialogue context. If none of them occurs in the user utterance, the original utterance is kept. Both cases are presented in the example in Figure 1.

	User Utterances	Rate (%)
Ellipsis	23,181	30.50
Coreference	19,993	26.31
Both	3,582	4.71
Neither	29,235	38.47
Total	75,991	100

Table 6: Statistics on utterances containing ellipsis and coreference.

4 Our Dialogue Dataset

Our dataset contains not only single-domain dialogues, but also a great amount of multi-domain dialogues where domains are naturally connected. For example, a user wants to travel from one place to another. After checking the air ticket or train ticket, she wants to ask for the local weather information as well. In this section, we will introduce our dataset from two aspects: data structure and data statistics.

4.1 Data Structure

As shown in Figure 1, each dialogue in our dataset consists of a user goal description in natural language, a label of dialogue domain, multiple user and system turns and a set of coreference clusters. In each user turn, the user act and dialogue state are annotated over the user utterance. We also label whether there are ellipsis or coreference phe-

Task	Model	Metrics	Single-domain	Multi-domain	All data

Table 7: Performance of benchmark models on single-domain, multi-domain and all dialogues of test set.

nomena in each user utterance. If so, a complete version of the user utterance is provided. In each system turn, the system utterance is labeled with the corresponding system acts.

4.2 Data Statistics

Dialogue Statistics: We reshuffle all created dialogues and divide them into the training/dev/test sets which maintain approximately the same distribution on domains. As shown in Table 5, the training set contains 10,000 dialogues with 134,580 turns. The development and test set contain 600 dialogues with more than 8K and 9K turns respectively. The 5th column of Table 5 shows the statistics on single-domain dialogues. Multi-domain dialogues (the 6th column of Table 5) cover 8 domains excluding *Computer*, *Car*, *Hospital* and *Education*.

After Chinese word segmentation via Jieba,[3] there are 1,658,645 tokens in total in RiSAWOZ. On average, there are 10.91 tokens in each turn and 13.57 turns in each dialogue. Multi-domain dialogues have more turns and utterances are longer than those in single-domain dialogues.

Annotation Statistics: As shown in Table 5, each dialogue contains an average of 1.46 dialogue acts per turn. Each user and system turn have an average of 1.79 and 1.13 dialogue acts respectively. The richness of dialogue acts also make our data set a new challenge. On average, there are 1.77 coreference clusters in each dialogue. As multi-domain dialogues are more complex, each dialogue has an average of 2.45 coreference clusters. Regarding utterance rewriting for ellipsis and coreference resolution, 75,991 user utterances are reformulated, as shown in Table 6. Only 38.47% of the user utterances have neither ellipsis nor coreference phenomena, and the remaining 61.53% have at least one of them.

5 RiSAWOZ as a New Benchmark

The large size and rich semantic annotations of RiSAWOZ make it a suitable testbed for various benchmark tasks. We conduct five different evaluation tasks with the benchmark models and in-depth analyses on RiSAWOZ in this section. We also discuss the applicability of RiSAWOZ for other tasks. Results of the 5 tasks are reported in Table 7.

5.1 Natural Language Understanding

Task Definition: In task-oriented dialogue system, the NLU module aims to convert the user utterance into the representation that computer can understand, which includes intent and dialogue act (slot & value) detection.

Model: We adapt BERT (Devlin et al., 2019) for the NLU task (intent detection and slot filling). We initialize BERT with the Chinese pre-trained BERT model (Cui et al., 2019) and then finetune it on RiSAWOZ. To take dialogue history into account, we employ the same BERT to model previous dialogue context. We also experiment on the situation without context. For fine-tuning BERT on RiSAWOZ, we set the learning rate to 0.00003 and the dropout rate to 0.1.

Results: From Table 7, we can clearly find that the model using dialogue context preforms better than not. Also, the model obtains lower F$_1$ scores

---

[3] https://github.com/fxsjy/jieba

on multi-domain dialogues than single-domain dialogues.

5.2 Dialogue State Tracking

Task Definition: Dialogue State Tracking (DST) is a core component in task-oriented dialogue systems, which extracts dialogue states (user goals) embedded in dialogue context. It has progressed toward open-vocabulary or generation-based DST where state-of-the-art models can generate dialogue states from dialogue context directly.

Model: To report the benchmark results of the DST task, we implement the TRADE model (Wu et al., 2019) and the MLCSG model (Quan and Xiong, 2020) which improves long context modeling through a multi-task learning framework based on TRADE and achieves the state-of-the-art joint accuracy on the MultiWOZ 2.0 dataset (Budzianowski et al., 2018). We train the models with a learning rate of 0.001 and a weight decay rate of 0.5. Early stopping and dropout are also used to prevent overfitting. The dropout rate is set to 0.2.

Results: As illustrated in Table 7, we show the joint accuracy results for the two models under two different word embedding initialization settings: random and fastText (Grave et al., 2018) initialization. When we use randomly initialized word embeddings of 100 dimensions, TRADE achieves 65.35%, 50.49% and 58.19% joint accuracy on single-domain, multi-domain and all data respectively. While using 300 dimensional pretrained word vectors from fastText, TRADE performs a little better. Under the same setting, MLCSG achieves the higher 73.04%, 58.77% and 66.16% joint accuracy. In general, the performances of the two DST models significantly drop on multi-domain dialogues.

5.3 Dialogue Context-to-Text Generation

Task Definition: We recast dialogue response generation a sequence-to-sequence problem: encoding dialogue context to decode system response.

Model: To this task, we use the Domain-Aware Multi-Decoder (DAMD) model (Zhang et al., 2019b) which achieves state-of-the-art performance on the MultiWOZ 2.0 dataset (Budzianowski et al., 2018). It's an end-to-end model proposed to handle the multi-domain response generation problem, which uses one encoder to encode dialogue context and three decoders to decode the belief span, system action and system response. We set the vocabulary size to 8,000 and randomly initialize 50-dimensional word embeddings. The size of hidden states is set to 100. We train the model with a learning rate of 0.005 and a decay rate of 0.5.

Results: As illustrated in Table 7, we report inform rate, success rate, BLEU (Papineni et al., 2002) and combined score for this task. The inform rate measures the percentage that the output contains the appropriate entity the user asks for, and the success rate estimates the proportion that all the requested attributes have been answered. The combined score is calculated via $(inform + success) * 0.5 + BLEU$ as an overall quality (Zhang et al., 2019b). Still, multi-domain dialogues exhibit a high difficulty level.

5.4 Coreference Resolution

Task Definition: We predict coreference clusters where all mentions are referring to the same entity for each dialogue.

Model: We use the e2e-coref model (Lee et al., 2017), which is the first end-to-end coreference resolution model, as the benchmark model for this task. The model predicts coreference clusters from texts end-to-end without using any auxiliary syntactic parser or hand-engineered mention detector. It considers all spans in a text as potential mentions and learn distributions over all possible antecedents for each mention. The whole process contains two steps: scoring potential entity mentions by calculating embedding representations of corresponding spans and estimating the score for an antecedent from pairs of span representations. The 300 dimensional word vectors from fastText (Grave et al., 2018) are used for the e2e-coref model. We set the size of hidden states to 200 and the number of layers to 3. The model is trained with a learning rate of 0.001 and a decay rate of 0.999. The dropout rate is set to 0.2.

Results: We report the standard MUC, B^3 and CEAFϕ_4 F_1 metrics using the official CoNLL-2012 evaluation scripts and an average F_1 score of the three metrics. As shown in Table 7, the e2e-coref model achieves 84.49%, 80.60%, 82.41% average F_1 score on single-domain, multi-domain and all data respectively. The model performs the worst on multi-domain dialogues where coreference links may cross different domains.

5.5 Unified Generative Ellipsis and Coreference Resolution

Task Definition: This is a new task reformulated recently (Su et al., 2019; Quan et al., 2019). It usually takes the current user utterance and dialogue context as input. If there exits ellipsis or coreference phenomena in the user utterance, a complete version of the utterance is generated according to the dialogue context. Otherwise, the original user utterance is kept.

Model: We adopt the GECOR model (Quan et al., 2019) which is an end-to-end generative ellipsis and coreference resolution model with two encoders and one decoder which can produce a pragmatically complete user utterance via generation and copying. We set both the size of hidden states and word embeddings to 300. We use 300 dimensional fastText (Grave et al., 2018) word vectors to initialize word embeddings in the embedding layer. We train the model with a learning rate of 0.003 and a decay rate of 0.5. Early stopping is used and the dropout rate is 0.5.

Results: We follow Quan et al. (2019) to use the exact match rate (EM), BLEU (Papineni et al., 2002) and Resolution_F_1 as the evaluation metrics for this task. EM measures whether the generated utterances exactly match the ground-truth utterances. Resolution_F_1 is calculated by comparing machine-generated words with ground-truth words only from the ellipsis / co-reference part of user utterances. As shown in Table 7, the GECOR model achieves 58.26% EM score, 87.50% BLEU score and 78.14% Resolution_F_1 score on all data, which are much lower than the results reported on CamRest676 by Quan et al. (2019).

5.6 Other Tasks

Apart from the five evaluation tasks introduced above, RiSAWOZ can also facilitate the research of many other tasks. For example, the text of dialogues, as well as the annotation of dialogue states and acts, can support the study of dialog policy learning (DPL), natural language generation (NLG) and user simulator. Dialogue act, text and goal description can be potentially used for the task of dialogue summarization (Goo and Chen, 2018). RiSAWOZ is also suitable for domain adaptation, zero-shot and few-shot learning for multi-domain task-oriented dialogue modeling due to its wide domain coverage. Rich linguistic annotations of RiSAWOZ would also promote the deep integration of discourse and dialogue. We leave these tasks for our future work.

6 Conclusion

In this paper, we have presented RiSAWOZ, to date the largest human-to-human multi-domain dataset annotated with rich semantic information for task-oriented dialogue modeling. We manually label each dialogue in RiSAWOZ not only with comprehensive dialogue annotations for various sub-tasks of task-oriented dialogue systems (e.g., NLU, DST, response generation), but also linguistic annotations over ellipsis and coreference in multi-turn dialogue. In addition, the process of data creation and annotation is described in detail. We also report the benchmark models and results of five evaluation tasks on RiSAWOZ, indicating that the dataset is a challenging testbed for future work. RiSAWOZ is featured with large scale, wide domain coverage, rich semantic annotation and functional diversity, which can facilitate the research of task-oriented dialogue modeling from different aspects.

Abstract

Large-scale dialogue datasets have recently become available for training neural dialogue agents. However, these datasets have been reported to contain a non-negligible number of unacceptable utterance pairs. In this paper, we propose a method for scoring the quality of utterance pairs in terms of their connectivity and relatedness. The proposed scoring method is designed based on findings widely shared in the dialogue and linguistics research communities. We demonstrate that it has a relatively good correlation with the human judgment of dialogue quality. Furthermore, the method is applied to filter out potentially unacceptable utterance pairs from a large-scale *noisy* dialogue corpus to ensure its quality. We experimentally confirm that training data filtered by the proposed method improves the quality of neural dialogue agents in response generation.[1]

1 Introduction

Some million-scale datasets such as movie scripts and social media posts have become available in recent years for building neural dialogue agents (Lison and Tiedemann, 2016; Henderson et al., 2019). Such large-scale datasets can be expected to improve the performance of dialogue response generation models based on deep neural networks (DNNs) since the combination of DNNs and large-scale training datasets has led to considerable performance improvement in many sentence generation tasks (Koehn and Knowles, 2017; Sennrich and Zhang, 2019; Adiwardana et al., 2020).

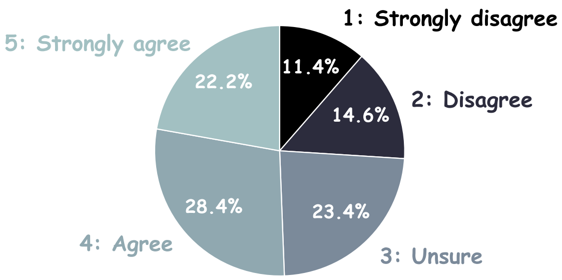

Figure 1: *Is the sequence of the two utterances acceptable as a dialogue?* Response acceptability scores are given by humans on the English OpenSubtitles corpus.

In contrast to the quantity of the data, the quality of the data has often been problematic. For example, OpenSubtitles (Lison and Tiedemann, 2016; Lison et al., 2018), the most widely used large-scale English dialogue corpus, was constructed by collecting two consecutive lines of movie subtitles under the simplified assumption that one line of a movie subtitle is one utterance and the next line is the next utterance follow it. Inevitably, this corpus includes unacceptable utterance pairs from the viewpoint of a conversational sequence, e.g., caused by scene switching or flashback. Several previous studies have identified such flaws and reported that the corpus is *noisy* (Vinyals and Le, 2015; Li et al., 2016; Baheti et al., 2018), where *noisy* refers to unacceptable utterance pairs in this context. Figure 1 shows the result of our experimental investigation regarding the acceptability rate of the utterance pairs in the OpenSubtitles corpus.[2] It can be noticed from the figure that only half of the utterance pairs can be considered *acceptable* (i.e., were rated with score 5: Strongly agree or 4: Agree), and over 25% of utterance pairs are clearly *unacceptable* (i.e., were rated with score 1: Strongly disagree or 2: Disagree) from the human perspective.[3]

With this situation, a straightforward research question arises, namely, *Can we further improve the performance of neural response generation models by ablating unacceptable utterance pairs*

November 16–20, 2020.

from training data? To the best of our knowledge, no previous study has explicitly focused on this question. Thus, the goal of this paper is to provide an answer to this question. Furthermore, it is not clear whether and how one can effectively discover unacceptable utterance pairs within large-scale training datasets. This study explores a way of constructing a scoring method for filtering *noisy* data filtering to improve the performance of response generation models.

To achieve the set goals, we started with a review of previous arguments about the criteria for identifying appropriate utterances in dialogues and designed our scoring function that is consistent with reflects as much of the community's consensus as possible. In particular, the proposed scoring method estimates the quality of utterance pairs based on the following two aspects: (i) the **connectivity** between source and target utterances and (ii) their **content relatedness** (Section 4).

The contributions of this study are the following:

- We propose a scoring method for estimating the quality of utterance pairs in an unsupervised manner (Section 5);
- We reveal that our scoring method effectively detects unacceptable utterance pairs, and thus, be appropriate for noisy data filtering (Section 6);
- We empirically prove that our proposed data filtering method improves the performance of neural response generation models (Section 7); and
- We confirm that our noisy data filtering approach is effective across different languages and dataset sizes (Section 8).

2 Task Definition: Noisy Data Filtering

Let x be an **utterance** and y be a **response** to x. Then, an **utterance pair** can be denoted as we refer to (x, y). Let $\mathcal{D}$ be a dataset that comprising a set of utterance pairs, $\mathcal{D} = \{(x, y)\}$. Then, the task can be formulated as ablating unacceptable utterance pairs from $\mathcal{D}$ to obtain a less noisy subset $\mathcal{D}' \subseteq \mathcal{D}$, hereinafter referred to as filtered dataset. $\mathcal{D}'$ can then be used to train response generation models. This paper refers to this process as **noisy data filtering**, where *noisy* means unacceptable utterance pairs in this context. Furthermore, we establish a function $S\colon \mathcal{D} \to \mathbb{R}$ is used to score the degree of *acceptability* of each utterance pair $(x, y) \in \mathcal{D}$.

3 Background

Response generation using noisy data. The following two approaches are widely used to address the problem of dialogue response generation noisy dialogue corpora. According to the *model approach*, models are trained while handling noise at the same time. For example, Shang et al. (2018) proposed a method with a calibration framework and demonstrated its effectiveness on a Chinese corpus. According to the *data approach*, training data are pre-processed with the aim of improving their quality before training models. In this study, we take the data approach in light of the success of noisy parallel corpus filtering in machine translation (MT). Additionally, it has become a reasonable strategy to reduce the size of training data since enormous dialogue data has been available. Csáky et al. (2019)'s method is most relevant to our study in that it cleanses dialogue corpora. However, the main goal of their method is to eliminate generic, or boring, responses, whereas the goal of the method proposed here is to eliminate unacceptable utterance pairs. This difference in goals leads to the essential difference in filtering strategies.

Effectiveness of filtering noisy data in neural machine translation. Researchers in the field of neural machine translation (NMT) have recognized that collecting high-quality training data to be equally or even more important than exploring sophisticated model architectures (Koehn et al., 2018; Junczys-Dowmunt, 2018; Morishita et al., 2018). Techniques used in neural response generation and NMT are nearly identical; e.g., sequence-to-sequence models (Sutskever et al., 2014) and Transformers (Vaswani et al., 2017) are often used as base model architectures. We hypothesize that high-quality filtered dialogue data can also improve the performance of dialogue response generators. However, the straightforward application of methods proposed for filtering noisy data in NMT may not work well due to the different nature of NMT and neural response generation tasks. In particular, MT data have one-to-one (ignoring paraphrases) correspondence in source and target sentences, whereas dialogues have many-to-many mappings (Zhao and Eskenazi, 2017). The experiments presented in this paper provide an answer to whether NMT filtering methods can perform well in dialogue response generation.

4 Requirements to Utterance Pairs

In this section, we investigate the requirements that should be satisfied by an acceptable utterance pair.

4.1 Criteria for Manual Evaluation

The instructions for manual evaluation provided by the dialogue community explain the key factors for distinguishing acceptable and unacceptable utterance pairs.

In many previous studies, human raters were asked to evaluate the **connectivity** of utterance pairs. For instance, Shang et al. (2015) asked whether a response could be considered as *an appropriate and natural response to the post*. Xing et al. (2017) asked whether *the response can be used as a reply*. Pei and Li (2018) asked whether *the answer is natural* for the question. Other studies have also evaluated the same or similar aspects by using keywords related to the connectivity, such as *semantically appropriate for* (Akama et al., 2017) or *coherent with* (Shen et al., 2017), and *coherence* (Lowe et al., 2017b).

Another frequently used metric is **content relatedness**. For instance, Galley et al. (2015) asked human evaluators to evaluate *each response in terms of their relevance to a given utterance*. Li et al. (2016) asked for the preference of responses *that were more specific to certain utterances*. Ritter et al. (2011) suggested that *an appropriate response should be on the same topic as the utterances*. Several other studies have also focused on evaluating the *relevance* between an utterance and its response (Xu et al., 2018b; Pei and Li, 2018; Lowe et al., 2017b).

In summary, the most widely used criteria can be categorized into connectivity and content relatedness of utterance pairs. In fact, these two aspects are considered in the field of sociolinguistics as crucial features of conversation (Sacks, 1989; Sidnell, 2010).

4.2 Observation

Furthermore, we investigated how the two aforementioned aspects can be observed in actual utterance pairs. For this investigation, we use the utterance pairs scored by human raters that were used in our preliminary experiments shown in Figure 1. Some examples are shown in Table 1.

We observe that typical phrase pair patterns can often be found in utterance pairs with high scores. For example, the pair (*where is* , *at*) in Table 1 is one of the typical phrase pair patterns that asks a place and provides an answer to it. Other typical examples include (*why*, *because*) and (*what do you want*, *I want*). In discourse linguistics, such phrase pair patterns are known as the concept of *cohesive devices*. Hereafter, we refer to such a typical phrase pair pattern as **key phrase pair**.

Moreover, in high scored utterance pairs, both an utterance and response are on the **same topic**. For example, in the third example listed in Table 1, both the utterance and response mention `[money]`.

5 Proposed Method

As per the discussion in the previous section, each acceptable utterance pair should satisfy the following criteria:

- **connectivity** — existence of key phrase pairs
- **content relatedness** — topic commonality

This section presents the proposed scoring functions to assess the degree of satisfying the above two criteria in an unsupervised manner.[4]

5.1 Connectivity

Let f and e represent phrases obtained from x and y, respectively. Let $\phi(x, y)$ be a function that returns a set of all possible phrase (n-gram) pairs obtained from the utterance pair (x, y). We can define a finite set of all possible phrase pairs obtained from the entire dialogue data $\mathcal{D}$ as $\overline{\mathcal{P}}_{\mathcal{D}} = \bigcup_{(x,y)\in\mathcal{D}} \phi(x, y)$. Then, let $\mathcal{P}$ represent a set of key phrase pairs (defined in Section 4.2). We assume that $\mathcal{P}$ is a subset of $\overline{\mathcal{P}}_{\mathcal{D}}$, i.e., $\mathcal{P} \subseteq \overline{\mathcal{P}}_{\mathcal{D}}$.

To obtain $\mathcal{P}$, we take advantage of a phrase table extraction technique developed in statistical machine translation, e.g., Moses (Koehn et al., 2007). In this task, we require only some phrase pairs that can contribute to the connectivity of an utterance pair (as mentioned in Section 4.2), unlike the translation task where the whole sentence must correspond in mutual. Accordingly, in our experiments, we set the null alignment ratio (i.e., probability of no alignment) to 0.5 and extend the phrase extraction algorithm to include only the explicitly corresponding range as phrases in our table.

Then, we define the scoring function S_{C} to esti-

---

[4] The reason for focusing on an unsupervised approach the lack of data that can provide good supervision for utterance pair evaluation.

	Utterance	Response	Human
1 :	It'll be like you never left. `[??]`	I painted a white line on the street way over there. `[painting]`	1.4
2 :	You're gonna get us assimilated. `[??]`	Switch to a garlic shampoo. `[??]`	1.8
3 :	I probably asked for too much money. `[money]`	Money's always a problem, isn't it? `[money]`	4.2
4 :	I wonder who I should call back. `[phone]`	They're saying they want to call one of you back. `[phone]`	4.4
5 :	Okay, so where's the rest? `[??]`	Electronically scanned and archived at headquarters but you'll have to speak with them about that. `[work]`	4.4

Table 1: Samples of pairs judged as unacceptable/acceptable in preliminary experiments. Human denotes the average score of five human evaluators on a scale of 1-5. Phrases considered to contribute to connectivity are highlighted . Estimated `[topic]` of utterance is written in the end of each utterance.

mate connectivity as:

$$S_{\mathbf{C}}(x,y) := \sum_{(f,e)\in\phi(x,y)\cap\mathcal{P}} \max\bigl(\mathrm{nPMI}(f,e),0\bigr)\cdot\frac{|f|}{|x|}\cdot\frac{|e|}{|y|}, \tag{1}$$

where $|\cdot|$ denotes the number of words in the phrase or utterance. To calculate the co-occurrence, we use the normalized pointwise mutual information (nPMI) (Bouma, 2009), which normalizes the value so that low-frequency phrases do not take an extremely large value. Note that we ignore the negative nPMI scores by the $\max(\cdot,0)$ operation because we aim only to consider the positive effect of connectivity. The intuition behind Equation 1 is as follows:

- If a phrase pair (f,e) has a high co-occurrence, the association strength of (x,y) including (f,e) might also be high.
- If a phrase f or e occupies almost the entire sentence x or y, (f,e) is a strong indicator of the association of (x,y).

5.2 Content Relatedness

Let $\boldsymbol{v}(x)$ and $\boldsymbol{v}(y)$ be sentence vector of x and y, respectively. We compute topic commonality of x and y, that is, content relatedness as follows:

$$S_{\mathbf{R}}(x,y) := \max\bigl(\cos(\boldsymbol{v}(x),\boldsymbol{v}(y)),0\bigr). \tag{2}$$

Cosine similarity between certain kinds of sentence vectors is known to be a good proxy of the topical relatedness of two sentences (Conneau et al., 2017; Subramanian et al., 2018; Xu et al., 2018a). For the same reasons as Equation 1, we ignore the negative cos scores by the $\max(\cdot,0)$ operation.

5.3 Summary

Eventually, combining the above two scoring measures, we propose the following function:

$$S_{\mathbf{C+R}}(x,y) := \alpha S_{\mathbf{C}}(x,y) + \beta S_{\mathbf{R}}(x,y), \tag{3}$$

where α, $\beta \in \mathbb{R}_{\geq 0}$ are hyperparameters that weigh the two viewpoints. For our experiments, we fix α and β as follows:

$$\alpha = \frac{1}{\frac{1}{|\mathcal{D}|}\sum_{(x,y)\in\mathcal{D}} S_{\mathbf{C}}(x,y)},\quad \beta = \frac{1}{\frac{1}{|\mathcal{D}|}\sum_{(x,y)\in\mathcal{D}} S_{\mathbf{R}}(x,y)}. \tag{4}$$

6 Experiments: Data Scoring

In this section, we describe our experiments that validate the effectiveness of the proposed scoring method.

6.1 Experimental Setup

Dataset. We conducted our experiments on a noisy English dialogue corpus from OpenSubtitles (Lison et al., 2018) containing roughly 441M lines. As explained in Section 1, this corpus includes many unacceptable utterance pairs (Section 1). We first applied several rule-based filtering as rudimentary preprocesses, which are typically used in the related literature. Then, we obtained 79,445,453 utterance pairs as our training data, which excludes our test and validation data.[5]

Proposed method: detailed setup. To compute the connectivity $S_{\mathbf{C}}$, we obtained a phrase table on our training data by using Moses (Koehn et al., 2007) with fastAlign (Dyer et al., 2013). We then removed phrase pairs with a low co-occurrence frequency (here, less than 200 times) or composed

Figure 2: Distributions between human scores and automatically computed scores by each method (English).

of the same phrases from the table. As a result, the phrase table included 68,891 phrase pairs, which were used as the key phrase set $\mathcal{P}$ as described in Section 5.1.

To compute the content relatedness $S_{\mathbf{R}}$, we created a sentence vector from pre-trained fastText word embeddings (Bojanowski et al., 2017; Mikolov et al., 2018) following Arora et al. (2017)'s method, i.e., using SIF weighting and common component removal. Their method is reported to be useful for computing the relatedness of two given sentences and used in many studies (Marelli et al., 2014b,a; Conneau et al., 2017; Subramanian et al., 2018; Baheti et al., 2018). We learned common components using 30K sentences randomly selected from the training costs appropriately. We then removed the first common component for all sentence vectors.

Baselines. For comparison, we prepared the following:

- Csáky et al. (2019): Entropy-based filtering to remove generic utterances from the training data for promoting less-boring response generation. SRC/TRG indicates that using the entropy of source/target utterances.
- Junczys-Dowmunt (2018): Filtering for NMT based on the dual conditional cross-entropy computed by a neural encoder-decoder model. It achieved the best performance on the Parallel Corpus Filtering Task at WMT 2018.[6]

Human evaluation. To validate the ability of the proposed method to estimate the quality of utterance pairs, we measured the correlation between its scores and those assigned by humans through crowdsourcing. We used Amazon Mechanical Turk.[7] We randomly extracted 200[8] scored utterance pairs and asked native English-speaking crowdworkers to answer the following question for each pair: *Is the sequence of the two utterances acceptable as a dialogue?* Workers were instructed to provide an answer on a five-point Likert scale (from 5: Strongly agree to 1: Strongly disagree) (Likert, 1932). Unqualified workers were filtered out using attention checks. Eventually, we used the average of the scores provided by five workers as the human score for each pair.

Scoring method	Spearman's ρ	p-value
Csáky et al. (2019) SRC	−0.1173	9.8×10^{-2}
Csáky et al. (2019) TRG	0.0462	5.2×10^{-1}
Junczys-Dowmunt (2018)	0.2973	1.9×10^{-5}
Ours $S_{\mathbf{C+R}}$	**0.3751**	$\mathbf{4.4 \times 10^{-8}}$
Ours $S_{\mathbf{C}}$ (ablation study)	0.2044	3.7×10^{-3}
Ours $S_{\mathbf{R}}$ (ablation study)	0.3007	1.5×10^{-5}

Table 2: Correlation coefficient between human scores and automatically computed scores (English).

6.2 Results and Analysis

Table 2 shows the correlation between human scores and those automatically computed by each method. Among the methods, $S_{\mathbf{C+R}}$ achieved the highest correlation with human scores. Additionally, we also evaluated $S_{\mathbf{C}}$ and $S_{\mathbf{R}}$ as an ablation study of $S_{\mathbf{C+R}}$. We found that both scores were less correlated than $S_{\mathbf{C+R}}$. This result supports the hypothesis that both aspects, namely, connectivity and content relatedness, should be considered when evaluating the quality of utterance pairs.

Figure 2 shows the distribution of automatically computed scores corresponding to human scores.[9] As shown in (c), $S_{\mathbf{C+R}}$ rarely overestimates utterance pairs with low human scores but underestimates those with high human scores. The baseline methods presented in (a) and (b) do not show such behavior. This behavior unique to $S_{\mathbf{C+R}}$ is safe for

[8] Same size as Sedoc et al. (2019) and Cho and May (2020).

[9] See Appendix E.1 for the distributions of other methods.

	Utterance	Response	$S_{\mathbf{C}}$	$S_{\mathbf{R}}$	$S_{\mathbf{C+R}}$	Human
1 :	What is the anarchy facing the jail of the sick passion?	Gosh, it's really cold!	0.32	0.00	**0.32**	1.4
2 :	Pushers won't let the junkie go free.	Across 110th Street.	0.00	0.42	**0.42**	2.4
3 :	It started when I was 17.	They'd make a cash drop,	0.63	0.00	**0.63**	2.0
4 :	A big nail should be put in your head	Who are they	0.74	0.00	**0.74**	1.2
5 :	He told me so.	Oh, he did, huh?	2.21	0.00	**2.21**	4.8
6 :	There's a laundry.	Have your clothes dry-cleaned, okay?	0.81	2.89	**3.70**	4.4
7 :	Then if I win, what are you going to do?	When you win?	1.04	7.01	**8.05**	4.2
8 :	But what do you want me to do?	We want you to kick her off the team.	10.20	1.53	**11.72**	5.0

Table 3: Samples of utterance pairs scored with our method and human judgements (English). The scores of $S_{\mathbf{C}}$ and $S_{\mathbf{R}}$ were normalized by α, β.

the noisy data filtering task since it can successfully detect lower-quality pairs with high precision. On the other hand, improperly underestimating some acceptable pairs (i.e., low recall) is one downside of $S_{\mathbf{C+R}}$, and we discuss its influences in Section 6.3. We emphasize that $S_{\mathbf{C+R}}$ has a desirable property for noisy data filtering in today's situation where a sufficiently large corpus is available; it allows us to obtain a sufficient amount of clean data even if discarding a certain portion of potentially clean data. Interesting future work is to investigate how to improve our methods not to underestimate acceptable pairs while maintaining high precision. It is nearly equivalent to develop an unsupervised approach of dialogue evaluation methods, and thus, this direction is a challenging and essential attempt.

Table 3 shows several examples of utterance pairs well-scored by $S_{\mathbf{C}}$, $S_{\mathbf{R}}$, and $S_{\mathbf{C+R}}$. Note that the score ranges differ; e.g., human scores are in $[1, 5]$, while $S_{\mathbf{R}}$ is in the range $[0, 1]$.[10] Thus, we discuss relative score values; the comparison of absolute score values across the different methods would be meaningless. These examples demonstrate that the complementary contributions of both $S_{\mathbf{C}}$ and $S_{\mathbf{R}}$ allow $S_{\mathbf{C+R}}$ to provide quality estimations close to human judgments.

6.3 Discussion on Low Recall Property
